THEORY OF THE END-POINT IN ELECTROMETRIC TITRATION

BY P. S. ROLLER

RECEIVED JUNE 17, 1927 PUBLISHED JANUARY 5, 1928

In a paper recently published by Eastman[1] on the theory of the electrometric titration of an acid by a base, certain conclusions among others were drawn to the effect that the inflection point in the e.m.f. titration curve would not appear when the ionization constant of the acid of a given concentration is below a certain magnitude, in particular that it would not appear when $K_A \leqq 10^{-12}$ for a 1.0 molar acid, or when $K_A \leqq 10^{-9}$ for a 0.001 molar acid. In attempting to confirm this result, we have been able to generalize the theory of the end-point in electrometric titration, and in a subsequent paper consider by the method of analysis here used the electrometric (and colorimetric) titration of polybasic acids, weak base salts, and their mixtures, by a base or mixture of bases.

We also find here that there is a discrepancy between our result for the appearance of the inflection point and that of Eastman. We may without sensible error consider the exact equation (10a) below as of the third degree and, testing for real roots, we find that the condition of the appearance of an inflection point in the titration of a weak acid by a strong base is that $cK_A > 27K_w$, where K_A is the ionization constant of the acid, K_w the ion product constant of water and c is a concentration defined by the following equation:

$$\frac{1}{c} = \frac{1}{a} + \frac{1}{b} \tag{1}$$

where a is the initial concentration of the acid and b is the initial concentration of the base in the titrating solution. We have checked this condition numerically. We see then that an inflection point should appear when K_A is as low as 3×10^{-13} for a 1 normal acid, neglecting dilution. The discrepancy between this result and that of Eastman appears to be **due** to an oversight in his numerical calculation of an otherwise correctly derived equation.

Determination of the H-Ion Concentration at the End-Point and at the Inflection Point

In a plot of E, the e.m.f. of the H_2 half cell, against n/n_e, the fraction of the number of cc.'s required to reach the end-point, the condition for an inflection point is, from the equation

$$E = 0.059 \log x = -0.059\, px \tag{2}$$

that

$$\frac{d^2n}{dx^2} = -\frac{1}{x}\frac{dn}{dx} \tag{3}$$

where x is the H-ion concentration in the solution, px is the PH of the solution and n is the number of cc. of titer.

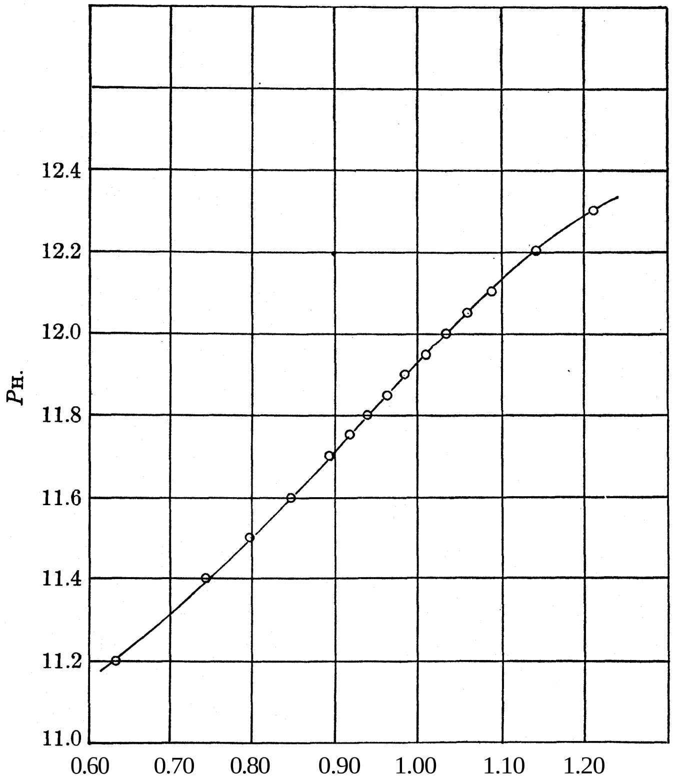

Fig. 1.—P_H *vs.* fraction titrated, n/n_e. $K_A = 10^{-11}$, $a = 0.1$, $b = 0.4$.

We can obtain an exact relation between n and x as follows. Let b represent the concentration of the base in moles per liter, v the initial volume of the solution, x the concentration of the non-ionized part of the acid HA of initial concentration a, and y the OH^- concentration in solution. In an infinitesimal addition of titrating solution the number of moles of

OH-ion added per unit volume is $[b/(V+n)]\mathrm{d}n$. This quantity is divided in the solution between increasing the OH--ion concentration, and decreasing the H^+ and HA concentrations. The following equation accounts for the distribution within the solution of the added OH^- ion, allowing for dilution of the solution by the added titer

$$\frac{b}{V+n}\,\mathrm{d}n = \mathrm{d}y - \mathrm{d}x - \mathrm{d}z + \frac{(y-x-z)}{V+n}\,\mathrm{d}n \tag{4}$$

This equation may be simply integrated if we take as the variables b and $(y - x - z)$. The integration constant is determined by the condition that, when $n = 0$, $(a - z) + y = x$, which expresses the electrical neutrality of the solution, so that upon integration of (4) we obtain

$$\frac{bn}{V} = a + \left(1 + \frac{n}{V}\right)(y - x - z) \tag{5}$$

n in (5) may be obtained as a function of x alone by eliminating y and z by means of the following ionization equations

$$xy = K_w \tag{6}$$

$$\frac{x\left(a\,\frac{V}{V+n} - z\right)}{z} = K_A \tag{7}$$

In (7), the ionization equation of the acid, we have assumed that the salt formed is 100% ionized. If it is not, a simple correction must be made to K_A for the degree of dissociation; or an activity coefficient correction may be applied to both K_A and K_w.

At the end-point we have by definition that

$$\frac{bn_e}{V} = a \tag{8}$$

We have then upon substituting from (6), (7) and (8) in (5) an equation in x_e, the H-ion concentration at the end-point

$$\left(1 + \frac{a}{b}\right)\left(\frac{K_w}{x_e} - x_e\right) - \frac{ax_e}{(K_A + x_e)} = 0 \tag{9a}$$

This is a third-degree equation in x_e, but from the physical nature of the problem two of these roots must be imaginary. Expanding $1/(K_A+x_e)$ in powers of x_e/K_A, we finally obtain, in the titration of a weak acid, that

$$x_e = \sqrt{\frac{K_w K_A}{c}}\left[1 + \frac{1}{2}\sqrt{\frac{K_w}{cK_A}} - \frac{1}{8}\,\frac{K_w}{cK_A}\cdots\right] \tag{9}$$

where c is a concentration defined by Equation (1).

This equation for the H-ion concentration at the end-point is practically identical with the usual result obtained in the calculation of the hydrolysis of a normal salt. The effect of dilution by the added titer is contained by virtue of c in the term $1/b$, the reciprocal of the concentration of the base in the titrating solution, which may usually be neglected, against $1/a$, the reciprocal of the initial concentration of the acid in the solution. In that event, we may replace c by a in (9).

We must now determine x_i, the H-ion concentration at the inflection point. Differentiating (4), (6) and (7) with respect to x and substituting in (2) we finally obtain

$$2\left(1+\frac{a}{b}\right)\frac{K_w}{x_i^3}+\frac{2aK_A}{(K_A+x_i)^3}=\left(1+\frac{a}{b}\right)\frac{K_w}{x_i^3}+\frac{aK_A}{x_i(K_A+x_i)^2}+\left(1+\frac{a}{b}\right)\frac{1}{x_i} \tag{10a}$$

This fifth-degree equation has at least one real root. We are interested in the root in the neighborhood of the end-point. Expanding then in a binomial series in powers of x_i/K_A we find for the H-ion concentration at the inflection point

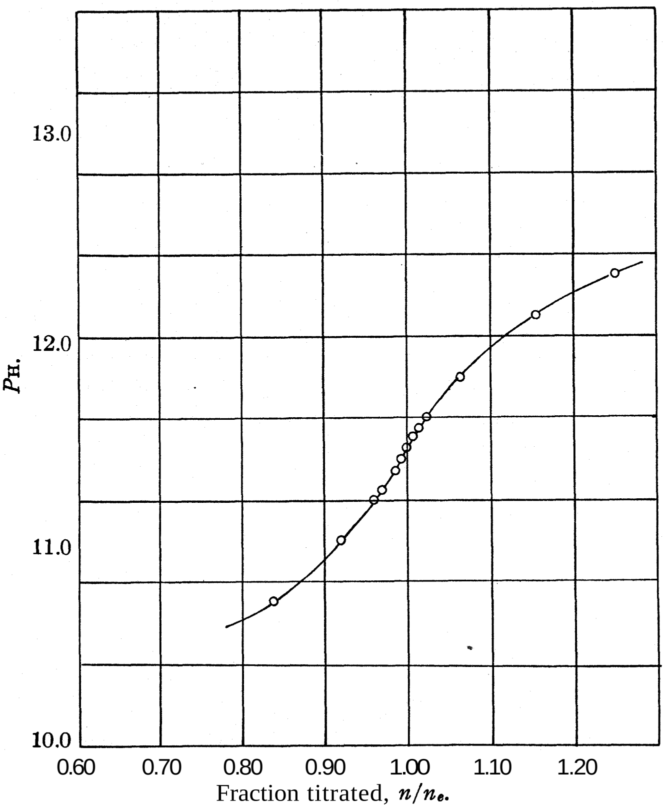

Fig. 2.—PH *vs.* fraction titrated, n/n_e. $K_A = 10^{-10}$, a = 0.1, b = 0.4.

$$x_i = \sqrt{\frac{K_wK_A}{c}}\left[1+2\sqrt{\frac{K_w}{cK_A}}+\frac{3}{2}\frac{K_w}{cK_A}+\ldots.\right] \tag{10}$$

From this approximation equation for a weak acid, which holds very closely for K_w/cK_A as large as 10^{-2}, we see that the H-ion concentration at the inflection point is finite and real, at least for all values such that the series is convergent, that is, for $cK_A > K_w$. However, from the exact equation (10a), the condition is $cK_A > 27K_w$. Since $x_i > x_e$ the inflection point always precedes the end-point, except when the acid is strong ($K_A \longrightarrow \infty$). In that case $x_i = x_e = \sqrt{K_w}$, a result obtained from (9a) and (10a).

We have for the difference in *PH* between the end-point and the inflection point from (9) and (10)

$$Px_e - Px_i = 0.65\sqrt{\frac{K_w}{cK_A}} \tag{11}$$

Thus from this equation the difference in *PH* between the end-point and the inflection point, which is seen to be very small, depends not only upon K_A but also, and in the same way, upon the acid and base concentration, that is, upon the product cK_A, where $1/c = 1/a + 1/b$ by (1), and increases as cK_A decreases.

This difference in *PH* may be obtained in terms of the difference in cc. of titer between the inflection point and end-point by means of the general relation

$$\frac{\Delta n}{n_e} = \left(\frac{\mathrm{d}n}{\mathrm{d}x}\right)_{x_e < x < x_i} \Delta x \tag{12}$$

$\Delta n/n_e$ represents the deviation of the end-point from the inflection point as a fraction of the total titer required to reach the end-point, Δx being equal to $x_i - x_e$, and An to $n_i - n_e$.

We thus obtain for the fractional deviation, $\Delta n/n_e$, upon calculation by means of this equation

$$\frac{\Delta n}{n_e} = -\frac{3K_w}{cK_A} \tag{13}$$

TABLE I

RESULTS OF CALCULATIONS

cK_A	$Px_e - Px_i$	Px_e ($c = 1.10$)	$100\frac{Px_e - Pxi}{Px_e}$	$-100\frac{Am}{n_e}$
10^{-8}	0.00065	10.0	0.01	0.0003
10^{-10}	.0065	11.0	.06	.03
10^{-11}	.0206	11.50	.18	.30
10^{-12}	.065	12.00	.54	3.0

In Table I above, we have made numerical calculations of the deviation of the end-point from the inflection point for a series of acids. In Col. 1 is given the product cK_A ranging from 10^{-8} to 10^{-12}. In the second column is given corresponding to each product cK_A the difference in PH between the inflection and end-points calculated from (11) with $Kw = 10^{-14}$, in the third column is the *PH* at the end-point for $c = 0.10$ calculated from (9), in the fourth column is the percentage deviation in *PH* between the end-point and the inflection point and in the last column is given the percentage titer deviation calculated from (13).

From this table it is seen that when the product of the concentration into the ionization constant is equal to 10^{-11} the titer deviation of the end-point from the inflection point is 0.3%, but only 0.03% when the product is equal to 10^{-10}, decreasing rapidly thereafter. For $cK_A = 10^{-12}$, the deviation is 3.0%. Inasmuch as when the product cK_A is as small as 10^{-12} the error of titration, if it can be performed at all, is of a greater magnitude than the last result would indicate, we must look for a different cause of the increased error. The answer seems to lie in the physical difficulty of locating the inflection point, in a plot of E against n/n_e, when the product of the concentration into the ionization constant becomes so small. This, of course, is a matter apart from the error due to the difference, $px_e - px_i$.

The Error of Locating the Inflection Point

In the neighborhood of the inflection point the curve is symmetric about a horizontal axis passing through it. Consider the points P and P' in the neighborhood of the inflection point symmetrically located with respect to it. If the tangent to all three points is the same, it is clear that it will be impossible to distinguish the inflection point lying between P and P', since then the curve degenerates into a straight line.

This leads us to suspect that it is the difference in slope at P (or P') and at the inflection point that determines the error of locating the latter on the curve. We distinguish the inflection point from other points by the fact that at that point the slope of the curve is a maximum and therefore is the more readily differentiated as its slope is greater than that of other points in its neighborhood. This may perhaps be more readily seen when we consider a plot[2] of $\Delta E/\Delta\left(\frac{n}{n_e}\right)$ against n/n_e, in which case the ordinates are proportional to the slope of the usual titration curve while the inflection point is now a maximum point. This maximum is the more accurately located the steeper the curve.

We have for the slope of the tangent to the curve at any point by differentiating (2)

$$\frac{\mathrm{d}E}{\mathrm{d}\left(\frac{n}{n_e}\right)} = -\frac{0.059}{2.302}\,\frac{1}{\left[\frac{K_w}{cx} + \frac{x}{a} + \frac{}{(K_A + x)^2}\right]} \tag{14}$$

At the inflection point, substituting for x_i from (10), we have

$$\left[\frac{\mathrm{d}E}{\mathrm{d}\left(\frac{n}{n_e}\right)}\right]_{x_i} = \frac{0.059}{4.604}\sqrt{\frac{cK_A}{K_w}} \tag{15}$$

Let us choose our arbitrary reference point P at the 91% neutralization point. We have by (7) for the H-ion concentration at P, $x_P = 0.1K_A$.

Upon substitution in (14) we obtain for the slope at the point of reference, P

---

[2] Cox, This Journal, 47, 2138 (1925).

$$\left[\frac{dE}{d\left(\frac{n}{n_e}\right)}\right]_{xP} = -\frac{0.059}{2.302}\,\frac{1}{\left(\frac{10K_w}{cK_A} + 0.0825\right)} \qquad (16)$$

Thus the difference in slope at P and at the inflection point depends by equations (15) and (16) only upon the product, cK_A, with $1/c = 1/a + 1/b$, similarly to previous results.

Table II

Calculated Differences

cK_A	$\frac{1}{0.059}\left[\frac{dE}{d\left(\frac{n}{n_e}\right)}\right]_{x_i}$	$\frac{1}{0.059}\left[\frac{dE}{d\left(\frac{n}{n_e}\right)}\right]_{xP}$	Difference
10^{-6}	2160	5.2	2155
10^{-8}	216	5.2	211
10^{-10}	21.6	5.2	16.4
10^{-11}	6.9	4.6	2.3
10^{-12}	2.4	2.4	0.0

In Table II we have calculated the differences in a plot of $E/0.059 (= P_H)$ against n/n_e between the slope at the 91% neutralization point and at the inflection point for cK_A from 10^{-6} to 10^{-12}. The first column gives the magnitude of the product cK_A, the second gives the slope at the inflection point, the third gives its value at the 91% neutralization point, the fourth shows the difference in slope at these two points.

It is seen that the difference falls off rapidly as we go from cK_A equal to 10^{-6} to cK_A equal to 10^{-11}. At cK_A equal to 10^{-12}, the slopes are practically equal, so that the whole curve in the vicinity of the inflection point tends to contract into a straight line. However, in spite of this, the inflection point may still be located even for $cK_A = 10^{-12}$, though here the error may be considerable in the usual plot of E against n/n_e, where, in order to observe that there is any inflection in the curve at all, it must be plotted over a large range in n/n_e, say from 0.65 to 1.25.

Graphical Illustration

In the titration of a weak monobasic acid by a strong base, we have plotted P_H against n/n_e from Equation (5) for the two acids $K_A = 10^{-10}$, $K_A = 10^{-11}$, each of initial molar concentration a = 0.10, and with b, the strength of the titrating solution, equal to 0.4.

Examination of these curves shows the following.

1. There is an inflection point in both cases. It is visible for $K_A = 10^{-11}$ only upon close scrutiny of the curve as a whole, but it may not be sharply located. The error of locating it will by comparison of the curves obviously be much less for the stronger acid, $K_A = 10^{-10}$.
2. Ascertaining the position of the inflection point as best we may, the difference in P_H at the end-point where $n/n_e = 1.0$ and at the in-

flection point appears to be $+0.09 \pm 0.06$ for $K_A = 10^{-11}$ and $+0.02 \pm 0.02$ for $K_A = 10^{-10}$. By Equation (11) we would calculate these PH differences to be $+0.073$ and \$0.023, respectively.

Corresponding to the above PH differences, we have again from the curves for the deviations in cc. of titer for $K_A = 10^{-11}$ $4 \pm 4\%$, for $K_A = 10^{-10}$ $0.3 \pm 0.3\%$. By Equation (13) we calculate these titer deviations to be 3.7 and 0.37%, respectively. While the calculated PH and titer differences agree well with the observed, there is an error in the observed values which is due to the uncertainty of locating the inflection point on the curve. The magnitude of this error is closely equal to the differences themselves.

The graphs here considered represent an ideal case in that there are no errors of reading the e.m.f., buret, etc., and the number of points taken is greater. Consequently in any experimental plot of e.m.f. against n/n_e, the error of locating the inflection point will doubtless be greater than is indicated by the above results.

The writer wishes to record his appreciation of the helpful advice rendered by Professor H. A. Fales of this University.

Summary

1. In the electrometric titration of a monobasic acid by a strong base, an inflection point in the e.m.f. titration curve will appear if $cK_A < 27K_w$.
2. Simple equations are deduced for the difference in PH and in cc. of titer between the inflection point and the end-point. The former always precedes the latter. The differences which are usually negligible increase with the weakness of the acid and with the dilution.
3. Apart from these calculable differences, there is an error of locating the inflection point. This error arises from the tendency of the curve to compress into a straight line in the neighborhood of the inflection point as the acid is weaker or the dilution greater.

THE CUPROUS CHLORIDE ELECTRODES

BY RALPH F. NIELSEN[1] AND DENTON J. BROWN

RECEIVED JULY 11, 1927 PUBLISHED JANUARY 5, 1928

The Copper Amalgam–Cuprous Chloride Electrode

Introduction

The copper-cuprous chloride electrode has been measured by Immerwahr,[2] by Luther and Wilson,[3] and by Noyes and Chow.[4] These investigations are subject to the errors of not using a reproducible form of copper, of not preparing the electrodes in the absence of oxygen and of not rotating the electrodes to insure equilibrium. Luther and Wilson employed the cell Cu, CuCl(s), KCl(N/20), N. E. Noyes and Chow employed the cell Cu, CuCl(s), HCl, H_2. Immerwahr used the cell Cu, CuCl(s), KNO_3(N) + HCl(N/20), N. E., in which the complete cell reaction is obviously doubtful.

In our work we first used the cell Cu(amalgam), CuCl, HCl, HgCl, Hg, since it has the advantage of having an electromotive force practically independent of concentration. We tried to follow the method of Ellis[5] in preparing the calomel electrodes, since he obtained results which varied only a few hundredths of a millivolt. This was essentially the electrolytic method of Hulett.[6] We were, however, unable to obtain constant values, and when we rotated the calomel electrodes for a day or two, as he recommends, we obtained values which were nearly ten millivolts too high, as indicated by comparison with hydrogen electrodes. The same results were obtained with a second preparation of electrolytic calomel. For this reason we employed the cell Cu(amalgam), CuCl(s), HCl, H_2.

Apparatus and Solutions

The copper amalgam was the same two-phase electrolytic amalgam as that described in our previous paper on the potential of copper.[7] Cuprous chloride was prepared directly in the electrode vessel by addition of a solution of chloro-cuprous acid to water, while a stream of purified nitrogen bubbled through the vessel. The chlorocuprous acid was prepared by reduction of a hydrochloric acid solution of cupric chloride

---

[1] This paper is taken from part of a thesis submitted by Ralph F. Nielsen for the degree of Doctor of Philosophy at the University of Nebraska. The problem of the determination of the free energies of copper compounds was selected by him at the suggestion of Professor Merle Randall of the University of California and this paper represents the work on the copper chlorides.

with copper. The amalgam, the supply of which was always kept under an acidified copper sulfate solution, had been previously put in the vessel after being washed. The glass stopper was then inserted and the solution brought to the proper concentration by repeatedly forcing out the solution with nitrogen and drawing in a solution of the required concentration. After drawing in each fresh supply, nitrogen was bubbled through the cell for a short time and the cell was shaken a few times. The solutions were often kept at about 40° to insure larger crystals and more rapid settling of the salt, but this seemed to have no influence on the results. The last addition of the solution was always below 25° so as to avoid any inrush of solution into the vessel when the stopcocks were opened for the potential measurements. The electrode was rotated in the thermostat four or five hours before being measured. Longer periods did not change the potential.

The hydrogen electrode consisted of a piece of platinized platinum foil. The electrode was prepared from clean platinum foil by electrolysis of a solution of pure chloroplatinic acid containing one per cent. of platinum. A four-volt battery was used and the current reversed every few minutes for one hour, as recommended by Ellis. The hydrogen entered the electrode vessel at the bottom and escaped through a trap. The platinum foil was only partially submerged in the solution. Hydrogen was prepared by electrolysis of sodium hydroxide solution and was passed through sulfuric acid before entering the preliminary washer which adjoined the electrode vessel in the thermostat and contained the same solution as the electrode vessel. Rubber connections were kept at a minimum and whenever they were used they were paraffined. In one of our measurements two hydrogen electrode vessels were used, the one receiving electrolytic hydrogen and the other hydrogen prepared from zinc and hydrochloric acid. The hydrogen from the latter source was passed through concentrated potassium hydroxide and over phosphorus pentoxide before entering the preliminary vessel. The difference in potential between the two electrodes was less than 0.01 millivolt. The hydrogen and cuprous chloride electrodes were joined through a beaker of the given solution, the arm of the cuprous chloride vessel having been protected by a plug during rotation in the thermostat. Both electrodes were set up four or five hours before being measured.

The hydrochloric acid solutions were made up from conductivity water, and weighed quantities were standardized with barium hydroxide, which in turn had been standardized with benzoic acid. Checks were obtained in all the titrations. All other apparatus and manipulations were the same as in our previous paper, such as "Type K" potentiometer, calibrated standard cell, thermostats, etc.

Electromotive Force of the Copper Amalgam Hydrogen Cell

In the following table the first column gives the number of the experiment, the second the molality of the acid used (moles per kilogram of water), and the third the partial pressure of hydrogen after correcting the

barometer reading for temperature and subtracting the vapor pressure of the solutions, assumed equal to that of water. The fourth column gives the observed electromotive force and the fifth column the activity coefficient for the given molality of acid, interpolated from the table of Lewis and Randall.[8]

All six measurements were obtained in succession. The close agreement of each pair seems to be a fair check on the experimental work. Calculations based on these measurements will appear in the theoretical discussion.

Study of the Cell $CuCl(s)$, $CuCl_2(aq.)$, $Cl_2(g)$

Introduction.—This is of course the only combination of electrodes which we could use if we wish to avoid liquid junctions, since copper or mercury would cause precipitation of cuprous chloride from the cupric chloride solutions. The $CuCl$-$CuCl_2$ electrode was studied by Luther and Wilson,[3] who measured the cell $CuCl$, $CuSO_4$ and KCl (each $MV/20$), N. E. Obviously we cannot use this measurement in our calculations.

Experimental Work.—With the exception of the preparation of the chlorine electrodes, all procedure was the same as given above, including preparation and rotation of the $CuCl$-$CuCl_2$ electrodes. In setting up the chlorine electrodes we followed essentially the method of Lewis and Rupert.[9] The bulb of a separatory funnel was sealed into the neck of a carboy by means of de Khotinsky cement. A mixture of air and chlorine was forced into the carboy under pressure, the partial pressure of air being at least ten times that of chlorine. The air was dried before entering the carboy and the chlorine was taken directly from a cylinder. The carboy contained some calcium chloride to serve as a drying agent. The chlorine electrode vessels were essentially like the hydrogen electrode vessels described above, except that bright platinum-iridium foil was used instead of platinum black.

The cupric chloride solutions were made up gravimetrically, with conductivity water, from a stock solution which had been standardized iodimetrically. The stock solution had been made up from crystals of the dihydrate, obtained by recrystallization of the best C. P. product from a solution containing excess of hydrochloric acid. These crystals were dried in a vacuum desiccator containing soda-lime. The solutions were kept in Pyrex flasks, over which watch glasses had been sealed with paraffin. The saturated electrode was set up by adding excess of the dihydrated salt to the electrode vessel at the time it was set up. The more dilute solutions contained about a drop of nitric acid in 500 cc. of solution to prevent the formation of a green precipitate, probably a basic salt.

In order to standardize the chlorine mixture the stem of the separatory funnel leading from the carboy was divided by means of a Y-junction. The mixture was thus allowed to go simultaneously through one pass into an electrode vessel containing the required cupric chloride solution and through the other pass into an electrode vessel containing 0.0478 M hydrochloric acid. The hydrochloric acid electrode was measured against a hydrogen electrode with the same hydrochloric acid solution. The Cl_2-$CuCl_2$ electrode was measured against the $CuCl$-$CuCl_2$ electrode, prepared similarly to the Cu-$CuCl$ electrodes described above. The two latter electrodes of course con-

tained cupric chloride of the same molality. The cells were measured almost simultaneously, after sufficient time had elapsed to insure equilibrium in all the electrode vessels. In other words, we obtained simultaneously the electromotive forces corresponding to both the following reactions

$$\tfrac{1}{2}Cl_2(p) + \tfrac{1}{2}H_2\ (700\ \text{mm.}) = HCl\ (0.0478\ M) \qquad (1)$$

$$\tfrac{1}{2}Cl_2(p) + CuCl(s) = CuCl_2\ (\text{given molality } m) \qquad (2)$$

The data of Lewis and Rupert were then used to determine the partial pressure of the chlorine in each case. The electrodes were joined only long enough to be measured and adjustments were such as to avoid flow from one to the other.

Electromotive Force of the Cell.—In the following table the first column gives the number of the experiment, the second the molality of the cupric chloride, the third the measured electromotive force of the hydrochloric acid cell and the fourth that of the cupric chloride cell. The partial pressure of hydrogen in this series was assumed constant at 700 mm.

Calculations and Theoretical Discussion

The Copper-Cuprous Chloride Electrode

Since the reaction which occurs in the cell (Table I) is Cu (in two-phase amalgam) + H^+Cl^- (at m) = CuCl(s) + $\tfrac{1}{2}H_2$ (at p), the relation between the observed e.m.f. E and that E_0 calculated for the case in which H^+, Cl^- and H_2 have unit activity is given by the expression

$$E_0 = E + 0.05915 \log \frac{(p/760)^{1/2}}{a_{H^+} \cdot a_{Cl^-}} \qquad (3)$$

in which the a's refer to the given activities. The geometric mean activity of the ions is equal to the molality m_{HCl} multiplied by the activity coefficient γ_{HCl}, provided the solubility of cuprous chloride is small, and the expression becomes

$$E_0 = E + 0.05915 \log \frac{(p/760)^{1/2}}{m^2\gamma^2} \qquad (4)$$

---

[10] From the solubility measurements of Reicher and van Deventer, *Z. physik. Chem.*, 5, 559 (1890).

The values of E_0 thus calculated are given in the third column of Table III, the first column giving the number of the experiment and the second the molality of hydrochloric acid for comparison of the data.

There are, however, two factors which influence the concentration of chloride ion in the hydrochloric acid solutions. The first is the formation of the complex ion $CuCl_2^-$, for which Noyes and Chow[4] found, at 25°, the relation

$$(CuCl_2^-)/(Cl^-) = 0.0661 \qquad (5)$$

the parentheses denoting concentrations. Activities may be substituted for the concentrations in accordance with the principle[8,16] that the activity coefficient in dilute solutions is determined chiefly by the total ionic strength and is nearly the same for all ions of unit charge. In **all** that follows, parentheses will denote activities. The second factor is the reaction

$$2CuCl(s) = Cu^{++} + 2Cl^- + Cu \qquad (6)$$

In the case of the most concentrated hydrochloric acid solutions (Table I), Equation 5 has a far greater effect than Equation 6 on the concentration of chloride ion. This will be evident in the subsequent calculations. Assuming that in the most concentrated solution (Cl^-) is reduced in the ratio 1/1.0661 by complex formation, and anticipating Equation 14, we shall correct the value of E_0 for the most concentrated solution by the amount 0.828.0.5915 log 1.0661 or 0.0013 volt and write[11]

$$Cu + Cl^- = CuCl(s) + E^-;\ \Delta F^\circ_{298} = 0.1298\,F \qquad (7)$$

By Equation 22,

$$CuCl(s) = Cu^{++} + Cl^- + E^-;\ \Delta F^\circ_{298} = 0.5758\ F \qquad (8)$$

Combining,

$$2CuCl(s) = Cu^{++} + 2Cl^- + Cu;\ \ \Delta F^\circ_{298} = 0.4460F = -RT\ln(Cu^{++})(Cl^-)^2 \qquad (9)$$

Then

$$(Cu^{++})(Cl^-)^2 = \text{antilog}\ \frac{-0.4460}{0.05915} = 2.82 \times 10^{-8} \qquad (10)$$

If we assume that for every Cu^{++} ion produced by Equation 6, two Cl^- ions are produced, and for every $CuCl_2^-$ ion produced, one Cl^- ion disappears, then the activity of Cl^- ion in the electrode chamber is given by

$$\begin{aligned}(Cl^-) &= \gamma_{Cl^-}\, m_{Cl^-} - (CuCl_2^-) + 2\gamma_{Cl^-}(Cu^{++})/\gamma_{Cu^{++}} \\ &= \gamma_{Cl^-}\, m_{Cl^-} - 0.0661(Cl^-) + \frac{2 \times 2.82 \times 10^{-8}}{(Cl^-)^2} \times \gamma_{Cl^-}/\gamma_{Cu^{++}} \qquad (11)\end{aligned}$$

from Equations 5 and 10. We may assume that the individual ion activity coefficients are the same for all ions of unit charge and are those given in Table I. The coefficients for Cu^{++} are taken from the table of Lewis and Randall for individual ions and are given in the fourth column of Table III. The fifth column gives the solution of Equation 11. It has been assumed that all the dissolved cuprous chloride is in the form of the complex ion.

---

[11] **The symbols and conventions used in this paper are those of Lewis and Randall, *See* Note 8.**

Before we can correct our potentials, we must consider another effect, namely, the summation of free energies of dilution and concentration in the composition gradient portion, which occur when the cell operates and which give rise to the so-called "liquid potential." The expressions for the electromotive forces of concentration cells have been derived by integration methods,[12] and their form indicates that for convenience a sharp boundary may be assumed. Since electrical neutrality will be maintained chiefly by ions present in the largest concentration, we may assume that hydrogen ion and chloride ion are the chief substances transferred. Since the concentration of hydrogen ion is the same on both sides of the junction, the free-energy change, due to transference, accompanying the passage of one Faraday is manifested in a potential

$$E_L = t_A \cdot 0.05915 \log a_1/a_2 \qquad (12)$$

where t_A is the transference number of the anion, and a_1 and a_2 are the activities of chloride ion on the two sides of the junction. If all the transference were accomplished by hydrogen ions, our values of E_0 would have to be corrected by the amount

$$\Delta E_T = 0.05915 \log \gamma m/(\mathrm{Cl}^-) \qquad (13)$$

since all the chloride ion formed would be at activity (Cl^-) rather than at γm. The effect of Equation 12 is to offset in part that of Equation 13, and we therefore obtain the value

$$AE = t_C \cdot 0.05915 \log \gamma m/(\mathrm{Cl}^-) \qquad (14)$$

to be added to the values of E_0. The cation transference number (t_C) is taken as 0.828.[13] The values of AE are given in the sixth column of Table III, and the corrected values of E_0 in the seventh column. The values of γm used in calculating E_0 are given in the eighth column for comparison with those of (Cl^-).

TABLE III

CALCULATED VALUES FOR THE COPPER AMALGAM-CUPROUS CHLORIDE ELECTRODE

No.	m_{HCl}	E_0	$\gamma_{\mathrm{Cu}^{++}}$	(Cl^-)	AE	E_0'	γm
1	0.02029	−0.13116	0.53	0.01731	0.0010	−0.1302	0.01813
2	.02029	− .13113	.53	.01731	.0010	− .1301	,01813
3	.00757	− .12915	.63	.00795	− .0026	− .1317	.00706
4	.00757	− .12907	.63	.00795	− .0026	− .1317	.00706
5	.03564	− .13116	.48	.02932	.0013	− .1299	.03115
6	.03564	− .13100	.48	.02932	.0013	− .1297	.03115

The calculated values of (Cl^-), as compared with γm, show that in the case of the most concentrated solution the effect of complex formation is

---

[12] See ref. 8, p. 337 and ref. 16, p. 782 (chapter by Harned).

[13] Partington, "Conductance, Ionization, and Ionic Equilibria," p. 546. Chapter XI of Taylor's "Treatise on Physical Chemistry," D. Van Nostrand Co., New York City, 1925.

predominant, while in the case of the most dilute solution the effect of formation of cupric chloride is predominant. This is qualitatively verified in the experiments. The experimental data show that the formation of cupric chloride did not take place to the extent calculated. This fact is somewhat surprising, considering the constancy and reproducibility of our electrodes. It might be mentioned that an error in the activity coefficient of Cu^{++} would have a marked effect on the calculated values of (Cl^-). We shall take the value of $\mathbf{E}_0'$ for the most concentrated solution, and regard this as the standard potential of copper amalgam and cuprous chloride in the presence of chloride ion at unit activity. This value is probably correct to within two- or three-tenths of a millivolt. We therefore write

$$\text{Cu (in two-phase amalgam)} + Cl^- = CuCl(s) + E^-;\ E^\circ = -0.1298 \text{ volt,}$$
$$\Delta F^\circ_{298} = 23074 \cdot 0.1298 \text{ cal.} = 2995 \text{ cal.} \qquad (15)$$

This value is to be used in calculating free energies and equilibrium constants. The values of $\mathbf{E}_0$ in Table III may be used when the electrode is employed as a reference electrode with a given hydrochloric acid solution.

Our value for the standard potential of this electrode is to be compared with that of Noyes and Chow,[4] who found —0.1200 volt for the standard potential, using copper plated on platinum. The standard potential of the amalgam in copper sulfate, as found in our previous paper, is —0.3502 volt. Lewis and Randall give —-0.3448 volt, based on the work of Lewis and Lacey,[14] for the standard potential of a copper sponge prepared by rapid electrolysis of copper sulfate on a platinum point. We have been unable to produce copper of as low reducing power as this by any method whatever, but this copper would give —0.1244 volt for the standard potential of the copper-cuprous chloride electrode. Comparison of this value with that of Noyes and Chow, ignoring the slight error introduced by the liquid junction, indicates that the smooth copper plate which they used contained energy stored in the form of distortion from a more stable form of copper.

Calculations: The Cuprous Chloride-Cupric Chloride Electrode

The reaction which occurs in the copper chloride cells (Table II) is

$$CuCl(s) + \tfrac{1}{2}Cl_2 \text{ (at p)} = CuCl_2 \text{ (at m)} \qquad (16)$$

That which occurs in the hydrochloric acid cell is

$$\tfrac{1}{2}H_2 \text{ (at 700 mm.)} + \tfrac{1}{2}Cl_2 \text{ (at p)} = HCl \text{ (at 0.0478 M)} \qquad (17)$$

The electromotive force that would be given by the latter cell if all substances were. at unit activity is 1.3594 volts, according to the tables of Lewis and Randall, based on the work of Lewis and Rupert.[9] If only the chlorine were at a fugacity or activity of one atmosphere and the other substances at the concentrations indicated by Equation 17, the electromotive force would be

---

[14] Lewis and Lacey, THIS JOURNAL, 36, 804 (1914).

$$1.3594 + 0.05915 \log \frac{(700/760)^{1/2}}{(0.861)^2(0.0478)^2} = 1.5222 \text{ volts}$$

the activity coefficient for the given hydrochloric acid being taken as 0.861 from Lewis and Randall. In order, therefore, to find the electromotive force that would be given by the copper chloride cells if the chlorine were at unit activity, the difference between the value 1.5222 and the observed value $\mathbf{E}_{\mathrm{HCl}}$ (Table II) must be added to the corresponding value of $\mathbf{E}_{\mathrm{CuCl_2}}$, since the same chlorine mixture was used in the two corresponding cells. These corrected values $\mathbf{E}_0$ for the copper chloride cells are given in the third column of Table IV, the first giving the number of the experiment and the second the molality of the cupric chloride used. The hydrolysis of the chlorine is negligible at the partial pressures used. The mean value of $\mathbf{E}_0$ at each molality is given in the fourth column.

As in the case of our copper-cuprous chloride electrodes, the concentration of chloride ion is affected by the formation of $CuCl_2^-$ and, in the case of the more concentrated solutions, by the formation of much $CuCl_3^-$ and various chloro-cuprate ions. We shall neglect all factors except the formation of $CuCl_2^-$, although these factors are by no means completely negligible in the concentrated solutions. If we assume that the concentration of chloride ion is cut down by cuprous chloride in the ratio 1/1.0661 in accordance with Equation 5, then the chlorine would become chloride ion at molality $2m_{\mathrm{CuCl_2}}$ and the cuprous chloride would form chloride ion at molality $2m_{\mathrm{CuCl_2}}/1.0661$. If all the transference were accomplished by positive ions, the chloride ions formed would remain at these molalities, and the value 0.05915 log 1.0661 would have to be subtracted from the values of $\mathbf{E}_0$ in Table IV to find the e.m.f. that would be obtained if the concentration of chloride ion were really $2m_{\mathrm{CuCl_2}}$. When the cell operates, however, some chloride ion is transferred from the chlorine electrode vessel to the cuprous chloride solution, which is more dilute with respect to chloride ion, and this has the effect of increasing the electromotive force by the amount $t_{\mathrm{A}} \cdot 0.05915 \log 1.0661$, where t_{A} is the transport number of chloride ion. We are assuming a sharp boundary, as explained in the previous section, and a constant activity coefficient at any one molality. We must accordingly subtract the value

$$AE = (1 + t_{\mathrm{A}})\ 0.05915 \log 1.0661 \qquad (18)$$

from the values of $\mathbf{E}_0$ to find the e.m.f. that would be obtained if the concentration of chloride ion were actually $2m_{\mathrm{CuCl_2}}$. These corrected e.m.f.'s, $\mathbf{E}'_0$, are given in the seventh column of Table IV.

It might be argued that the $CuCl_2^-$ ion cannot be regarded as a foreign ion, since storing up an ion in the form of a complex might not be qualitatively different from storing it up as a hydrated ion or in any other unactivated form. In our treatment it is, of course, assumed that, of the total chloride ion present, the instantaneous fraction in active equilibrium with solid CuCl and cuprous ion is reduced very nearly in the ratio 1/1.0661 by complex formation.

In dilute solutions we shall take t_A as 0.6 by analogy with various electrolytes. In very concentrated cupric chloride solutions the transport numbers for the anion become greater than unity, owing to the formation of chloro-cuprate ions, according to the work of Kohlschütter.[15] Since we are regarding complex ions as foreign ions, our value of t_A must be the fraction of the current carried by the chloride ions alone, and we have selected the rather arbitrary values given in the fifth column of Table IV. This procedure ignores the fact that other ions are transferred to different environments, but the corrections are small and at any rate the presence of cuprous chloride makes the molalities and the calculated activity coefficient doubtful in the most concentrated solutions. The values of AE calculated from Equation 18 are given in the sixth column and the corrected values of E_0 in the seventh column, these corrected values, E'_0, having the significance stated above.

From the reaction of Equation 16, the following relation must hold between the values of E'_0

$$E'_{0x} - E'_{0y} = 0.05915 \log \frac{(\gamma_y m_y)^3}{(\gamma_x m_x)^3} \qquad (19)$$

in which the x and y refer to the number of the experiment and $\gamma m = \sqrt[3]{(Cu^{++})\,(Cl^-)^2}$ where the parentheses denote activities. The "mean activity coefficient," γ, as calculated by Equation 19, is given in the eighth column of the table, that for the 0.01 molal solution being calculated from the table of individual ion coefficients of Lewis and Randall.

TABLE IV

CALCULATED VALUES FOR THE CUPROUS CHLORIDE-CUPRIC CHLORIDE ELECTRODE

No.	m_{CuCl_2}	E_0	Mean E_0	t_A	ΔE	E'_0	γ_{CuCl_2}
7	0.01	1.1328	1.1330	0.6	0.0026	1.1304	(0.700)
8	.01	1.1331					
9	.02	1.0889	1.0889	.6	.0026	1.0863	.620
10	.02	1.0889					
11	.2	.9523	.9523	.5	.0025	.9498	.365
12	.2	.9520					
13	.2	.9528					
14	1	.8368	.8367	.4	.0023	.8344	.326
15	1	.8365					
16	5.82[11]	.6605	.6605	.2	.0020	.6585	.55

Various causes may be given for the trend of the activity coefficient. The "electrostatic virial" theory of Debye and Hückel[16] as extended by Hiickel''

---

[15] Kohlschütter, *Ber.*, 37, 1153 (1904).

[16] Debye and Hiickel, *Physik. Z.*, 24, 185 (1923). See also Noyes, THIS JOURNAL, 46, 1080 (1924).

[17] Hiickel, *Physik. Z.*, 26, 93 (1925)

probably accounts for the greater portion of the trend. Scatchard[18] has suggested that hydration may be another factor in determining the values of γ. Many factors enter into consideration for the concentrated cupric chloride solutions, including hydration, formation of ionic and molecular complexes, etc. The factors are probably linked up with the color changes, the color changing from blue to green or from dark green to a dark reddish-brown on saturation with cuprous chloride, in the case of the most concentrated solutions. The molality, and hence the calculated activity coefficient, is somewhat in doubt in the case of the saturated solution, owing to the large solubility of cuprous chloride. Other complicating factors have been mentioned previously.

Since the cell reaction for this set of experiments is that given by Equation 16, we may calculate the standard potential of the cuprous chloride-cupric chloride electrode by the relation

$$E^\circ = E_0' + 0.05915 \log (Cu^{++}) (Cl^-)^2 + E^\circ_{Cl_2} \qquad (20)$$

using any value of E_0' and the corresponding values for the activities. This value, E^0, is the value which, if the standard potential of the chlorine electrode be subtracted from it, gives the electromotive force that would be obtained from our cupric chloride cells if the activity of both ions were unity. Using the values for the 0.01 molal solution, including the "mean activity coefficient" of 0.700 and the standard potential of the chlorine electrode given previously, Equation 20 becomes

$$E^\circ = 1.1304 + 0.05915 \log 4(0.700 \cdot 0.01)^3 - 1.3594 \qquad (21)$$

We may therefore write

$$CuCl(s) = Cl^- + Cu^{++} + E^-;\ E^\circ = -0.5758 \text{ volt},$$
$$\Delta F^\circ_{298} = 23074 \cdot 0.5758 = 13{,}285 \text{ cal.} \qquad (22)$$

This value, as well as our activity coefficients, is slightly in doubt, owing to the calculation of γ at 0.01 M from individual ion coefficients. The values of E_0 may be employed when this electrode is used as a reference electrode.

Standard Free Energies Based on Both Electrodes

Subtracting the standard chlorine potential from Equation 22, we obtain

$$CuCl(s) + \tfrac{1}{2}Cl_2(g) = CuCl_2 \text{ (aq. at unit activity)}$$
$$\Delta F^\circ_{298} = -(1.3594 - 0.5758)23074 = -18{,}080 \text{ cal.} \qquad (23)$$

Subtracting the standard potential of chlorine from Equation 15, we obtain

$$Cu \text{ (in two-phase amalgam)} + \tfrac{1}{2}Cl_2(g) = CuCl(s)$$
$$\Delta F^\circ_{298} = -(1.3594 - 0.1298)23074 = -28{,}370 \text{ cal.} \qquad (24)$$

Combination of Equations 23 and 24 gives

$$Cu \text{ (in two-phase amalgam)} + Cl_2(g) = CuCl_2 \text{ (aq. at unit activity)}$$
$$\Delta F^\circ_{298} = -46{,}450 \text{ cal.} \qquad (25)$$

---

[18] Scatchard, THIS JOURNAL, 47, 2096 (1925).

From the value of E_0 for the saturated cupric chloride solution we may obtain the free energy of the dihydrate. The equation is

$$CuCl(s) + \tfrac{1}{2}Cl_2 \text{ (1 atm.)} + 2H_2O \text{ (in sat. } CuCl_2 \text{ sol.)} = CuCl_2{\cdot}2H_2O(s)$$
$$E = 0.6605 \text{ volt} \qquad (26)$$

From the vapor-pressure data of Ewan and Ormandy,[19] the activity of the water is found to be 0.65. Hence the value 0.05915 log $(0.65)^2$, or —0.0221, has to be subtracted from Equation 26, and we obtain

$$CuCl(s) + \tfrac{1}{2}Cl_2(g) + 2H_2O\ (1) = CuCl_2{\cdot}2H_2O(s)$$
$$\Delta F^\circ_{298} = -23074\ (0.6605 + 0.0221) = -15{,}750 \text{ cal.} \qquad (27)$$

Combination with Equation 24 gives

$$Cu \text{ (in two-phase amalgam)} + Cl_2(g) + 2H_2O(l) = CuCl_2{\cdot}2H_2O(s):$$
$$\Delta F^\circ_{298} = -44{,}100 \text{ cal.} \qquad (28)$$

From Equation 9,

$$2\ CuCl\ (s) = CuCl_2\ (aq.) + Cu \text{ (in two-phase amalgam);}$$
$$\Delta F^\circ_{298} = 23074.0.4460 = 10{,}290 \text{ cal.} \qquad (29)$$

Summary

By measurements of the cell Cu (in two-phase amalgam), CuCl(s), HCl, H_2, the standard potential of the copper amalgam-cuprous chloride electrode was determined (Equation 15). The results were compared with those of other investigators.

By measurements of the cell Cl_2 (at low pressures), $CuCl_2$ (aq.), CuCl(s), the standard potential of the cuprous chloride-cupric chloride electrode was determined (Equation 22), as well as the activity of cupric chloride over a limited range (Table IV).

To insure reliable results, copper amalgam was used instead of metallic copper, oxygen was excluded and the electrodes were rotated in the thermostat. Chemical reactions affecting the concentration of chloride ion were treated mathematically and corrections made for them. Views regarding the liquid junctions and the trend of the activity coefficients were expressed.

The standard free energies of the two solid chlorides and of aqueous cupric chloride were calculated (Equations 24, 25 and 28) as well as the standard free energies of several other reactions.

COPPER SULFATE AS THE DEACON CHLORINE CATALYST?[1]

BY RALPH ALONZO BEEBE AND DONALD BALCH SUMMERS

RECEIVED AUGUST 16, 1927 PUBLISHED JANUARY 5, 1928

Introduction

If we may judge from the literature, there is considerable doubt concerning the role of cupric sulfate when employed in the catalytic process of Deacon for the direct oxidation of gaseous hydrogen chloride. In the First Report of the Committee on Contact Catalysis,[2] following a discussion of a possible mechanism for cupric chloride catalyst, we find the statement, "when we start with copper sulfate as the catalytic agent, which may be done, the whole thing becomes hopelessly complicated." Levi and Bettoni[3] suggest an intermediate hydrate formation

$$CuSO_4 + 2HCl + {}^1/_2O_2 = CuSO_4{\cdot}H_2O + Cl_2$$
$$CuSO_4{\cdot}H_2O = CuSO_4 + H_2O$$

Now Hensgen[4] and others have shown that many of the metal sulfates are attacked by dry hydrogen chloride gas to form the corresponding chlorides and liberate sulfuric acid. This work suggests the possibility of the conversion of cupric sulfate according to the following equation

$$CuSO_4 + 2HCl = CuCl_2 + H_2SO_4$$

If this be true, then it is probable, if we start with copper sulfate in the Deacon Process, that the copper chloride formed is the catalyst, and the mechanism is the same as if copper chloride had been used initially.

The available data for the action of hydrogen chloride on copper sulfate are rather controversial and indefinite as regards experimental conditions, especially temperature. Hensgen finds an addition compound of $CuSO_4{\cdot}2HCl$ (approximately) by the action of dry hydrogen chloride on anhydrous copper sulfate at room temperature. He suggests that this compound, $CuSO_4{\cdot}2HCl$, plays an important role in the Deacon reaction. In a later article,[5] Hensgen shows that 2.18 moles of hydrogen chloride are absorbed per mole of pentahydrated copper sulfate, giving this observation to support the following equation

$$CuSO_4 + 2HCl = CuCl_2 + H_2SO_4$$

Other writers[6,7] find addition compounds or partial conversion to copper chloride. With the exception of one experiment by Hensgen, all these

reactions were run at temperatures well below that used in the Deacon Process.

To clear up any doubt, it seemed desirable to determine whether hydrogen chloride gas alone, or admixed with oxygen, does indeed quantitatively liberate sulfuric acid from copper sulfate with the concomitant formation of a chloride or oxychloride of copper, this test to be made at about 450°, the temperature used in the Deacon Process.

Preparation of Materials

The hydrogen chloride gas was prepared by dropping concentrated sulfuric acid on a solution of C. P. concentrated hydrogen chloride. The gas bubbled through two wash bottles containing concentrated hydrogen chloride solution, and thence passed through calcium chloride towers. The train of wash bottles and towers served effectively to remove any mechanically carried sulfuric acid. By counting the bubbles in the wash bottles it was possible to estimate rate of flow.

The oxygen was supplied from a commercial tank, passed through a bubbler containing paraffin oil to estimate rate of flow and thence through calcium chloride.

The copper sulfate was prepared by heating C. P. pentahydrated copper sulfate to about 450° in a stream of dry air. Analysis for copper and sulfate showed the product to have the composition of anhydrous cupric sulfate.

Procedure

In his experiments, Hensgen tested the reaction, $CuSO_4 + HCl$, by determining the composition of the residual copper salt. At the temperature employed by us cupric chloride is partially dissociated into cuprous chloride and chlorine. Moreover, in the experiments where oxygen was mixed with the hydrogen chloride, some oxychloride was probably formed. The residual copper salt would be a mixture of cupric and cuprous chloride and, in some experiments, probably oxychloride of copper $CuO \cdot CuCl_2$. Hence it was thought better to test the completeness of the reaction, $CuSO_4 + 2HCl = CuCl_2 + H_2SO_4$, by determining the sulfuric acid evolved.[8]

Hydrogen chloride alone, or hydrogen chloride mixed with oxygen, was passed over a weighed sample of anhydrous copper sulfate contained in a hard glass tube which was electrically heated to about 450° as measured by a nitrogen filled mercury thermometer. When hydrogen chloride alone was used, the rate of gas flow was estimated at 12 liters per hour; when the mixture was used, the rate was 15 liters per hour. In these experiments on the liberation of sulfuric acid from the sulfate, a

[8] At 450°, the sulfuric acid is, of course, largely dissociated into sulfur trioxide and water.

variation of 20° was found to have no effect on the total amount of sulfuric acid liberated; hence it was considered safe to keep the temperature between 440 and 460°. Preliminary to a run, the tube was swept out with dry hydrogen chloride and was brought to the desired temperature. The tube was then opened at the end where the gases were admitted, the sample of copper sulfate contained in a porcelain boat was quickly inserted and the tube was closed. The sulfuric acid in the effluent gas was absorbed in a train of four spiral wash bottles filled with concentrated hydrogen chloride solution. Concentrated hydrogen chloride was here preferred to water because its use eliminated the danger that the solution might suck back due to the too rapid solution of hydrogen chloride gas. The long train was found necessary to effect the complete absorption of the sulfuric acid. After action was complete, the liquid contained in the wash bottles was boiled down to a small volume to expel most of the hydrogen chloride. The residual liquid was neutralized by ammonia, then made slightly acid by hydrogen chloride, diluted and analyzed for sulfate content by precipitation of barium sulfate.

Results

Action of Hydrogen Chloride Alone.—The white color of the anhydrous copper sulfate gradually changed to a dirt-brown, resembling that of anhydrous cupric chloride. After five to six hours the mass began to liquefy and sublimed cuprous chloride was apparent on the cooler portions of the tube. At this stage, and not before, evolution of sulfuric acid was found to be complete.

Table I gives a comparison between the weight of barium sulfate calculated according to the equation, and the actual weight found by analysis.

TABLE I

ACTION OF HYDROGEN CHLORIDE ON COPPER SULFATE AT 450° (APPROX.)

volume, of 4:1. The observations concerning color change, time for completion, etc., were not sensibly different from those when hydrogen chloride alone was used. The results are tabulated in Table II.

Rate of Evolution of Sulfuric Acid.—In order to get an estimate of the course of the reaction with time, the absorption train was replaced at various time intervals by a duplicate and the amount of sulfuric acid evolved during the various intervals was determined by separate barium sulfate precipitations. The anhydrous copper sulfate used here weighed **0.2707** g.; the yield of barium sulfate should, therefore, have been **0.3960** g. when conversion was complete. The sum of the weights in Col. 2 of Table III is 0.3985 g. Col. **3** lists the percentages of sulfuric acid evolved in the various time intervals and Col. 4, the total percentage at the end of each interval.

TABLE III

RATE OF EVOLUTION OP SULPURIC ACID

Time interval, minutes	$BaSO_4$ found, g.	for interval, %	Total H_2SO_4, %
0–22	0 0347	8.77	8.77
22–60	.0809	20.22	28.99
60–100	.0460	11.62	40.61
100–140	.0450	11.37	51.98
140–230	,1527	38.75	90.73
230–380	.0392	9.88 .	100 61

It will be observed that the copper sulfate was not immediately decomposed. After 140 minutes only 52% had yielded up its sulfate, and **9.3%** remained unchanged even after 230 minutes or almost four hours. The action was complete, however, at the end of six hours. This rate of evolution of sulfuric acid should be taken only as a roughly quantitative statement. Obviously the rate would be influenced by many factors such as amount of surface of copper sulfate exposed, size and shape of containing tube and variations in temperature.

The foregoing data prove definitely that a quantitative yield of sulfuric acid is obtained by heating copper sulfate to 450° in a stream of hydrogen chloride or hydrogen chloride-oxygen mixture. After six hours' time no sulfate is left in the catalyst mass. Hence, if we start with copper sulfate in the Deacon Process, the catalyst, after six hours' time, must be copper chloride and cannot be copper sulfate.

In one experiment the following test was made on the effluent gas produced when hydrogen chloride—oxygen mixture passed over copper sulfate. The gas stream was divided in two parts. One part bubbled through barium chloride solution to test for sulfate, the other through potassium iodide to test for chlorine. As nearly as could be determined, the evolution of sulfuric acid and the production of chlorine began almost simultaneously at the end of about five minutes from the time the catalyst was inserted. This time was doubtless needed to bring the catalyst to the temperature of the furnace. Since chlorine was not produced before the sulfuric acid began to come off, it is needless to assume that copper sulfate acted as catalyst even at the very start of the action; because as soon as a very small amount of copper sulfate was converted into chloride, the latter could function as the catalyst.

Summary

1. At 450°, sulfuric acid is quantitatively displaced from copper sulfate by the action of dry hydrogen chloride gas alone, or admixed with oxygen. We may assume that the residual salt is entirely in the form of copper chloride or oxychloride.
2. Hence the mechanism of the Deacon Process when copper sulfate is used as the initial form of the catalyst is no more complicated than it is when cupric chloride is used initially.

VAPOR PRESSURE DATA FOR ISOPROPYL ALCOHOL AND TERTIARY BUTYL ALCOHOL

BY GEORGE S. PARKS AND BERNARD BARTON

RECEIVED SEPTEMBER 6, 1927 PUBLISHED JANUARY 5, 1928

The literature apparently contains no data for the vapor pressures of *iso*propyl alcohol and tertiary butyl alcohol over a range of temperatures. In view of the increasing importance of these substances, the present investigation was undertaken to remedy the deficiency.

Experimental Part

Two methods for measuring the vapor pressures of the liquids were employed. From 20 to 90° the static method of Smith and Menzies[1] was utilized. The isoteniscope was of the U type and was immersed in a small hand-regulated thermostat. The temperatures were measured to 0.01° by a thermometer which had been calibrated against a similar thermometer standardized by the United States Bureau of Standards. The manometer was U-shaped, with the evacuated side permanently connected to a high-vacuum pump consisting of a bulb of activated charcoal immersed in liquid air.

A second static method, developed in this Laboratory, was employed in measurements on *iso*propyl alcohol from 0 to 30° and on undercooled *tert.*-butyl alcohol at 20 and 25°. In this case our apparatus was essentially similar in principle to that described by Johnston,[2] although at the

---

[1] Smith and Menzies, THIS JOURNAL, 32, 1419 (1910).

[2] Johnston, *Z. physik. Chem.*, 62,333 (1908).

time of its development we were unaware of anything similar in the literature. However, we dispensed with the large manometer employed by Johnston, as none of our pressure readings by this method were above 70 mm. For a pump we again used a tube of activated charcoal in liquid air. Manometer readings were made by a brass cathetometer reading to 0.05 mm.

The *iso*propyl alcohol was prepared from "refined" material supplied by the Eastman Kodak Co. This was subjected to four treatments and distillations with lime in the ordinary manner and then to two very careful fractionations. The middle 50% was used for the measurements. It had a density of 0.78091 at 25°/4°, corresponding to a purity of 99.97% on the basis of the criteria[3] previously employed.

The *tert.*-butyl alcohol was a refined material (m. p. 12°) given to us by the Petroleum Chemical Corporation. It was first subjected to ten fractional crystallizations. The resulting product was treated with lime and distilled, then treated with a small amount of metallic sodium and redistilled. The distillate thereby obtained was next subjected to fifteen additional fractional crystallizations. The final product had a freezing point of 25.50°.

Three or more sets of determinations were carried out upon each alcohol by the two-different methods, the measurements being made over the temperature ranges previously indicated at intervals of approximately 5°. The results obtained were in general very concordant. The vapor pressure values for each alcohol were plotted against the corresponding temperatures; a smooth curve was then drawn and from this the vapor pressures were read at exactly five degree intervals. These are the results appearing in Table I. In the case of the isopropyl alcohol they are probably accurate to within 0.2 mm. at the lower temperatures and to within 0.8 mm. at the highest temperatures; for the *tert.*-butyl alcohol the errors may be 50% greater than these, owing to more difficulty in the purification

[3] Parks and Kelley, THIS JOURNAL, 47, 2090 (1925).

of the sample. In all cases the pressures are expressed in terms of millimeters of mercury at 0°.

Derived Data

If we neglect the volume of the liquid in the well-known Clausius-Clapeyron relationship and assume the perfect gas equation for the vapor, we obtain the approximation, $\frac{-R\,\mathrm{d}\ln p}{\mathrm{d}(1/T)} = \Delta H$, where ΔH is the heat of vaporization per mole. In the present case the values for $-R \ln p$ were plotted against the reciprocals of the absolute temperatures for both alcohols and the slopes of the two curves were measured at points corresponding to 25 and 50° and the respective boiling points. The values thus obtained for 50° and for the boiling point were then decreased by 1.0 and 4.0%,[4] respectively. The resulting heats of vaporization in calories per mole appear in Table II; they are probably accurate to within 150 calories for the isopropyl alcohol and to within 200 calories for the *tert.*-butyl alcohol. The values at the boiling points compare favorably with the scanty calorimetric data in the literature.[5]

Following Hildebrand,[6] we have also calculated the molal entropy of vaporization (Table II, Col. 5) at the temperature at which the concentration of vapor is 0.00507 mole per liter. As 27.4 cal. per degree is the mean value obtained by Hildebrand for normal liquids, our higher results indicate that these two alcohols are decidedly "polar."

TABLE II

THERMAL VALUES DERIVED FROM THE VAPOR PRESSURE DATA

Alcohol	Heat of vaporization (cal. per mole) At 25°	50°	B. p.	Molal entropy of vaporization (cal. per degree)
*iso*Propyl	10,620	10,490	9,600 (at 82.28°)	33.8 (at 38.7°)
tert.-Butyl	10,890	10,680	9,480 (at 82.86°)	34.4 (at 39.4°)

Summary

1. Vapor pressure measurements have been made on isopropyl alcohol from 0 to 90° and on *tert.*-butyl alcohol from 20 to 90°, inclusive.

2. From these experimental results the heats of vaporization of the two liquids have been estimated for several temperatures. The molal entropies of vaporization indicate that these alcohols are polar liquids.

[4] These corrections were decided upon after a careful survey of the deviations from the perfect gas law found by Young, Proc. Roy. *Soc.* (Dublin), 12, 376 (1910), for the vapors of alcohols, esters, etc., at corresponding temperatures. The error involved in their use is probably less than 0.5%.

THE NATURE OF ACTIVE NITROGEN: THE SYNTHESIS OF AMMONIA FROM THE ELEMENTS[1]

BY BERNARD LEWIS[2]

RECEIVED SEPTEMBER 6, 1927 PUBLISHED JANUARY 5, 1928

The question concerning the nature of glowing active nitrogen has been a much discussed and controversial subject. It is unnecessary here to sketch historically the study of active nitrogen which has led to the atomic and molecular hypotheses of its nature[3] since this has been amply recorded in other works. Birge,[4] Sponer[5] and Birge and Sponer[6] have shown that the eleventh vibrational state of the 9.3-volt electron level, from which the strongest bands in the afterglow proceed, corresponds to 11.4 volts above the normal level and this represents the true energy of combination of nitrogen atoms. This checks with other evidence as discussed by Birge and Sponer[6] as well as with the extrapolated value of the first band in the Lyman-Birge-Hopfield band system formerly attributed to NO by Sponer[4b] but now known to belong to the nitrogen mole-

[2] National Research Fellow in Chemistry.

[3] It is very important to make clear the distinction between the atomic and molecular theories with respect to the formation of the afterglow. According to the former, the carriers issuing from the discharge are neutral, unexcited nitrogen atoms which potentially have it within their power to create the glow by means of an activating process involving, as far as our knowledge will allow us to judge, a triple collision between two N atoms and a N_2 molecule. An uncertainty exists regarding the necessity for a triple collision because, unlike the H_2 molecule, the N_2 molecule has definite and known quantized states from which it can radiate, corresponding to the energy of dissociation plus the relative kinetic energy of the atoms. While a three body collision in the ease of the combination of H atoms is an absolute necessity, since there is no molecular quantum state here from which radiation is possible, yet in the N_2 molecule it is possible that two N atoms may combine without the presence of a third body. There are certain difficulties confronting the assumption of a three body collision in active nitrogen (see Bonhoeffer and Kaminsky[8]). It is hoped to treat this in a forthcoming publication. At any rate an excited N_2 molecule results (probably unstable) which gives rise to emission of the afterglow; the a-bands are emitted by transition from vibrational states in level B to several vibration states in level A (see Birge and Sponer[6]), those probably being meta stable. According to the molecular theory the activating process does not occur outside the discharge, since the carriers are held to be metastable excited molecules which originate in the discharge. These have a long life and eventually emit radiation. In the atom theory excitation of metal atoms (Hg, etc.) occurs either by a triple collision with N atoms or by a collision with the resulting excited N_2 molecule. In the molecular theory this excitation takes place directly by collisions with excited N_2 molecules,

cule.[7] Furthermore, a study[8] of the dependence of the afterglow intensity on the concentration of the active constituent at constant total nitrogen pressure reveals that the relation is bimolecular in character. This and other evidence points strongly to the atom theory. The results of Willey and Rideal,[9] while correct as far as they go, cannot be taken to mean that active nitrogen is composed only of 2-volt excited molecules. These authors neglect to consider many reactions initiated by active nitrogen which require much more energy than 2 volts. The varied phenomena caused by active nitrogen make it evident that 2-volt level nitrogen molecules do not issue from the discharge. It is rather more probable that these vibrational states in the normal electron level, which in all probability are truly metastable, are brought into existence by collisions of the second kind between an ordinary nitrogen molecule and an excited nitrogen molecule in level B. The former takes up from 1 to $3^1/_2$ volts and the latter drops to level A. Vibrating molecules in the normal electron level may also be brought about by a jump from some higher electron level. We can attribute Willey and Rideal's results to molecules in these low vibrational states. In a recent work Constantinides[10] concludes that active nitrogen is an excited molecule having a metastable state between 9.4 and 10.4 volts. This is at variance with our knowledge concerning the origin of the first positive bands as mentioned above. This work will be discussed briefly in a later section.

The importance of determining whether active nitrogen contains atomic nitrogen is evident. The present experiments were undertaken with this in mind and they probably furnish the first kinetic evidence of its kind that nitrogen atoms are present in active nitrogen. In principle the experiments depend upon the formation of ammonia from the elements. It is easily shown that if unactivated nitrogen gas is mixed with atomic hydrogen (prepared by Wood's method), at least four successive and selective collisions passing through intermediate unstable compounds are necessary in order to form ammonia. The following set of equations is not intended to indicate the order of the steps involved nor the possibility of their occurrence, only that such a sequence is required to reach the final product.

$$N_2 + H = N_2H \tag{1}$$

$$N_2H + H = N_2H_2 \tag{2}$$

$$N_2H_2 + H_2 = N_2H_4 \tag{3}$$

$$N_2H_4 + H_2 = N_2H_6 \longrightarrow 2NH_3 \tag{4}$$

If the gases are brought together at low pressures the chance is very small that the entire series will be completed especially in view of the

[10] Constantinides, *Phys. Rev.*, 30, *95* (1927).

rarity of such encounters as depicted by Equation 2. Similarly it can be shown that on bringing together unactivated hydrogen and active nitrogen three or four successive and selective encounters are required, depending on whether the series commences with molecular or atomic nitrogen. In both of these types of experiments the chance for forming ammonia should be very slight. If now atomic hydrogen is mixed with active nitrogen there are two possibilities; with the metastable nitrogen molecule the sequence is composed of four steps similar to that given above; on the other hand if atomic nitrogen is present, only two steps are necessary, neither of them being of rare occurrence, since Wood's hydrogen contains a considerable amount of atomic hydrogen.

$$N + H = NH \quad (1)$$
$$NH + H_2 = NH_3 \quad (2)$$

Thus the synthesis of ammonia has the best chance of occurring, if at all, only when both gases are activated and provided the activated nitrogen contains atomic nitrogen. The alternative to such a series of steps would necessitate a triple, quadruple or quintuple collision which would still place the last-mentioned possibility in the most favorable position for ammonia formation. Of course, the presence of neutral, tri-atomic hydrogen might form ammonia in a single step, but its existence is extremely doubtful.[11]

There is one other possibility to be considered, namely, the following reaction with excited nitrogen molecules.

$$N_2' + H = NH + N \quad (1)$$
$$NH + H_2 = NH_3 \quad (2)$$

If this were taking place Caress and Rideal[12] would have observed ammonia formation in the gas phase at potentials corresponding to the numerous vibrational states in the 7.9-volt and 9.3-volt electron levels in the nitrogen molecule. Instead they found ammonia formation beginning at 13 volts, which they represented as a series of steps commencing with ordinary nitrogen and an excited H'_{13v}. Since their electron tube was not calibrated and a tungsten filament was employed, this voltage may be in error by at least one volt. While the hydrogen atom has critical potentials from 10.2 volts and up, it is strange why, if their mechanism is correct, ammonia is not formed in the gas phase at 10.2 volts, the first resonance potential of the hydrogen atom. Now this is very significant in view of the fact that level C (see Birge and Sponer[6]) of the nitrogen molecule begins at 13 volts and that the vibrational states of level B beginning at 9.3

volts extend up to about 12.8 volts. It is well known that in contradistinction to iodine and oxygen molecules, the nitrogen molecule does not dissociate in a primary act. According to Birge and Sponer in the case of certain excited electronic states (such as level B in nitrogen) dissociation does not take place when the energy of dissociation is reached even with collisions occurring. Assuming that one product of dissociation is an excited atom, their predicted break in the series of vibrational states to account for this is observed in C level, $n = 4$ at 13.94 volts. This may correspond to a collisional dissociation of the molecule into a normal nitrogen atom and a 2.5-volt excited N atom, which is possible from certain findings by Hopfield.[13] This is in agreement with conclusions derived from the extrapolated convergence limit of the upper band of the Lyman-Birge-Hopfield band system.' Thus Caress and Rideal's observed reaction in the gas phase at 13 volts ± 1 volt may, in the light of the foregoing, be represented more logically by excitation of the nitrogen molecule above its dissociation energy (probably to some vibrational state in the C level), followed by collisional dissociation into atoms. Ammonia is then easily formed through the medium of atoms as represented in a mechanism above.

Experimental

The electrodeless discharge for preparing active nitrogen, employed by other workers with excellent results, was substituted for the usual condensed discharge with internal electrodes, since the gas pressure was low. The experimental arrangement is shown in Fig. 1. The active nitrogen was prepared in a spherical bulb A (12.7 or 8.7 cm. in diameter) wound with a few turns of heavy copper wire. The electrical connections are evident. **A** zinc spark-gap was employed and the plate-glass lead foil condenser (5 in number, 18 X 20 inches) was immersed in transformer oil. The transformer primary was supplied with 9 to 10 amperes at 110 volts, 60 cycles, and the secondary voltage was about 20,000 volts. At a well-defined pressure (about 0.1 mm. in the 12.7 cm. and about 0.05 mm. in the 8.7 cm. bulb) a brilliant ring discharge appeared from which glowing active nitrogen was drawn and under good conditions could be observed to last between one and two minutes. Tank nitrogen was passed over heated copper to remove most of the oxygen, through soda lime and phosphorus pentoxide tubes and then through a liquid air trap L, nearly atmospheric pressure being maintained by a mercury trap M. By means of a needle valve V, the pressure in **A** could easily be regulated at any desired value. Atomic hydrogen was prepared in a Wood's discharge tube B, 2 meters long and 2 cm. in diameter with cylindrical aluminum electrodes. The transformer primary was supplied with from 10–14.5 amperes at 110 volts, 60 cycles, and the secondary voltage was about 20,000 volts. The atomic hydrogen, whose presence could be shown by a glowing platinum strip, was drawn from the center of the discharge tube where the brilliant spectrum due to the Balmer series was always in evidence. The hydrogen was prepared from a potassium hydroxide solution in a long armed U-tube continuous generator G, care being taken to prevent the oxygen from mixing with the hydrogen by allowing the platinum electrodes to just touch the liquid surface in each arm. Any caustic in the gas was carefully removed. The pressure was regulated as

---

[13] Hopfield, Phys. *Rev.*, 27, 801 (1926).

before by means of a needle valve. A calibrated McLeod gage was connected to both the nitrogen and hydrogen systems just before each gas entered its respective discharge tube. The entire apparatus with the exception of the needle valves was constructed of Pyrex glass. The gases, after leaving the discharge, were brought together in a chamber C, the hydrogen through a 1mm. nozzle about 24 cm. from its discharge tube and the nitrogen through a 2mm. stopcock about 20 cm. from the electrodeless discharge. The tubes leading from both discharges were grounded in several places with tin-foil to eliminate as far as possible stray high-frequency currents. Both transformers were at some distance from the discharges. A little excess pressure could be maintained on the hydrogen side. With due precaution exercised in starting an experiment, it was found that no mixing of the gases occurred outside the mixing chamber during the progress of a run. Any diffusion and mixing of the gases in either is immediately noticeable by suppression of the Balmer lines in the hydrogen tube and the appearance of a pinkish color instead of the usual greenish-yellow in the nitrogen discharge. All three types of experiments were carried out under the same conditions. Condensable gases were frozen out in a ground-glass jointed liquid-air trap D, the gases being pulled through the system by two high-vacuum oil pumps joined in parallel. At the close of an experiment the trap was removed, distilled water added while still in liquid air and the tube stoppered. Tests for ammonia were made with freshly prepared Nessler reagent and for hydrazine with selenious acid and silver nitrate, the hydrazine first having been stabilized with a drop of sulfuric acid. With selenious acid a reddish precipitate develops and with silver nitrate silver precipitates. Blank tests were made in every case with distilled water.

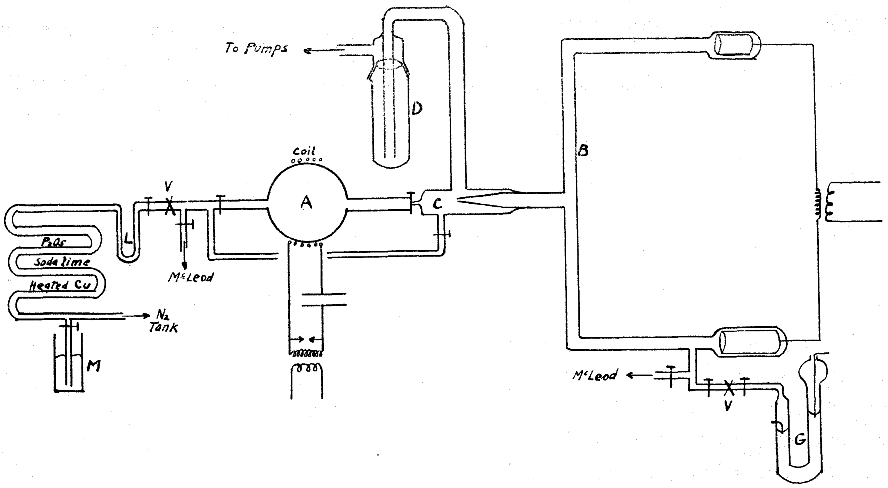

Fig. 1.

Results

The following table presents the results of a series of runs.

The results show that *ammonia is formed only when active nitrogen is mixed with atomic hydrogen.* From considerations presented above, this can be interpreted to indicate the presence of nitrogen atoms in active nitrogen.

TABLE I

RESULTS OF A SERIES OF RUNS

Press., mm. of Hg N_2	H_2	Gas activated	Time of run, min.	Result and remarks
0.15	0.26	H_2	30	No NH_3. After one day no difference between test solution and blank test
.31	.42	H_2	60	No NH_3
.25	.375	H_2	60	No NH_3; no N_2H_4
.33	.38	H_2	85	No NH_3; no N_2H_4
.17	.28	H_2	60	No NH_3; no N_2H_4
.04	.10	H_2	60	No NH_3; no N_2H_4
.09	.15	N_2 and H_2	60	NH_3 present, deep yellowish-red characteristic color with $^1/_3$ of solution. No N_2H_4
.076	.076	N_2 and H_2	90	NH_3 present, deep characteristic color with $^1/_3$ solution. No N_2H_4
.04	.044	N_2 and H_2	85	NH_3 present; deep yellow color with tinge of red with $^1/_2$ of solution. No N_2H_4
.25	.39	Blank run, no activation	60	No NH_3; no N_2H_4
.045	.045	N_2	60	No NH_3; no N_2H_4
.047	.040	N_2	50	No NH_3; no N_2H_4

Discussion

To the author's knowledge this is the first attempt to bring together active nitrogen and atomic hydrogen after the activation of each gas separately. Previously either nitrogen or hydrogen alone or a mixture of the two gases was activated. The results of these experiments activating the nitrogen only are in agreement with those of other investigations.[14,9] *Active nitrogen has no effect on molecular hydrogen, no ammonia being formed.* The evidence for the formation of ammonia upon mixing ordinary nitrogen with atomic hydrogen is conflicting. Hirst[15] found ammonia and traces of hydrazine when hydrogen in the presence of nitrogen was activated by collision with optically excited mercury atoms. This may have been due to the presence of a mercury surface, which agrees with the observations of Caress and Rideal[12] on the formation of ammonia on a metal surface with hydrogen atoms and nitrogen molecules. At pressures above but not below atmospheric, W. A. Noyes, Jr.,[16] obtained ammonia at the temperature of boiling mercury by a similar method of hydrogen activation. On the other hand, H. S. Taylor,[17] employing the same means for excitation failed to detect any ammonia. Bon-

hoeffer[18] also failed to find ammonia using the Wood's discharge tube for producing atomic hydrogen. Cario and Franck[19] also obtained negative results with atomic hydrogen and molecular nitrogen. Willey and Rideal[20] state that they were able to obtain ammonia when a stream of nitrogen at 10 mm. pressure was led into a stream of hydrogen at a point 150 cm. (corrected by Dr. Willey) from a discharge tube through which hydrogen was flowing at the same pressure. The gas pressure was far too high for the preservation of atomic hydrogen 150 cm. from the discharge.[21] In Willey and Rideal's experiment the presence at the mixing point of any form of ionic hydrogen or an electronically excited atom is precluded and, since the existence of H_3 is problematic, it is a little difficult to understand what variety of active hydrogen they were dealing with. It may be concluded from the present results and other evidence available that *no ammonia is formed by atomic hydrogen and unexcited molecular nitrogen.*

In support of the present results on the formation of ammonia when both hydrogen and nitrogen were activated separately may be cited the experiments of Andersen[22] and Storch and Olsen[23] on the formation of ammonia from gaseous mixtures of nitrogen and hydrogen with slow electrons and in the low-voltage arc. Olsen[24] concludes that the main synthesis of ammonia is brought about by the presence of both normal nitrogen atoms and normal hydrogen atoms.

Brief mention should be made of Constantinides' experiments.[10] If the effects observed by him represent ionization, then it would appear that active nitrogen is able to ionize iodine but not mercury (ionization potentials, 9.4 volts and 10.4 volts, respectively). From this it was concluded "that active nitrogen is an excited molecule of nitrogen having a metastable state between 9.4 and 10.4 volts." This does not eliminate the atom theory as it would at first appear. Our knowledge of energy transfer in triple collisions is still obscure. Physical intuition would indicate that all the energy of combination of nitrogen atoms might not be transferred to systems like iodine or mercury, expecially in view of the known low vibration states in the normal electron level in the nitrogen molecule. This would be equally true whether these systems collided directly with two nitrogen atoms or with an excited nitrogen molecule. Furthermore, it is unreasonable to assume that a symmetrical collision between two nitrogen atoms and a nitrogen molecule would in-

volve the same energy transfer as a collision between two nitrogen atoms and iodine or mercury. This argument is very significant if the combination of nitrogen atoms involves a two body collision only. It is not at all surprising, therefore, to find that active nitrogen is incapable of transferring 10.4 volts to mercury. Active nitrogen even seems to be incapable of producing an active variety of hydrogen,[20] the dissociation of which requires only 4.2 volts. One prediction may possibly be allowable. The higher the nitrogen pressure the more readily are the α bands eliminated due to secondary collisions in which the excited nitrogen molecules are divested of small amounts of energy. This is borne out by observations on the afterglow decay time and intensity with increasing nitrogen pressure. At low pressures, therefore, active nitrogen may be expected to transfer more energy to mercury. Indeed, Ruark, Foote, Rudnick and Chenault,[25] by recording the emission of the mercury $2^3P_1 - 6^3D$ series at 0.02 mm. nitrogen pressure, showed that at least 10 volts could be transferred to mercury. It is possible that at this and lower pressures some mercury atoms may be ionized.

Conclusion

It may be concluded from these experiments that active nitrogen contains atomic nitrogen. Until the atomic origin of active nitrogen is shown definitely to be erroneous, this can be taken as supporting the present interpretation of spectroscopic data. Since the nitrogen molecule may exist in many states of excitation, it is evident that at any moment glowing active nitrogen would consist of a non-homogeneous mixture of normal nitrogen atoms and nitrogen molecules in a number of excited states. An intimation that active nitrogen contains more than one active constituent may be gathered from a conclusion of Lord Rayleigh (Strutt)[26] that "there does not appear to be any definite connection between the development of spectra by active nitrogen and the chemical actions in progress." Since this paper was originally written, a private communication from Dr. a. J. B. Willey and later his letter to *Nature*,[27] also a suggestion by Bonhoeffer and Kaminsky,[8] indicate that these workers also suspect the non-homogeneity of active nitrogen.

Summary

Experiments are described for determining whether atomic nitrogen is a constituent of glowing "active nitrogen." The latter, prepared at low pressures by an electrodeless discharge, was passed into a stream of atomic (Wood's) hydrogen. The resulting mixture yielded ammonia. Under the same conditions no ammonia was obtained when either the

nitrogen or hydrogen was activated alone. No hydrazine was found under any conditions. Considerations are presented showing that at low pressures ammonia would be expected, if at all, only when both the nitrogen and hydrogen are activated simultaneously and provided atomic nitrogen were present in the former. It is concluded that active nitrogen contains atomic nitrogen, which may be taken as support for the present interpretation of spectroscopic data. In addition it is concluded that glowing active nitrogen consists of a non-homogeneous mixture of nitrogen atoms and excited nitrogen molecules.

THE SYSTEM WATER AND THE SULFATES OF SODIUM AND MAGNESIUM[1]

BY WALTER C. BLASDALE AND HOMER L. ROBSON

RECEIVED SEPTEMBER 12, 1927 PUBLISHED JANUARY 5, 1928

In 1915 D'Ans[2] summarized the work of van't Hoff,[3] Roozeboom[4] and others on this system, and made sufficient new determinations to indicate the equilibrium relations in this system between 0 and 90°. The isotherm at 25° was determined by W. C. Blasdale in 1920 in connection with a study of the salt pair, sodium chloride--magnesium sulfate,[5] and the isotherm at 103° was similarly determined by Mayeda[6] in the same year. Archibald and Gale[7] in 1924 determined isotherms of this system at 0°, 10°, 18.7°, 25°, 30°, 40°, 50°, 60°, 80° and 100°, combining new determinations with the results of previous investigators. Their isotherms below 60° are in very fair agreement with those given by D'Ans, but those at 80 and 100" differ considerably. Mayeda's measurements disagree with those of D'Ans and of Archibald and-Gale and are somewhat different from the values given in this paper.

The salts which occur below 60° are: the dodecahydrate, heptahydrate and hexahydrate of magnesium sulfate; sodium sulfate, decahydrate and

anhydrous; and the double salt, astrakanite ($MgSO_4.Na_2SO_4.4H_2O$). We have found that these salts come to equilibrium with their aqueous solutions with reasonable rapidity. Above 60° loweite ($MgSO_4.Na_2SO_4.$-$2/5H_2O$), vanthoffite ($MgSO_4.3Na_2SO_4$) and kieserite ($MgSO_4.H_2O$) occur. These salts come to equilibrium much more slowly and easily form supersaturated solutions. This is probably the cause of the disagreement of previous workers in this region.

We have made equilibrium measurements between **67** and 100°, including a determination of the isotherm at 75, 85, 95 and 100°, and have made sufficient measurements between 100 and 210° to indicate roughly the equilibrium relations within this temperature range. These measurements have been carefully compared with those of previous investigators and isotherms have been constructed for all temperatures for which data were available. Fig. 1 has been constructed from the isotherms as described below. From this figure the composition of any stable solution in this system may be found for the temperature interval 0 to 210°.

The heavy lines in Fig. 1 represent univariant systems and form a figure similar to that employed by D'Ans. They give the composition of solutions in equilibrium with two solid phases; the points which they intersect give the composition of invariant solutions. Temperature is measured on the horizontal axis and the composition of the solution on two vertical axes, one extending above and one below the heavy horizontal line. The upper vertical axis gives the magnesium sulfate concentration of the solution in grams of magnesium sulfate per 100 g. of water, and the lower gives the concentration of sodium sulfate similarly expressed; therefore the magnesium sulfate concentration of any univariant solution may be found from the line representing it in the upper part of the diagram and the sodium sulfate concentration from the corresponding line in the lower part. The circles represent equilibrium measurements given in Table II.

The fine lines give the total concentration of salts in grams per 100 g. of water. From them the composition of any solution in equilibrium with a single salt may be determined. Thus, to find the sodium sulfate concentration of a solution in equilibrium with astrakanite at 45°, which contains **46** g. of magnesium sulfate per 100 g. of water, the point in the upper part of the diagram corresponding to 46 g. of magnesium sulfate at 45° would be found. This lies between the fine lines representing total salt concentrations of **56** and 57 g. per 100 g. of water, and a value of **56.7** is obtained **by** interpolation. As **46** g. of this is due to magnesium sulfate, the remaining 10.7 grams would be the concentration of sodium sulfate in the solution. In this manner isotherms can be constructed from this diagram for any temperature between 0 and 210°.

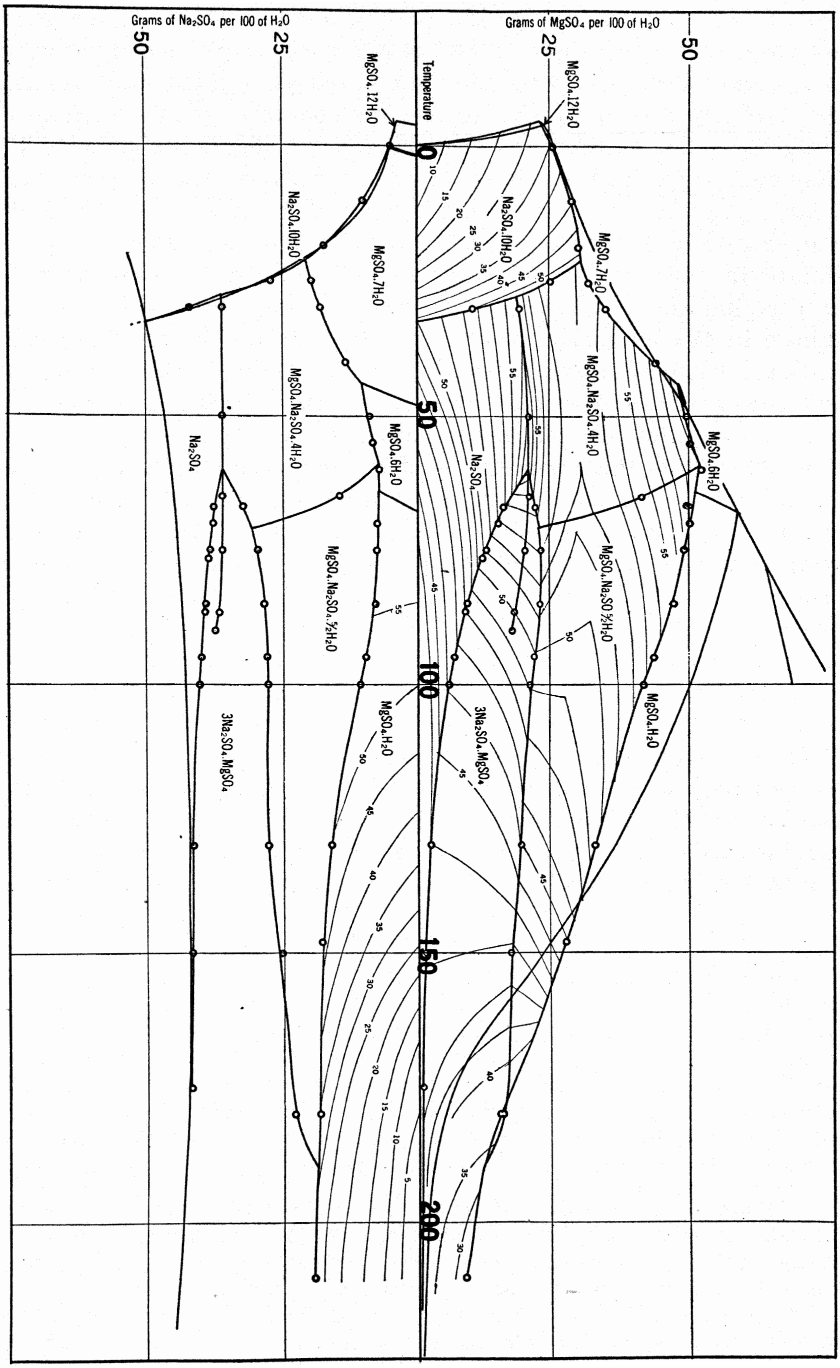

Fig. 1.—The system between —5 and 210°.

In attempting to correlate the data of previous observers it was found advantageous to eliminate the water as a variable and to plot the per cent. of magnesium sulfate in the total anhydrous salts in the solutions against the temperature, according to the method of Jänecke.[8] Data which disagreed when plotted as isotherms or on a diagram similar to Fig. 1 frequently agreed reasonably well when plotted on this type of diagram, a large part of the discrepancies being due to an error in the total salt concentration rather than in the ratio of magnesium sulfate to sodium sulfate in the solution. Smooth curves were drawn through the data on this diagram and these gave the ratio of magnesium sulfate to sodium sulfate in the univariant solutions. The data on the total salt concentration for each univariant system were then plotted against temperature and smooth lines drawn through the points, which met corresponding lines representing other univariant systems at the invariant points. From these two plots the compositions of the univariant systems were determined and plotted as the heavy lines of Fig. 1. Next, series of isotherms at intervals of 5 and 10° were made, based on the data for the univariant systems which had been determined as above described. The published measurements of Roozeboom and of Archibald and Gale and those which we determined were plotted on these isotherms and smooth lines drawn through the points. From the data given by these, the fine lines in Fig. 1 were constructed, alterations in the isotherms being made where necessary to avoid improbable distortion of the fine lines. The fine lines were placed at intervals of 5 g. of total salts per 100 g. of water in the areas representing solutions in equilibrium with sodium sulfate decahydrate and kieserite, as the diagram would be unduly complicated by placing them at unit intervals. Unit intervals are employed for the areas representing astrakanite, loweite, vanthoffite and thenardite (anhydrous sodium sulfate).

Preparation of Salts

Commercially obtainable epsomite ($MgSO_4.7H_2O$), mirabilite ($Na_2SO_4.10H_2O$) and thenardite were employed for these salts and their filtered solutions for the preparation of the others. Magnesium sulfate hexahydrate is easily prepared by the evaporation of a solution of magnesium sulfate between 50 and 75°. Astrakanite was prepared by evaporating equimolecular solutions of the component salts at 50–55° and good crystals up to 1 cm. in length were grown from solutions at 60–95°. We did not succeed in growing single crystals at temperatures below 50° which were suitable for goniometer measurements.[9] Löweite was prepared by the slow evaporation of a

---

[8] Janecke, *Z. anorg. Chem.*, *51*, 132 (1906). This method has been described by Blasdale, "Equilibrium in Saturated Salt Solutions," A. C. S. Monograph Series, 1927, employing this system as an example. The diagram there given does not include the results of our measurements, which were unfinished at the time of writing.

[9] For data on the crystallography of astrakanite, see von Jeremejeff, *Z. Kryst.*, 23, 269 (1891). In the literature this salt is also referred to as bloedite and as simyonite, see Jaeger, *Tschermaks' Min. Pet. Mitt.*, 22, 102 (1903).

solution containing magnesium and sodium sulfates in the molecular ratio of 3:2 at the boiling point, with additions of an equimolecular solution from time to time to maintain a constant composition of the solution. The precipitated salt was centrifuged and then pressed between filter paper while still warm. Each batch was analyzed and found to contain very little excess magnesium sulfate and nearly the theoretical water. A small amount of astrakanite was detected by microscopic examination. The presence of this small amount of astrakanite ordinarily does not matter and it can be removed by drying the salt in a partly closed vessel at 110° when necessary.

Vanthoffite was prepared by the slow evaporation of its congruent solution close to the boiling point, the solution being well seeded and vigorously agitated with a stream of compressed air. The salt was centrifuged and dried at 110°. It is very difficult to prepare this salt at temperatures below 95° as thenardite and astrakanite form more readily than the stable vanthoffite.

Kieserite was prepared by drying epsomite in air as described in a previous paper" and by stirring solutions of magnesium sulfate in contact with seed at 80–100°. The latter method gives a product which is very difficult to dry and is best stored wet at a temperature above 70°.

Identification of Compounds

The solid phases in contact with the analyzed solutions were identified by analysis and by their optical properties, which are in Table I.[11]

TABLE I

OPTICAL PROPERTIES OP THE SALTS

Salt	a	β	γ	2V	Sign	Disp.	Orientation	System
Hexahydrate	1.438	1.463	1.465	29"	−	$\rho > v$	Y = b, $X_\wedge c$ −25"	Mono.
Kieserite	1.523	1.525	1.596	57"	+	$\rho > v$	Y = b, $Z_\wedge c$ 76.5°	Mono.
Thenardite	1.464	1.474	1.485	84°	+	$\rho > v$(w)	X = b, Y = c	Ortho
Vanthoffite	1.485	1.488	1.489	84°?	−	$\rho < v$	....	Mono.?
Astrakanite	1.486	1.488	1.489	71°	−	$\rho < v$(str.)	Y = b, $X_\wedge c$ 41.1"	Mono.
Löweite	...	1.471	1.490	Uni-axial	−	...	....	Rhombo-hedral

Löweite is easily recognized by its uniaxial interference figure, hexahydrate by its figure and low index of refraction, and kieserite by its fine-grained structure and high index. Vanthoffite and astrakanite were difficult to distinguish and closely resemble thenardite from which they may be distinguished by their lower birefringence. The crystal form and optical orientation were frequently made use of. Many of the crushed fragments of thenardite have a diamond-shaped appearance, with an angle close to 60° (theor. 61° 44' for $110_\wedge 1\bar{1}0$); vanthoffite forms some diamond-shaped crystals with a much sharper angle. Astrakanite occurs in laths and in combinations of the base, unit prism and dome (001, 110 and 101). The presence of vanthoffite, astrakanite and thenardite was verified by analysis or by means of a check on the salts added.

---

[10] Robson, THIS JOURNAL, 49, 2772 (1927).

[11] Larsen, "The Microscopic Identification of the Non-Opaque Minerals," Bulletin 679, U. S. Geological Survey, 1921. The data for magnesium sulfate hexahydrate are those given by Robson, ref. 10.

In examining the optical properties of the various solid phases a small portion was removed, rubbed dry on warmed blotting paper and examined with a petrographic microscope employing suitable immersion media. When an analysis of the solid phase was required, 2–5 g. was removed from the solution and quickly dried with filter paper, weighed, made up to volume and analyzed. No attempt was made to employ the residue method of Schreinemakers.[12]

The presence of astrakanite in samples known to contain thenardite or loweite, and of vanthoffite in samples containing thenardite or loweite, was determined from the ratio of magnesium sulfate to water in the sample. All doubtful analyses were rejected. Vanthoffite and astrakanite would not occur together except along the univariant line between 60 and 71°.

In making many of the measurements the solid phases were first prepared and analyzed, weighed amounts added to the solubility tubes and a solution of the expected equilibrium concentration, prepared by the evaporation of standardized stock solutions of the two sulfates to a definite strength, was added, The volume was noted before and after stirring. Any alteration in the solid phases would have been readily detected by comparing the analysis of the final solution with the known amount of water and salts added to the tubes.

The optical examination of the solid phases greatly facilitated the preliminary work and gave positive identification in cases where other methods alone would have left some room for doubt.

Transition Points

The transition point of magnesium sulfate dodecahydrate and heptahydrate was determined by Cottrel[13] to be 1.8' and the cryohydric point, dodecahydrate-ice-solution of magnesium sulfate, to be —3.9°. We assume that the corresponding point, dodecahydrate-mirabilite-ice-solution of sodium and magnesium sulfates, will be about —5° and the invariant point, dodecahydrate-mirabilite-epsomite-solution of sodium and magnesium sulfates, about 0°. The invariant point, epsomite-mirabilite-astrakanite-solution, was determined by van't Hoff[1c] thermometrically to be 20.6° and the invariant point, mirabilite-astrakanite-thenardite-solution, thermometrically by D'Ans[2] as 27°. The transition of epsomite to hexahydrate was found to occur at 48.4° by Carpenter and Jette,[14] and this temperature is probably lowered 4° by the presence of astrakanite. We determined the invariant point, hexahydrate-astrakanite-löweite-solution, dilatometrically, to be about 59.5'. Two tubes were employed, the first giving a contraction below 58.5' and an expansion above 60.5°, and

---

[12] Blasdale, ref. 8, page 86.

[13] Mentioned by van't Hoff, Meyerhoffer and Smith, *Sitzb. preuss. Akad. Wiss.*, Berlin, 1901, p. 1035; "Untersuchungen," p. 173.

[14] Carpenter and Jette, THIS JOURNAL, 45, 578 (1923).

the second a contraction at 59° and an expansion at 60.2°. The invariant point, astrakanite-vanthoffite-thenardite-solution was found to be 60° by interpolation as the equilibrium was established so slowly it was not possible readily to determine the point by dilatometric or tensimetric methods. Van't Hoff, Meyerhoffer and Smith[13] found the transition of hexahydrate to kieserite to occur at 68° in contact with a solution of magnesium sulfate; the presence of loweite would probably lower this temperature by 4°. The invariant point, astrakanite-löweite-vanthoffite-solution, was found by van't Hoff and O'Farrelly[3e] to lie at 71° by dilatometric investigation.

The transition of loweite to vanthoffite and kieserite occurs above 100°. Jänecke[15] obtained seemingly conclusive evidence for a transition temperature between 120 and 130° with a strong expansion accompanying the transition. We were unable to verify his findings. Two Pyrex dilatometers, the lower portion of one of which is represented in Fig. 2, were employed, with balancing columns of mercury three meters high in a tube 0.8 mm. in diameter and a bulb of 60 cc. capacity. With these the region between 115 and 137° was explored very carefully and no expansion was observed. The tubes were loaded with finely powdered kieserite, loweite and vanthoffite, with about 10% of astrakanite to provide the proper solution on melting at 71°. These were exhausted rapidly at 80°, filled with paraffin oil (Nujol) and sealed off; after filling the arm with mercury they were brought to equilibrium at 115 and 120°, respectively. A slow contraction accompanied the conversion of the kieserite in the charge to loweite, and this was completed in three days at 120°. At the conclusion of the trial with the second dilatometer, which lasted three weeks, the bath was brought to 120° and the dilatometer gave the initial reading. The room temperature was kept within one degree of 22° for one half hour preceding measurements to avoid any effect of temperature on the mercury column. An expansion corresponding to the initial contraction could have been easily observed without this precaution.

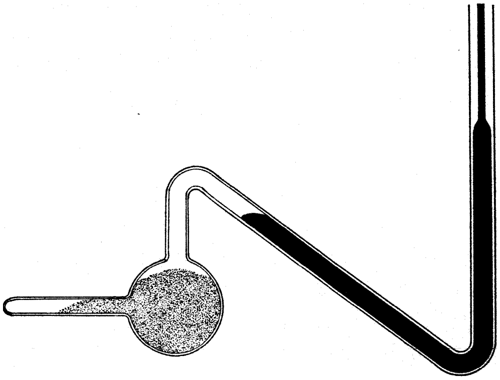

Fig. 2.—Cross section of lower portion of tensimeter.

This type of apparatus became awkward for making **observations** at higher temperatures than 137°, so experiments were continued employing

---

[15] Jänecke, *Kali*, 11, 12 (1917).

the solubility bomb described below. The bomb was charged with a saturated equimolecular sodium and magnesium sulfate solution and loweite, with a small amount of kieserite and vanthoffite as seed, and stirred at the required temperature for one or two days. At the conclusion of stirring the solution was drained from the solid phase by inverting the bomb and opening the valve until all the liquid had passed out; the bomb was then quickly opened and the solid phase examined with the petrographic microscope. Löweite was clearly detected in all mixtures stirred, up to 180°, but was replaced by vanthoffite and kieserite at 210°. The exact transition point, representing the equilibrium

$$3MgSO_4.Na_2SO_4.5/2H_2O \longrightarrow MgSO_4.3Na_2SO_4 + 2MgSO_4.H_2O + \text{solution}$$

was not determined, but probably lies close to 190°.

Solubility Determination

The equilibrium determinations below the boiling point were made by stirring the mixtures of salt and water in tubes of Pyrex glass 4 cm. X 30 cm. with a screw stirrer 10 cm. long and 2.5 cm. wide. The stem of the stirrer was 0.8 cm. thick and 30 cm. long, and rotated in a Pyrex tube which passed through two close-fitting rubber stoppers, one at the top of the tube and one below the level of the oil in the bath. This arrangement prevented water from distilling out of the tube or condensing on the cooler portions inside it. Individual motor drives were found to be more satisfactory than a main pulley drive. A load of 150 g. of solution and 100 g. of salts was usually charged.

In the preliminary experiments the stirrers were driven at 150 r. p. m. With this speed of stirring, equilibrium was attained very slowly and in some cases variable results were obtained after several weeks of stirring. With a stirring speed of 1000 to 1500 r. p. m. equilibrium was attained much more rapidly. We did not observe any shift in the equilibrium with variation in the speed of stirring. Some experiments were made in which the proper amounts of thenardite and epsomite were added in lieu of vanthoffite and loweite, but the solutions obtained were supersaturated unless stirred for an impractical length of time.

The experiments above 100° were made with an apparatus similar to one already described,[10] except that a different head was made for the bomb. The diagram of the head is given in Fig. **3.** The nipple of the condenser is fastened into the head by a threaded sleeve. The opening into which this fits is closed by a plug during stirring. The solution on passing the filter and needle valve had only to travel through 15 mm. before entering the nipple of the condenser, which is 3 mm. wide and 40 mm. long. This is attached to the main condenser tube, which is 10 mm. wide and 50 cm. long, the last 30 cm. being bent in the form of a U-tube, which was immersed in ice water during sampling. This arrangement has been employed in working with solutions of potassium chloride and sulfate and has proven very satisfactory. Different filter disks (Alundum disks, mix R. A. 225, supplied by the Norton Co.) from those employed for the system magnesium sulfate-water were employed and these let a small amount of very finely-divided kieserite through, giving the mixtures a milky appearance. Only one-third by weight of the charge was solution, to avoid any possibility of supersaturation. The exact amount of error from the kieserite passing the filter was not determined, but measurements of the solubility of magnesium sulfate alone under similar conditions gave results very little above the known curve and the error is probably less than 2 g. of magnesium sulfate per 100 g. of water. Preliminary measurements showed that the solutions did not come to equilibrium between 100 and 175° very much faster than between 75 and 100°.

Solutions supersaturated with respect to vanthoffite were prepared by evaporating appropriate mixtures of the stock solutions of the two sulfates. These precipitated astrakanite spontaneously and came to equilibrium in two or three hours. If seeded with about 2% of vanthoffite and stirred rapidly, stable equilibrium was obtained in one or two days. Solutions supersaturated with respect to löweite came to equilibrium with it most rapidly when the ratio of sodium sulfate to magnesium sulfate approached that required for equilibrium with vanthoffite; those with a higher ratio of magnesium sulfate to sodium sulfate required one or two days' stirring before reaching equilibrium. Solutions containing up to 50% more magnesium sulfate than that required for equilibrium with kieserite were easily prepared by evaporation. These required four to six days' stirring in contact with 10–20% of seed to come to equilibrium.

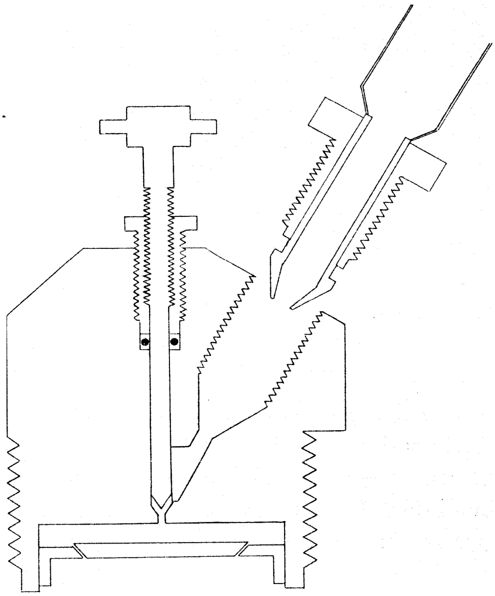

Fig. 3.—Cross section of upper part of bomb used for solubility determinations.

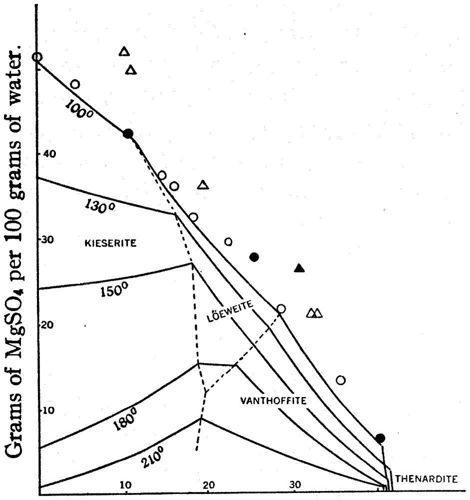
The behavior of a solution upon evaporation may be predicted from Fig. 4, which gives the isotherms at 100, 130, 150, 180 and 210°. The measurements of Archibald and Gale at 100° and of Mayeda at 103° are given on this diagram; our data are not given individually. Unless well seeded, the solution will be 10 to 20% supersaturated during concentration. Vanthoffite will not form under 95° unless a comparatively slow rate of concentration is employed. Appreciable amounts of kieserite will form if solutions supersaturated with respect to it are boiled for three hours or more, but with rapid evaporation its formation should be negligible. We sampled several freely boiling solutions which had deposited 10% by weight of salts and found them to be slightly more supersaturated than would correspond to the isotherm given by Archibald and Gale.



Grams of Na_2SO_4 per 100 grams of water.
○ Mayeda, 103°; △ Archibald and Gale. 100°;
A Univariant points.

Fig. 4.—Isotherms of the system.

The data are given in the table below. The first column gives the temperature and the second the reference, if the data are taken from previously published works. The third gives the experimentally determined fraction of magnesium sulfate of the total anhydrous salts in solution and the following column gives the average of the values. The fifth column gives the average value for the total salts, as grams per 100 g. of water, obtained by drawing a smooth curve through available data, as previously explained. The last two columns give the grams per 100 g. of water of magnesium and sodium sulfates.

The values in the third column are in each case those experimentally determined. Where the data of other observers have been employed, the most satisfactory value has been given in the table; the others have been given consideration in the construction of the initial diagram and the isotherms. The values given in this table are plotted in Fig. 1. They are not entirely concordant but sufficiently so to justify the construction of this type of figure. Owing to the limited number of measurements, the data above 100° cannot be considered as accurate as those at temperatures below the boiling point.

Summary

1. An apparatus has been developed with which equilibrium measurements in systems composed of two salts and water may be made at temperatures above the boiling point of the solution.

2. The literature relating to the system magnesium sulfate-sodium sulfate–water has been reviewed and presented along with new data obtained at temperatures between 67 and 210°.

3. The invariant point, löweite-hexahydrate-astrakanite-solution, has been found dilatometrically to lie close to 59.5°; and the invariant point, löweite-kieserite-vanthoffite-solution, to lie between 180 and 210°.

4. It has been shown that the disagreement in the previous data on this system between temperatures of 60 and 100° was probably caused by the extreme slowness with which the stable double salts come to equilibrium with their solutions.

5. The indentification of the salts occuring in this system by optical means has been discussed.

THE VALUE OF THE HAGENBACH FACTOR IN THE DETERMINATION OF VISCOSITY BY THE EFFLUX METHOD

BY WILLIAM RIEMAN III

RECEIVED SEPTEMBER 19, 1927 PUBLISHED JANUARY 5, 1928

Historical Introduction

For a more complete outline of the history of viscosity and in particular the value of the Hagenbach factor "m" in the kinetic energy correction, the reader is referred to Bingham's "Fluidity and Plasticity."[1] It is necessary to emphasize here only the following points. Numerous investigators have attacked the problem from the theoretical point of view, and have derived results identical in all respects except that the value of the constant m differs. None of the authors (prior to Bienias and Sauer-

---

[1] Bingham, "Fluidity and Plasticity," McGraw-Hill Book Co., New York, 1922, pp. 1–21,

wald) have obtained experimental data to support their conclusions. Knibbs'[2] work in this field is unique. He devised an excellent mathematical treatment whereby m can be derived from experimental data, but instead of performing the necessary measurements himself he used Poiseuille's[3] data. The average value for m for 14 tubes is 1.135, with a mean deviation of ±0.153. Because of the large probable error this result cannot be regarded as an indisputable confirmation of Bousinesq's[4] theoretical value of 1.12.

For years the science of viscosimetry has been handicapped by lack of definite knowledge concerning this constant. Some scientists use Bousinesq's value, others prefer Couette's[5] value of 1.00. As Bingham suggests, the best method of avoiding serious error is to select a viscometer of such dimensions that the kinetic energy correction is only 1 or 2% of the entire viscosity. Then a small error in the constant will cause only an insignificant error in the final result. Recently N. E. Dorsey[6] has studied the configurations produced by a stream of colored liquid flowing from a circular capillary with smooth, square edges directly into the clear water contained in a reservoir. "All the distances from the terminus to the walls of the reservoir are severally so great that the distribution of the flow of the liquid is essentially the same as if they were infinite." His own observations and the data of W. N. Bond[7] led him to draw the following conclusions. The value of m is zero and the value of the Couette correction, λ, is 1.146 R when Reynolds' number[8] is less than 10. When Reynolds' number is greater than 10, two situations are possible; in one m is still zero and λ is 1.146 R; in the other m is a constant, probably 1, and λ is 0.573 R. When Reynolds' number exceeds 700, m decreases and approaches the value of 0.735. These values apply only to the ideal conditions; variations in the shape of the capillary or its ends or in the shape of the reservoirs may cause variation in the value of m and λ.

Dorsey also calculated the value of m from Poiseuille's data and found a value of 1.04. This is at wide variance with Knibbs' result. The author's calculations of Poiseuille's data agree with those of Knibbs.

The problem of the Hagenbach factor has been attacked recently from a new angle by Bienias and Sauerwald.[9] These authors are primarily

interested in the viscosity of molten metals. Their viscometer was designed especially to meet the difficulties peculiar to this type of work and is not capable of as high a degree of accuracy as the instruments of Thorpe and Rodger,[10] or Bingham or other modern investigators. It consists essentially of a vertical capillary whose lower end is immersed in a bath of the metal contained in a carbon crucible. The upper end of the capillary is expanded into a bulb and is connected to a vacuum system and to a manometer. The determinations are made by applying suction and measuring the time required for the liquid to fill the bulb between two electrical contacts.

The dimensions of the apparatus are such that both the kinetic energy correction and the correction for varying hydrostatic head within the instrument must be applied. As Bingham[11] has demonstrated, when the hydrostatic pressure within the viscometer is greater than one-thirtieth of the pressure applied externally, it is not sufficiently accurate to consider the mean of the initial and final internal hydrostatic heads. We must consider the "chronological mean."[12] This value is greater than the mean of the initial and final values. In most viscometers the kinetic energy correction is necessary only at high velocities, whereas the correction for varying internal hydrostatic head is necessary only at low velocities. The necessity, encountered by Bienias and Sauerwald, of applying both corrections to the same measurement is unusual.

The procedure of Bienias and Sauenvald for the determination of m was as follows. Mercury at room temperature was sucked up into the viscometer and the time measured. Since the viscosity of mercury was known, all terms in the equation

$$\eta = \frac{\pi g P R^4 t}{8VL} - \frac{m\rho V}{8\pi L t}$$

were known or could be measured readily except m and P. The term P represents the pressure used to drive the liquid through the capillary. It is the difference between the manometer pressure, P„ and the chronological mean internal hydrostatic pressure, P_h,

$$P_m - P_h = \mathrm{P}$$

By assigning values to m we can calculate the value of P and hence of P_h. Dividing P_h by density, p, we get H, the chronological mean hydrostatic head.

The value of the chronological mean head was also determined by direct observation. The level of the mercury in the tube was measured at noted intervals of time. A curve between time and hydrostatic head was plotted and graphically integrated to obtain the chronological mean. This value ought to check the value calculated by the first method, pro-

vided the proper value of m was used in the calculation. The results of Bienias and Sauerwald are given in Cols. 1, 2, 3 and 4 of Table I.

TABLE I

RESULTS OF BIENIAS AND SAUERWALD

No.	Chron. mean head, cm. $m = 1$	$m = 1.12$	Chron. mean head by direct obs.	Probable error of calcd. value
1*	12.58	12.56	12.58	±0.02
2	12.29	12.24	12.29	± .04
3	12.18	12.10	12.17	± .05
4*	12.62	12.60	12.62	± .02
5*	12.30	12.24	12.28	± .04
6*	12.52	12.50	12.52	± .02
7	12.33	12.26	12.31	± .04
8	12.27	12.16	12.24	± .05
9*	12.81	12.78	12.80	± .02
10*	12.49	12.44	12.48	± .04
11	12.40	12.31	12.30	± .05
12	11.06	10.97	11.04	± .04
13	11.04	10.92	11.02	± .05
14	11.04	10.87	11.03	± .06

From these results Bienias and Sauerwald conclude that the correct value of m is unity.

A consideration of the errors involved in the work, however, reveals that their conclusion is not well established. They state that the probable error of their viscosity determinations is 1%. The same error would be attached to the determination of P by the method described above. Since P_h is obtained by subtracting P from P„ an error of 1% in P does not necessarily involve the same percentage error in P_h; but the probable error of P_h and H can readily be calculated. The results of these calculations are given in Col. 5, Table I. (The error in measuring the manometer pressure was assumed to be negligible.)

It is now obvious that the six results marked with an asterisk are meaningless, since the observed hydrostatic head (Col. 4) agrees with both calculated values (Cols. 2 and 3) within the limit of error of the latter values. In the majority of the remaining cases the probable error is so large, compared with the other differences, that very little dependence can be placed on the results. In one case (No. 11) the value, $m = 1.12$, gives the better agreement.

From these considerations it is evident that the conclusions of Bienias and Sauerwald concerning the value of m are drawn from meager, inaccurate and, in part, contradictory data. Apparatus designed for use with molten metals is not suitable for an accurate determination of the Hagenbach factor.

Apparatus

The work described herein had as its sole objective an accurate and reliable determination of m under experimental conditions similar to those generally used by modern investigators in the determination of viscosity.

The apparatus, in general design, is so similar to that recommended by Bingham,[13] that a detailed description is not necessary.

The viscometer, however, is somewhat different. Since it is desirable to change the capillary it was not fused into the viscometer but attached in a horizontal position to the two limbs of the instrument with stout rubber tubing. Since no change in working volume of liquid could be detected during use, we can feel certain that no appreciable leak occurred at the joints. In all other respects, such as traps, shape of bulbs, etc., the viscometer resembled Bingham's. It was immersed in a well-stirred water-bath whose temperature was automatically controlled within a few hundredths of a degree.

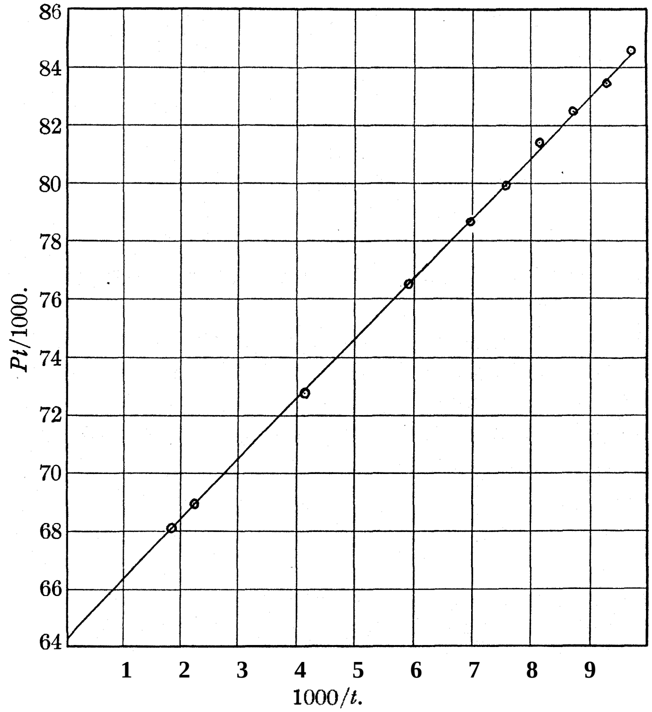

Fig. 1.

The volume of the viscometer and the dimensions of the capillary were selected so that at high pressures the kinetic energy correction, $m\rho V/8\pi Lt$ would be a large fraction, $^1/_7$ to $^1/_4$, of the uncorrected viscosity, $\pi gPR^4t/8VL$. At the same time care was taken to avoid the critical velocity and to avoid the use of apparatus too small to allow accurate measurements.

[13] Ref. 1, pp. 67 and 295–311.

Procedure

The volume of the bulb of the viscometer was carefully measured The capillary was selected and the edges were ground perpendicular to the axis. The length was measured with a micrometer caliper. The capillary was then attached between the limbs of the viscometer with heavy rubber tubing. The viscometer was filled with water and the time of efflux measured under a pressure of about 850 g. per sq. cm. This determination was run in duplicate or triplicate. Then the pressure was reduced somewhat, all other conditions remaining the same, and the time again measured. This process was repeated until a series of about ten readings was obtained for which only the pressure and time varied.

These results were then treated mathematically by the method of Knibbs. The equation is put in the form

$$Pt = \frac{8\eta VL}{\pi g R^4} + \frac{m\rho V^2}{\pi^2 g R^4}\cdot\frac{1}{t}$$

The values of Pt are plotted as ordinates and the values of $1/t$ as abscissas. From the above equation it is evident that if m is constant, the curve should be a straight line. Within the very small experimental error it was found to be such.

The intercept on the Y axis represents the value of Pt when the time is infinite, that is, when the kinetic energy is zero. Then

$$Pt = \frac{8\eta VL}{\pi g R^4}$$

Since the viscosity of water is known, we can use this equation to calculate the value of R. This gives a value of much greater precision than can be attained by microscopic measurement or by weighing a mercury slug.

The slope of the line, s, is equal to the coefficient of $1/t$.

$$S = \frac{m\rho V^2}{\pi^2 g R^4}$$

By use of this equation the value of m can be calculated.

Results

As an example of the method of plotting and calculating the value of m, the complete data for Series 6 are given in Table II.

TABLE II

COMPLETE DATA FOR SERIES 6

Detn. no.	P	t	$Pt/1000$	$1000/t$	Reynolds' number
1	826.3	102.35	84.57	9.770	1013
2	773.7	107.9	83.48	9.268	961
3	718.8	114.8	82.51	8.711	903
4"	662.2[a]	123.0[a]	81.45[a]	8.130[a]	843[a]
5	605.8	131.9	79.91	7.582	786
6	548.6	143.4	78.67	6.974	723
7	452.0	169.3	76.52	5.907	613
8	301.0	241.8	72.78	4.136	429
9	160.0	431.0	68.97	2.320	240
10	126.2	539.8	68.11	1.852	192

Temp. = 36° η = 0.007085 V = 10.018

L = 1.9278 g = 980.2 p = 0.9937

[a] Reject these values. High value for time, probably because of dust caught in capillary.

The results are plotted in Fig. 1.[14] From the figure we can see that the Y intercept is 64.173.

$$64{,}173 = \frac{8 \times 0.007085 \times 10.018 \times 1.9278}{\pi \times 980.2\, R^4}$$

Solving for R we find that $R^4 = 0.55394 \times 10^{-8}$ or

$$R = 0.0086270 \text{ cm.}$$

From the figure the slope is 2.089.

$$2{,}089{,}000 = \frac{m\ 0.9937\ (10.018)^2}{\pi^2\ 980.2 \times 0.55394 \times 10^{-8}}$$

$$m = 1.122$$

A summary of all the results obtained up to the present time is given in Table III.

TABLE III

SUMMARY OF RESULTS

Series no.	Cap.	L	Temp., °C.	$R\mu$	m
1	1	0.8096	25.00	52.463	1.110
2	1	.8096	22.00	52.498	1.127
3	1	.8096	36.10	52.467	1.134
4	1	.8096	25.00	See below	1.128
5	2	1.9278	34.00	86.278	1.124
6	2	1.9278	36.00	86.270	1.122

V = 10.018; av. m = 1 124; av. deviation = ±0.006.

In Series 4, methanol was used instead of water. A c. P. sample was further purified by fractional distillation and the portion distilling between 64.46 and 64.51' was collected for use. Its density was 0.79158 at 20° and 0.78695 at 25° Because of uncertainty concerning the viscosity of methanol and also because of the possibility of impurities in the sample used, no attempt was made to calculate R in this determination. Instead, the average of the three previous values was used for the calculation of viscosity. The viscosity was found to be 0.005508 at 25°. Interpolating the results of Thorpe and Rodger to the same temperature, we find a value of 0.005527. Since Thorpe and Rodger took more care in the purification of their sample, their result is probably more nearly correct. It should be noted, however, that Thorpe and Rodger used 1 for the Hagenbach factor. If they had used the value, 1.12, their result would have been 0.005521.

Microscopic Measurements.—Although microscopic measurements of the capillary radius are not sufficiently precise for use in the calculation of m, they must be used to gain knowledge concerning the shape of the capillary. The two ends of the thermometer tubing, which before break-

---

[14] In drawing the line which runs through the points with the minimum error, the graphical method cannot be considered sufficiently accurate. The mathematical treatment given on p. 327 of Mellor's "Higher Mathematics for Students of Chemistry and Physics," 4th edition. Longmans, Green and Co., New York, 1913, was used.

ing were in juxtaposition to the portion used in the viscometer, were used to prepare cross-section slides for the microscope. From these slides the major and minor axes of both ends of the capillary were determined by use of a filar micrometer. It was assumed that the cross section was elliptical, a fact which was supported by the appearance of the slide under the microscope. The formula of Knibbs

$$R = \sqrt[4]{\frac{3R_1^3R_2^3}{R_1^2 + R_1R_2 + R_2^2} \cdot \frac{(1 - e^2)^3}{1 + e^2}}$$

was used to calculate the value of R which should be used in the viscosity equation. In this formula, R_1 is the arithmetical mean of the semi-axes at one end, R_2 is the mean of the semi-axes at the other end; e is $(B - C)/(B + C)$, where B is the mean of the major axis and C is the mean of the minor axis. The results are given in Table IV.

TABLE IV

RESULTS

	Capillary 1	Capillary 2
End A. Major radius, μ	53.78	95.20
End A. Minor radius, μ	50.82	79.45
End B. Major radius, μ	54.20	95.20
End B. Minor radius, μ	50.46	79.35
R by micrometry	52 26	86.60
R by viscometry	52.476	86.274

The slight differences in the values of R obtained by the two different methods are due to errors in the microscopic measurements or to irregularities in the capillary between the two ends.

Discussion of Results

Precision.—In the individual measurements of length, volume, time and pressure, the precision varied from about 0.01 to 0.1%. Since the maximum internal hydrostatic pressure was less than one-thirtieth of the manometer pressure, the correction for varying internal head is less than the experimental error and can be omitted. The value of R^4 as determined by the viscosimetric method is attended by an error probably not greater than 0.1%. The percentage probable error of m is greater than that of R^4 in about the ratio, kinetic energy correction at high pressures to uncorrected viscosity. That is, the percentage probable error of m is 4 to 7 times that of R^4 or about 0.4 to 0.7%. This agrees with the mean deviation of m.

To the length, as actually measured, some investigators add the Couette end correction, nR, where n is a constant. Couette originally assigned to n a value of 6. More recent investigation indicates that the correction is much smaller, perhaps even zero. The correction has not been applied in our calculations because of the uncertainty of the correct value of n

and because it has only an insignificant effect on the calculated value of m. For example, if we use Dorsey's value ($n = 0.573$) in calculating the data of Table II we find $m = 1.125$, or 0.003 greater than the value calculated without the Couette correction.

Conclusions.—Within the range studied the value of m is 1.124 ± 0.006. This agrees with the theoretical value of Bousinesq, 1.12, within the experimental error. The question arises whether this result may be applied to other tubes and other liquids.

The choice of liquids was restricted to those which do not attack rubber. Although only two were used in this investigation, there is no reason to believe that the value of m depends on the nature of the liquid.

The shape of the capillary may affect the value of m. In this investigation an effort was made to secure capillaries which were as nearly as practical right circular cylinders. Therefore, we are not entirely justified in extending the value, $m = 1.12$, to capillaries which deviate from the ideal shape more than the capillaries described here. Let us consider two possible manners of deviation from the right circular cylinder.

In the first place the capillary may be a frustum of a cone, that is, the cross-sectional area may be different in different parts of the tube. In a capillary of uniform cross section the loss of kinetic energy occurs only at the ends. In a conical tube, however, there would also be a loss or gain of kinetic energy inside of the capillary. Consequently, it is possible that the Hagenbach factor may have a different value in conical tubes. The capillaries used in this investigation had almost uniform cross sections.

In the second place, the cross section, although uniform throughout the length of the capillary, may be elliptical rather than circular. Indeed, it is impossible to find thermometer tubing of perfectly circular bore. The capillary cross section of greatest deviation from the circle was end B of capillary 2, with an eccentricity of 0.553.

The shape of the ends of the capillary and the shape and size of the reservoir may also affect the value of m. The exit reservoir of our viscometer differed widely from the ideal conditions described by Dorsey. The liquid leaving our capillary flowed into a trap, provided for the settling of dust particles, then into a bulb, provided to facilitate the adjustment of the working volume, and finally into the larger bulb of measured volume. This difference in reservoirs may account for the difference between our results and Dorsey's.

It should be noted, however, that our viscometer is fundamentally similar to the viscometers used by Thorpe and Rodger and other investigators who are interested in the practical determination of viscosity rather than the theoretical laws of flow under ideal conditions. Therefore, it is very probable that the value, $m = 1.12$, is the correct one to be applied to instruments like those of Thorpe and Rodger and Bingham. Our data do not support Dorsey's view that m decreases when Reynolds' number exceeds 700.

Further investigations are being conducted in this Laboratory to determine the value of m for capillaries of other shapes.

Summary

1. Within the range of experimental conditions studied, the Hagenbach factor has been found to be **1.124** ± 0.006.
2. The viscosity of methanol at 25° has been determined and a value obtained which agrees with the value of Thorpe and Rodger within 0.3%.

CHEMICAL AFFINITY IN METALLIC ALLOYS, ESPECIALLY SOLID SOLUTIONS: A STUDY IN COMPRESSIBILITY

BY ROBERT FRANKLIN MEHL[1] AND BEVERIDGE JAMES MAIR[2]

RECEIVED SEPTEMBER 22, 1927 PUBLISHED JANUARY 5, 1928

The study of the properties of solid solutions is one of the chief aims of metallurgical science. Its practical importance is evidenced by the fact that of the alloys useful because of their superior mechanical properties most are wholly or partly solid solutions. Numerous researches[3] have shown that, with one or two exceptions,[4] terminal solid solutions are simple in structure, showing the space lattice of the solvent metal only, the atoms of the solute having simply replaced atoms of the solvent; intermediate solid solutions are more complicated in structure. The behavior, physical and chemical, of the lattice so modified is, therefore, dependent upon the interaction of the different atoms, and this will be intimately related to their different chemical natures, and also to their specific crystallographic tendencies. From a chemical standpoint the chief effect of interest is that of a partial fixing of the valence electrons, an effect to be expected from the normal chemical affinities between the unlike atoms, and indicated by the enormous decrease in electrical conductivity resulting from solid solution formation. From a mechanical point of view the interaction between unlike atoms is presumably intimately related to the large increase in hardness observed.

Such a partial fixing of the valence electrons is of course not stoichio-

metric, and the chemical affinities operative in solid solutions are more nearly like those governing adsorption than like those in saline compounds. The factors determining the composition of intermetallic compounds (which exhibit apparently ambiguous valence relations) have not been explained, though for a complete valence theory such an explanation is obviously necessary. These compounds are highly crystalline, and their heats of formation indicate that the chemical forces at play are commensurable with those in saline compounds.[5] In fact, evidence has been presented[6] in proof of the salt-like nature of certain of these compounds.

Whatever the nature of the chemical forces governing the composition of the intermetallic compounds, it seems reasonable that similar forces should be operative in metallic solid solutions, and it appears likely that an evaluation of the magnitude of these forces should be of value in explaining the behavior of solid solutions, especially the electrical and mechanical, and that ultimately a study of these forces should be of value to the study of chemical affinity in general and the solid state in particular.

It may be said (somewhat truistically) that two metals form solid solutions when the potential energy of their atoms in the state of solid solution is less than that in the elementary states. The problem of measuring the tendency of two metals to form solid solutions (the answer to which would explain quantitatively the phenomenon of limited miscibility) is therefore the problem of evaluating this potential energy decrease. Such an analysis does not now seem possible, though the recent work on lattice energetics may finally lead to this. To be orthodox chemically, such a measurement should be in terms of free energy decrease. For a solid alloy the only practicable method is that involving a measurement of the heat of formation of the alloy and the specific heats of the component metals and of the alloy over a wide temperature range.[7]

[6] Owen and Preston, *Proc. Phys. Soc. London, 36,* 14 (1923).

[7] Considerable time was spent in attempting to evaluate this quantity calorimetrically. The simplest and most general method for determining the heat of formation is to dissolve the alloyed and the unalloyed metals in similar quantities of a solvent in a system of known heat capacity, and by the difference in the temperature rises observed in the two cases to calculate the heat of formation by application of the law of constant heat summation. The method has been applied especially to intermetallic compounds6 and to the copper–zinc system, exclusive of the a-solid solutions [Baker, *Z. physik.* Chem., **38,** 630 (1901)]. The adiabatic calorimetric method developed by Richards [THIS JOURNAL, 32, 431 (1910)] was used, with hydrochloric acid as a solvent.

The most advisable course seemed to be to investigate those terminal solid solutions in which cubic metals play the role of solvent. Accordingly a series of the a-aluminum-magnesium alloys was prepared. The calorimetric system, including 941.4 g. of $HCl\cdot 20H_2O$, had a heat capacity of 810.0 cal./deg. The reaction between the elementary magnesium and the acid (in the blank determination) was slowed by partly lacquering the magnesium particles (which were roughly $^1/_8''$ in diameter) and by imprisoning them

The e.m.f. method is apparently inapplicable because of the practical difficulty in setting up a cell representing the reaction between the component metals to give an alloy of the composition desired, though the Nernst-Reinders theory[S] of the equilibria between solid solutions and aqueous solutions of salts of the component metals appears to make such a determination possible, when the solution pressures of the component metals are not too greatly different.[9] However, because of the difficulties in obtaining a reversible electrode truly representative of the composition of solid solution desired, it is unlikely that the e.m.f. method will be of value for this purpose.

in an inverted platinum cone wired to the bottom of the platinum wire basket. **A** drop of chlorplatinic acid served to catalyze the dissolution of the aluminum.

Before making any determinations on alloys, the heat of solution of magnesium in $HCl \cdot 20.05H_2O$ was determined. Three determinations using **0.7481** g. of magnesium in each gave temperature rises of **4.193, 4.189** and **4.192°,** an average of **4.191°** which, multiplied by **810.0 cal./deg.,** gives **2594.7** cal. at a temperature of **20".**

The aluminum-magnesium alloys were prepared in an apparatus similar to one previously developed by one of the authors [Mehl, ***Trans. Amer. Electrochem. Soc.,*** **46,** October, **1924)** except that argon instead of hydrogen was used for an atmosphere. After preparation the alloys were annealed for **24** hours just below their melting points. The synthetic compositions of the alloys prepared were **5.5, 8.0** and **9.0** percentage of magnesium by weight. The temperature rises observed for **0.6948** g. of each composition were, respectively, **3.964, 3.957** and **3.961".** The blank determinations, using equivalent quantities of the unalloyed metals, gave, for the same compositions, **3.961, 3.963"** and **3.960°,** apparently identical with the first.

The sensitivity of the calorimetric method as applied to these alloys is probably around **0.006°,** indicating that the heat of formation of the a-solid solution in this system is probably less than **8** cal. per gram.

A similar series of measurements was carried out on the or-solid solutions in the aluminum–zinc system, though the method is less satisfactory in its application to these alloys, for it takes approximately **7** g. of zinc to give the desired four degrees rise, as contrasted to **0.7** g. of aluminum. Any segregation in the alloy, therefore, leads to **greatly** different heats of solution when constant weights of the alloys are dissolved. Prolonged annealing of the castings prevented such segregation in considerable degree, but it soon became apparent that another disturbing factor was present. An alloy of **14.49%** of zinc by weight, quenched after twenty-four hours' annealing at **575°,** gave a temperature rise of **4.057° (0.8050** g.); after a month this had fallen to **3.988°.** An alloy of **19.27%** of zinc by weight, quenched after twenty-four hours' annealing at **550°,** gave **4.053" (0.8500** g.); after a month this had fallen to **3.990'.** It therefore appears that there is some transition in this region of the system, possibly the precipitation of the β-solid solution, resulting in a lower heat content. This point, however, was not the immediate, and the work was abandoned as unfruitful. It is to be noted that the interesting magnesium–cadmium system could be investigated by this method, but only **if** sufficient refinement of method were developed, for the investigation of this system is likewise made difficult by the disparity in the heats of solution of the component metals.

[9] In the case of the a-solid solution in the copper–zinc system, for example, the aqueous solutions of the mixed sulfates of copper and zinc in equilibrium with the solid solution would contain only a trace of the copper ion.

Any measurement of chemical affinity which does not determine free energy change must be considered indirect and from the standpoint of chemical theory less valuable. Such a criticism may be made of the following study, in which changes in compressibility are investigated, but it will be seen that the compressibility point of view has some distinct and unique advantages as applied to metal systems.

The Compressibility of Metallic Alloys, Especially Solid Solutions

That compressibility is a property directly related to the cohesive forces in solids has been repeatedly emphasized by Richards.[10] In elementary solids these cohesive forces are physical in the sense that electrochemical effects involving the displacement of electrons are absent. In compounds the increase in cohesion caused by chemical interplay between unlike atoms is manifested by a decrease in compressibility. This basic idea is very simple in its application to alloys, especially to terminal solid solutions of the simple substitutional type, for here the components in almost every case are solid at room temperature and the effect of the chemical affinity between the unlike atoms may be shown simply by the difference between the compressibility of the unalloyed metals and that of the alloy. That such a comparison leads to results which are of some value to present metallurgical science may be seen in the following.

Some measure of success was assured this work by two determinations made by Adams, Williamson and Johnston,[11] in the course of their investigations of the compressibility of various solids, upon an α-brass and a tin-bismuth alloy. The first was found to give a compressibility coefficient much lower (25%) than the rule of mixtures value, and the second a coefficient very close (within 5%) to the calculated value. No explanation of these results was attempted, except to point out that the copper–zinc system exhibits physical properties which "do not bear a simple relation to the properties of the end members of the series," whereas in the tin–bismuth system many of the physical properties vary linearly with the composition.

The earlier results of Regnault[12] and of Amagat[13] on steel and brass are not comparable in accuracy with modern data.

The extensive work of Lussana on metal systems[14] shows little connection between compressibilty and constitution and in certain cases indicates compressibility coefficients for terminal solid solutions greater than the

rule of mixtures values.[15] An inspection of his data for the pure metals discloses the fact that they disagree with the best modern data from —37% for aluminum to +64% for lead, and also indicate abnormal temperature coefficients.[16] It seems necessary to conclude from this that Lussana's data are not to be compared in accuracy with the best of modern data, though there is a qualitative agreement. But for the investigation of alloys, where the difference between the calculated (rule of mixtures) value and the observed value is the datum sought, a difference including three experimental inaccuracies, one for each of the component metals and one for the alloy, measurements of high accuracy are essential.

Bridgman[17] has given a value for the compressibility of commercial nichrome wire and also a value for steel, which will be considered later. E. Madelung and R. Fuchs[18] have published values for brass and for steel.

Beckman[19] determined the compressibility for a series of silver-gold alloys. The coefficient given for pure gold, 1.55×10^{-6}, however, is greatly in excess of Bridgman's, 0.572×10^{-6}, and the value extrapolated for pure silver is 1.50×10^{-6}, also greatly in excess of Bridgman's value, 0.987×10^{-6}.[20]

So far as the authors are aware these are the only published data on the direct determination of the compressibility of alloys. Compressibility coefficients have been calculated for a number of alloys from the modulus of elasticity in tension (E, Young's modulus) and the modulus of elasticity in shear (C, the modulus of transverse elasticity or rigidity),[21] especially by E. Grüneisen.[22] Although the compressibility coefficients obtained in this way agree well with those determined directly, except for the soft metals, the method is of less general applicability because of its sensitivity to plastic flow, to slight inhomogeneities in the structure of the material

---

[15] For example, Lussana's value for an alloy of copper-aluminum, 7% by weight (20% by volume) aluminum, an α-solid solution, is 1.19×10^{-6} between 1 and 1000 atm. whereas the calculated value is 0.88×10^{-6}. In this system seven values are in excess of the rule of mixtures values and only one below.

[16] Lussana gives 0.88×10^{-6} for the compressibility of aluminum at 2000 atm. and 14.7°, whereas Richards gives 1.47×10^{-6} (corrected in the present work to 1.40×10^{-6}) over a range of 100 to 500 megabars at 20°, and Bridgman gives 1.334×10^{-6} at 30° and zero pressure. Lussana gives 0.96×10^{-6} for the same metal at the same pressure and at 27.0' whereas Bridgman finds 1.391×10^{-6} at 75°, an increase of only 4% over a temperature range of 45'. Lussana's value for lead at 500 atm. and 10° is 3.81×10^{-6} whereas Richards finds 2.33×10^{-6} at 20° between 100 and 500 megabars.

[18] Madelung and Fuchs, *Ann. Physik*, [4] 65,289 (1921).

[19] Beckman, *Dissertation*, Upsala, 1910; International Critical Tables, Vol. II, 215.

[20] The original of this paper was not available. The method of measurement used by Beckman is unknown to the authors.

[21] Compressibility $= \beta = 9C - 3E/CE = 3(1 - 2\sigma)/E$, where σ is Poisson's ratio.

[22] Grüneisen, *Ann. Physik*, 22,801 (1907); 25,825 (1908).

measured and because of the apparently great difficulty in applying it to the very brittle intermetallic compounds. In addition it gives no indication of the variation of the compressibility with pressure. Grüneisen determined the compressibility of iron, steel, constantan and manganin. G. Angenheister[23] carried out similar measurements on alloys of silver and copper, but the values calculated from his data for the compressibilities of silver and copper, 0.80×10^{-6} and 0.58×10^{-6}, do not agree with those of Grüneisen (0.92×10^{-6} and 0.74×10^{-6}, respectively). The compressibilities calculated for the intermediate compositions show a decided departure from the rule of mixtures values. A minimum comes at 50% by volume and indicates a maximum decrease from the calculated value of 0.26×10^{-6} (from 0.70×10^{-6} to 0.44×10^{-6}). The curve obtained is gently sagging throughout its course and shows no critical points at the limits of solid solubility (copper dissolves 1% by volume of silver and silver 7% copper). The curve shows a progressive departure from a straight line in the heterogeneous fields, where linearity should be strictly observed.

It is clear, therefore, that there are not sufficient data available for the study of the cohesive forces in alloys by means of compressibility. In order to satisfy this lack the present work was undertaken, but as a preliminary study only, for a complete set of data for binary alloys would require investigation of over 400 binary systems. In order first to survey the field, a number of typical alloys was chosen, with the hope that the results would be sufficiently illuminating to indicate the most fertile paths for additional research.

Experimental

Method of Measurement.—The method and apparatus developed by Richards[24] were used without modification. Measurements were made at 25° and required the use of a correction factor for water previously determined by the authors.[25] The piezometers used were of the usual type, sufficiently large to hold an alloy piece with a volume of 25 $cm.^3$. Duplicate determinations were made on each alloy except certain intermediate solid solutions and intermetallic compounds. Divergent results almost always could be traced to the accidental introduction of impurities into the piezometer capillary and when such was the case the results were discarded. Divergencies which could not be traced to such experimental imperfections were discredited by a sufficient number of consistent determinations. In each case, however, the divergent results are noted in the table of data.

Materials.—The preparation, heat-treatment and analysis of the alloys presented a task impossible of accomplishment within the time at our disposal, and it was only through the kindly help of a number of industrial metallurgists that the work was made possible; several of the alloys were given additional treatment after their receipt. Table I lists the alloys investigated, with the percentage composition by weight and by volume, and with the heat and mechanical treatment noted for each alloy.

Each alloy was machined into a cylindrical bar 1.516 cm. in diameter and 13.8 cm. long, except the brittle intermetallic compounds, which were cast in graphite tubes.

TABLE I

ALLOYS INVESTIGATED

Alloy	Composition		
no.	by weight	by volume	Treatment
1	55% Cu; 44% Ni; 1% Fe	55% Cu; 44% Ni; 1% Fe	Cast; rolled; annealed at 1000° for 3 hours
2	36.27% Ni; 63.24% Fe; 0.15% C; 0.49% Mn; 0.15% Si; 0.05% Cr	33.7% Ni; 65.6% Fe; 0.7% Mn	Forged
3	92.34% Cu; 7.66% Al	78.4% Cu; 21.6% Al	Slightly hot-rolled; drawn cold to 0.705' from 1.000"; annealed 1 hour at 850°
4	87.1% Cu; 12.9% Al	66 9% Cu; 33.1% Al	Hot-rolled to 0.705' from 1.000'; annealed 1 hour at 850° and quenched in water
5	81.94% Cu; 17.95% Zn; 0.06% Pb; 0.05% Fe	78.5% Cu; 21.5% Zn	Cast; annealed 1 hour at 810°; cold-rolled to $12^1/_2\%$ reduction in height (to $^3/_4$" bar); annealed 2 hours at 500°
6	64.27% Cu; 35.61% Zn; 0.09% Pb; 0.03% Fe	59.0% Cu; 41.0% Zn	Cast; annealed 3 hours at 700°; cold-rolled to $12^1/_2\%$ reduction in height: annealed 2 hours at 500°; cold-rolled to $16^1/_2\%$ reduction in height (to $^3/_4$" bar); annealed 2 hours at 600°
7	51.43% Cu; 48.57% Zn; 0.06% Pb; 0.04% Fe	45.8% Cu; 54.2% Zn	Cast; hot-rolled at 600°; annealed 2 hours at 500°; heated to 800.°, cooled to 600° and quenched in oil
8	88.53% Cu; 11.44% Sn; 0.03% Fe	86.3% Cu; 13.7% Sn	Cast; annealed 10 hours at 600°; cold-rolled to 20% reduction in height; annealed 2 hours at 650°
9	61.16% Cu; 38.78% Sn; 0.06% Fe	56.3% Cu; 43.7% Sn	Cast in hot graphite tube; annealed 3 hours at 500°
10	67.43% Cu: 32.53% Sn; 0.04% Fe	62.8% Cu; 37.2% Sn	Cast in hot graphite tube; annealed 3 hours at 500°
11	87.24% Al; 12.56% Mg; 0.085% Si; 0.12% Fe	81.7% Al; 18.3% Mg	Extruded; annealed at 430° for 18 hours

TABLE I (*Concluded*)

Alloy no.	Composition by weight	Composition by volume	Treatment
12	99.941% Al; 0.013% Si; 0.022% Fe; 0.022% Cu; 0.002% Ti		Cast
13	96% Cu; 4% Si	86.6% Cu; 13.4% Si	Cast; annealed 4 hours at 850°; hammered on anvil to reduce diameter of bar from 0.723' to 0.690'
14	0.89% C; balance Fe (Armco iron base)		Cast; heated to 900°; quenched in cold water
15	Same as 14		Heated to 940° and cooled at a uniform rate to 480° over a period of $3^1/_2$ hours
16	1.36% C; balance Fe (Armco iron base)		Cast; heated to 900°; quenched in cold water
17	Same as 16		Heated to 940° and cooled at a uniform rate to 480° over a period of $3^1/_2$ hours

Experimental Results.—Two piezometers were used, numbered 1 and 2. Table II gives the standardization data for each. The validity of the standardizations is attested by the agreement among the various separate determinations and also by the agreement between the compressibilities measured and the results obtained by other investigators. All measurements were made at 25°. Two values are given for the quantities of mercury corresponding to a pressure range of 100 to 500 megabars: one was obtained in passing from 500 to 100 megabars, and the other in

Experimental Results.—These are given in Tables II, III and IV, together with other data necessary to the calculation of compressibility.

The compressibility coefficients represent the average compressibility between 100 and 500 megabars. The densities were determined on the bars upon which the compressibility measurements were made and serve as a valuable criterion of the solidity of the samples. It is, of course, essential for this work that the bars be free from voids. The anomalous density found for the copper-silicon alloy seemed to indicate the presence of voids and the excessively high value found for the compressibility also suggested this. In order to eliminate this possible source of confusion five of the alloy bars were subjected to x-ray inspection (numbers 2, 3, 6, 8 and 13) while immersed in methyl iodide. Four of the bars were found to be wholly free from voids, but the copper-silicon alloy was found to be very faulty, the x-ray photograph revealing casting pipe-cones throughout its length. The results on this alloy have, therefore, been discarded.

The densities were determined by the usual water displacement method, using a tare with each weighing and making correction for displacement of air. The data are summarized in Table IV. The calculated densities and compressibilities are obtained from the volume percentage compositions given in the second column. The values for β are the average values from Table III.[26]

Discussion.—In the simplest metallic solid solution, that is, of two metals crystallizing in the same crystal system (such as copper and nickel) and in which solid solution formation takes place by substitution of one atom of the solute for one atom of the solvent, the atoms are arranged crystallographically as they are in the pure component metals. As a consequence of the specific attraction between the unlike atoms (which may be taken as roughly indicated by the relative positions of the elements in the periodic table), the composite lattice will possess a rigidity greater than that of the component metals, in the same volume proportion, originating in the greater attractive (and repulsive) forces. Such a lattice will, therefore, have a smaller compressibility and the difference between the calculated and the observed compressibility coefficients will be indicative of the intensity of the attraction.

In the simplest case this should lead to an increase in density, and in general this is found to be the case, though the x-ray diffraction data on the copper–gold system indicate an exceptional behavior,[27] and a recent

---

[26] Compressibility coefficients for the pure metals were taken from the data of Richards, THIS JOURNAL, **37,** **1646** (1915), except for aluminum, which was redetermined, and for nickel and copper (0.53 X 10^{-6} and 0.72 X 10^{-6}, respectively), which were calculated from Bridgman's data;[17] the densities of the pure metals are from the International Critical Tables, Vol. I, p. 103.

[27] Lange, *Ann. Physik,* **76,** 476 (1925), plotted *a*, the side of the unit face-centered cell, against atomic percentage composition and found a straight line relation within his experimental error. Kirchner, *Ann. Physik,* **69,** 59 (1922), found an increase in *a*, over the rule of mixtures value, with *a* plotted against atomic percentage composition,

study of the copper-rich copper-tin terminal solid solution is distinctly exceptional.[28] Davey[29] states that solid solutions of aluminum in silver, tin in silver and silicon in copper show in each case an increase in the dimensions of solvent lattice caused by the smaller solute atom. It is evident that it is questionable whether density is of any value as a criterion of the attraction between unlike atoms. Compressibility, however, is unaffected by this argument, since the forces effective in more tightly binding the atoms should also be effective in producing a diminished compressibility.

With respect to solid solutions of metals with different space lattices the foregoing argument requires some elaboration, as noted under the discussion of the experimental results on the various alloys of this type.

The specific attraction between the unlike atoms must be of immediate importance in the mechanical behavior of solid solutions. Solid solutions are much harder than required by the rule of mixtures, and a number of workers[30] have suggested that at least part of the increase in hardness must be caused by the attraction between unlike atoms. Hardness is a complicated property and each method of measurement brings the different factors concerned into play in varying degrees. Empirically it is defined as the resistance to permanent deformation. The tendency among metallurgists at present is to interpret this to mean resistance to slip along atomic planes.[31]

In solid solutions of normal grain size, free from foreign material of any kind and free from mechanical strain, the hardness must, by this theory, be caused only by the warping of the atomic planes, introducing resistance to slip, and by the attraction between the unlike atoms, tending to hold the lattice as a whole more rigid. Abnormally small grain size gives rise to a large increase in hardness, and mechanical strain, caused by cold-work

---

amounting at the maximum to 0.9%, which is in excess of the probable experimental error. It is, however, not correct to plot a against atomic percentage composition, though this seems to be the general practice, for not a but a^3 is a linear function of atomic percentage composition when additivity is assumed. The correct procedure is to cube the values of a determined experimentally for the elementary metals, and by means of the atomic percentage composition calculate the values for a^3 for intermediate compositions and then to extract the cube root in order to obtain values for a truly representative of the rule of mixtures. Such a calculation for copper and gold will give a curve for a against atomic percentage composition slightly concave to the composition axis. Kirchner's data very nearly conform to this curve, falling at the greatest *0.5%* too high.

[28] Weiss, *Proc. Roy. Soc. (London),* ***108,*** *643* (1925), concluded from his x-ray data that this terminal solid solution is not of the simple substitutional type but that an atom of tin replaces several atoms of copper, leading to abnormally low densities.

[31] The slip-resistance theory of hardness has been summarized by Jeffries and Archer, *Chem. Met. Eng.,* ***24,*** *1067 (1921).*

(plastic deformation), produces a similar result in smaller degree. It is the virtue of compressibility that it measures (in solid solutions) only one of these factors, namely, that caused by the attraction between unlike atoms. Bridgman[32] found that cold-rolled copper and iron gave the same values for compressibility as annealed copper and iron, within the accuracy of the measurements. This significant experiment demonstrates the essential identity of cold-worked and annealed metal, for an amorphous phase, in which the directional forces of the atoms producing the lattice characteristic of the metal are no longer nicely oriented with those of adjacent atoms or, in other words, in which the points of atomic attachment are no longer adjusted, should have a compressibility appreciably greater than that of the crystalline phase.[33]

In pure metals, which are mostly of high symmetry and free from the distortion solid solution formation produces, hardness is a periodic property[34] which, when compared to Richards' periodic curve of compressibility,[35] shows a striking and nearly perfect parallelism.[36] Exceptional metals are those of extraordinarily low symmetry.

Thus compressibility may be taken as a measure of the lattice rigidity factor in hardness. For solid solutions, the difference in compressibility of the solid solution and the value calculated on the basis of the rule of mixtures may be taken as a measure of the additional interatomic forces resulting from the chemical affinity operative between the unlike atoms, resulting in an increase in the lattice rigidity. Applied to alloys in this way, compressibility may be said to measure "chemical hardness." The other effects promoting slip resistance may be said to produce "physical

Without doubt the chemical factor is subordinate in magnitude to the physical, but the latter must be considered as intimately related to the chemical, for the warping of the atom planes, as a result of the introduction

[33] Bridgman's experiment (in which linear compressibility was measured) likewise points out the complete compressibility isotropy of these cubic lattices, for the process of cold-rolling inevitably produces preferred orientation. Similar experiments on a non-cubic metal, such as zinc, would, however, show nothing concerning the nature of cold-worked metal, since the preferred orientation produced by cold rolling would cause a very appreciable difference because of the well-known difference in compressibility along the different crystallographic axes.

[35] Ref. 26, p. 1643.

[36] Traube, Z. *anorg. Chem.*, 34, 413 (1903), pointed out the parallelism between hardness and internal pressure. This had been suggested (with the help of a few examples) by Richards in 1901. *Proc. Am. Acad. Arts Sci.*, **37**, 1 (1901).

[37] The value in the use of such terms is purely utilitarian: they serve to classify descriptively a series of facts or conditions producing a common effect.

of solute atoms, is caused by the difference in atomic volumes, modified in some way by the chemical attraction between the unlike atoms and the relative compressibilities of the partially ionized atoms.

System Copper–Nickel.—The only previous determination of an alloy in this system was made by **Grüneisen**,[22b] who determined E and a for a sample of commercial constantan. The compressibility coefficient calculated was **0.62** X 10^{-6}, agreeing with the value here determined.

The alloy measured was "Constantan," containing approximately **55%** copper, **44%** nickel, and **1%** manganese, by weight. No analysis was made of this alloy since the compressibility coefficients of these three metals are so nearly equal that only a very large departure from the reported composition could cause an appreciable variation in the calculated compressibility. The calculated compressibility was obtained from the value for nickel obtained by **Bridgman** expressed in terms of average compressibility between **100** and **500** megabars. namely, **0.53** X 10^{-6}.[38] The value **0.73** X 10^{-6} was taken as the most representative value for copper."[39] The calculated coefficient, **0.64** × 10^{-6}, is only very slightly greater than the observed value, **0.62** X 10^{-6}. The density increase, 0.1%, is also slight. Copper and nickel both crystallize in face-centered cubes. with approximately the same lattice constants, **3.597** and **3.499** **8..**respectively,@and are very similar chemically. No great decrease in compressibility is therefore to be expected.

System Iron–Nickel.—The only measurement made in this system was on a commercial alloy "Invar," received in the forged condition, containing 36.27% nickel. Filings of the alloy were examined by x-rays **for structure**, using the **Hull** powder method, and found to consist wholly of face-centered cubes, characteristic of nickel and **γ-iron**.[41] The compressibility coefficient found, **0.85** X 10^{-6}, is much higher than that calculated using the coefficient of a-iron (which is **0.60** X 10^{-6}), namely, 0.58 X 10^{-6}, and appears to mean that the **compressibility** of y-iron is much greater than that of **α-iron**.

System Copper–Aluminum.—Alloy **3** is in the a-field near the limit of solid solubility. Alloy **4** is a **β-solid** solution. There appears to be an appreciable increase in the cohesive forces in the b-solid solution, but a lower symmetry doubtless favors a **greater** hardness.

An accident prevented an investigation of annealed and age-hardened **duralumin**, but on **the** basis of the results presented here, especially those on steel, it may be predicted that the age-hardening, now known to be **produced** by the resistance to slip offered by submicroscopic particles of **$CuAl_2$** (in a pure copper-aluminum **alloy**)[42] will have only a very slight, probably inappreciable, effect upon the compressibility.

System Copper–Zinc.—A number of measurements have been reported on "brass," but with one exception there has been no accompanying analysis. Adams, Williamson and Johaston measured the compressibility of a leaded brass with **61.76%** copper. **35.92%** zinc, **2.26%** lead and **0.05%** iron. Their value (corrected) at zero pressure is **0.86** X 10^{-6}. For a brass of unstated composition **Madelung** and **Fuchs** found **0.90** X 10^{-6}

---

[38] Richards' value for nickel, **0.43** × 10^{-6}, is apparently low.

[39] Bridgman's value (recalculated) is **0.730** X 10^{-6}, and the value **found** by Adams, Williamson and Johnston (corrected) is **0.725** X 10^{-6}. The above value is taken in preference to the slightly higher value of **0.75** X 10^{-6} given by Richards and **Grüneisen**.

[40] Davey, ***Phys. Rev.*, 25, 753 (1925).**

[41] This is in confirmation of the work of **McKeehan**, *Phys. Rev.*, **18, 657 (1921)**, and **Osawa**, **J.** Iron ***Steel Inst. London*,** May, **1926.**

between 50 and 200 megabars. The other data appearing in the literature are of inferior accuracy, most of the values reported being higher than those obtained here. The higher value found by Adams, Williamson and Johnston may be explained in part by the lead present. The other higher values probably refer to copper-zinc alloys of higher zinc content.

Three compositions were investigated. An a-brass, half-saturated (18% zinc by weight), gave a compressibility of 0.75 X 10^{-6}, a decrease of 20% from the rule of mixtures value. An a-brass very near to the limit of solid solubility (35.6% zinc by weight), gave 0.80 $\times 10^{-6}$, a decrease of 29% from the rule of mixtures value. Despite this tremendous decrease, the hardness increase at the limit of solid solubility is only about 15%.[43] It is possible that this discrepancy is in some way related to the extraordinary elongation recently observed in a single crystal of α-brass,[44] a condition indicating, apparently, that certain of the factors which produce "physical hardness" in elementary zinc are no longer present when the zinc atom crystallizes on the copper lattice.

The decrease in compressibility is paralleled by an increase in density, which is 2.8% at the maximum.[45] In the elementary state the zinc is the more compressible element and it seems likely that the increase in density is taken up mostly by the zinc atoms, which on the copper lattice are forced out of their normal shape (that of a prolate spheroid) into approximately a sphere. The distance of closest approach of the zinc atoms in elementary zinc is 2.66 Å.,[46] whereas the distance of closest approach in copper is 2.56 Å.,[40] and the saturated solid solution 2.56 Å.,[47] so that the zinc atoms in a-brass are compressed on all sides, but mostly at the poles. It is possible that the zinc atom in brass is rotated in such a way that its major axis lies in the [111] direction in the copper lattice. If this were the case, a denser packing could result without any great compression of the zinc, assuming that the zinc atom lies wholly within the periphery of a prolate spheroid. Whether the copper atom is also compressed, as suggested by the increase in density, or expanded, as suggested by the apparent decrease in the cohesive forces (the compressibilities of the brasses are all less than that of pure copper, and it will be shown in a subsequent publication that the internal pressures are probably also less), appears at present to be beyond the reach of experiment.

The compressibility of the β-solid solution shows a decrease from the rule of mixtures value of 26%. The greater hardness of the β-solid solution is doubtless to be ascribed to a lower order of symmetry.[47]

System Copper–Tin.—The or-solid solution shows a compressibility slightly smaller than the rule of mixtures value, despite the fact that each tin atom replaces not one but several copper atoms.[28] Alloy 10, which is the δ-solid solution, appears to show a greater decrease than Alloy 9, the compound Cu_3Sn, and also exhibits a greater Brinell hardness,[48] though it is claimed that Cu_3Sn shows a greater scratch hardness.[49]

System Aluminum–Magnesium.—The composition investigated, 12.56% by weight of magnesium, is in the $a + \beta$ field[50] near the limit of solid solubility. The percentage decrease in compressibility observed, 8%, is relatively small, as is the percentage increase in density, which is 3%.

---

[43] Harris, *J. Inst. Metals,* 28,327 (1922) states that the Brinell number of a 66–34 a-brass is 48. The Brinell number of pure copper is ordinarily taken as 40.

Two determinations by other workers remain to be discussed. Bridgman[17] determined the linear compressibility at 30° of a piece of nichrome wire, approximating in composition to 80% nickel and 20% chromium by weight, or 76% nickel and 24% chromium by volume. Taking the compressibility coefficient of nickel from Bridgman's data, **0.53** X 10^{-6}, and that of chromium from Richards's data (after approximate conversion to Bridgman's units), **0.89** X 10^{-6}, the rule of mixtures value for this composition may be calculated to be **0.72 X** 10^{-6}. Bridgman found **0.55** X 10^{-6}, which is considerably lower.

Grüneisen's[22b] determination of the elastic constants for manganin leads to a compressibility coefficient of **0.81** X 10^{-6}. The calculated value for this alloy, assuming a composition of **82.1%** copper, **0.6%** iron, 15.0% manganese and 2.3% nickel, is **0.76** X 10^{-6}, appreciably lower than the determined value. There is some uncertainty concerning the composition of the alloy measured by Grüneisen (who gives no analysis), but the possible variation in composition from that assumed could hardly reconcile the calculated and the assumed values. It is the author's opinion that a direct measurement of the compressibility of thoroughly equilibrated manganin would show a compressibility coefficient only slightly different from the rule of mixtures value and that this difference would be negative, that is, that the coefficient calculated would be greater than that measured.

System Iron–Carbon.—The superior hardness of quenched steels has engaged the attention of metallurgists for many years. Although the problem is by no means solved, it is certain that the quenching hardness is related to the partially arrested transformation of austenite into pearlite and is directly caused by the constituent martensite. Most recent theories tautly assume that the hardness of martensite is chiefly the aforenamed "physical hardness," that is, it is caused by factors which impede slip without increasing the cohesive forces in the alloy.[51]

Most investigators of compressibility have made measurements on iron and steel but none seem to have investigated the special point of the effect of heat-treatment. The early values for the compressibility of iron were actually obtained from measurements on mild steel. Grüneisen,[22b] from measurements of the elastic moduli, calculated the compressibility of iron and of "steel," and found them to be the same, namely, **0.60** × 10^{-6}. Bridgman[52] measured the linear compressibility of Bessemer boiler plate and of annealed tool steel (1.25% carbon), and for the first found **0.530** X 10^{-6} (an average of two determinations, one made parallel to the direction of rolling and the other perpendicular to it) and for the second 0.525 **X** 10^{-6}. These figures are probably too low.[17]

Adams, Williamson and Johnston[n] measured the volume compressibility of Bessemer steel (**0.2%** carbon) and of tool steel (**0.8%** carbon), finding **0.575** X 10^{-6} for each. Madelung and Fuchs[18] found **0.61 X** 10^{-6} for both iron and steel ("silver steel").

The present work confirms previous work in the similarity of the compressibilities of annealed steel and iron, but gives a higher compressibility for hypereutectoid steel than would be expected from the measurements of Bridgman on annealed **1.25%** carbon steel.

In order to determine whether quenched steel possesses any superior cohesive forces, two sets of experiments were performed. A eutectoid steel (**0.89%** carbon) was quenched drastically (the heat treatments of these steels are given in Table I), a treatment which rendered it highly martensitic, and increased its hardness almost three-fold

---

[51] Modern opinion on the nature of martensite and on the factors causing hardness in quenched steel has recently been summarized by Sauveur, Trans. Am. *Inst.* Mining Met. *Eng.,* No. 1532-C, 1926.

[52] **Ref.** 32 a, p. **255.**

(from a Brinell number, 3000 kg. load, of 241, to 653). The compressibility of this steel, an average of three determinations, was found to be 0.61 X 10^{-6}. The steel was then annealed thoroughly and its compressibility again determined, giving an average of three determinations, a value of 0.61 X 10^{-6}.

Similarly a hypereutectoid steel (1.36% carbon) was quenched as before and its compressibility found to be 0.83 X 10^{-6}, an average of three determinations. After annealing, the value found, an average of four determinations, was 0.85 × 10^{-6}, which within the possible error is identical with the first value.

It is therefore apparent that the hardening of steel by quenching is not caused by any appreciable increase in the normal cohesive forces, for the compressibility is not changed by quenching or annealing. It seems extraordinary indeed that a glass-hard steel should suffer the same volume decrease with increase in pressure as an annealed steel, but the result is not strange when examined in the light of the slip interference theory of hardness (with which it is in full accord), for this theory postulates no increase in the binding forces between the atoms in steel and assumes the hardness to be caused only by the mechanical arrangement of the structural units. It seems highly probable from the apparent identity of the compressibility values of the steels in the quenched and annealed conditions that the structural units in quenched steel are not greatly different from those in annealed steel, and this is in agreement with the explanation of the hardening of steel by the slip interference theory enunciated by Jeffries,[53] in which martensite is taken to be an aggregate of submicroscopic cementite and ferrite, differing from pearlite only in the size and arrangement of the cementite and ferrite grains.

Judging from Bridgman's experiment on rolled metals[32] neither variations in grain size nor mechanical strain appear to make any difference in compressibility (though it is conceivable that a decrease in density resulting from cold work or very small grain size should result in a slightly higher compressibility), so that an increase in hardness caused by either or both of these effects would make no difference in compressibility. On the other hand, lattice distortion, which has been postulated as a cause of hardness in steel, could be produced presumably only by an alteration in the interatomic forces, and this should result in an appreciable compressibility difference. The Hanemann-Schrader theory[54] assumes an ϵ- and an η-phase in equilibrium with austenite, and designates the η-phase as the bearer of the martensitic hardness because this phase is assumed to contain a hard iron carbide of the formula $Fe_{24}C$. It is assumed that the "hardness of martensite" is "caused by a definite arrangement of the iron and carbon atoms in an iron-carbon compound" ($Fe_{24}C$), and that this compound is hard because of the nature of its space lattice and because of the directional forces which inhere in the lattice. It is obvious that the compressibility results here presented limit the possible interpretations of this theory. The inherent hardness of the hypothetical compound $Fe_{24}C$, which is assumed to be much greater than that of ferrite or pearlite, must be explained either by (1) an extraordinarily low symmetry, or (2) interatomic forces between the iron and carbon atoms very much greater than those in austenite or pearlite, or by both (1) and (2). The assumption of the presence of large quantities of a compound of low symmetry seems to be untenable in the light of the results of x-ray diffraction studies on the structure of steel, for only the face-centered cube (characteristic of γ-iron) and the body-centered cube (characteristic of α-iron) have been found,[55] both lattices of high symmetry. The alternative (2) seems definitely denied by the compressibility measurements, which show no appreciable difference in the cohesive forces in quenched and an-

---

[54] *Trans. Am. Soc. Steel Treat.*. 9,229 (1926).

[55] X-ray research on steel has recently been summarized by G. L. Clark, "Applied X-Rays," McGraw-Hill Book Co., New York, 1926, p. 210.

nealed steel. It is not impossible, of course, that there should be small quantities of a carbide such as $Fe_{24}C$ present in quenched steel, but the only large contribution such a compound could make to the superior hardness of martensite would be by virtue of a very fine state of subdivision. In such a form the Hanemann-Schrader is nearly indistinguishable from the more generally accepted slip-resistance theory, and in the assumption of the presence of an unknown compound of iron and carbon seems much less likely.

The compressibility of the eutectoid steel is only slightly higher than that of iron (0.61×10^{-6} and 0.60×10^{-6}, respectively), whereas the compressibility of the hypereutectoid steel is proportionately much greater (0.83×10^{-6}). The reason for this lack of proportionality is not now evident. The presence of voids in the hypereutectoid steel would of course account for the proportionately higher value, but this possibility is denied by the normal density (Table II). It is to be noted that though the compressibilities of eutectoid steel and of pure iron are nearly identical, the Brinell numbers are 241 and 75, respectively.

The authors wish to acknowledge the very kind assistance lent in the preparation, heat-treatment and analysis of the alloys measured—to Mr. John L. Christie of the Bridgeport Brass Company for Alloys 5, 6, 7, 8, 9 and 10; Mr. W. H. Bassett of the American Brass Company for Alloys 3 and 4; Mr. John A. Mathews of the Crucible Steel Company of America for Alloy 2; Mr. George A. Lennox of the Driver-Harris Company for Alloy 1; Mr. Junius D. Edwards of the Aluminum Company of America for Alloy 12; Mr. R. L. Kenyon of the American Rolling Mill Company for Alloys 14, 15, 16 and 17; Mr. H. E. Bakken of the American Magnesium Corporation for the preparation of Alloy 11 and Mr. H. V. Churchill of the Aluminum Company of America for its analysis.

In addition they are indebted to Mr. H. H. Lester of the Watertown Arsenal for the x-ray photography of alloys; and to the Carnegie Institution of Washington and the Anonymous Fund of Harvard which provided the funds with which the building of the apparatus was financed.

Finally, the authors are deeply indebted to Professor T. W. Richards and Professor Albert Sauveur for their kind interest and for many fruitful discussions on the general nature of the problem.

Summary

1. The importance of a knowledge of the chemical affinity operative between unlike atoms in metallic solid solutions is emphasized. An attempt to measure the heat of formation of certain aluminum-magnesium and aluminum-zinc alloys is reported, in which the heat of solution of magnesium in $HCl.20H_2O$ is determined.

2. The compressibility of solid solutions is discussed and it is pointed out that in certain simple solid solutions the compressibility is a datum by which the intensity of the chemical affinity therein operative may be estimated.

3. Previous data on the compressibility of alloys are critically reviewed

and a series of new measurements on sixteen alloys, differing widely in type, is presented. It is shown that the greatest departure from simple additivity occurs in solid solutions of metals differing greatly in chemical type and that this departure is negative in every case under observation.

4. The basic importance of compressibility as a criterion of lattice rigidity in the study of the mechanical properties of metals and alloys, especially hardness, is emphasized, and the results of the compressibility measurements are correlated with the known mechanical properties and are interpreted to be in harmony with the slip-resistance theory of hardness. Measurements on quenched and annealed carbon steels are interpreted to indicate that the quenching hardness in these steels is not caused by an increase in the cohesive forces.

INTERNAL PRESSURES IN METALLIC SOLID SOLUTIONS

BY ROBERT FRANKLIN MEHL[1]

RECEIVED OCTOBER 1, 1927 PUBLISHED JANUARY 5, 1928

The importance of compressibility in the study of chemical affinity in metallic solid solutions and intermetallic compounds has recently been emphasized, and it has been shown that from compressibility data interesting conclusions may be drawn concerning the metallurgical behavior of alloys.[2]

The problem of the attraction between unlike atoms in solid solutions may be attacked in a different way, namely, by the use of the concept of internal pressure. T. W. Richards,[3] and others,[4] have emphasized the importance of internal pressures among the factors which determine the existence and behavior of solids. Richards has correlated the conception with his equation of state for solids.[5,3a]

The quantity π_0, the internal pressure, was first calculated by the equation

$$\pi_0 = \frac{R}{V_A \alpha_s} \tag{1}$$

where V_A is the atomic volume, α_s the coefficient of cubic thermal expansion and R the gas constant. Richards recently modified this equation,[6] and now regards (1) as only an approximation. The new equation is

[5] Richards, THIS JOURNAL, 46, 1419 (1924).

[6] Ref. 3a. p. 3067.

$$\pi_0 = \frac{n'}{n' - m} \cdot \frac{R}{V_A\, \alpha_s} \tag{2}$$

n' and m are exponents in an abbreviated form of Richards's equation of state: $p + \pi_0 (V_0/V)^m = (\pi_p + P_\Theta)(V_0/V)^{n'}$, in which p is the external pressure. π_0 the intrinsic cohesive pressure, π_p the intrinsic distending pressure and P_Θ the thermal pressure. Using Equation (2) a series of values has been calculated for most of the cubic metals.

The simple structure of terminal solid solutions of cubic metals (of the simple substitutional type) immediately suggests that Equation (1) or (2) could be applied to estimate the chemical affinity between metals in the state of solid solution in terms of pressure, a step in the direction of evaluating this affinity in energy units. The data required are the mean atomic volume compressibilities and the coefficients of thermal expansion only, but it is necessary that the data for the pure component metals be known with an accuracy comparable with that for the alloys and also that these data refer to alloys of high purity. These two requirements appear to eliminate most of the current data on thermal expansion[7] with the exception of those on the copper-zinc system,[8] but the application of the internal pressure equation to this system is somewhat uncertain because zinc is not normally cubic. Richards prefers to limit the application of this form of his equation to cubic metals.

The recent work of C. H. Johansson,[9] however, on the thermal expansion of binary alloys of a series of cubic metals, is well adapted to the present purpose, especially since the crystal structure of each of the six systems investigated had been determined by x-ray diffraction studies which therefore give the necessary data on the mean atomic volumes.

Johansson measured the linear expansion of alloys in the systems: silver-palladium, copper-nickel, copper-gold, gold-palladium, copper-palladium and silver–gold. The coefficients at 35° are used in the calculation of the internal pressure. The datum desired is the increase in internal pressure over the rule of mixtures value for each composition. The atomic percentage composition of each alloy is required in order to calculate the mean atomic volume (which is a linear function of atomic composition when simple additivity is assumed), and the volume percentage composition in order to calculate the rule of mixtures coefficient of expansion. The cubic coefficient is obtained from the linear merely by multiplying by three; n' and m for each composition are calculated from the volume composition, since they are exponents of volume quantities. The rule of mixtures value for the internal pressure is calculated using Equation (2) and the rule of mixtures values for α_s and V_A; the "actual" internal pressure is calculated using Johansson's data (multiplied by three) and

[a] McKeehan, *Phys. Rev.*, 20, 428 (1922), found the lattice constants in this series of alloys to be very closely given by the rule of mixtures.

[b] Lange, Ann. *Physik*, 76, 476 (1925), found the lattice constants to be given within the possible experimental error by the rule of mixtures.

[c] The x-ray data on the crystal structure of this system are conflicting, as pointed out in a previous paper (ref. 2). It seems advisable to assume a simple additivity as best representative of the available data.

[d] Holgersson and Sedstrom, Ann. *Physik*, 75, 154 (1924), found the lattice constant in this series to deviate from the rule of mixtures value at the greatest by 0.6%, falling slightly below it. This variation is probably within the limit of accuracy of the measurements of the coefficient of thermal expansion and no correction need be made for it.

[e] Holgersson and Sedstrom, Ann. *Physik*, 75, 160 (1924), give values for the lattice constant which vary slightly above and below the rule of mixtures values. In general the intermediate compositions give values for a somewhat too low, but the irregularity of these values probably indicates a close adherence to the rule of mixtures. One alloy (45.5 atomic % palladium) gave evidence of the cesium chloride structure, rather than the face-centered cubic.

[f] Irregular results have been obtained for the lattice constants in this series by McKeehan, *Phys. Rev.*, 20, 428 (1922), who found *a* to depart from the rule of mixtures 1% at the maximum. On the other hand, Weiss, Proc. *Roy. Soc.* (London), 108, 643 (1925), found a strictly linear relation. Simple additivity of the atomic volume is assumed in the above calculations.

Copper and nickel are very similar chemically and have atomic volumes that are not greatly different, and the same is true of gold and silver. Accordingly there is little increase in π_0 over the rule of mixtures value (4 and 2%, respectively, at the maximum). Copper and gold are also very similar chemically, though the tendency to form compounds which they manifest in the solid state is reflected in the somewhat greater increase in π_0, though the difference in atomic volumes may also be contributory. The greatest increase in π_0 comes in the system silver-palladium (16%), elements adjacent in the periodic table. Then in order come gold-palladium (12%) and copper-palladium (10%).

It is to be noted that the increase in π_0 is apparently independent of the relative values for the component metals and independent of the difference in the lattice constants (and therefore the atomic volumes) of the component metals. With respect to the lattice constants, copper and gold differ by 0.468 Å. and give a $\Delta\pi_{\max.}$ value of 6%, whereas nickel and copper differ by 0.098 Å. and give a $\Delta\pi_{\text{max.}}$ value of 4%, and silver and palladium differ by **0.220** Å. and give a $\Delta\pi_{\text{max.}}$ value of 16%.[10]

The results are especially interesting in connection with the mechanical properties of solid solutions. Internal pressures are closely parallel to hardness for the pure metals and may be taken as an index of the lattice rigidity factor in hardness as distinguished from those factors which induce hardness by reason of lattice dissymmetry.[2] The percentage increase in internal pressure in a series of solid solutions may be compared with the percentage increase in hardness, and the magnitudes of these should give an analysis of the "chemical" and the "physical" factors in determining the hardness of solid solutions.[11]

High-grade hardness data are not available for all of the systems investigated by Johansson, but for the systems copper-nickel, silver-gold and gold-copper excellent data on the scratch hardness have been published by Kurnakov and Zemczuzny.[12]

Fig. 1 gives the percentage increase in π_0 and in the scratch hardness, plotted against volume percentage composition for the system silver-gold. At the maximum these are, respectively, 2 and 104%. If, therefore, the internal pressure and hardness be taken as directly proportional for the pure metals, it may be concluded that the hardest alloy in this series owes only about one-fiftieth of its hardness to the attraction between the unlike atoms.

A similar calculation for the copper-nickel system gives an increase of 4% in the internal pressures as compared to 63% in the hardness so that the "chemical hardness" in this system is 7% of the total hardness. In the copper-gold system these values are 6 and 100%, respectively, yielding a "chemical hardness" of 6% of the total.

The slip-resistance theory of hardness (in which hardness is defined as resistance to slip along atomic planes) recognizes two basic factors causing hardness in solid solutions.[13] These are (1) the attraction between unlike atoms and (2) crystalline dissymmetry caused by the warping of the atom planes with the introduction of the foreign atom. The calculations here presented are an attempt to evaluate the relative magnitudes of these two factors. In the nature of the case such an evaluation can only be semi-

---

[10] The lattice constants for these metals are taken from Davey, *Phys. Rev.*, 25, 753 (1925).

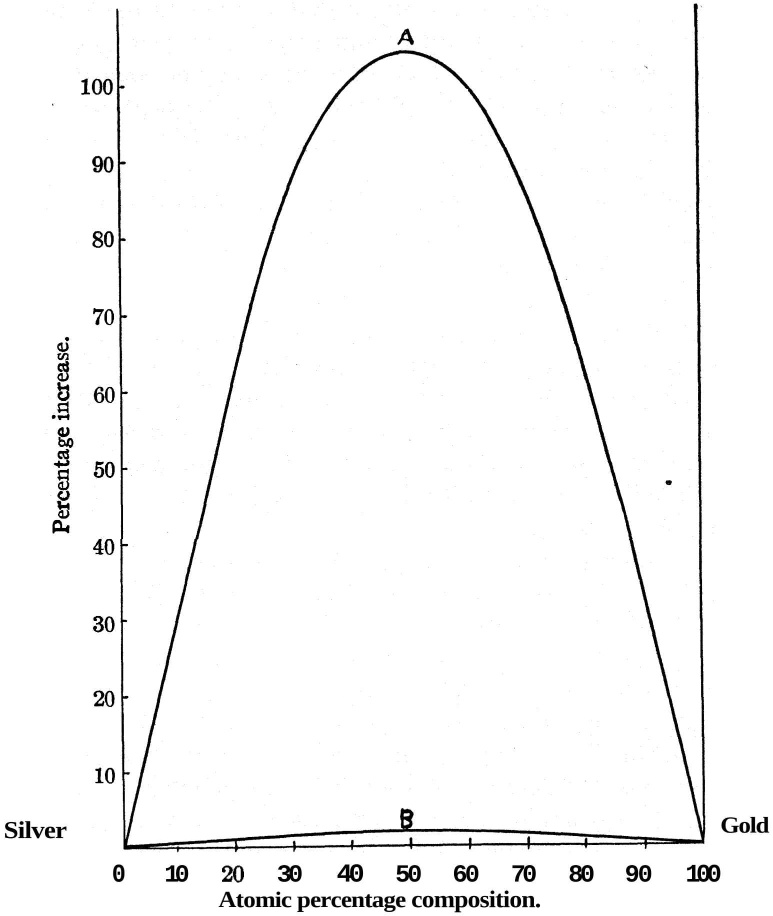
[11] Cold-work, which is very powerful in hardening metals and alloys, appears to have little or no effect upon the coefficient of thermal expansion [Jubitz, *Z. tech. Physik*, 7, 522 (1926)], and therefore upon the internal pressure calculated therefrom This emphasizes the fact that internal pressures are concerned only with purely cohesive forces and are not affected by lattice distortion or grain-size differences. It has already been pointed out (ref. 2) that compressibility is similarly unaffected by cold-work.

[12] Kurnakov and Zemczuzny, *Z. anorg. Chem.*, 54, 164 (1907); 60, 16 (1908).

[13] Jeffries and Archer, *Chem. Met. Eng.*, *24*, 1057 (1921).

quantitative, so that the percentages given must be regarded only as approximations.

Norbury[14] made measurements of hardness on a series of a-solid solutions of copper, and concluded that the hardening power of a solute atom is proportional to the difference in atomic volumes of the solute and the solvent. Rosenhain[15] has concluded that the hardness of solid solutions is largely caused by the lattice distortion introduced by the difference in size of the solvent and solute atoms. It is clear from the foregoing that Norbury's conclusion concerning the a-solid solutions of copper cannot be applied to the system silver-gold, nor perhaps to nickel-copper,



Curve A, hardness; Curve B, internal pressure.

for though the atomic volumes are nearly identical in each metal pair (10.28 and 10.22, and 7.12 and 6.59, respectively), the hardness reaches a maximum increase of 100.4% in the first and 63% in the second. The conclusion seems inescapable that the hardness in these solid solutions is not caused simply by the difference in sizes of the unlike atoms. In fact, if it be assumed that the internal pressures calculated in Table I apply to each separate atom it is clear that the atomic volumes of the atoms in solid solution cannot be the same as in the elementary state. In the silver-gold system, with increasing percentage of gold, the internal pressure increases from 199 kilomegabars for pure silver to 238 kilomegabars for pure gold, an increase of 39 kilomegabars. Obviously a pressure increase of such a magnitude would diminish the volume of the silver atom very appreciably. Conversely, in an alloy rich in silver, the gold atom, subjected to a smaller internal pressure than in the pure state, would increase in volume. This variation in volume would produce a slip-resistance not indicated by the relative atomic volumes of the metals in the pure state. It is not possible to calculate this volume change from the compressibilities of the pure metals, for even if the extrapolation to these high pressures and the approximation of the expansibility of the atom under an internal pressure decrease, be admitted, it must be remembered that because of the chemical attraction between the unlike atoms in the solid solution each atom is very probably partially ionized, and that .the ordinary compressibility coefficients are not applicable to the metal atom in this state. It is a significant fact, however, that the lattices of these solid solutions possess a high degree of symmetry, as shown by the sharpness of the reflection spectra obtained with x-rays. Whatever the volume changes suffered by the atoms, their symmetrical lattice positions must be accounted for, and the net volume change must be in accord with the observed small deviations from the rule of mixtures values for the densities.

As applied to non-cubic metals, the internal pressures calculated from the coefficient of linear expansion and the mean atomic volume may be taken to represent an *average* pressure around the periphery of the atom,[16] and accepting this extension of the foregoing argument, some interesting analogies can be drawn for the α-copper-zinc solid solutions.

Reference has already been made to coefficients of expansion for copper and the α-brasses.[8] There appears to be no satisfactory measurement for the coefficient of volume expansion for zinc at a comparable temperature but the linear coefficients determined by Bridgman[17] parallel and perpendicular to the hexagonal axis may be combined into a volume coefficient,

0.0	0.0	...	82.6	9.16	9.16	82.6	109	109	..	..

[a] This value for copper differs from that given in Table I since the coefficient $n'/(n' - m)$ has been dropped. This coefficient is unknown for zinc, but its elimination can have only a very slight effect upon the figures in the last column.

This increase in internal pressure runs closely parallel with the related properties, as shown by Table III.

TABLE III

Weight % of copper	% Decrease in specific volume[a]	% Decrease in compressibility	% Increase in internal pressure
100.0	..	..	..
90.0	1.05	13	4.2
80.0	1.71	21	11.9
70.0	2.49	26	16.5
63.0	2.95	30	20.0

[a] The figures in the second column have been calculated from those cited by Jeffries and Archer, *Chem. Met. Eng.*, **29**, 925 (1923). Those in the third column are approximated from the values determined by the author in collaboration with B. J. Mair (ref. 2). Each column refers to the percentage change from the rule of mixture value.

A fifth column, giving the percentage increase in hardness, could be appended to this table, but this had not been done because of the disagreement among the various investigators concerning the hardness of the α-brasses.[19] However, the greater hardness of the a-brasses is clearly influenced by the chemical attraction between unlike atoms and the resultant denser packing, as illustrated by the last three columns in Table III. The probable effect

---

[18] Bridgman's linear coefficients are, respectively, 57.4×10^{-6} and 12.6×10^{-6}. The volume coefficient is therefore $2\ (12.6 \times 10^{-6}) + 57.4 \times 10^{-6}$.

[19] Harris, *J. Inst. Metals*, **28**, 327 (1922), reported in International Critical Tables, Volume II, p. 555, finds that the Brinell numbers for a-brass with 90, 80 and 70 percentage copper by weight are identical, namely, 45, whereas that for the 66% copper alloy is 48. Taking 40 as the Brinell number for pure copper and 39 for zinc, this is an increase over the rule of mixtures value of only 20%. Jeffries and Archer, *Chem. Met. Eng.*, **29**, 967 (1923), state that the Brinell number rises from 35 for pure copper to 55 for a 70–30 brass, an increase over the rule of mixtures value of approximately 53%.

upon the zinc atom of this denser packing on the copper lattice has been discussed in a previous publication.[2]

Summary

1. It is pointed out that the chemical attraction between unlike atoms in metallic solid solutions of the simple substitutional type should manifest itself by increased internal pressures.

2. The average internal pressures in a series of binary systems of cubic metals have been calculated and it has been shown that the increase in internal pressure is positive and that it may amount to as much as 46 kilomegabars (in the silver-palladium system).

3. The results of the calculations of internal pressure have been applied in an analysis of the factors controlling hardness in solid solutions and it has been shown that the increased cohesive forces account for only a small fraction of the total hardness increase.

4. Similar calculations have been applied to the copper-zinc system, with limiting assumptions, and various properties affected by the increase in internal pressure have been correlated.

THE ACID-FORMING PROPERTIES OF OSMIUM TETROXIDE

BY DON M. YOST AND ROBERT J. WHITE

RECEIVED OCTOBER 8, 1927 PUBLISHED JANUARY 5, 1928

Introduction

There has been difference of opinion as to whether osmium tetroxide, OsO_4, is an acid anhydride. Ephraim[1] concludes that the oxide probably does not form an acid from the supposed facts that its solubility in solutions of strong bases is the same as in water, that it does not react with them to form salts and that the concentration of hydroxide ion does not change when the tetroxide is dissolved in alkaline solutions. He did not regard as conclusive the evidence afforded by the results of Tschugaeff,[2] who prepared substances of the type $OsO_4.CsOH$ and $OsO_4.2KOH$. Since then Krauss and Wilkins[3] have also prepared unstable substances such as $OsO_4.2CsOH$. Hofmann[4] measured the electrical conductivity of osmium tetroxide solutions and found it to be very small; thus, with **1 g.** dissolved in **100** cc. of water the specific conductivity was found to be 10.9×10^{-6}, while that of the water used was 5×10^{-6}. He concludes that solutions of the

tetroxide are neutral and not acid. The qualitative experiments of von Wartenberg[5] constitute good evidence that the substance is an acid anhydride. He found that, while it could be almost completely extracted from its solutions in water by a few shakings with carbon tetrachloride, it could in turn be extracted almost completely from the carbon tetrachloride by four treatments with a 25% solution of sodium hydroxide. Finally, Professor W. C. Bray has pointed out to us that, inasmuch as the solutions of the tetroxide in water are nearly colorless while those in alkaline solutions are orange-yellow, a new substance must have been formed, which is probably an anion of the acid[6] H_2OsO_5.

This article describes an investigation of the distribution-ratios of osmium tetroxide between carbon tetrachloride and water and sodium hydroxide solutions, from which an ionization constant of perperosmic acid H_2OsO_5 has been calculated. Experiments with potassium chlorate solutions were also made to determine by an independent method whether or not osmium tetroxide forms a complex with chlorate ion; for Hofmann[4] found that the solubility of potassium chlorate is greater in solutions of the tetroxide than in water, and from these results concluded that a complex exists.

We wish to express here our appreciation of the helpful suggestions made by Professor A. A, Noyes. The investigation was aided on the financial side from a grant made to him by the Carnegie Institution of Washington,

Experimental Procedure

The water and carbon tetrachloride used in the experiments were freed from oxidizable impurities by well-known methods.

To a definite volume of the stock solution of osmium tetroxide in well-cleaned, glass-stoppered tubes definite volumes of water or solutions were added in amounts sufficient to make the total volume 25.00 cc. To this 25.00 cc. of carbon tetrachloride was added, the glass stoppers were inserted, the tubes placed in a thermostat at 25°, and shaken vigorously at frequent intervals. It was found that equilibrium was easily attained.

The method of analysis used was substantially that described by Krauss

---

[5] Von Wartenberg, Ann., 440, 97 (1924).

[6] The naming of this acid offers special difficulty. It is highly desirable that the analogous acids of the elements manganese, iron, ruthenium and osmium have corresponding names. The acids H_2MnO_4, H_2FeO_4, H_2RuO_4, H_2OsO_4 are universally called manganic, ferric, ruthenic and osmic acids; and there exists an acid $HRuO_4$ which, in analogy with permanganic acid, is called perruthenic acid. This excludes the use of this name for the acid H_2RuO_5 (corresponding to RuO_4); and if the name perosmic acid be used, as it often is, for H_2OsO_5, it will introduce an inconsistency in the nomenclature of the related acids. A new type of name is therefore needed for the two acids of the elements with valence eight, and Professor A. A. Noyes has suggested to us that the most suggestive names would be derived by doubling the prefix *per*, thus designating H_2RuO_5 and H_2OsO_5 as perperruthenic and perperosmic acids.

and Wilkins.[3] It consisted in pipetting definite volumes of each liquid phase into 50 cc. of 2 N hydrochloric acid containing 2 g. of potassium iodide in stoppered flasks and titrating the liberated iodine with standard thiosulfate. Carbon tetrachloride was added to the mixtures in which it was not already present. It was necessary to extract the tetroxide from the chlorate solutions with carbon tetrachloride and analyze the extracts, since chloric acid reacts with iodide. The main objection to this method of analysis is the difficulty of determining the end-point in the dark green solutions of reduced osmium, especially when very dilute thiosulfate is used. The concentrations of thiosulfate varied from 0.00249 *N* to 0.0259 *N*, depending on the amount of osmium present in the sample analyzed.

Results of the Distribution Experiments

Table I contains the results. The distribution-ratios r are calculated directly from the concentrations by the expression $r = c_{\text{CCl}_4}/c_{\text{Aq}}$.

TABLE I

RESULTS OF THE DISTRIBUTION EXPERIMENTS AT 25°

Number	Millimoles of OsO_4 per liter in CCl_4 layer	Millimoles of OsO_4 per liter in Aqueous layer	Aqueous layer	Distribution-ratio r
1	6.40	0.532	Water	12.0
2	6.47	.545	Water	11.9
3	6.51	.541	Water	12.0
4	6.53	.532	Water	12.3
5	6.86	.558	Water	12.3
6	13.0	1.03	Water	12.7
7	13.1	1.02	Water	12.8
8	5.08	2.35	NaOH, 0.0587 N	2.16
9	5.09	2.36	NaOH, 0.0587 N	2.16
10	5.92	1.54	NaOH, 0.0277 *N*	3.84
11	5.92	1.54	NaOH, 0.0277 N	3.84
12	6.83	0.634	$KClO_3$, 0.2000 N	10.8
13	6.83	.632	$KClO_3$, 0.2000 N	10.7

The values of the distribution ratio between the tetrachloride and water show a slight increase with the concentration of the tetroxide, which is probably to be ascribed to error in the analyses of the more dilute solutions.

The Ionization Constant of Perperosmic Acid

We may assume that osmium tetroxide unites with water to form an acid which ionizes according to the equation $H_2OsO_5 = H^+ + HOsO_5^-$, and that correspondingly the reaction with hydroxide is $H_2OsO_5 + OH^- = HOsO_5^- + H_2O$. It is obvious then by the mass-action law, if K_w and K_A are the ionization constant of water and acid, respectively, that

$$\frac{(H^+)\,(HOsO_5^-)}{(H_2OsO_5)} = \frac{K_w(HOsO_5^-)}{(OH^-)\,(H_2OsO_5)} = K_A \qquad (1)$$

Now the quotient of the distribution ratio r_s for the alkaline solution and that, r_w, for water is evidently

$$\frac{r_s}{r_w} = \frac{(\mathrm{H_2OsO_5})}{(\mathrm{H_2OsO_5}) + (\mathrm{HOsO_5^-})} \text{ whence follows } \frac{(\mathrm{HOsO_5^-})}{(\mathrm{H_2OsO_5})} = \frac{r_w - r_s}{r_s}. \qquad (2)$$

Combining this with Equation (1) we get

$$K_A = \frac{K_w(r_w - r_s)}{(\mathrm{OH^-})r_s} \qquad (3)$$

The value of r_w is taken as 12.3, the average of experiments 1–7.

The values of K_A calculated with $K_w = 10^{-14}$ and r_s as given by experiments 8–9 and 10–11 are 8.0×10^{-13} and 7.9×10^{-13}, respectively. The agreement is very satisfactory.

This acid has therefore a constant even smaller than that of HCO_3^- (6×10^{-11}) and is one such that its salt $NaHOsO_5$ would be about 30% hydrolyzed in a 0.1 *M* solution. In view of the extreme weakness of the acid, it is not surprising that the tetroxide has not heretofore been proved to be an acid anhydride.

The results of experiments 12 and 13 show that a complex between osmium tetroxide and chlorate ion is probably formed, although it is not a very stable one.

Summary

The distribution ratio of osmium tetroxide between carbon tetrachloride and water has been found to have an average value of 12.3 when the concentrations are expressed in quantities per unit volume. The ratio is found to be much less when the aqueous phase consists of 0.0277–0.0587*N* sodium hydroxide, showing that much of the tetroxide is converted into a salt by the alkali. From the results, the ionization constant is calculated to be 8.0×10^{-13} for the first hydrogen of the acid H_2OsO_5, which it is proposed to call perperosmic acid.

THE CATALYSIS OF ETHYL FORMATE BY MONOCHLORO-ACETIC ACID AND ETHYL ACETATE BY DICHLORO-ACETIC ACID IN NEUTRAL SALT SOLUTIONS

BY HERBERT S. HARNED AND J. ERSKINE HAWKINS

RECEIVED OCTOBER 10, 1927 PUBLISHED JANUARY 5, 1928

With the exception of a few results obtained by Taylor[1] on the catalysis of ethyl acetate by dichloro-acetic acid and trichloro-acetic acid in potassium chloride solutions, few experimental data are available on ester hydrolysis by moderately strong acids in neutral salt solutions. To fill in this gap in the experimental material and to suggest a method of calculating the results are the objects of the present study.

Experimental Results

The usual method of titrating portions of the reaction mixtures with sodium hydroxide and barium hydroxide or with sodium hydroxide alone was employed. The unimolecular equation for the velocity was used. In the case of ethyl acetate hydrolysis, the variation of the velocity constants from the mean value during a given experiment was never greater than ±2% and was usually less than this amount. The calculation

of the results for the hydrolysis of ethyl formate showed some indication of autocatalysis. However, the results up to half decomposition of the ester showed little variation and their mean value was taken. In Table I the experimental results are given. All measurements were carried out at 25 ± 0.02°.

In Fig. 1 the velocity constants of the hydrolysis of ethyl acetate in the dichloro-acetic acid-salt solutions are plotted against the concentration of the added salt. Upon the first addition of the halides or sodium nitrate a very rapid increase in velocity constant occurs and as the salt concentration increases the velocity constant reaches a maximum and then decreases. No increase is observed in the case of potassium nitrate. With barium chloride the saturated solution is reached before a maximum occurs. Upon the addition of sulfates a rapid decrease in velocity constant is to be observed. As will be shown this is due to the removal of hydrogen ions to form HSO_4^-. In general this behavior parallels the neutral salt action on the velocity of hydrolysis of ethyl formate either in pure aqueous salt solutions or in salt solutions containing monochloro-acetic acid.[2,3]

Warned, THIS JOURNAL, 49, 1 (1927).

Calculation of Results

(1) Halide Solutions

We may express the velocity of hydrolysis by the equation

$$v = k m_e m_{\mathrm{H}} F \qquad (1)$$

where m_e and m_{H} are the concentrations of the ester and hydrogen ion, respectively, and F is a kinetic factor which differs from unity because of the electrical field effects caused by the presence of the ions. If F equals $\gamma_e \gamma_{\mathrm{H}}$, the activity rate theory results, and if F equals $\gamma_e \gamma_{\mathrm{H}}/\gamma_i$, we obtain the equation of Brönsted.[4] γ_e, γ_{H} and γ_i are the activity coefficients of the ester, the hydrogen ion and the collision complex, respectively. In concentrated solutions and when dealing with reactions between ions and electrically neutral substances, recent experimental

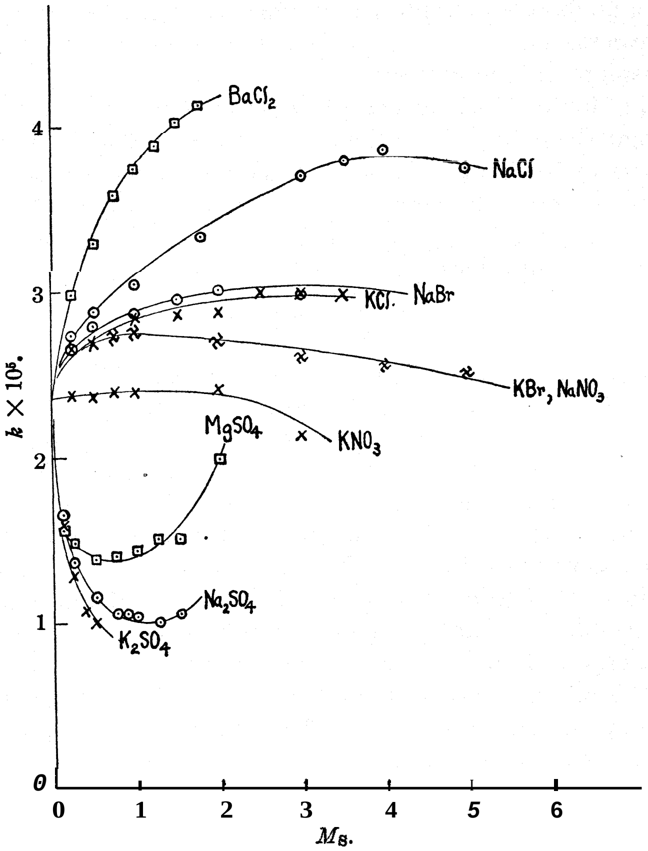

Fig. 1.—Velocity constants of hydrolysis of ethyl acetate by dichloro-aceticacid in salt solutions.

---

[4] Brönsted, *Z. physik. Chem.*, 102, 169 (1922).

work seems to indicate that F is a more complicated factor than that given by either of the above theories. In any case thermodynamics demands that F be expressed, in part at least, in terms of the activity coefficients of the species present. In a recent investigation[3] of the autocatalysis of ethyl formate in aqueous neutral salt solutions, approximate results were obtained by making F unity. This, in these cases of ester hydrolysis, is not an exact procedure. Consequently, we have resorted to a method of computation by which the salt effect, F, is eliminated from the calculation.

Two assumptions are necessary:

(1) That hydrochloric acid at **0.1** M is completely dissociated.

(2) That the activity coefficients of the ester and ionic species are the same in the hydrochloric acid-salt solution containing the ester as in the dichloro-acetic acid-salt solution containing the ester at the same ionic strength.

Upon these assumptions, we find that

$$\frac{k_{\mathrm{HCl}}}{k_{\mathrm{di}}} = \frac{0.1}{m_{\mathrm{H}}} \tag{2}$$

where k_{HCl} is the velocity constant in the hydrochloric solutions and k_{di} is the velocity constant in the presence of the dichloro-acetic acid solutions.[5] In this way, the concentration of the hydrogen ion, m_{H}, in the dichloro-acetic acid solutions may be evaluated. The results of this calculation for potassium and sodium chloride and sodium bromide are given in Table II. Col. 1 contains the salt concentrations, m_{S}, Col. 2 the velocity constants of hydrolysis of ethyl acetate in **0.1** N hydrochloric acid solutions containing potassium chloride and sodium chloride taken from the results of Harned,[6] and sodium bromide from the results of Bowe.[7] Col. **3** contains the velocity constants read off from the curves of the data in Table I. Col. 4 contains the values of the hydrogen-ion concentration computed by Equation 2. The dissociation constant of dichloroacetic acid is given by

$$K = \frac{\gamma_{\mathrm{H}}\gamma_{\mathrm{Ac}}}{\gamma_{\mathrm{HAc}}}\frac{m_{\mathrm{H}}^2}{m_{\mathrm{HAc}}} = \gamma_{\mathrm{A}}\frac{m_{\mathrm{H}}^2}{m - m_{\mathrm{H}}} \tag{3}$$

By substituting **0.0816** for m_{H} and **0.202** for m, we obtain 5.53 X 10^{-2} for $\frac{m_{\mathrm{H}}^2}{m - m_{\mathrm{H}}}$, which agrees with the value 5.1 X 10^{-2} obtained from conductance data.[8] To evaluate K, we take γ_{A} to equal $\frac{\gamma_{\mathrm{H}}\gamma_{\mathrm{OH}}}{a_{\mathrm{H_2O}}}$ or **0.60** at an ionic

---

[5] This method of computing kinetic results has been employed by Bronsted and King, THIS JOURNAL, 47, 2523 (1925).

strength of 0.0816.[9] Hence K equals 3.32×10^{-2}. From this value of K, and from the values of m_H in Col. 4, γ_A for the salt solutions of different strengths was calculated by Equation 3. The results are given in Col. 5.

The results for the monochloro-acetic acid hydrolysis of ethyl formate had to be calculated by a somewhat different method. Since no data are available on the hydrolysis of ethyl formate in hydrochloric acid-salt solutions, a direct determination of m_H by Equation 2 cannot be made. If we assume that the relative salt effect in this case is the same as in the case of ethyl acetate, then m_H may be evaluated by

$$\frac{k_{HCl}}{k_{mono}} = \frac{0.1\,R}{m_H} \qquad (4)$$

where R is a constant factor which relates the acetate with the formate hydrolysis. This was determined by calculating m_H in the 0.287 M monochloro-acetic acid solution. K was taken to be 4.2×10^{-3}, whence m_H equals 0.04 if γ_A is assigned the value 0.65 which is the ionic activity coefficient product of water at an ionic strength of 0.04.[10] Substituting

---

[9] Harned, THIS JOURNAL, 47, 930 (1925).

[10] The value used for the dissociation constant is higher than the value, 1.6×10^{-3}, obtained by Ostwald, *Z. physik. Chem.*, 3, 170 (1889). Our justification for using 4.2×10^{-3} is the agreement obtained between γ_A for monochloro- and dichloro-acetic acids in a given salt solution at the lower concentrations.

the values of k_{HCl} and k_{di} in Equation (4), we obtain 0.591 for R. The values for γ_A in the salt solutions were then calculated by Equation (4). These are compiled in Table III.

TABLE III

THE ACTIVITY COEFFICIENTS OF MONOCHLORO-ACETIC ACID IN POTASSIUM AND SODIUM CHLORIDE SOLUTIONS

$CH_2ClCOOH$(0.287 *M*) $K = 4.2 \times 10^{-3}$ $R = 0.59$

Molal salt concn.	$k \times 10^5$	m_H	γ_A
		(1) KCl

3	24.2	.0321	1.05
		(2) NaCl	
0.2	23.3	0.0459	0.49
.5	25.1	.0463	.49
1	26.6	.0441	.52
2	28.4	.0390	.69
3	29.0	.0333	.96

The results of this calculation are given in Fig. 2. In the lower part, γ_A is plotted against $\mu^{1/2}$ where μ is the ionic strength. The solid lines and points are the values of the dichloro-acetic acid in the designated salt solutions, and the dotted lines represent the activity coefficients product of monochloro-acetic acid in potassium and sodium chloride solutions. In the upper part of the figure are the values of the activity coefficient product of water as determined by Harned[9] and Harned and James.[11] The inked-in circles in the lower part are the values of $\gamma_H\gamma_{OH}/a_{H_2O}$ in sodium chloride solutions. These are seen to agree very well with the values of γ_A of mono- and dichloro-acetic acid in the same salt solutions. It is also interesting to note that the order of the curves for $\gamma_H\gamma_{OH}/a_{H_2O}$ and γ_A in the three salt solutions are the same and their distribution similar. A better agreement is hardly to be expected and is a considerable improvement over the earlier calculations of Harned[8] on the neutral salt catalysis of ethyl formate in aqueous solutions.

(2) Sulfate Solutions

We attribute the decrease in velocity caused by the addition of sulfates to the formation of HSO_4^-. Since in these solutions the predominating influence is that of the removal of hydrogen ions, we may obtain an approximate solution by neglecting the salt effect, or by assuming that F in

---

[11] Harned and James, *J. Phys. Chem.*, 30, 1060 (1926).

Equation (1) equals unity. Upon this assumption, the velocity constants will be proportional to the concentration of the hydrogen ion.

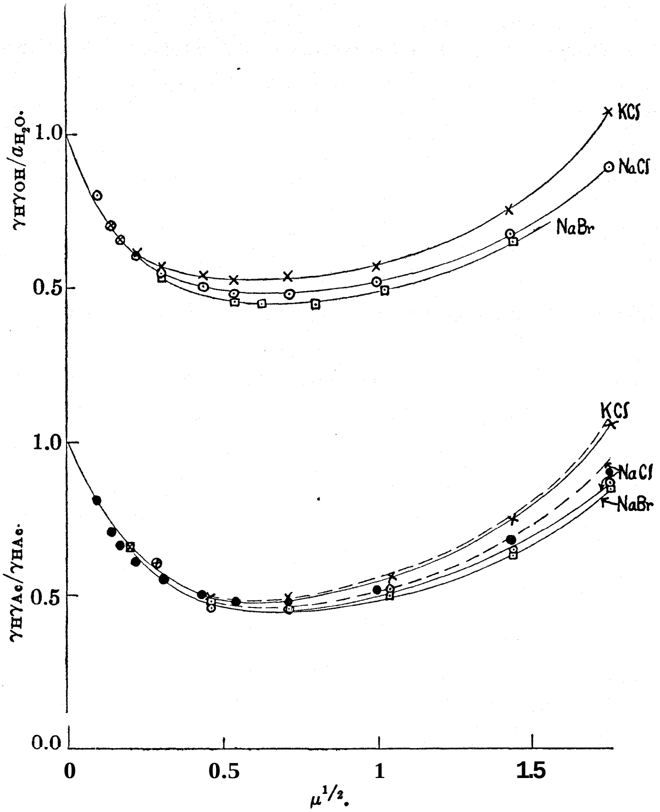

Fig. 2.—The activity coefficient products of mono- and dichloro-acetic acids in some halide solutions.

Let

$$\gamma_S = \frac{\gamma_H\gamma_{SO_4}}{\gamma_{HSO_4}};\quad \gamma_A = \frac{\gamma_H\gamma_{Ac}}{\gamma_{HAc}}$$

where the "γ's" are the activity coefficients of the species denoted by subscripts.

Let

M_{SO_4} = molal concentration of sulfate
M_{Ac} = molal concentration of dichloro-acetic acid
m_H = molal concentration of hydrogen ion
m_{Ac} = molal concentration of dichloro-acetate ion
m_{HSO_4} = molal concentration of HSO_4^-
m_{SO_4} = molal concentration of SO_4^{--}
m_{HAc} = molal concentration of undissociated dichloro-acetic acid molecules.

Then

$$\begin{cases} M_{\mathrm{Ac}} = m_{\mathrm{Ac}} + m_{\mathrm{HAc}} \\ M_{\mathrm{Ac}} = m_{\mathrm{H}} + m_{\mathrm{HSO_4}} + m_{\mathrm{HAc}} \\ M_{\mathrm{SO_4}} = m_{\mathrm{SO_4}} + m_{\mathrm{HSO_4}} \end{cases} \quad \text{or} \quad \begin{cases} m_{\mathrm{Ac}} = M_{\mathrm{Ac}} - m_{\mathrm{HAc}} \\ m_{\mathrm{HSO_4}} = M_{\mathrm{Ac}} - m_{\mathrm{H}} - m_{\mathrm{HAc}} \\ m_{\mathrm{SO_4}} = M_{\mathrm{SO_4}} - m_{\mathrm{HSO_4}} \end{cases} \tag{5}$$

In dilute solution, according to the theory of Debye and Hückel

$$\log \gamma_{\mathrm{S}} = -2\sqrt{\mu};\ \log \gamma_{\mathrm{A}} = -\sqrt{\mu}$$

and, therefore

$$\gamma_{\mathrm{S}} = \gamma_{\mathrm{A}}^2$$

Hence

$$K_1 = \gamma_{\mathrm{A}}^2 \frac{m_{\mathrm{H}}\, m_{\mathrm{SO_4}}}{m_{\mathrm{HSO_4}}} \tag{6}$$

$$K_2 = \gamma_{\mathrm{A}} \frac{m_{\mathrm{H}}\, m_{\mathrm{Ac}}}{m_{\mathrm{HAc}}} \tag{7}$$

Divide Equation (6) by the square of Equation (7) and obtain

$$\frac{K_1}{K_2^2} = \frac{m_{\mathrm{SO_4}}\, m_{\mathrm{HAc}}^2}{m_{\mathrm{H}}\, m_{\mathrm{HSO_4}}\, m_{\mathrm{Ac}}^2} \tag{8}$$

By substituting in the latter the values of the concentrations given in (5)

$$\frac{K_1}{K_2^2} = \frac{(M_{\mathrm{SO_4}} - M_{\mathrm{Ac}} + m_{\mathrm{H}} + m_{\mathrm{HAc}})\, m_{\mathrm{HAc}}^2}{m_{\mathrm{H}}\,(M_{\mathrm{Ac}} - m_{\mathrm{H}} - m_{\mathrm{HAc}})\,(M_{\mathrm{Ac}} - m_{\mathrm{HAc}})^2} \tag{9}$$

is obtained. By means of this equation m_{HAc} may be evaluated by arithmetical approximation since all other quantities are known. γ_{A} may then be determined by Equation (7) in the form

$$K_2 = \gamma_{\mathrm{A}} \frac{m_{\mathrm{H}}\,(M_{\mathrm{Ac}} - m_{\mathrm{HAc}})}{m_{\mathrm{HAc}}} \tag{10}$$

For K_2 we have taken the value previously employed, namely, 3.32×10^{-2} and for k, the value 1.15×10^{-2}.[12] The values for γ_{A} calculated by this method are given in Table IV.

---

[12] Noyes and Sherrill, This Journal, 48, 1861 (1926).

In Fig. 3 the values of γ_A in Table IV are plotted against the square root of the ionic strength. The values represented by triangles are the squares of the theoretical activity coefficients of a uni-univalent electrolyte computed by the Debye and Hückel equation

$$\log \gamma = -\frac{0.357\sqrt{2\mu}}{1 + A\sqrt{2\mu}}$$

where A represents the term containing the mean ionic diameters. A probable value of 0.8 was assigned to A. It is obvious that as μ decreases, the values of γ_A in these sulfate solutions approach the theoretical values.

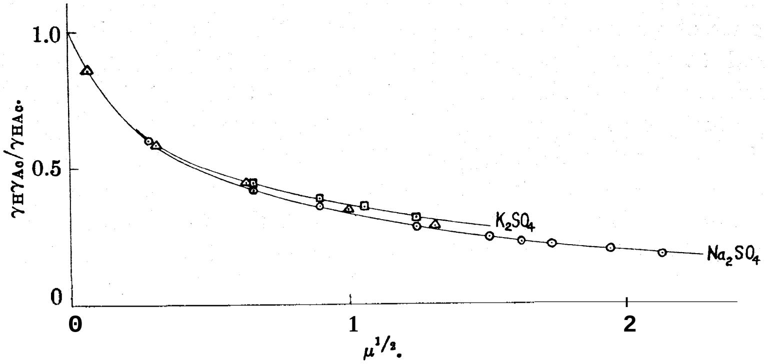

Fig. 3.—The activity coefficient product of dichloro-acetic acid in sulfate solutions.

Further, γ_A is greater in a potassium than a sodium sulfate solution of a given strength, a fact which agrees with the distribution of the ionic activity coefficient product of water as determined by Åkerlöf.[13]

Summary

(1) The velocity of hydrolysis of ethyl acetate at 25°, catalyzed by dichloro-acetic acid, has been determined in a number of salt solutions.

(2) Similar results have been obtained for the velocity of hydrolysis of ethyl formate, catalyzed by monochloro-acetic acid.

(3) A method of computing the activity coefficients of the acids from the kinetic data has been worked out and shown to yield reasonable results.

(4) An approximate method has been employed with success in computing the activity coefficients of the catalyzing acid in sulfate solutions. Although approximate, the method shows that the catalytic behavior in the sulfate solutions is largely determined by the formation of acid sulfate ions.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. V THE ELECTRIC MOMENTS OF CERTAIN ORGANIC MOLECULES IN CARBON DISULFIDE AND HEXANE SOLUTION

BY JOHN WARREN WILLIAMS AND EARL F. OGG

RECEIVED OCTOBER 18, 1927 PUBLISHED JANUARY 5, 1928

The utility of the Debye modification of the Clausius-Mossotti law for the calculation of the electric moments of certain molecules has been shown by several investigators.[1] At the present writing data for the moments of various types of organic molecules, calculated in the manner referred to above, are accumulating rapidly. In general, these figures are being obtained either from dielectric constant and density data for their solutions in benzene or from the temperature variation of the dielectric constant of their vapors. In this series of articles the dielectric constants of binary mixtures are being studied; therefore, it is concerned only with the first type of calculation, with the important modification, however, that other solvents besides benzene are being used. The third paper of this series[2] presented values for the electric moments of certain organic molecules, calculated from dielectric constant and density data of their solutions in carbon tetrachloride. The purpose of this paper is to show that carbon disulfide and hexane may also be used successfully as solvents for the purpose in hand. The electric moments of several organic molecules have been calculated from dielectric constant and density data in these solutions, data similar in all respects to those presented in previous papers of this series.

Method

The method used for the determinations of the dielectric constants of the solvents, carbon disulfide and hexane, and their solutions, was the electrical resonance method described in the first paper of the series.[3] The same frequency, 10^6 cycles per second, and the same temperature, 25°, were used for the measurements in every case.

Density determinations on the solutions were made at 25° using a 50cc. pycnometer of the Ostwald-Sprengel type. The usual precautions for precision work were observed throughout.

Purification of Materials

Carbon Disulfide.—The carbon disulfide was agitated with mercury to remove

foreign sulfides. It was dried by means of phosphorus pentoside, after which it was submitted to fractional distillation; boiling point 45.3–45.6°.

Hexane.—This liquid was obtained from the Eastman Kodak Company. It was thoroughly dried with phosphorus pentoxide and fractionally distilled; boiling point 67.5–70.5°. Owing to the difficulty of obtaining absolutely pure hexane, it was necessary to use the fraction as given. Since the material contained only saturated hydrocarbons, it served well as an electrically inert solvent.

Benzene.—The benzene was obtained in a thiophene free condition from the Eastman Kodak Company. It was dried and fractionated in the manner described by Richards and Shipley[4] and gave practically the same physical constants reported by these investigators.

Nitrobenzene.—The nitrobenzene used was obtained from the J. T. Baker Chemical Company. It was subjected to repeated fractional crystallizations and fractional distillations; boiling point 210.6–210.8°.

Chlorobenzene.—This material was obtained from the Eastman Kodak Company. It was carefully dried and fractionated; boiling point 130.7–131.0°.

Naphthalene.—Naphthalene, obtained from Merck and Company, was purified by crystallization and sublimation; melting point 80.1°.

Anthracene.—This material was purified by recrystallizing from toluene and washing with alcohol; melting point 217.6°.

Phenol.—Merck and Company "U. S. P.—C. P.—Loose Crystals" phenol was melted and fractionally distilled; boiling point 179.5–180.0°.

Benzoic Acid.—This material, obtained from the Mallinckrodt Chemical Company, was recrystallized from toluene and sublimed. The final product was in the form of pure white crystals; melting point 121.8'.

Cinnamic Acid.—Cinnamic acid, obtained from Kahlbaum, was purified by recrystallization from alcohol; melting point 132.6'.

Iodine.—The iodine, a Mallinckrodt product, was resublimed. It was used without further treatment.

Experimental Results

The results of the experimental work are presented in Tables I and II. In Table I dielectric constant and density data for solutions in carbon disulfide are given and in Table II similar data for solutions in hexane. The columns of these tables give, from left to right, the mole fraction of the solvent, in Table I, M. F. CS_2, in Table II, M. F. C_6H_{14}; the density of the solution compared to water at 25°, d_{25}^{25}; the observed dielectric constant of the solution, ϵ; the molar polarization of the solution, $P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2}\frac{f_1M_1 + f_2M_2}{d} = f_1P_1 + f_2P_2$; and the molar polarization of the second component $P_2 = \frac{P_{1,2} - f_1P_1}{\mathrm{fa}}$. The dielectric constant data are accurate to within 0.1 of one per cent.

It will be noted that these data are somewhat different in certain respects. In the case of the binary liquid mixtures the two components are mutually soluble in all proportions, while in the case of the binary systems in which the solute is a solid substance, examples are presented

---

which show widely varying solubilities. The solubilities of the benzoic acid, cinnamic acid and anthracene in carbon disulfide and the solubility of the benzoic acid in hexane were so slight that the calculation of their molar polarizations was not attempted. However, their dielectric constant and density data have been included in the tables.

Calculation of the Electric Moments of the Various Solute Molecules

The dielectric constant and density data using carbon disulfide and hexane as non-polar solvents for certain organic molecules are exactly similar to those obtained for the binary systems considered in the three preceding papers of this series,[1d,2,5] in which either benzene or carbon tetrachloride was used as the solvent. The calculations of the electric moments of the various solute molecules to be presented in this article

[5] Williams and Allgeier, THIS JOURNAL, 49, 2416 (1927).

were made in the same manner and making the same assumptions, so that the details will be omitted.

The electric moments of the various solute molecules, calculated from dielectric constant and density data of their solutions in carbon disulfide, are given in Table III. In Table IV are given the results of similar calculations for the electric moments of certain solute molecules from like data in hexane solutions. The symbols of the previous articles have been retained throughout.

TABLE III

ELECTRIC MOMENTS OF SOLUTE MOLECULES (CARBON DISULPIDE AS SOLVENT) AT 25°

	P''_2, cc.	P'_2, cc.	$\mu \times 10^{18}$
Phenol	27.5	56.1	1.63
Naphthalene	43.5	10.5	0.69
Benzene	25.8	2.7	0.09
Nitrobenzene	32	314	3.89
Chlorobenzene	31	61	1.52
Hexane	29.6	2	0.08

TABLE IV

ELECTRIC MOMENTS OF SOLUTE MOLECULES (HEXANE AS SOLVENT) AT 25°

	P''_2, cc.	P'_2, cc.	$\mu \times 10^{18}$
Carbon disulfide	21.1	2	0.08
Naphthalene	43.5	11.5	0.72
Benzene	25.8	2	0.08
Nitrobenzene	32	314	3.89
Chlorobenzene	31	53	1.55

It is of interest also to consider benzene as the solvent in the case of the systems carbon disulfide-benzene and hexane-benzene. This permits a calculation of the electric moments of the carbon disulfide and hexane molecules, the results of which are given in Table V.

TABLE V

ELECTRIC MOMENTS OF CARBON DISULPIDE AND HEXANE (BENZENE AS SOLVENT) AT 25°

	P^{a}_{2}, cc.	P'_2, cc.	$\mu \times 10^{18}$
Carbon disulfide	21.1	1.1	0.06
Hexane	29.6	0.9	0.05

Discussion of Tables of Electric Moments

One exceedingly important conclusion can now be drawn from the data made available by this series of articles, namely, that the value of the electric moment for the solute molecules, calculated from dielectric constant and density data in various non-polar solvents, is quite independent of the solvent used. This point is illustrated by the data collected in Table VI.

TABLE VI

ELECTRIC MOMENT DATA FOR CHLOROBENZENE AND NITROBENZENE IN VARIOUS SOLVENTS—TEMPERATURE, 25°

Solvent	e (solvent)	P_2 (C_6H_5Cl)	$\mu \times 10^{18}$ (C_6H_5Cl)	P_2 ($C_6H_5NO_2$)	$\mu \times 10^{18}$ ($C_6H_5NO_2$)
Carbon disulfide	2.633	82.5	1.55	346	3.89
Benzene	2.283	82	1.55	344[a]	3.84
Hexane	1.904	84	1.56	346	3.89

[a] The value for $P_2(C_6H_5NO_2)$ in benzene solution was taken from Miss Lange's work, Lange, *Z. Physik*, 33, 169 (1925). This value has recently been checked in the Wisconsin Laboratory by Mr. C. H. Schwingel in the course of an investigation of the dielectric properties of certain nitro derivatives of benzene and toluene in benzene solution, the results of which will be published shortly.

It might have been predicted that since the dielectric constant of the solvent changes, a change in the molar polarization of the solute molecule, and therefore in its electric moment, should result. Indeed it may be said that from the meager data available to the time of these researches slight differences were indicated in the molar polarization values depending on the non-polar solvent used. The present authors believe that for the first time sufficiently accurate data have been accumulated to prove that such is not the case.

The data of this article have been used to calculate the electric moments of the molecules of the solvent media and their values have been included in the tables. The moments for benzene, carbon disulfide and hexane are practically zero; in other words they are non-polar in nature. This fact permits their use as solvents in studies of the type previously referred to.[1] The value $\mu = 0.08 \times 10^{-18}$ for benzene is of interest in connection with the article of Sänger,[6] in which this author shows from dielectric constant data on pure benzene and certain theoretical considerations that this molecule should have practically a zero moment.

The value found for the electric moment of naphthalene, $\mu = 0.70 \times 10^{-18}$, is of special interest to the organic chemist. If the structural formula for the substance is written in the conventional way, there results a molecule which appears to be symmetrical, or in the terms used here, it would appear to have a zero moment. The result presented above is not surprising since it is well known that the second benzene ring of the naphthalene behaves quite differently chemically from the first. The data for anthracene indicate that it has a much higher molar polarization, and therefore a higher electric moment, than naphthalene.

Phenol dissolved in carbon disulfide gave a value of $\mu = 1.63 \times 10^{-18}$, in excellent agreement with that found in benzene solution,[5] $\mu = 1.70 \times 10^{-18}$.

The agreement between the values of the electric moments found for

---

[6] Sänger, *Physik. Z.*, 27, 165 (1926).

chlorobenzene and nitrobenzene in the various solvents used leaves nothing to be desired. This agreement is shown amply in Table VI.

Summary

1. Using an electrical resonance method previously described, dielectric constant data have been obtained for carbon disulfide solutions of benzoic acid, phenol, cinnamic acid, iodine, naphthalene, anthracene, benzene, hexane, nitrobenzene and chlorobenzene, and for hexane solutions of benzoic acid, naphthalene, benzene, nitrobenzene and chlorobenzene, Corresponding density determinations have been made.

2. The data have been applied to the calculation of the electric moments of a majority of the solute molecules.

3. The data of this article prove that the molar polarization, and therefore the electric moment, of a solute molecule is independent of the non-polar solvent used.

4. The solvents benzene, carbon disulfide and hexane have been shown to be non-polar in character.

THE ENTROPY OF HYDROGEN CHLORIDE. HEAT CAPACITY FROM 16°K. TO BOILING POINT. HEAT OF VAPORIZATION. VAPOR PRESSURES OF SOLID AND LIQUID

BY W. F. GIAUQUE AND R. WIEBE

RECEIVED OCTOBER 20, 1927 PUBLISHED JANUARY 5, 1928

The results presented in this paper were obtained in the first of a series of researches on low temperature calorimetry of condensed gases. This research, which was started in 1922, is in active continuation. It is hoped that the more important substances of simple structure which are gases under ordinary conditions will be investigated, or perhaps we should say re-investigated since data exist in many cases. In addition to the data presented in this paper, measurements on hydrogen bromide and hydrogen iodide have been completed but will not be available until the completion of the laborious calculations.

Our immediate purpose is the testing of the third law of thermodynamics and more particularly the comparison of the entropy, as obtained from this law, with that obtained from various theories with the assistance of spectroscopic data It seems almost unnecessary to state that such a purpose imposes severe requirements on the accuracy of the measurements.

Hydrogen chloride was selected because of the reliability of band spectra measurements and their interpretation for this substance. While the measurements were in progress the results of a similar investigation by Eucken and Karwat[1] and by Karwat[2] appeared. However, our experimental data are in considerable disagreement with those of the above authors, thus necessitating a different conclusion as to the interpretation. This confirms our previous conclusion regarding the desirability of new determinations in other cases.

Preparation of Hydrogen Chloride.--The preparation of pure anhydrous hydrogen chloride in large quantities proved to be one of the most difficult parts of the work. The amount required to fill the calorimeter was about 3.5 moles, and it was necessary to work with as much as 10 moles to allow for losses during the purification. At first the gas was prepared by the addition of sulfuric acid to sodium chloride in a system which had been evacuated. The gas was further dried by passing through sulfuric acid and through phosphorus pentoxide before condensation in a bulb cooled with liquid air. C. P. reagents only were used. Hydrogen chloride prepared in this manner had two properties which required further investigation; first, the condensed material was of a reddish pink color; second, on melting it was obviously impure since solid white particles could be seen in the colorless liquid.

Pink Hydrogen Chloride.—The most obvious assumption would be that some impurity caused the pink color but additional experiments did not support this explanation. The reddish pink color was obtained only when the condensation by liquid air took place *in vacuo.* When hydrogen chloride was passed into a condensation bulb which contained air and was left open to the atmosphere, the crystalline material was white. When the liquid air was removed from a bulb containing pink crystals, thus allowing the temperature to rise, the pink color disappeared abruptly, leaving white crystals. This occurred at a temperature very little above that of liquid air, probably within 10 or 20 degrees above the boiling point. Subsequent cooling in liquid air did not restore the pink color. The intensity of the color varied with the conditions, a greater intensity resulting when the gas was more slowly admitted to the condensation bulb. The possible sources of impurity were the reagents and stopcock grease. Since other reagents could be used, the following methods of preparation were carried out with stopcocks in the system.

$NH_4Cl + H_2SO_4$,	HCl dried with H_2SO_4 and with P_2O_5
HCl (aq.) + H_2SO_4,	HCl dried with H_2SO_4 and with P_2O_5
$NH_4Cl + H_3PO_4$,	HCl dried with P_2O_5 only
$NaCl + H_2SO_4$,	HCl dried with H_2SO_4 only

C. P. phosphorus pentoxide was available from several sources, and samples from some lots turned brown on treatment with concentrated H_2SO_4. Such material was not used, and we believe that the phosphorus pentoxide which was used for preparation purposes was of the highest quality.

---

[1] Eucken and Karwat, *Z. physik. Chem.*, 112, 467 (1924).

[2] Karwat, *ibid.*, 112, 486 (1924).

Pink hydrogen chloride was produced by each of the above methods, in one of which phosphorus pentoxide was carefully eliminated. Finally, a closed apparatus was constructed without stopcocks in which, after evacuation by a mercury diffusion pump and sealing off, sodium chloride and sulfuric acid could be mixed and the gas condensed in a bulb either after or before drying with phosphorus pentoxide. This also produced pink hydrogen chloride. One of the bulbs of this apparatus had purposely been made of thick glass with a thin spot on one side. It was found that in this case the material on the thin spot was pink while the remainder was white. This explains the effect produced by the presence of air, namely, that unless the inside wall of the vessel is kept practically at the temperature of liquid air the pink modification will not form. It was not possible to obtain the pink form in the calorimeter since the gas was necessarily liquefied first in the process of filling. There was a transition at 98.36°K. in the calorimeter but both forms are colorless, as could readily be observed by freezing the liquid and cooling the solid to about 83°K. in glass. It seems probable that the reddish pink material is an unstable crystalline form of hydrogen chloride. Since it was always mixed with some white material it may be presumed that the color of the pure unstable form would be considerably darker than the color observed. The existence of a third crystalline form is supported by the work of Simon and Simson,[3] who found by x-ray analysis that the form stable at the melting point had a face-centered cubic structure, while at the temperature of liquid air the observed twenty-eight characteristic distances prevented interpretation. In the above experiment the hydrogen chloride was examined on a metal plate on which it had been condensed in *vacuo* by liquid air. This may have resulted in the presence of two forms simultaneously. If such was the case an experiment in which a second exposure, made after the material has been allowed to warm somewhat above the temperature of liquid air and then been recooled, would result in the disappearance of approximately one-half of the characteristic distances. By difference this would enable the identification of both forms occurring in the mixture. It would also seem that the observed intensities might assist in the interpretation of the data as they are, unless chance provided two forms in nearly equal proportion. Simon and Simson did not include the data.

Pink hydrogen chloride has also been observed by Loeb[4] to whom we had suggested our technique of preparation.

Purity of Hydrogen Chloride.—As previously mentioned, hydrogen chloride prepared from sodium chloride and sulfuric acid and further dried with sulfuric acid and phosphorus pentoxide contained considerable

---

[3] Simon and Simson, *Z. Physik*, 21, 168 (1924).

[4] Loeb, *Proc. Nat. Acad. Sci.*, 12, 35 (1926).

impurity. It was noticed that the amount of impurity increased when the amount of phosphorus pentoxide used for drying was increased. After evaporation-of the hydrogen chloride, there remained a white solid which melted near the ice point, and a test on a water solution of the material showed the presence of phosphate. It seems probable that the material was phosphorus oxychloride, $POCl_3$, which melts at 1.25° and may be prepared by the interaction of hot hydrogen chloride and phosphorus pentoxide.

The method finally adopted for drying made use of concentrated sulfuric acid followed by liquefaction in a bulb containing phosphorus pentoxide and maintained at a temperature of approximately 195°K. by solid carbon dioxide and ether for about a week. The liquid hydrogen chloride was intimately mixed with a large amont of phosphorus pentoxide. The liquid was then repeatedly fractionated, the middle fractions being retained.

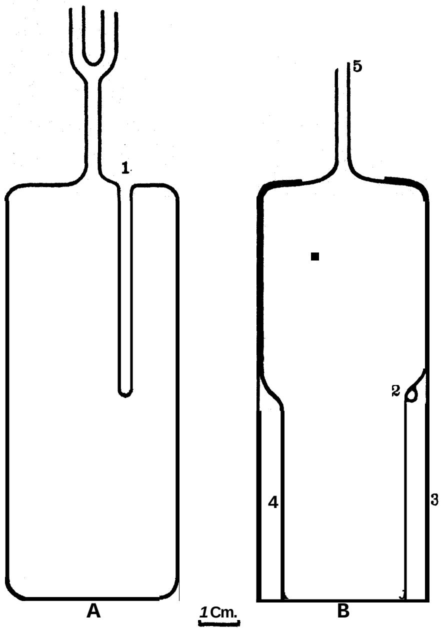

Fig. 1.

Apparatus for Vapor Pressures and for First Heats of Vaporization.—The apparatus used for temperature control was the same one used for calorimetric purposes by Gibson and Giauque,[5] except that the copper calorimeter was replaced by one of glass. Several glass containers were tried, none of which were very satisfactory since they often cracked when the hydrogen chloride was cooled to the temperature of liquid air. The first type tried is shown at A in Fig. 1. This type on two occasions broke at point 1 where the tube for holding the thermocouple was set into the container. Two glass tubes of about 2.5 mm. inside diameter are shown attached to container A. One of these was attached to a manometer while the other served as an inlet and outlet tube. When heat was introduced for the purpose of measuring the heat of vaporization it was found by means of the separate tube to the manometer that the pressure increase inside the calorimeter was less than 1 mm. of Hg and thereafter the second tube was discarded. The heater covered only the lower half of the glass vessel since it was desirable not to supply heat to the material which had been evaporated. For this reason only the material in the upper half of the calorimeter was used for heat of vaporization measurements.

The final glass calorimeter used is shown at B in Fig. 1. The thermocouple was placed in a long glass pocket shown at 2. The pocket was filled with paraffin to improve thermal contact. A copper sheath shown at 3 was shrunk on to the upper portion of B. This acted as a radiation shield for the number thirty constantan wire heater, shown at 4, returning radiated heat to the calorimeter. A thermocouple was also attached to

---

[5] Gibson and Giauque, THIS JOURNAL, 45, 93 (1923).

the sheath. To assist heat conduction a heavy sheet of platinum was coiled and placed in the interior of the glass calorimeter. Platinum was used because the better conducting gold was not immediately available. The inlet tube was closely wound with a heater of number thirty constantan wire which could be used to avoid the presence of solid within the tube. The inlet tube was sealed to the protective copper cylinder by Rose metal at point 5, Fig. 1. The vapor pressures were measured by means of a manometer constructed of Pyrex glass tubing 2 cm. in diameter, and a Société Génévoise cathetometer accurate to a few hundredths of a millimeter and with a precision of 0.01 mm. A trap filled with thin gold foil protected the calorimeter against distillation of mercury from the manometer. The copper-constantan thermocouple used for the vapor pressure measurements was calibrated by means of the transition, melting and boiling point temperatures of hydrogen chloride. Our determination of these temperatures on the absolute scale will be described later in this paper.

Vapor Pressure Results.—The vapor pressures of solid hydrogen chloride are given in Table I. The pressures are expressed in international cm. of Hg. The calculated pressures given in the third column were obtained from the equation.

$$\log P(\text{cm. Hg}) = -\frac{1114}{T} - 1.285 \log T - 0.0009467T + 11.00500 \quad (1)$$

The constants of equation (1) were chosen to fit the observed data.

TABLE I

VAPOR PRESSURES OF SOLID HYDROGEN CHLORIDE

T, °K.	$P_{\text{obs.}}$, international cm. of Hg	$P_{\text{calcd.}}$	$T_{\text{obs.}} - T_{\text{calcd.}}$
132.48	0.558	0.554	−0.05

148.44	3.705	3.709	+ .01
154.29	6.692	6.710	+ .03
155.04	7.221	7.215	− .01
158.91	10.370 10.371	10.371	.00

The vapor pressure of solid hydrogen chloride has been measured by Henglein[6] who gives the equation

$$\log P_{(\text{mm. Hg})} = -\frac{1966.3}{T^{1.1600}} + 7.5030 \quad (2)$$

and by Karwat[2] who gives an equation which is evidently in error since it does not reproduce his table of calculated data.

Henning and Stock[7] made one pressure measurement on the solid, namely, 7.56 cm. at 155.55°K. Equation (1), representing our data, gives 155.57°K. for the temperature corresponding to that pressure.

---

[6] Henglein, Z. Physik, 18, 64 (1923).

[7] Henning and Stock, Z. Physik, 4, 226 (1921).

Near the melting point Equation (1) gives values 0.16' lower than that of Henglein (2) and 0.44' lower than the calculated value of Karwat. In the region about 130°K. Equation (1) gives values 0.35' higher than that of Henglein (2) and 0.36' lower than the calculated value of Karwat. Henglein evidently failed to observe the melting point since he records a pressure of 12.22 cm. for the solid at 161.0°K.; whereas our measurements show a pressure of 10.371 cm. at the triple point, 158.91°K. In addition to our triple point pressure data recorded in Table I, two preliminary measurements, made about a year previous with a less precise cathetometer, had each given 10.370 ± 0.005 cm. Karwat's observed value was 10.344 cm. at 159.34°K.

The vapor pressure data on liquid hydrogen chloride are given in Table II. The calculated pressures given in the third column are obtained from the equation of Henning and Stock[7]

$$\log P_{(\text{mm. Hg})} = -\frac{905.53}{T} + 1.75 \log T - 0.005077T + 4.65739 \qquad (3)$$

The observed differences tabulated in Col. 4 show very close agreement of our data with those of Henning and Stock. Our temperatures may be in error by 0.05' in an absolute sense while having a higher relative accuracy.

The vapor pressure of liquid hydrogen chloride has also been measured by **McIntosh** and Steele.[8] However, their temperatures appear to be 0.3" too high near the melting point and about 2.0' too high at the boiling point.

Calorimetric Apparatus.—The copper sheathed glass apparatus used for the vapor pressure measurements could have been used for heat capacity measurements. However, it was known from the experience of others in this Laboratory that glass calorimeters were unsatisfactory, principally because the poor thermal conductivity decreases the accuracy with which small temperature intervals can be measured. For this

---

[8] McIntosh and Steele, *Z. physik. Chem.*, 55, 129 (1906).

reason no heat capacity measurements were made with the **glass** apparatus, although measurements of the heat of vaporization were made by a method which avoided the necessity of high precision in the measurement of temperature. This will be discussed later in this paper. The major purpose of the glass calorimeter had been for the acquisition of experience before proceeding to the construction of a more elaborate apparatus.

For purposes of identification we shall in future papers refer to the calorimeter described below as gold calorimeter II. This calorimeter is shown in Fig. 2. The cylindrical calorimeter **A** was made from gold sheet 0.75 mm. in thickness, with welded seams. The height was **12** cm. and the diameter 3.75 cm. Twelve radial vanes were placed inside to assist in attaining temperature equilibrium. The gases were introduced through a glass tube, of inside diameter about 2.5 mm., which was sealed to a short platinum tube, extending from the top of the calorimeter, by means of a lead and a cobalt-lead glass seal. The glass inlet tube was wound with a heater similar to that used in the glass calorimeter. **A** combined resistance thermometer-heater[9] was used for measuring temperature intervals and introducing energy. This was made of gold since it was to be wound on the gold calorimeter, thus minimizing strain due to temperature change. **A** gold thermometer had previously been used by Keesom and Onnes.[10] The gold from which the thermometer wire was made contained 0.175% of silver, which was desirable, since Onnes and Clay[11] have found that the presence of silver prevents the resistance from falling to small values at low temperatures. This was advantageous since the wire was also used for heating. The gold was drawn to a diameter of 0.025 cm. (B. and S. No. 30) through steel dies, being washed with nitric and sulfuric acids after every pull, as recommended by Onnes and Clay.[11] Diamond dies were then used to reduce the diameter to 0.008 cm. (B. and S. No. 40). The wire was annealed after the last pull and then doubly insulated with silk. The construction of the thermometer-heater was as follows. The sides of the gold calorimeter were coated with Bakelite lacquer and baked at 110° for thirty minutes. The wire was then wound on, impregnated with Bakelite lacquer and dried for one week. The exterior was then coated with gold leaf to minimize radiation. Following this the calorimeter was heated to 120° for a few minutes.

[11] Onnes and Clay, *ibid.*, No. 99c (1907).

The thermometer-heater was divided into two approximately equal parts. The total was used in all measurements except for the determinations of the heat of vaporization, in which case the lower half was used for energy input. The total resistance at room temperature was about 350 ohms and decreased to about 81 ohms at 15° K. From the results of Onnes and Clay we had expected the resistance to be less than 30 ohms at 15° K. At each end and in the center of the thermometer a lead wire of size B. and S. No. 30 copper was attached and brought into good thermal contact with the calorimeter to prevent possible gold-copper thermo-electric effects. This wire was connected to the thermometer terminals by means of 2.5 cm. of B. and S. No. 40 copper wire. One of the thermometer terminals is shown at G, Fig. 2.

The calorimeter was suspended by means of the glass connecting tube which was fastened to the protective cylinder C by means of Rose metal, shown at D, Fig. 2. The Rose metal also greatly diminished heat leak along the glass tube from above.

The protective cylinder consisted of 1750 g. of lead located in the upper portion, while the exterior walls and the lower portion of the cylinder consisted of 1850 g. of copper. The other details, such as the electrical connections and heaters for the protective cylinder, the vacuum-tight joint in the steel container for the apparatus, the high vacuum system, apparatus and methods for the electrical measurements necessary for the determination of energy and temperature were essentially the same as those described by Gibson and Giauque.[5]

The temperature of the protective cylinder and that of the steel container were obtained by means of thermocouples. The protective cylinder was suspended from the cover of the steel container by means of heavy string.

A hydrogen liquefier was located directly above the steel container. The interchanger was made from 160 meters of copper tubing of 0.2 cm. inside diameter and walls 0.05 cm. thick. The steel container and the interchanger were enclosed in a large Pyrex glass Dewar tube of about 11 cm. inside diameter and 74 cm. inside depth. The expansion valve of the liquefier could be controlled by a valve stem leading out of the apparatus. An insulated tube was included by which warm hydrogen could be blown on the valve in case of stoppage by solidified air which might accidentally get inside the hydrogen cycle. By this device the valve could be warmed sufficiently within a minute and without warming the interchanger to any great extent. Proper care in keeping the hydrogen pure made it unnecessary to make much use of the valve warmer, but it has proved valuable on several occasions. The large Dewar tube was enclosed in a vacuum-tight Monel Metal container which could be immersed in liquid air, although this was ordinarily unnecessary even when hydrogen was being liquefied. Directly above the cover of the Monel Metal container was a precooling coil consisting of about 15 meters of copper tubing similar to that in the interchanger. The precooling coil could be immersed in liquid air which, after evaporation, was utilized to surround the exterior of the whole apparatus with cold air, thus making unnecessary the immersion referred to above. In addition to the interchanger and precooler already referred to, there was a pre-interchanger to interchange heat between the temperature of liquid air and that of the room. This pre-interchanger consisted of 40 meters of copper tubing in each of four parallel tubes to eliminate a large pressure drop. The general plan of the liquefier and hydrogen cycle was similar to that described by Latimer, Buffington and Hoenshel.[12]

The hydrogen compressor delivered about 0.45 cubic meter (16 cubic feet) of hydrogen per minute at 160 atmospheres. A cast iron gas meter of large capacity in the hydrogen return line was very valuable for control purposes. A vacuum pump with a displacement of 4.25 cubic meters (150 cu. ft.) per minute was used to reduce

---

[12] Latimer, Buffington and Hoenshel, THIS JOURNAL, 47, 1571 (1925).

the temperature of the liquid air or liquid hydrogen by evaporation at low pressures. This pump would reduce the pressure to 2.5 cm. of mercury.

Calibration of Resistance Thermometer.—The resistance thermometer was calibrated by means of standard copper-constantan thermocouple No. 18 which had been calibrated in terms of a hydrogen gas thermometer by Giauque, Buffington and Schulze[13] and a hydrogen vapor pressure thermometer by Giauque, Johnston and Kelley.[14] The thermocouple was used under as nearly as possible the same conditions as those existing in the original calibration. Since it was very important to carry out the calibration while the measurements were in progress, this was our invariable procedure. The high precision of the resistance thermometer enabled the measurement of small temperature intervals with an accuracy unattainable with the thermocouple alone. The absolute temperatures given are believed to be accurate to 0.05°. The resistance thermometer calibration data were treated by a graphical method which consisted of plotting deviations from a linear equation, except at the temperatures of liquid hydrogen where a large plot of resistance against temperature proved to be more convenient.

Measurement of Heat Capacities.—The method of calculating energy input, heat transfer from the surroundings and temperature rise was similar to that used by Gibson and Giauque.5 However, we have investigated more thoroughly a small source of error in the measurement of an increment of temperature. The necessity for a correction to the temperature rise observed on the resistance thermometer arises in the following manner. Excepting the lowest temperatures of measurement, the protective cylinder was maintained at a temperature slightly above the final temperature attained in a heat capacity determination. This was in order to avoid distillation from the calorimeter into that portion of the inlet tube in thermal contact with the protective cylinder. Thus at all times the calorimeter was receiving a small amount of heat from its surroundings. It is obvious that any sort of thermometer located on the exterior of the calorimeter would record a temperature above that of the average temperature since the distribution of heat requires a thermal head. Favorable location of a thermometer in the interior of a calorimeter might reduce this effect, but would make it nearly impossible to apply a correction. The necessary data for making the correction were supplied by the measurements of current and voltage during energy input. From these data the resistance and therefore the temperature of the thermometer-heater wire at any time during energy input could be calculated. The average temperature of the calorimeter at the corresponding time was known. The rate of energy input being known, it was possible to

---

[13] Giauque, Buffington and Schulze, THIS JOURNAL, 49, **2343** (1927).

[14] Giauque, Johnston and Kelley, *ibid.*, 49, **2367** (1927).

determine the relation of thermal head to energy flow. This permitted the estimation of the thermal head due to an observed heat leak. In gold calorimeter II this correction was usually about one-tenth of one per cent, or less, and did not exceed three-tenths of one per cent. When this correction is not made the heat capacity results will be high. This is general for any temperature relation of calorimeter and its surroundings, provided the temperature of the surroundings is constant during a measurement. A calorimeter with poor heat conductivity will have a relatively large correction of this sort. This is particularly true when such a calorimeter is made of glass. The thermal head between the thermometer-heater wire and the average location of heat capacity in gold calorimeter II was ordinarily about one degree or less during energy input. This temporary rise in the external temperature of the calorimeter was considered in correcting for the heat received from the surroundings.

During the heat capacity measurements a small amount of material evaporated into the unfilled volume of the calorimeter and into the line. It was necessary to record the pressure at the beginning and end of each heat capacity determination in order to correct for the heat absorption accompanying this effect.

The density of solid hydrogen chloride has been determined by Simon and Simson,[3] while that of liquid hydrogen chloride has been determined by Baumé and Perrot.[15]

Heat Capacity Data.—The heat capacity data of hydrogen chloride are given in Table III. The first column contains the absolute temperature and the second column the heat capacity in calories per mole per degree.

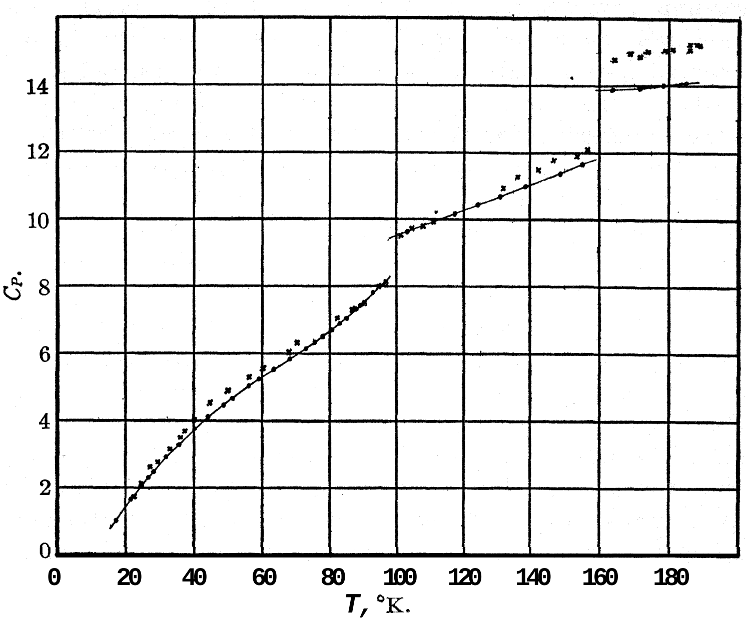
[15] Baumé and Perrot, J. chim. phys., 12, 225 (1914).

The above results are shown graphically by means of the points with the connecting curve in Fig. 3. The results of Eucken and Karwat are plotted as crosses. The measurements are in agreement at the temperatures of liquid hydrogen and of liquid air, but at all other temperatures the values of Eucken and Karwat are higher. It is difficult to explain such large discrepancies as those indicated. It appears that the temperature scale of Eucken and Karwat was somewhat in error, since they record the transition temperature as 98.75°K. as compared with our 98.36 ± 0.05°K., while Karwat gives the melting point as 159.34°K. as compared with our 158.91 ± 0.05°K. However, since the results deviate in only one direction it is improbable that the difficulty can be primarily due to an inaccurate temperature scale. Even an approximate knowledge of the extremes of the temperature range investigated would mean that if some results were too high others would necessarily be made too low. It does not seem possible to attribute the unsystematic deviations to incorrect standards of e.m.f. or resistance necessary for the energy measurements. Our standards were either calibrated by the U. S. Bureau of Standards or compared with standards newly received from the Bureau both before and after the experiments. Our standard of time was obtained from the astronomical observatory of this University. We believe that the error in the results of Eucken and Karwat is due primarily to the



X Eucken and Karwat. ● Giauque and Wiebe.

Fig. 3.—Heat capacity in calories per mole of hydrogen chloride.

use of too small an amount of material, and secondarily due to the use of a poorly conducting glass calorimeter. The amount of hydrogen chloride used by Eucken and Karwat was about **0.17** mole, whereas **3.72** and **3.57** moles were used in our experiments.

Nearly all of our measurements fall within 0.1 or **0.2%** of a smooth curve through the points. A few are off by about 0.5%. A smooth curve through the data should represent the heat capacity to an accuracy of about 0.2%, except in the case of the lowest measurement where, as the result of a poor vacuum and other experimental difficulties, the value may be in error by over 1%.

Transition Temperature and Melting Point Temperature.—Both the transition and the melting point temperatures were very sharp. Each was observed over a period of several days with occasional small input of energy and return of equilibrium. The temperature of the protective cylinder was maintained very closely at the same temperature as the calorimeter during these measurements. At the transition temperature the resistance thermometer showed an extreme variation of 0.02° over a period of seventy hours, while during the same time interval the thermocouple varied over a range of 0.05°. The transition temperature was **98.36** ± 0.05°K.

At the melting point an extreme variation of 0.01° was observed on the resistance thermometer over a period of seventy hours, while the thermocouple varied over a range of **0.06"**. The melting point temperature was **158.91** ± 0.05°K.

Heats of Fusion **and** of Transition.—The heat of fusion and that of transition were measured in the usual way of starting the heat input at a temperature somewhat below the melting or transition temperature and ending the input when the temperature had risen somewhat above. A correction for the $\int CpdT$ was applied. The results are given in Table

TABLE IV

HEAT OF TRANSITION OF HYDROGEN CHLORIDE

IV in the column headed G. and W. The results of Eucken and Karwat[1] are included for comparison.

Karwat[2] has calculated the heat of fusion from his measurements of the vapor pressure of solid hydrogen chloride combined with those of Henning and Stock on the liquid. He obtains the value 498.2 cal. per mole, in fair agreement with the calorimetric value of 504.5 obtained by Eucken and Karwat. A similar calculation based on our vapor pressure data leads to a value of 462 cal. per mole. However, we can expect no high accuracy from this calculation and we give it no weight as compared with our calorimetric value of 476.0. In the above calculation the equation of Berthelot was assumed in correcting for the imperfection in the gas state. The above correction lowered the value only by about three calories below the value which would have been obtained on the assumption of a perfect gas.

Measurement of **the** Heat of Vaporization.—The amount of material evaporated was obtained by absorption in a solution of 30% sodium hydroxide. The gas was bubbled through a small mercury trap in the bottom of the absorption bulb. The absorption solution was protected by two U-tubes, each containing on one side calcium chloride and on the other soda lime. One of the U-tubes was removable for weighing.

Two methods of measurement were employed. The first one designated as I in the tables was as follows. Two identical absorption bulbs were attached to a line leading from the calorimeter in such a way that a three-way stopcock controlled the flow of gas. The heating current was turned on and the stopcock opened into one of the absorption bulbs. After several minutes a steady state was reached and the stopcock was turned to direct the flow of gas into the other bulb. At the same time a calibrated stopwatch was started. The pressure remained constant to one millimeter. The second method, designated II in the tables, was as follows. With one absorption bulb on the line and the stopcock closed, the warming rate was observed as in a heat capacity determination. Then at a predetermined time the current was turned on, the stopwatch started, and shortly after this the stopcock was opened. At the end the current was turned off and after the flow of gas had practically ceased the stopcock was closed and the warming rate again taken. In both methods a correction for heat received from the surroundings during a run was made on the assumption of Newton's law of heat transfer and our knowledge of the temperature of the exterior of the calorimeter. In gold calorimeter II the external temperature was obtained as an average of the wall, by means of the thermometer-heater, of the bottom, by means of the attached thermocouple, and of the top, from the evaporation temperature as indicated by the pressure. The external temperature was about one degree above the evaporation temperature. The temperature of the protective cylinder and that of the steel container were kept above the evaporation temperature to prevent condensation. The container temperature was controlled by means of solid carbon dioxide condensed on its surface. The temperature of the solid carbon dioxide was controlled by reduced pressure. The hydrogen chloride was evaporated in amounts of from 10 to 15 g. for each determination. Only the liquid above the heater was used for this purpose. The determinations made with gold calorimeter II utilized the material on which the measurements of heat capacity had been made. The initial and final pressures were observed for each determination and a small correction was made for the amount of material in the line volume which was known by calibration. From the known density of liquid hydrogen chloride the correction for the volume of the liquid replaced by gas could be made. Method II involved a knowledge of the heat capacity of calorimeter and substance.

We feel more confidence in Method II, and the results obtained by this method show a smaller deviation from the mean than do those obtained by Method I. The results on the heat of vaporization at one atmosphere are given in Table V. The actual evaporation pressures were slightly above one atmosphere, but a small correction has been made to allow for this. Method I was used only with the glass calorimeter which was somewhat of a handicap, although the copper sheath and the coiled platinum sheet in the interior removed most of the disadvantages of the glass type of apparatus. The agreement, to one calorie, of the average values obtained from the two different methods and calorimeters must be regarded as fortuitous. In the measurements with the glass calorimeter the rate of evaporation was varied by a factor of more than three without producing any systematic deviation of the results. Also, the total amount of material within the calorimeter seemed to produce no appreciable effect. The slow evaporation rate of less than one-third mole per hour, which was used in the final measurements, eliminated the possibility of any appreciable loss due to spray. Observation on exposed glass bulbs of similar cross section, and a rate of evaporation many times that of any used, showed that evaporation proceeded without the formation of visible bubbles.

The heat of vaporization of hydrogen chloride has been determined directly or by calculation from vapor pressure measurements by a number of observers. While the accuracy of these various results is such that they can be given no weight, we include them as Table VI for the sake of completeness.

TABLE VI

PREVIOUSLY PUBLISHED VALUES OF HEAT OF VAPORIZATION OF HYDROGEN CHLORIDE

AH. cal./mole	Method	Observer
3540	**Indirect**	**McIntosh and Steele[8] (1906)**
3560	**Direct**	**Elliott and McIntosh[16] (1908)**
3601	**Direct**	**Estreicher and Schnerr[17] (1910)**
4040	**Indirect**	**Henglein[6] (1923)**

In the two indirect determinations given above the gas was assumed to be perfect. This assumption leads to serious error in such calculations. For example, if we make use of the algebraically convenient equation of state of Berthelot

$$PV = RT\left[1 + \frac{9PT_c}{128P_cT}\left(1 - 6\frac{T_c^2}{T^2}\right)\right]$$

combined with the thermodynamic equation $\frac{dP}{dT} = \frac{AH}{TAV}$, the density of liquid hydrogen chloride as given by Baumé and Perrot,[15] namely 1.706–0.00276T, and the equation of Henning and Stock which is in agreement with our data for the vapor pressure of liquid hydrogen chloride, we obtain the value of **3881** cal. per mole. Considering the assumption, this value compares favorably with our direct determination of **3860.** However, we hasten to add that this approximate agreement should be taken to indicate that Berthelot's equation happens to represent the deviation of hydrogen chloride from the gas law rather than as a confirmation of our value for the heat of vaporization. The similar use of van der Waals' equation leads to a more inaccurate value of **3932 cal./** mole.

Eucken and Donath[18] have by an ingenious and apparently quite accurate method obtained heats of condensation to the solid form for a number of gases. They state that their data on hydrogen chloride are somewhat more inaccurate than those on other substances, due to a slight amount of reaction with the metal apparatus. They give the value **4594 ± 7** cal. per mole at 156°K. Using our various calorimetric data, and assuming that Berthelot's equation may be used with the thermodynamic equation,[19]

$$\left(\frac{\partial H}{\partial P}\right)_T = V - T\left(\frac{\partial V}{\partial T}\right)_P$$

to give the deviation of the heat content of the gas from that of the ideal state, we obtain a value of **4580,** which is in satisfactory agreement with

the value of Eucken and Donath when it is considered that our use of Berthelot's equation involved a correction amounting to 25 cal. per mole.

The Entropy of Hydrogen Chloride from the Third Law.—The entropy of hydrogen chloride was obtained in the usual manner by graphical integration of the equation $S = \int_0^T C_p \mathrm{d} \ln T$ plus the entropy changes accompanying each change of state. In extrapolating below the lowest temperature of measurement we have made use of the Debye function with an $h\gamma/k = 128$. In doing so it has been assumed that at the lower temperatures the absorption of energy is determined by but one characteristic frequency. This assumption is based on the fact that the low temperature data show a tendency to approach a value asymptotically of about six calories per degree per mole. This may be noted in Fig. 2. It is plausible that at low temperatures molecule units in the crystal may be vibrating in a manner similar to that of a monatomic solid. The data agree quite well with the Debye function up to a temperature of 40°K. While we recognize the arbitrariness of 'the above procedure, the absolute error should be small on a total extrapolated amount of 0.30 entropy units.' A summary of the entropy calculation is given in Table VII.

TABLE VII

CALCULATION OF ENTROPY OF HYDROGEN CHLORIDE

Solid stable below 98.36°K.	Cal. per deg. per mole

Fusion 476.0/158.91 =	3.00
Liquid	...
158.91 to 188.07°K., graphical	2.36
Vaporization, 3860/188.07 =	20.52
Entropy of hydrogen chloride gas at boiling point =	41.2 ± 0.1 E. U.

Since we are about to compare the above value of the entropy with that obtained from theories assuming a perfect gas, it will be necessary to consider the effect due to the imperfection of hydrogen chloride gas. We have previously shown that Berthelot's equation of state gives the molal volume of hydrogen chloride gas with considerable accuracy. Since reliable data of state are lacking, we can do no better than to use Berthelot's equation in the calculation of this correction. Combining this with the thermodynamic equation $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ we obtain for the entropy change accompanying expansion from one atmosphere to zero pressure

$$\Delta S = -R\left[\int_{P=1}^{P=0} \mathrm{d} \ln P + \frac{27T_c^3}{32T^3P_c}\int_{P=1}^{P=0} \mathrm{d}P\right]$$

The entropy change accompanying compression from zero pressure to an ideal state of one atmosphere (fugacity = 1) is given by

$$\Delta S = -R \int_{P = 0}^{P = 1} P = 0 \; \mathrm{d} \ln P$$

Combining, it is found that the entropy of a Berthelot gas is lower than that of ideal gas by an amount of $R27T_c^3P/32T^3P_c$. For hydrogen chloride at its boiling point this amounts to 0.10 cal./deg. per mole.

Theoretical Calculation of the Entropy of Hydrogen Chloride from Spectroscopic Data.—The entropy of a gas may be considered to consist of two parts, first, that resulting from the volume and the translational motion of the molecules and, second, that resulting from all the other degrees of freedom. It is best not to separate the treatment of these latter degrees of freedom, since the absorption of energy by one often has an appreciable effect on the others.

The first portion may be obtained from the Sackur equation[20] where

$$S = \frac{3}{2} R \ln M + \frac{3}{2} R \ln T + R \ln V + S_0$$

S = entropy per mole, R = gas constant per mole, M = the molecular weight, V = the molal volume and S_0 = a constant. The form of this equation has been supported by considerable data. There are, however, two theoretical methods of evaluating S_0 which lead to nearly the same value and yet are apparently irreconcilable since each makes use of natural constants known to a considerable degree of accuracy. Neither is free from questionable assumption. The first method[20,21,22] makes use of quantum assumptions and statistical mechanics. The second method is used by Lewis[23] and is based on the theory of ultimate rational units proposed by Lewis and Adams.[24]

The expression for the constant as determined by Tetrode is

$$S_0 = R \ln \frac{(2\pi k)^{3/2}\, e^{5/2}}{h^3\, N^{5/2}} = -11.06$$

The expression obtained from U. R. U. is

$$S_0 = R \ln \frac{k^{3/2}\, C^3}{N^{5/2}(4\pi l)^6} = -11.38$$

where e is the base of natural logarithms, h is Planck's constant, c the velocity of light and l the elementary electronic charge.

The values adopted for all fundamental and derived constants used in this paper are those given in the International Critical Tables.[25]

The second portion of the entropy is obtained from the spectroscopically determined possible energy states combined with some assumption as to the distribution of the molecules between these various possible states. The first calculation of this kind utilizing the actual energy levels is due to Hicks and Mitchell.[26] Their calculation is based on a choice of a *priori* probabilities, 2, 4, 6, etc., which now appear to be incorrect. Also, they neglected to include the zero point entropy of R ln 2 which results from a weight of 2 for the initial state. Hicks and Mitchell unnecessarily used a laborious method in calculating the entropy. This was due to their failure to observe that theoretical equations of the type concerned can be integrated exactly even when the actual quantum states are used. Since they had calculated values of the heat capacity at various temperatures, they obtained that fraction of the entropy concerned by graphical integration of $S = \int_0^T C\, d \ln T$. It will be shown in the following paragraphs that the calculation of entropy from spectroscopic data involves less expenditure of labor than is necessary to obtain the heat capacity at **a** single temperature and, moreover, involves the use of summations which are common to both calculations. The value of this observation will be more apparent to those who undertake the labor required for calculations of this type.

In addition to translational energy, hydrogen chloride has, at ordinary temperatures, nearly fully excited rotational energy and a small amount of vibration. The integration required in the calculation of the rotational entropy of a rigid molecule has been performed by Urey[27] graphically, and by Tolman and Badger,[28] who substituted the limitation of rigidity before carrying out the integration. Hicks and Mitchell have tabulated the total energy above the zero point state for a sufficient number of the rotation levels accompanying zero, one and two units of vibration. Following the usual nomenclature, we designate, by Em,n, the energy corresponding to the state having m and n as its rotational and vibrational quantum numbers, respectively The rotational-vibrational heat capacity is then shown by Hicks and Mitchell to be

$$C_{R+V} = \frac{N}{kT^2}\left[\frac{\Sigma m\Sigma n\ pm,n\ E^2m,n\ e^{-\frac{Em,n}{kT}}}{\Sigma m\Sigma n\ pm,n\ e^{-\frac{Em,n}{kT}}} - \left(\frac{\Sigma m\Sigma n\ pm,n\ Em,n\ e^{-\frac{Em,n}{kT}}}{\Sigma m\Sigma n\ pm,n\ e^{-\frac{Em,n}{kT}}}\right)^2\right]$$

where pm,n is the a *priori* probability, k is Boltzmann's constant, and N is Avogadro's number. As is well known, an expression of this type may be written as

---

[26] **Hicks** and Mitchell, THIS JOURNAL, 48, **1520 (1926).**

[27] **Urey,** *ibid.*, 45, **1445 (1923).**

[28] **Tolman and Badger,** *ibid.*, 45, **2277 (1923).**

$$C_{R+V} = \frac{R}{T^2}\frac{\mathrm{d}^2 \ln Q}{\mathrm{d}\left(\frac{1}{T}\right)^2}$$

where Q represents the distribution function $\Sigma m \Sigma n \; p_{m,n} \; e^{-\frac{E_{m,n}}{kT}}$; for example, see Reiche.[29] Then using the same integral as that used by Tolman and Badger

$$S_{R+V} = \int_0^T \frac{R}{T^2}\frac{\mathrm{d}^2 \ln Q}{\mathrm{d}\left(\frac{1}{T}\right)^2}\,\mathrm{d}\ln T$$

$$= R\left[\ln Q - \frac{1}{T}\frac{\mathrm{d}\ln Q}{\mathrm{d}\left(\frac{1}{T}\right)}\right]_0^T$$

$$= R\left[\ln \Sigma m \Sigma n \; p_{m,n} \; e^{-\frac{E_{m,n}}{kT}} + \frac{1}{kT}\cdot\frac{\Sigma m \Sigma n \; p_{m,n} \; E_{m,n} \; e^{-\frac{E_{m,n}}{kT}}}{\Sigma m \Sigma n \; p_{m,n} \; e^{-\frac{E_{m,n}}{kT}}}\right]_0^T$$

It may be observed that the only assumption concerning $p_{m,n}$ and $E_{m,n}$ is that they are independent of temperature. The above method also holds if an electronic transition is included in the energy absorption. In summing the above series we have used the *a priori* probabilities 1, 3, 5, 7, etc., corresponding to the respective quantum states $^1/_2$, $^3/_2$, $^5/_2$, $^7/_2$, etc. Each vibrational state has been given unit weight; thus $p_{m,n}$ is essentially p_m. The use of $p_m = 2m$ is supported by the intensity measurements of Bourgin[30] on the absorption spectrum of hydrogen chloride He shows that his data correspond with the above weights in agreement with the requirements of the wave mechanics theory of Schrodinger.

Kemble[31] has carried out a re-analysis of the data of Colby, Meyer and Bronk[32] on the infra-red absorption bands of hydrogen chloride. He presents the results in the form of equations with estimates of the probable error of the coefficients. From these equations, which apply to the lighter isotope, may be obtained the energies of the various states with which we are concerned. We have used these more accurate values in preference to the data as tabulated by Hicks and Mitchell. It is particularly important to have accurate values for the energies of the first few states.

A consideration of the isotope effect on the rotational-vibrational entropy shows that the use of the data for the lighter isotope leads to a value which is low by only 0.0016 cal./deg. per mole.

With the above data and method we have calculated the value of the entropy of ideal hydrogen chloride at the temperature of its boiling point,

[32] Colby, Meyer and Bronk, *Astrophys. J.*, 57, 7 (1923).

188.07°K. The value obtained is 41.45 or 41.13 cal./deg. per mole corresponding, respectively, to the use of the Tetrode or Lewis constant for the Sackur equation. A similar calculation has been made for a temperature of 298.1°K. (25°C.). These results are compared with the experimental values in Table VIII. We believe that our experimental value for the actual gas at 188.07°K. is accurate to about 0.1 cal./deg. per mole. This is based on the assumption of no appreciable error in the 0.3 entropy units extrapolated. We hesitate to estimate the accuracy with which Berthelot's equation gives the correction from the actual to the ideal state Fortunately this correction is small. The necessity for this correction may be eliminated by obtaining the entropy of the gas through use of the vapor pressure and entropy of the solid. At these lower pressures the error introduced by the use of such an equation as that of Berthelot is negligible. Such a calculation, making use of vapor pressure equation (1) at the melting point temperature, 158.91°K., leads to a value of 41.2 E. U. for the entropy of ideal hydrogen chloride at 188.07°K. A similar calculation starting at 132°K. leads to a value of 41.3 E. U.

While this method eliminates an uncertain correction, we believe our first method to be more reliable. Fortunately both methods lead to the same value. The "experimental" value given for 298.1°K. was obtained by adding the theoretical difference between 188.07°K. and 298.1°K. to the 41.3 cal./deg. per mole obtained at 188.07°K.

TABLE VIII

COMPARISON OF THEORETICAL AND EXPERIMENTAL VALUES OF THE ENTROPY OF HYDROGEN CHLORIDE

	Theoretical		Experimental	
T, °K.	Tetrode constant	Lewis constant	Actual gas	Corrected to ideal state
188.07	41.45	41.13	41.2 ± 0.1	41.3
298.1	44.64	44.32	......	44.5

Eucken, Karwat and Fried[33] have summarized the available data on condensed gases in terms of chemical constants. They have been recalculated in the form of absolute entropies in a chapter added, by the translator, to the German edition of "Thermodynamics" by Lewis and Randall.[34] The value given for the work of Eucken and Karwat[1] on hydrogen chloride is 45.4 E. U. at 298.1°K., for which these authors had expressed an accuracy of ±0.2 E. U., which definitely placed it in disagreement with the theoretical values.

The close agreement of our experimental and theoretical values is very good evidence, not only for the validity of the theoretical considera-

---

[33] Eucken, Karwat and Fried, *Z. Physik*, 29, 1 (1924).

[34] "Thermodynamik und die freie Energie chemischer Substanzen," von Lewis und Randall, übersetzt von Redlich, Julius Springer, Wien, 1927.

tions as closely approximating the actual properties of the substance, but also for the third law of thermodynamics.

Tests of the Third Law.—We shall test the third law, first by means of the reactions

$$\begin{array}{llcll}
\text{(a)} & \tfrac{1}{2}\mathrm{H_2} + \tfrac{1}{2}\mathrm{Cl_2} & = & \mathrm{HCl\,(aq)}; & \Delta F^{\circ}_{298} = -31{,}375 \\
\text{(b)} & \mathrm{HCl\,(aq)} & = & \mathrm{HCl\,(g)}; & \Delta F^{\circ}_{298} = 8{,}604 \\
\hline
\text{(c)} & \tfrac{1}{2}\mathrm{H_2} + \tfrac{1}{2}\mathrm{Cl_2} & = & \mathrm{HCl\,(g)}; & \Delta F^{\circ}_{298} = -22{,}771^{35}
\end{array}$$

The free energy change of (b) is taken from the manuscript soon to be published by Randall and Young, who have reconsidered the available data, while that of (a) is taken from Lewis and Randall[36] and corrected by use of the data given by Randall and Young. The heat of reaction, ΔH, for (c) is given as 22,000 cal. by both Thomsen and Berthelot. From the relation $\Delta F = \Delta H - T\Delta S$ we find $\Delta S_{298} = 2.6$ E. U. for reaction (c). The entropy of one-half a mole of chlorine gas as given by Gerke[37] is $\frac{1}{2}S_{\mathrm{Cl_2}} = 27.1$ E. U. Bakhuyzen[38] gives a value for $\frac{1}{2}S_{\mathrm{H_2}}$ at low temperatures which leads to 14.8 E. U. at 298°K. From these data $S_{\mathrm{HCl}} = 44.5$ in exact agreement with our experimental value. Such close agreement is undoubtedly fortuitous. The principal uncertainty lies in the ΔH value given by Thomsen and by Berthelot, while the other data used may be in error by an amount corresponding to several tenths of an entropy unit.

The second test makes use of the reactions

$$\begin{array}{llcll}
\text{(d)} & \tfrac{1}{2}\mathrm{H_2} + \mathrm{HgCl} & = & \mathrm{Hg} + \mathrm{HCl\,(0.1\ M)}; & \Delta F = -\ 9{,}175 \\
\text{(e)} & \mathrm{HCl\,(0.1}\ M) & = & \mathrm{HCl\,(g)}; & \Delta F = 11{,}604 \\
\hline
\text{(f)} & \tfrac{1}{2}\mathrm{H_2} + \mathrm{HgCl} & = & \mathrm{Hg} + \mathrm{HCl(g)}: & \Delta F = 2{,}429
\end{array}$$

The free energy changes of (d) and (e) are both given by Randall and Young. Their new measurements on the mercury-calomel electrode show that the older determinations are in error due to the effect of dissolved oxygen. The ΔH for (d) is given as —8291 by Lewis[39] who measured temperature coefficients of a cell utilizing this reaction. We have calculated the heat of reaction (e) from the measurements of Wrewsky and Sawaritzky[40] and find the value 17,660 cal. for $H_{\mathrm{HCl\,(g)}} - \overline{H}_{\mathrm{HCl\,(0.1\ \mathit{M})}}$ where $\overline{H}$ refers to the partial molal heat content of hydrogen chloride in solution. Lewis and Gibson[41] give the entropy of liquid mercury $S_{\mathrm{Hg}} = 17.8$ E.U., and that of calomel $S_{\mathrm{HgCl}} = 23.2$. Thus we find $S_{\mathrm{HCl}} = 43.5$ as against our measured value of 44.5. The difference is well within the limits

---

[35] The data used for the two tests of the third law have not been corrected by use of the I. C. T. constants since the difference is not important in this case.

of accuracy of the various data, the greatest uncertainty being in the heat of solution of hydrogen chloride. The older value of 17,300 found by Thomsen for this reaction would more than double the discrepancy. This again emphasizes the observation of Lewis, Gibson and Latimer[42] that as more accurate data are obtained the discrepancies from the third law are reduced,

We express our appreciation to J. A. Roebling Sons Co. for insulating the delicate gold wire, to W. J. Cummings for the glass blowing, particularly of the metal-glass seal which so successfully withstood temperature changes, and to G. F. Nelson, who was responsible for the mechanical construction of the apparatus. This assistance contributed in no small measure to the success of our experiments.

Summary

The heat capacity of the two solid forms and of liquid hydrogen chloride has been measured from 16°K. to its boiling point.

The transition temperature is 98.36 ± 0.05°K., the melting point 158.91 ± 0.05°K. and the boiling point 188.07 ± 0.05°K.

Calorimetric determinations of the heats of transition, fusion and vaporization have been made.

The vapor pressures of both solid and liquid have been measured.

What is believed to be a third crystalline form of hydrogen chloride, with a reddish pink color, has been observed.

The entropy of hydrogen chloride gas has been calculated from the calorimetric data. It has also been calculated from spectroscopic data and the Sackur equation.

The procedure for the calculation of entropy from the energy levels of a molecule as given by band spectra is discussed.

The calculated and theoretical values agree well, thus supporting not only the theoretical method but also the third law of thermodynamics.

The third law has been tested by means of two series of reactions and is further confirmed within the limits of accuracy of the data.

THE PHOTOCHEMICAL DECOMPOSITION OF AZOMETHANE

BY HERMAN C. RAMSPERGER[1]

RECEIVED OCTOBER 31, 1927 PUBLISHED JANUARY 5, 1928

The rate of the thermal decomposition of azomethane has been shown to be unimolecular over a small range of high pressures,[2,3] but the constant becomes somewhat smaller at low pressures.[4] This effect is expected if the reaction is due to molecules activated by collisions with other molecules. Rice and the author[5] considered two such theories and derived equations showing the way in which the rate would fall off with decreasing pressure. These have been applied to the decomposition of azomethane,[6] and the experimental values check one of the theories (Theory II) quite well. There is the possibility that in the case of azomethane there may be a chain reaction, especially since the reaction is certainly exothermic, as is indicated by the explosive nature of the gas.[7] This would require quite a different explanation of the reaction rate as, for example, that postulated by Christiansen and Kramers.[8]

The length of a chain reaction can be determined in the case of activation by light by measurements of the photochemical efficiency. Activation by light may produce molecules with a more definitely specified total energy and energy distribution than is the case with thermally activated molecules. This would be especially true if the light were very nearly monochromatic and if the molecule had an easily resolvable band spectrum, for then absorption of one particular spectrum line would determine both the initial and final states of the molecule. Thermally activated complex molecules would not be greatly restricted as to total energy or energy distribution. If, however, it is sufficient for reaction that a molecule have a certain minimum total energy independent of the nature of this energy, then we should expect the reaction to be similar for these photochemically activated molecules. If it is necessary that a particular degree of freedom obtain a minimum of energy, as in Theory II of Rice and Ramsperger,[5] and this energy may be obtained from any other degrees of freedom by repeated redistribution within the molecule between collisions, then it will not matter in what part of the molecule the light energy

---

[1] National Research Fellow in Chemistry.

[2] Ramsperger, THIS JOURNAL, 49, 912 (1927).

[3] Experimental work now in progress shows that the range over which the reaction is unimolecular is greater in the case of other azo compounds, as for example azo*iso*propane.

was absorbed.[9] Nevertheless, the energy of a photon, or light quantum, of the light used (77,800 cal.) is so much larger than the heat of activation (51,200 cal.) that if the length of any reaction chain were a function of the energy in excess of the activation energy, the photochemical chain reaction would be even longer than the thermal one. It will be found experimentally that only about two molecules decompose for each photon absorbed. Evidence will be presented to show that the thermal decomposition also is probably not a long chain reaction.

The Absorption Curve

Liquid azomethane has a very slight yellow color. The gas would therefore be expected to have a strong absorption band in the near ultraviolet. Quantitative absorption measurements were made by the method of Ramsperger and Porter.[10]

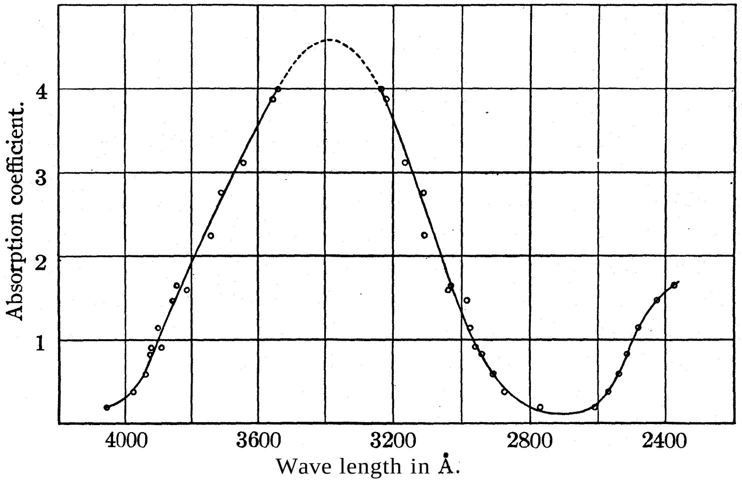

Fig. 1.—Ultraviolet absorption curve of azomethane.

Light from a quartz mercury arc was passed through a quartz cell 60 cm. long containing azomethane and was photographed with a Hilger quartz spectrograph. On the same plate another photograph was taken of the same source of light through the same cell evacuated and through a copper gauze screen of known absorption. The blackening of the plate is the same in the two photographs at any wave length for which the particular screen and the azomethane gas have the same absorption. Positions of equal intensity were determined by the method given by Ramsperger and Porter.[10] Absorption coefficients were calculated by the relation $I_t/I_0 = 10^{-ecd}$, where I_t/I_0 is the fraction of light transmitted, e is the molecular absorption coefficient, c the concentration in moles per liter and d the length of the cell (60 cm.). There was no evidence of a band spectrum. The results are given in Table I and plotted in Fig. 1.

---

[9] It is possible also that the absorption of light energy will involve some energy states that do not occur at all in molecules activated thermally, and these may not have the same effect in producing reaction.

[10] Ramsperger and Porter, THIS JOURNAL, 48, 1267 (1926).

Monochromatic Light

The source of light for the decomposition experiments was a vertical 220-volt Cooper-Hewitt mercury arc. An attempt was made to use a Hilger Monochromator, but the intensity of the three lines, 3663, 3654 and 3650 Å. was hardly great enough to permit accurate measurements of the decomposition. A filter was therefore used. It was a modification of the one used by Eggert and Noddack.[11] The filter cell was 5 cm. in diameter and 4.5 cm. long. A blue cobalt glass was sealed on each end of the cell in place of the ammoniacal copper sulfate solution used by Eggert and Noddack. A solution of 0.10 g. per liter of phenosaphranine was circulated through the cell at the rate of 50 cc. per hour. The transmitted light consisted almost entirely of the three lines mentioned above. This was proved by photographing the transmitted light with a quartz spectrograph. The strong blue line at 4046 Å. and several weak lines closer to the three ultraviolet lines were each about as dense as the strong line 3663 Å. was with an exposure only one-thousandth as long. No other lines were visible on the plate. However, this filter transmitted some deep red and infra-red light which had to be corrected for in the energy measurements.

Apparatus

The apparatus was arranged in the following order: the mercury arc, a quartz lens two inches in diameter and three inches in focal length, the filter cell described above, a camera shutter and then either a linear thermopile in case energy measurements were made or the quartz reaction vessel containing azomethane. The mercury arc had a metal plate attached which was as wide as the arc and 1.5 cm. high. The lens was placed so as to form a sharp image of the arc 1.85 cm. high. The thermopile was a ten-junction Coblentz linear thermopile, the slit of which was a little less in height than the image of the arc and could either be placed with the sharp image of the arc on the thermopile surfaces or could be swung through 90° to face a Bureau of Standards standard of radiation lamp exactly two meters distant. This thermopile could be moved with a screw device back and forth across the image of the arc. The quartz reaction cell was 3 cm. in diameter and 9.13 cm. long. It could be placed so that the entire beam of light came well within the cell.

Energy Measurements

A high sensitivity, low resistance, D'Arsonval galvanometer was used to measure the thermopile current. With a scale at 3.5 meters from the galvanometer large deflections were obtained. When very large deflections were to be measured a resistance of 3 ohms was shunted across the

---

[11] Eggert and Noddack, *Z. Physik*, 20, 299 (1924).

galvanometer. This reduced the deflections by an experimentally determined factor of 2.61.

The general method of determining the radiation density was to move the thermopile across the image of the arc, taking readings at every millimeter near the center of the image where the radiation density was very great and every 2 mm. on the edges of the image. These deflections (properly corrected for infra-red radiation) were plotted on coordinate paper as ordinate and the position of the thermopile as abscissa. The area under this curve was determined. This area multiplied by the radiation density per sq. mm. per sec. per cm. deflection, as determined by calibration of the thermopile galvanometer arrangement against the standard lamp and then multiplied by the height of the image in mm., gives the total radiation of the three mercury lines falling per second on the cell.

The actual procedure was as follows. Before each experiment the arc was allowed to become constant, which required at least thirty minutes after starting. The thermopile was evacuated and the mercury diffusion pump was kept running during the entire experiment, as it was noticed that the thermopile sensitivity was more constant if pumping was continuous. The thermopile-galvanometer arrangement was calibrated by means of the radiation standard supplied by the Bureau of Standards and according to the specifications supplied with it. Usually about five readings were made which were constant to about 1%. The calibration was repeated after the energy measurements were complete and an average was taken. The deviation from the average was usually about 1%.

Readings were started on one edge of the image of the arc. Three readings were made at each position of the thermopile, (1) with the shutter closed; (2) with the shutter open and a sheet of "Crookes A" glass and a sheet of fused quartz in the path of the light; (3) with the shutter open and only the sheet of quartz in the path. The quartz sheet was similar to the front window of the reaction cell and the radiation passing through this sheet would correspond to the radiation entering the cell. The "Crookes A" glass absorbs all of the ultraviolet radiation, as was proved by photographing the ultraviolet spectrum with a sheet of "Crookes A" glass in the light path. It was also found that not all of the radiation passing through the filter cell was absorbed by the "Crookes A" glass and that the per cent. of this infra-red radiation varied for different parts of the image of the arc but was usually 20 to 25% of the total radiation. A second sheet of "Crookes A" glass was found to transmit 75% of the radiation transmitted by the first sheet. The galvanometer deflection corresponding to the three ultraviolet lines can then be calculated by the equation (3–2)—(2–1)/3.

The deflections calculated in this way for the first energy determinations of Expt. 3 are plotted in Fig. 2. The area under this curve is 1826 mm. deflections. The standard lamp when burning on 0.350 ampere gives an energy density of 8.4 ergs per $mm.^2$ per sec. at two meters' distance, and gave under these conditions a deflection of 19.3 cm. at the beginning and 18.9 cm. at the end of the energy determination. The energy density per mm. height of image is therefore $(1826 \times 8.4)/(19.1) = 803$ ergs per sec. The arc is uniformly intense from top to bottom and even if there were slight variations, the thermopile covered most of the height and would have recorded an average energy density. The height of the image was 18.5 mm. which gives as the total energy 803 X 18.5 = 14,860 ergs per sec. There is yet a possible correction due to a greater reflection or absorption of the ultraviolet light as compared to that for the light of the standard lamp by the fluorite window of the vacuum thermopile. The difference in reflection is negligible. There are no data on the absorption of different wave lengths by fluorite, but this is certainly only a small correction and will not be considered.

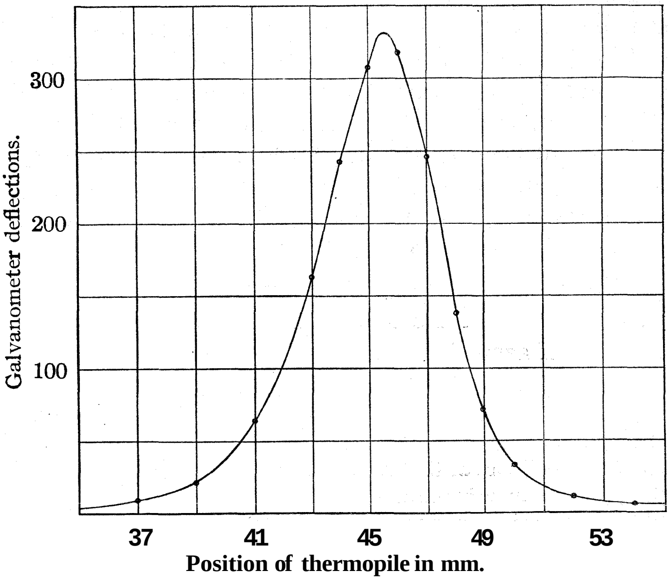

Fig. 2.—Energy distribution curve.

Decomposition of Azomethane

Pour experiments were made at a temperature of 20° and at initial pressures from 0.1207 cm. to 25.74 cm. The pressure measurements of Expts. 1 and 2 were made on a closed tube manometer and in Expts. 3 and 4 a small McLeod gage was used. In all of these experiments the total number of moles decomposed is readily calculated from the total volume and the change in pressure, since it had been shown[2] that the decomposition is largely by the equation $CH_3NNCH_3 = N_2 + C_2H_6$. The final pressure actually is 2.04 times the original pressure, due to a small amount of side reaction. The number of moles decomposed is therefore given by the equation

$$N = \frac{\Delta P V/1.04}{RT}$$

where ΔP is the increase in pressure and V is the total volume.

The volume of the quartz cell was 67 cc. and the connecting tubing to the top of the mercury surface had an average volume of **14** cc. in Expt. **1** and 12 cc. in Expt. 2. The low pressure Expts. **3** and **4** were made with apparatus similar to that used in a previous research.[3] The volume of the cell and the tubing connecting it to the mercury trap was *70* cc., the volume of the trap and tubing connecting it to the McLeod gage was 2.8 cc. and the volume of the gage was 8.9 cc. The total volume was therefore 81 7 cc.

The Fraction of Light Absorbed

The fraction of the light absorbed can be calculated from the absorption coefficient, knowing the length of the cell and the pressure of azomethane in the cell. Diffusion will be sufficiently rapid to give the same partial pressure of azomethane throughout the reaction cell, but practically no diffusion will occur into the tubing leading to the manometer in Expts. 1 and 2. The partial pressure of azomethane will therefore be less in the cell than in the tubing after some decomposition has occurred. Since only a small part of the azomethane was decomposed, this will make very little difference. However, the correct partial pressure of azomethane in the cell is readily calculated. It is given by the equation

$$P_1 = P_i - \Delta P V/V_1 - \Delta P V_2 X_A/1.04 V_1$$

where P_i is the initial pressure, AP the increase in pressure, V the total volume, V_1 the volume of the cell, V_2 the volume of the tubing and X_A the mole fraction of azomethane entering the tubing from the cell.

This is shown as follows. The partial pressure of azomethane in the manometer tubing at any time *t* is given by $P_2 = P_i + \Delta P X_A$. X_A is given with sufficient accuracy by the equation $X_A = (P_i - \Delta P/1.04)/(P_i + AP)$ where *AP* is the average of the total increase in pressure at that reading and the previous reading. Let N_1 represent the moles of azomethane in the cell, N_2 the moles of azomethane in the tubing and N the total moles of azomethane at any time *t*. We have $N_1 = P_1V_1/RT$, $N_2 = P_2V_2/RT$, $N = (P_i - \Delta P/1.04)V/RT$. Also $N = N_1 + N_2$. If now the above value of P_2 is substituted, we obtain the equation given above for P_1. In Expts. **3** and 4 the calculation of the pressure of azomethane in the cell was the same as given in a previous paper:' As formerly, P'_A denotes the pressure of azomethane in the cell before the reading with the McLeod gage was made and P''_A denotes the pressure of azomethane after the reading.[12] The average value of the pressure of azornethane in the cell during each time interval is obtained by averaging the value of P''_A of one reading and P'_A of the next reading. This is the pressure of azomethane upon which the absorption is based.

The absorption coefficient for light of wave length 3660 Å. is found from the curve of Fig. 1 and to be 3.10. This absorption coefficient was checked by use of the thermopile. The cell filled with azomethane gas for Expt. I was placed between the light source and the thermopile. The galvanometer deflection was read, the azomethane was frozen out with liquid air and another reading made. After correcting for the infra-red radiation as in the energy measurements it was found that 63% of the ultraviolet light of the three mercury lines was absorbed. The absorption calcu-

---

[12] The equation for P''_{At} given on page 1496 of ref. **3** should of course have read $P''_{At} = P'_{At}\,P''_t/P'_t$.

lated from the absorption coefficient, the length of the cell (9.13 cm.) and the concentration in moles per liter (0.0141), was 60%. Considering the uncertainty of the corrections this is a good agreement. The absorption has been calculated for each time interval and is based on the absorption coefficient, 3.10, and the average concentration of azomethane in the cell.

In addition to the absorption so calculated, a fraction of the light from the two surfaces of the rear window is absorbed. From Fresnel's formula for the reflection of perpendicularly incident light, that is, $r = \left(\frac{n-1}{n+1}\right)^2$, where n is the index of refraction of quartz for $\lambda = 3660$ Å., approximately 12% of the transmitted light is reflected from these two surfaces. The absorption of this reflected light is calculated as before. Secondary reflections are neglected.

The results of the four experiments are given in Table II.

The final result to be calculated is the number of molecules decomposed per photon of light absorbed. This number is given by $\phi = h\nu \times$ moles decomposed × 6.06 × 10^{23}/ergs absorbed, where $h\nu$ is the energy in ergs of a photon of light of the wave length λ = 3660 Å. The values of ϕ are as follows.

Expt.	1	2	3	4
ϕ	1.91	2.21	2.29	2.22

Temperature Coefficient

An attempt was made to determine the temperature coefficient of the photochemical decomposition. The absorption 'curve was not appreciably changed at 100°. A very slight deposit was formed on the front window of the reaction chamber. This actually reduced the rate below that at 20°, due probably to the absorption of light by this film. It was found, however, that on changing the gas to 20° the rate in moles decomposed was the same as it was at 100° just before the temperature was changed. Experiments at low pressures would have avoided the difficulty but they were not undertaken owing to lack of time. It seems, however, that the temperature coefficient of the photochemical decomposition is very nearly zero, and certainly not greater than 1.02 for an increase in temperature of 10°.

Discussion of Results

The value of ϕ is practically constant over a 200-fold pressure range and is approximately 2. Expt. 1 is a little lower than the rest, probably because a similar deposit to the one produced at 100° may have formed.

This would be most serious at high pressures and would produce a steady lowering of the rate of decomposition as the experiment progressed, which was actually the case in Expt. 1.

It might be supposed that some molecules would be deactivated by "collisions of the second kind" and that this deactivation would be most serious at high pressures. The constant value of ϕ over this large pressure range would indicate no such deactivation. Either collisions are not effective in deactivating activated molecules, which is not likely, or else they react in a time shorter than the time between collisions at the high pressures. The time between collisions at 25 cm. pressure is about 2 X 10^{-10} seconds if the diameter of the molecule is taken as 6 × 10^{-8} cm.

In the case of thermal decomposition we can calculate the ratio of molecules reacting to molecules deactivated by collisions if we accept Theory II of Rice and the author.[5,6] This ratio is given by b_ϵ/aN, where

$$b_\epsilon = \frac{K_\infty \Gamma\left(\frac{n}{2}\right)}{\Gamma\left(\frac{n+1}{2}\right)} \frac{e^{\frac{\epsilon_0}{kT}}}{(kT)^{\frac{1}{2}}} \frac{(\epsilon - \epsilon_0)^{\frac{n-1}{2}}}{\epsilon^{\frac{n-2}{2}}}, \quad a = 4s^2\sqrt{\frac{\pi kT}{m}}$$

and N is the number of molecules per cc. T is taken as 290° to correspond to K = 1.4 X 10^{-4}. For the molecular diameter 6 X 10^{-8} is used. N is calculated for a pressure of 25 cm. and the number of degrees of freedom is 25, this being the value of n required to fit the experimental data; ϵ_0 is 50,600 cal. per mole. If now we take as ϵ 77,800 cal. per mole, which is the energy of a photon of λ = 3660 Å., we get for the ratio 14/1. This calculation does not allow for the internal energy of the molecule before it absorbs the photon. This energy is of course not known, but the average internal energy of all of the molecules is roughly 5,000 cal. per mole, giving ϵ a likely value of 82,800 cal. The ratio then becomes 47/1. The result of this calculation requires that an activated molecule with this very high energy must react within about 10^{-11} seconds after activation. If the type of activation were the same in the photochemical as in the thermal reaction, then deactivation could seldom occur by collision even at the highest pressures, nor could the molecule be deactivated by radiation of the energy, since the time required for radiation is generally more than 10^{-8} sec. The constant value of ϕ over this large pressure range is the expected result if the type of activation and mechanism of reaction were the same in both photochemical and thermal reactions.

The fact that approximately two molecules are decomposed per photon absorbed may possibly be explained by the energy of a newly formed ethane molecule being transferred to a molecule of azomethane which is then activated. This is only possible because of the large excess of energy in the photon and could not be repeated indefinitely, thus producing a long chain. For example, a gram mole may have 83,000 cal. after the photon is absorbed. At least 20,000 cal. is obtained as heat of the reaction itself.[6] This gives more than 103,000 cal. to be divided between a N_2 gram molecule and an ethane gram molecule. The ethane would get by far the larger portion of this energy if statistical equilibrium between the various degrees of freedom of both molecules exists. It must then impart some 60,000 cal. or more to an average azomethane gram molecule to make its reaction probable. Unless the heat of the reaction is very much higher than 20,000 cal., or the energy of surrounding molecules very great, the third molecule of azomethane in such a chain would not have sufficient energy to react, especially if the pressure were high.

Summary

The photochemical decomposition of azomethane has been studied in order to determine the length of the photochemical reaction chain and to test further certain theoretical interpretations of the unimolecular thermal decomposition.

The quantitative absorption curve for ultraviolet light has been determined from 4060 to 2370 Å. There is an absorption maximum at 3390 Å., with increasing absorption again toward the extreme ultraviolet.

The light used for the decomposition consisted of three mercury lines at about 3660 Å., which were isolated by means of a filter. The total energy falling on the reaction cell was determined by means of a thermopile and the fraction of the light absorbed was calculated from the absorption coefficient.

The decomposition was followed by pressure measurements. Four experiments were made at pressures from 0.1207 cm. to 25.74 cm. Two molecules were found to be decomposed for each photon absorbed in all four experiments.

The temperature coefficient was found to be very nearly zero.

On the basis of Theory II of Rice and the author,[5,6] most of the thermally activated molecules having energies corresponding to the average energy of all of the molecules plus the energy of the photon will react even at the highest pressure. Deactivation by collision seldom occurs, because the life of a molecule is less than the time between collisions even at the highest pressure. A constant value of moles decomposed per photon absorbed is the expected result if the mechanisms of the photochemical and thermal reactions are similar.

The decomposition of two moles per photon absorbed may possibly be explained by the transfer of sufficient energy by a newly-formed ethane molecule to an azomethane molecule to cause it to react.

BERKELEY, CALIFORNIA

NOTE

A New Apparatus for Preparing Aluminum Chloride.—For the preparation of a very reactive aluminum chloride, much superior to the ordinary commercial article for the Friedel and Crafts reaction, the apparatus shown and described below has proved entirely satisfactory in this Laboratory. The product, obtained without difficulty as a uniform, fine powder, can be kept with good mechanical stirring in perfect suspension in the reaction mixture and so gives the best possible results.

The apparatus of Pyrex glass[1] may be made to any scale, but the specifications as given will meet all, ordinary laboratory requirements. The tube in which aluminum is heated has a wall thickness of an eighth of an inch, an internal diameter of 1 inch and a length of 22 inches. At one end it is bent at a right angle and expands into a funnel that has a depth of 3.5 inches, a diameter of 3 inches at the bottom and is provided with a quarter-inch ground flange. The latter fits a similar flange on the jar where the product is collected. These surfaces, when thinly coated with vacuum grease, make a tight joint from which vapors do not escape while the reaction is going on. The jar has a diameter of 3 inches, a depth of 4 inches and is equipped with a quarter-inch side-outlet 1 inch below the flange. Such an apparatus is capable of turning out 120 g. of aluminum chloride at a single run. It is not expensive and with reasonable care should last for a long time. The original apparatus has been used in this Laboratory for a great many runs and apparently is as good now as in the beginning.

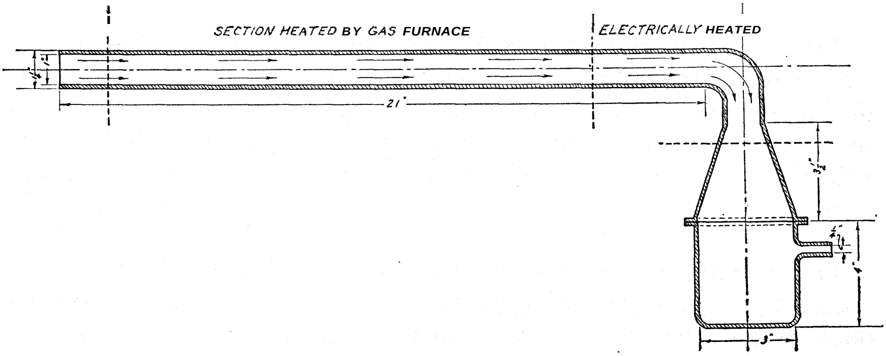

Fig. 1.—An apparatus for making aluminum chloride.

The tube containing the aluminum is heated in a small combustion furnace and the space between the furnace and the top of the funnel is covered with asbestos paper and then wound with 14 feet of 16 gage (B. and S.) nichrome resistance wire. This heating coil is connected with

[1] Supplied by the Corning Glass Company, Corning, New York.

a 110-volt line and the current regulated by a 110 ohm. 7 ampere cage rheostat to produce a temperature of 250" within the tube. The proper setting on the rheostat is determined by a blank trial with a thermometer inside the tube. An asbestos insulation around-the electrically heated area is advisable. Since the receiving jar becomes quite hot during the experiment, it is well to set it in a pneumatic trough filled with water to within a half inch of the outlet-tube. To prevent staining of the heating area, aluminum is introduced into the tube in alundum boats of suitable size.

As soon as air is driven from the system by a rapid stream of dry hydrogen chloride, the flow of gas is checked somewhat and heating is begun at the funnel end by turning on the electric current. The resistance of the rheostat is gradually reduced until at the setting established in the blank trial. The inside of the tube reaches the desired temperature in about half an hour. The furnace burners are then lighted and the stream of hydrogen chloride is increased to its former velocity. At the temperature required for the reaction, white fumes appear in the funnel and settle as a powder on the bottom of the jar. A little of the sublimate collecting on the walls obscures the interior and some escapes through the outlet-tube with the hydrogen. The quantity, however, is negligible. It forms a loose deposit in the outlet-tube and can be easily removed by a stiff wire.

The reaction runs best in a rapid stream of hydrogen chloride at a dull red heat just below the fusion point of aluminum. With these conditions once established, the operation requires little attention. Aluminum chloride is obtained in nearly theoretical yield as an easily removable, white powder. It is at once transferred to the reaction flask, or kept in a desiccator in a tightly closed bottle until needed.

The author wishes to express his thanks to Professors W. H. Warren and B. S. Merigold for advice and assistance in constructing the apparatus and carrying out the process.

THE ALCOHOLYSIS AND HYDROLYSIS OF SOME ALKYL HALIDES IN NEUTRAL SOLUTION

BY BEN H. NICOLET AND DONALD R. STEVENS[1]

RECEIVED MAY 20, 1927 PUBLISHED JANUARY 5, 1928

It might be not unreasonable to expect that the reactions of alkyl halides would be among the simplest to interpret with which organic chemistry has to deal. The extensive literature of the subject,[2] which cannot be reviewed here shows that this expectation is by no means justified.

A tempting start in the interpretation of these reactions as a class would be to correlate relative reaction rates with polarity of the halogen involved. Now, on the basis of almost any polar theory, one of the striking differences to be expected would be that between primary and secondary halides. For practical purposes the suggested comparison would have to be based on the relative reactivities of propyl and *iso*-propyl iodides, as these constitute the only suitable pair for which any considerable variety of determinations is available.

Propyl iodide reacts more rapidly than isopropyl iodide with sodiomalonic ester, with triethylamine, with sodium ethylate, with sodium phenolate, with sodium benzylate[2] and with sodium thiosulfate.[3] In the case of the chlorides, the same order is observed[4] for reaction with potassium iodide. In fact, with the exception of the work of Brussoff[5] on the velocity of olefin formation with alcoholic potash, which is open to a variety of interpretations, we have found recorded but one reaction in which isopropyl iodide reacts more rapidly than the normal iodide. This is the reaction of the halides with silver nitrate in alcohol solution, studied by Burke and Donnan,[6] who found that the chief change taking place was not ethyl nitrate formation, but alcoholysis of the halide. The reaction was catalyzed both by silver nitrate and silver halide.

The present paper describes measurements of the rate of reaction of the four halides propyl bromide and iodide and *iso*propyl bromide and iodide with ethyl alcohol containing varying small amounts of water. The results may be considered to supplement those of Burke and Donnan in giving a measure of the uncatalyzed alcoholysis. They also permit the calculation of relative rates of hydrolysis under the same conditions.

Experimental Part

An accurately weighed portion of the halide was dissolved in sufficient alcohol of the chosen concentration to give 150 cc. of solution. The solutions were 0.33–0.35 molar. This solution was now transferred to the reaction flask, which contained 4 g. of powdered calcium carbonate,[7] and rapidly heated to boiling under efficient reflux. At the end of chosen periods, usually 2, 4, 6, 8 and 10 hours, samples were removed, cooled to 25° and suitable volumes measured for analysis.

For the analysis the samples were submitted to rapid steam distillation until all of the organic halide was removed and the non-volatile halide was then titrated by the Volhard method with *N*/30 silver nitrate.

Due to the large excess of alcohol, and in most cases of water also, which was present, velocity constants were calculated by the usual equation for reactions of the first order. The K so obtained is a combination of the constants of the two competing reactions, hydrolysis and ethanolysis. A typical run is illustrated in Table I.

TABLE I

RESULTS OF A TYPICAL RUN

Isopropyl iodide (*0.330 M*) in 96.08%[a] alcohol

Time, hours	% Reaction	$K \times 10^3$ (hours)
2	4.9	25.1
6	14.4	26.0
8	18.8	26.1
10	23.2	26.4
	Average	25.9
	Average variation	0.4

[a] All alcohol concentrations are in per cent. by weight.

The variation in the constants calculated for other runs was approximately the same as for the one shown. For the sake of brevity, the remaining series of experiments on the four halides are represented in Table II only by the average values of K obtained in similar runs. The columns headed "% reaction (10 hours)" is included to show how far the reaction had progressed at the time measurements ceased. Laboratory regulations made it impracticable to continue the runs for longer periods.

Discussion of Results

The assumption that two reactions, hydrolysis and alcoholysis, are involved, and that these alone take place, requires some justification. This is found, primarily, in the degree of agreement (shown in the last three columns of Table II) between observed values of K and those calculated

---

[7] The calcium carbonate was necessary to prevent the accumulation of halogen acids in the solution. Without it there was definite evidence of the disappearance of HBr or HI by reaction with the solvent alcohol. The constancy of the results obtained indicates that the carbonate caused no serious disturbance. While its use had the theoretical disadvantage that water was formed in the solution ($CaCO_3 + 2HX = CaX_2 + H_2O + CO_2$) during the reaction, calculation will show that the effect was quantitatively of little importance under the conditions actually employed.

when it was assumed (see above) that the observed rates were made up of two linear components proportional, respectively, to the concentrations of alcohol and of water present in each series.

The reaction of alcoholysis involves ether formation. In the experiments tabulated, the isolation of the ethers would have been excessively difficult and their quantitative determination practically impossible. A special experiment, in which a larger proportion of iso-amyl iodide was refluxed for several days with absolute alcohol containing an excess of calcium carbonate, did however result in the isolation of several grams of *iso*-amylethyl ether. The reaction of alcoholysis does, then, take place under such conditions as have been employed. We have not attempted as yet to show the absence of olefin formation under these conditions but we do not know of any case in which this reaction has been observed in dilute, essentially neutral solutions.

Again, the use of the equation for a reaction of the first order in calculating the results given appears at first sight anomalous. In the most extreme case (line 1, Table II) the solution contained 0.330 mole of isopropyl iodide and only 0.065 mole of water. It contained, however, 17.0 moles of alcohol, and the proportion of isopropyl iodide reacting with water to that reacting with alcohol in any given time would thus have been (see values of Ka and Kw and discussion below) $(0.246 \times .065)/(0.0171 \times 17.0) = 0.67$. As the amount of isopropyl iodide which had reacted at the close of the experiment was $0.1622 \times 0.330 = 0.0536$ mole, the amount reacting with water would have been $0.0536 \times 0.057 = 0.0036$ mole, or 5.6% of the water present. As this is much the most extreme case of low water concentration considered, the policy of neglecting changes in the concentration of water during reaction is thought to be justified.

The values of K obtained with a given halide, when plotted against the water content of the alcohol used, fall near a straight line which may be represented by the equation

$$A + B \text{ (wt. fraction water)} = K$$

Here A and B are constants. Table II shows the calculated values of K determined from such a straight line. If Ka and Kw represent the respective constants for the reactions due to alcoholysis and hydrolysis, then the equation may also be written

$$Ka \text{ (wt. fraction alcohol)} + Kw \text{ (wt. fraction water)} = K$$
$$\text{Here } Ka = A \text{ and } Kw = Ka + B$$

The values of Ka and Kw thus derived are included in Table II. Ka should represent with some accuracy the value of K for 100% alcohol. Kw is rather less accurate and may bear little relation to the rate which would be found in pure water. The ratios of the values of Kw obtained for the different halides should, however, be more significant.

Attention is called to the fact that the rate of reaction found is in each case greater for the secondary halides. The ratio of Ka for isopropyl iodide to that for propyl iodide is 3.24; for the bromides this ratio is 1.65. Similar ratios of Kw are 4.42 for the iodides and 1.89 for the bromides. It is certainly a remarkable fact that the secondary halides react the more rapidly in neutral solution and yet the less rapidly in alkaline solution.[2] Pending further data, no explanation is here offered. It is, however, of interest to note that the rate ratios found are greater in the case of the iodides. If the polarities of the halogen atoms are responsble for the variations in rate, one would expect to find the divergence widest in the case of the iodides, since iodine is a less definitely negative element than bromine and should thus be capable of showing a greater variation in polarity under a given stimulus.

Corresponding to the catalytic effect of silver salts reported by Burke and Donnan, it was found that the alcoholysis of the halides studied was markedly catalyzed by the corresponding mercuric halides. Thus 0.34 molar isopropyl bromide reacts some 20 times as rapidly in the presence of 0.17 molar mercuric bromide, and the influence of dissolved mercuric iodide on the reaction of isopropyl iodide was even greater. Satisfactory constants have not as yet been obtained, but the catalyst appears to be inactivated according to the equation $HgX_2 + 2X^- = HgX_4^{--}$.

Summary

1. The rates of alcoholysis and hydrolysis of propyl and isopropyl bromides and iodides in boiling alcohol containing definite small amounts of water have been measured.
2. The reactions considered differ from most of those which have been studied with alkyl halides in that the secondary halides show in each case a more rapid reaction than the corresponding primary halides.
3. The reactions are strongly catalyzed by the corresponding mercuric halides.

ANOMALOUS EFFECT OF ORTHO-PARA ORIENTING GROUPS ON THE MELTING POINTS OF DIHALOGENATED BENZENE DERIVATIVES

BY G. B. HEISIG

RECEIVED JUNE 18, 1927 PUBLISHED JANUARY 5, 1928

Introduction

The introduction of an additional substituent into the benzene nucleus usually results in the formation of a compound which has a higher melting point than the parent substance. For this reason the observation that symmetrical tribromobenzene has a somewhat higher melting point than its amino derivative led to a study of the melting points of halogenated benzenes and their derivatives. The investigation showed that the melting points of derivatives of halogenated benzene increased with the number of substituents in the nucleus, except in the case of those compounds which are formed by the entrance of a group which causes ortho-para substitution into a para halogenated benzene.

Symmetrical chloro-bromo-iodobenzene and its amino derivatives were prepared in order to show the effect of the introduction of the amino group on the melting points of the trihalogenated benzenes.

Study of the Melting Points

An examination of the melting points of the disubstituted halogen benzene derivatives showed that the amines of the ortho and meta halogen derivatives melted at a higher temperature than the corresponding dihalogenated benzene, whereas the melting points of the amino derivatives of para halogenated benzene are lower. In a similar way the melting point of a derivative of an ortho or meta dihalogenated benzene is raised when a halogen or a methyl group instead of an amino group enters the molecule while that of the para compound is lowered.

On the other hand, when a nitrile group replaces a hydrogen of a dihalogenated benzene, the melting point of the para as well as those of the ortho and meta compound is raised. The fact that the nitrile group had a different effect from the amino, halogen and methyl groups seemed to indicate that substituents which caused the formation of meta disubstituted derivatives of benzene raise the melting points of all three types of dihalogen benzene derivatives upon entering the molecule, while those groups which cause the formation of ortho and para derivatives of benzene raise the melting points of ortho and meta halogenated benzene but lower that of the para when a trisubstituted benzene derivative is formed.

A further examination of the effect of other groups which cause meta substitution showed that they had the same effect as the nitrile group.

The data are given in tabular form below.

TABLE I

EFFECT OF A THIRD SUBSTITUENT ON THE MELTING POINTS OF DIHALOGENATED BENZENES

ND—No substituted dihalogenated benzene derivative is described.
+ Melting point of the dihalogenated benzene is raised on substitution.
− Melting point of the dihalogenated benzene is lowered on substitution.

Groups present		Groups entering	Ortbo deriv.	Meta deriv.	Para deriv.
Cl	Cl	I	ND	ND	−
Cl	Cl	Br	+	+	−
Cl	Cl	Cl	+	+	−
Br	Br	Cl	+	+	−
Br	Br	Br	+	+	−
Br	Br	I	ND	+	−
I	I	I	ND	+	−
Cl	Cl	OH	+	+	+
Br	Br	OH	+	+	ND
I	I	OH	+	+	−
Cl	Cl	CH3	Liq.	Liq.	−
Br	Br	CH_3	+	+	−
I	I	CH_3	+	+	ND
Cl	Cl	NH_2	+	+	−
Br	Br	NH_2	+	+	−
I	I	NH_2	+	+	−
Cl	Br	NH_2	+	+	−
Cl	I	NH_2	+	+	ND
Br	I	NH_2	+	+	ND
Cl	Cl	CN	ND	+	+
Br	Br	CN	ND	+	+
Cl	Cl	NO_2	+	+	+
Br	Br	NO_2	+	+	−
I	I	NO_2	+	+	−
Cl	Br	NO_2	+	+	+
Cl	I	NO_2	ND	+	+
Cl	Cl	SO_3H	ND	ND	+
Br	Br	SO_3H	+	+	+
Cl	Cl	CHO	+	+	+
Cl	Cl	COOH	+	+	+
Br	Br	COOH	+	+	+
Cl	Br	COOH	+	+	+

The table shows that none of the iodo derivatives of o- or *m*-dichlorobenzene are described in the literature, but that the iodo derivative of *p*-dichlorobenzene has a lower melting point than that of p-dichlorobenzene. The + or − signifies that the melting points of all of the isomers described in the literature, which are formed by the entering group, have a higher or lower melting point, respectively, than that of the parent dihalogenated benzene.

From the table we may make the following generalizations.

1. The melting point of an ortho or meta disubstituted halogen derivative is raised by the entrance of a third group. This has been found to hold for the substitution of a chlorine, bromine or iodine atom or an hydroxyl, methyl, amino, nitrile, nitro, sulfonic acid or carboxyl group.

2. The melting point of a para disubstituted halogen derivative is raised by the entrance of a third substituent if the group entering is one which causes meta substitution.

3. The melting point of a para disubstituted halogen derivative is lowered by the entrance of a third substituent if the group entering is one which causes ortho-para substitution.

It can be seen that there is no exception to rule number 1; two exceptions to rule number 2 (1-nitro-2,5-dibromobenzene and 1-nitro-2,5-di-iodobenzene melt lower than the corresponding dihalogenated derivatives); and one to rule 3 (1-hydroxy-2,5-dichlorobenzene melts 4 degrees higher than the dihalogenated benzene). The three compounds having melting points which were exceptions to rules 2 and 3 were prepared and their melting points were found to agree with those given in the literature.

It should be noted that Holleman[1] and Francis and co-workers[2] have shown that the —NO_2 group has less meta directing influence than the —SO_3H group, and this less than the —COOH group. Nitro compounds offer the only exception to rule 2.

The reason for the lowering of the melting points of the para dihalogenated benzenes by the entrance of certain groups is not clear. It is known that the amino group, for instance, has a strong effect on the ortho and para positions and it was thought that this lowering might be due to the influence of the entering amino group on the halogen it finds ortho or para to it. In that case, however, we should expect that any trisubstituted benzene derivative in which the amino group was ortho or para to a halogen would have a lower melting point than the corresponding dihalogen derivative; but this is not true. It is only when the halogens are para to each other that the amino or similar group has this property.

An examination of the melting points of the trisubstituted amines shows that, in, general, the melting point of the trisubstituted benzene compound is lower than that of the corresponding trisubstituted aniline with the exception of symmetrical tribromo-aniline and 3,4,5-tri-iodo-aniline. In the latter compounds the corresponding amine has a lower melting point than the trihalogenated benzene. Inasmuch as the trisubstituted aniline derivatives containing chlorine, bromine and iodine in the same molecule were not known it seemed worth while to prepare them and note the relation of their melting points to the parent trisubstituted hydrocarbon.

---

[1] Holleman, *Chem. Reviews*, 1,202 (1924).

[2] Francis, Andrews and Johnston, THIS JOURNAL, 48,1625 (1926).

It was found in each case that the amine melted at a higher temperature than the corresponding trihalogenated benzene.

A search for the dielectric constants and refractive indices of the compounds whose melting points have been studied was made, to see whether there was a corresponding difference in these constants for the para halogenated benzene derivatives, but sufficient data from which to draw conclusions could not be found.

Compounds which have small external fields of force should have lower melting points than similar compounds having larger fields of external force. Inasmuch as compounds having larger external fields of force should be more reactive than those having a smaller field of force, it would seem that the trisubstituted derivatives formed from ortho and meta compounds by substituting an ortho-para orienting group should be more reactive than the trisubstituted derivative formed from the para compound. This phase of the problem will be further investigated.

There are some indications that the lowering of the melting point of para disubstituted benzene derivatives by the introduction of groups causing ortho-para substitution holds for other than the halogen compounds.

Experimental

A sample of each compound whose melting point was to be determined was placed in a vacuum desiccator over concd. sulfuric acid and was allowed to remain under a pressure of 25 mm. for at least twenty minutes to remove traces of the solvent. The melting point was determined by immersing a capillary tube containing the sample in a bath of concentrated sulfuric acid about 10° below the melting point of the compound. The acid was agitated by means of a ring stirrer while the temperature was very gradually raised.

For the preparation of the three amines of symmetrical trihalogenated benzene, *p*-bromo-acetanilide, p-chloro-acetanilide and *o*-chloro-aniline were used. To prepare 2-chloro-4-bromo-6-iodo-aniline, *p*-bromo-acetanilide was chlorinated by means of HOCl according to the method of Chattaway and Orton,[3] producing 2-chloro-4-bromo-acetanilide. This anilide was then saponified and iodine was introduced into the benzene nucleus by using iodine monochloride. The amine was dissolved in acetic acid and the vapors of iodine monochloride were passed into the solution. The iodine monochloride was prepared according to the method of Jackson and Whitmore.[4]

The 2-bromo-4-chloro-6-iodo-aniline was prepared in a similar manner, starting with p-chloro-acetanilide. The bromine was introduced into the benzene ring by the method of Mannino and Di Donata.[5] In this method bromine formed by the action of nitric acid on hydrobromic acid reacts with the anilide.

In attempting to prepare 2-chloro-4-iodo-6-bromo-aniline it was found that iodine monochloride reacted with o-chloro-aniline to form products which had a much higher melting point than that of 2-chloro-4-iodo-aniline. This compound had been previously prepared by Dains, Vaughan and Janney[6] and was found to melt at 70–71°.

---

[3] Chattaway and Orton, Ber., 33, 2398 (1900); *J. Chem. Soc.*, 79, 274–280 (1901).

[4] Jackson and Whitmore, THIS JOURNAL. 37, 1528 (1915).

[5] Mannino and Di Donata, *Gazz. chim. ital.*, [2] 38, 24 (1908).

[6] Dains, Vaughan and Janney, THIS JOURNAL, 40,933 (1918).

The 2-chloro-4-iodo-aniline was prepared from o-chloro-aniline by refluxing with iodine, water and ether, according to the directions given by Dains, Vaughan and Janney[6] and was then brominated by dissolving in acetic acid and adding bromine.

The three amines were diazotized using alcohol, sodium nitrite and sulfuric acid. The same trisubstituted benzene was obtained in each case; thus proving that the amino derivatives were symmetrical trihalogen anilines.

Action of ICl on 2-Chloro-4-bromo-acetanilide

One g. of the 2-chloro-4-bromo-acetanilide, m. p. 150–151°, prepared by the general method of Chattaway and Orton,[3] was dissolved in acetic acid and ICI vapor passed into the solution. Upon the addition of water, 0.7 g. of a white precipitate was formed, which proved to be unchanged **2-chloro-4-bromo-acetanilide.** The small amount remaining in the mother liquor was discarded.

Saponification of 2-Chloro-4-bromo-acetanilide

Eight and seven-tenths g. of the **2-chloro-4-bromo-acetanilide** was refluxed with 6.1 g. of potassium hydroxide dissolved in 75 cc. of alcohol for about eight hours. The alcohol was distilled off on the steam-bath and water added. The amine was filtered from the cold solution, washed with cold water and crystallized from petroleum ether; b. p. 100–115°. Six and one-tenth g. of product having a melting point of 70–71° was obtained, which corresponds to an 84.6% yield.

Direct Iodination of 2-Chloro-4-bromo-aniline

The direct iodination of 2-chloro-4-bromo-aniline was carried out following the procedure of Wheeler and his co-workers.[7]

One g. of the amine gave a black tar which was subsequently discarded, and 0.3 g. of 2-chloro-4-bromo-6-iodo-acetanilide. The melting point was 97–97.5° after crystallizing from petroleum ether; yield, 18.6%. The product was identical with that obtained by **the** action of ICl on 2-chloro-4-bromo-aniline.

Preparation of 2-Chloro-4-bromo-6-iods-aniline

One g. of the amine was dissolved in about 20 cc. of glacial acetic acid and sufficient water was added so that the mixed solvent was nearly saturated with the amine. **One g.** of ICl vapor was blown into the solution, and a light-colored, crystalline precipitate settled out. The precipitate was dissolved in the mother liquor by warming and then allowed to crystallize. One and three-tenths g. of 2-chloro-4-bromo-6-iodo-aniline was obtained, m. p. 94–95', corresponding to a yield of 81%. On recrystallizing from petroleum ether, a product melting at 97–97.5° was obtained. Further crystallizations from alcohol by the addition of water, and from ethyl acetate by the addition of petroleum ether failed to change the melting point.

Anal. Subs., 0.5064: N_2, 21.2 cc. at 24°; 743.1 mm. (corr.) collected over 23.1% KOH. Calcd. for $C_6H_4NClBrI$: 4.21. Found: 4.59.

Preparation of 2-Bromo-4-chloro-6-iodo-aniline

2-Bromo-4-chloro-acetanilide was prepared from 4-chloro-acetanilide by the method of Mannino and Di Donata[5] and converted to the corresponding amino compound by saponification. One g. of the 2-bromo-4-chloro-aniline was dissolved in 20 cc. of acetic acid and water added until the solution became turbid. One g. of ICl vapor was then blown into the solution. One and six-tenths g. of crude 2-bromo-4-chloro-6-iodo-aniline

---

[7] Wheeler and others, *Am. Chem. J.,* 42,441461 (1909); 44,127,493–507 (1910).

precipitated. The crude material was crystallized from petroleum ether; 1.5 g. having a melting point of 109.5–110° was obtained, corresponding to a 93.3% yield.

Anal. (semi-micro). Subs., 0.0475 g.: N_2, 1.92 cc. at 21°; 737 mm. (corr.) collected over 33% KOH. Calcd. for $C_6H_4NClBrI$: 4.21. Found: 4.48.

This analysis was carried out according to an unpublished method of Lauer and Sunde.

Preparation of 2-Chloro-4-iodo-6-bromo-aniline

Method A. By Bromination of 2-Chloro-4-iodo-aniline

Seven and seven-tenths g. of 2-chloro-4-iodo-aniline, prepared according to the directions of Dains, Vaughan and Janney[6] was dissolved in 35 cc. of glacial acetic acid and 5 g. of bromine was added. The reaction mixture warmed up and after a little while crystals began to appear. These were filtered off and water was added. Eight and five-tenths g. of crystals were obtained which had a constant melting point of 115.5–116° after 2 crystallizations from alcohol. Recrystallizing from petroleum ether failed to change the melting point. The yield was 84.2% of the calculated.

Anal. (semi-micro). Subs., 0.0223 g.: N_2, 0.77 cc. collected over 33% KOH at 26°; 759.3 mm. (corr.). Calcd. for $C_6H_4NClBrI$: 4.21. Found: 4.04.

Method B. By the Chlorination of 2-Bromo-4-iodo-acetanilide

Six g. of finely ground *p*-iodo-acetanilide was brominated according to the general method of Mannino and Di Donata.[5] Seven and two-tenths g. of the pure anilide was obtained, melting at 140–140.5° after crystallizing from alcohol; yield, 92.3%.

Anal. (semi-micro). Subs., 0.0320 g.: N_2, 1.21 cc. at 22° and 737.2 mm. (corr.) over 33% KOH. Calcd. for C_8H_7ONBrI: 4.12. Found: 4.18.

One and eighty-five hundredths g. of 2-bromo-4-iodo-acetanilide was saponified and treated in the usual manner. One and four-tenths g. of the amine which melted at 77.5–78° after crystallizing from petroleum ether was obtained; yield, 70.4%. A small portion of the amino compound was converted to the anilide by treatment with acetyl chloride. The melting point was 139–140°, thus proving the identity of the positions before and after saponification. The picric acid addition compound melted at 125°.

The 2-bromo-4-iodo-aniline was converted to 2-bromo-4-iodo-6-chloro-aniline by dissolving in glacial acetic acid and adding the calculated amount of chlorine dissolved in glacial acetic acid. A white precipitate having a high melting point was immediately formed. On filtering and adding water, the trihalogenated aniline was obtained. It was crystallized from alcohol and from petroleum ether. A mixed melting point proved its identity with the 2-bromo-4-iodo-aniline obtained by brominating 2-chloro-4-iodo-aniline.

Preparation of *Sym.*-chloro-bromo-iodo-benzene

1. Diazotization of 2-Iodo-4-chloro-6-bromo-aniline

Forty-one hundredths g. of 2-iodo-4-chloro-6-bromo-aniline was refluxed for half an hour on a steam-bath with 1.64 cc. of ethyl alcohol, one and six-tenths cc. of concd. sulfuric acid and 1.1 g. of sodium nitrite. The mixture was then diluted and the reddish precipitate which separated was thoroughly washed and finally dried in a vacuum desiccator. Thirty-five hundredths g of product was obtained which melted at 85.5–86° after 2 crystallizations from alcohol. The yield was 89.5%.

2. Diazotization of 2-Chloro-4-bromo-6-iodo-aniline

Six-tenths g. of this amine was refluxed for half an hour with 0.14 g. of sodium nitrite, 2.5 cc. of ethyl alcohol and 1 cc. of concd. sulfuric acid. The mixture was then diluted with water and the reddish colored oil which soon solidified was thoroughly washed with water. After drying in a vacuum desiccator **0.55** g. of product was obtained which after two crystallizations from alcohol melted at 85.5–86°. The red color was removed by boiling the alcohol solution with a little Norit. A yield of 96.2% was obtained.

3. Diazotization of 2-Chloro-4-iodo-6-bromo-aniline

To **2.15** g. of the amine was added **0.5** g. of sodium nitrite, **3.5** cc. of concd. sulfuric acid and **10** cc. of ethyl alcohol. After refluxing for half an hour and evaporating the alcohol, the residue was steam distilled. One and five-tenths g. of a white crystalline substance was obtained from the distillate on cooling. After one crystallization from alcohol, the substance melted at 85.5–86.0°. The yield was **73.2%.**

Mixed melting points of the halogenated benzenes obtained from the three trisubstituted anilines showed that the products were identical. The fact that the three amines gave the same compound on diazotization proves the symmetrical arrangement of the halogens.

Summary

1. A study of the melting points of halogenated benzene derivatives shows that the melting points are raised by the introduction of additional groups except in the case of one class of compounds. Contrary to the general rule, the melting points of para dihalogenated benzene derivatives are lowered by the introduction of a group causing ortho-para substitution.

2. Symmetrical trihalogenated benzene derivatives containing iodine, bromine and chlorine in the same ring have been prepared for the first time.

3. The amino derivatives of these compounds have higher melting points than the parent hydrocarbons.

MINNEAPOLIS, MINNESOTA

ACTION OF THIONYL CHLORIDE ON ORGANIC ACIDS[1]

BY L. MCMASTER AND F. F. AHMANN

RECEIVED JUNE 20, 1927 PUBLISHED JANUARY 5, 1928

Thionyl chloride is a reagent which has become very important for the synthesis of a large variety of organic compounds. In a recent article by Silberrad,[2] a summary of the work upon thionyl chloride is given. It is mentioned as a chlorinating and dehydrating agent, as a reagent for the removal of hydrogen from mercaptans, as a condensing agent and as a catalyst. The most frequent use of this reagent is for the conversion of an acid into its chloride, since it is easier to handle than phosphorus pentachloride. This investigation was begun some months previous to the review by Silberrad and had for its object a systematic study of the reaction of thionyl chloride on organic acids.

---

[1] This paper was presented before the Division of Organic Chemistry of the American Chemical Society, Richmond, Virginia, April **11** to 16, **1927.**

[2] Silberrad, J. *Soc. Chem. Ind.*, **45,** 37, 55 **(1926).**

Experimental Procedure

Pure acids in quantities of 15 to 25 g. were treated with two or three times their weight of pure thionyl chloride. In some cases the reaction took place immediately but usually the mixture had to be refluxed with stirring at the boiling point of the thionyl chloride to complete the reaction. In a few cases several days' refluxing were required. In most cases the acid dissolved in the thionyl chloride and a solvent was unnecessary. When a solvent was required, benzene, ether, petroleum ether, gasoline, pyridine and other inert solvents were tried. Since the by-products of the reaction are gaseous, they were readily removed and any excess thionyl chloride was distilled off. Usually the thionyl chloride replaced the OH group by Cl, forming an acid chloride, but in some cases with the dibasic acids anhydrides were formed. These products were purified either by vacuum distillation or by crystallization. In cases where acids were found not to react, various catalyzers such as pyridine, aluminum chloride and iodine were tried.

TABLE I

SUBSTITUTED ACETIC ACIDS

Acid	Amt. in g.	Time, hours	Product	% Yield
Chloro-acetic	15	24	Monochloro-acetyl chloride	55
Trichloro-acetic	15	48	None	..
Amino-acetic	12	12	None	..

The three negative chlorine groups in trichloro-acetic acid evidently prevent the formation of an acid chloride. With the amino-acetic acid a reaction took place and the thionyl chloride turned intensely red but we were unable to isolate any products of the reaction. It is probable that the amino group was attacked.

TABLE II

ALIPHATIC DIBASIC ACIDS

Acid	Amt. in g.	Time, hours	Product	% Yield
Oxalic	15	72	None	..
Malonic	15	2	Malonyl chloride	60
Succinic	20	6	Succinic anhydride	78
Glutaric	15	6	Glutaric anhydride	78

It was thought that thionyl chloride might react with diethyl oxalate to form oxalyl chloride, but no reaction took place upon refluxing the mixture for forty-eight hours. This is the only method by which malonyl chloride can be prepared, since phosphorus pentachloride converts malonic acid into carbon suboxide. It is a liquid which distils at 55° (15 mm.) and turns dark red on standing. The literature records that succinic anhydride can best be made by this method. Suberic and sebacic acids are reported[3] as forming dichlorides.

---

[3] Hans Meyer, Monatsh., 22, 415, 777 (1901).

The Hydroxy Acids

The action of this reagent on the hydroxy acids has not been studied very extensively. Malic acid is mentioned as forming a dichloride, while no reference is made to tartaric acid. Lactic acid yields a variety of products.[4] Tartaric acid is the only one of this group studied by us. 15 g. of the acid was refluxed for several days with 40 cc. of thionyl chloride without any result. No suitable solvent for the acid could be found in which to carry out the reaction.

Unsaturated Dibasic Acids

Fumaric, mesaconic and bromomaleic acids are described3 as forming dichlorides, while maleic, citraconic and itaconic acids form anhydrides. We obtained a 90% yield of maleic anhydride but could not get fumaric acid to react. Benzene, petroleum ether and pyridine were used as solvents without success. We intend to repeat the action of thionyl chloride on the other unsaturated dibasic acids mentioned, since our work does not agree with the results given in the literature.

TABLA III

SUBSTITUTED BENZOIC ACIDS

15 g. of acid used in each case

Acid	Time, hours	Product	% Yield
o-Nitrobenzoic	3	o-Nitrobenzoyl chloride	90
m-Nitrobenzoic	3	m-Nitrobenzoyl chloride	86
p-Nitrobenzoic	6	*p*-Nitrobenzoyl chloride	73
o-Aminobenzoic	3	None	..
m-Aminobenzoic	3	m-Aminobenzoyl chloride	83
p-Aminobenzoic	4	*p*-Aminobenzoyl chloride	88

Heumann and Koechlin[5] studied the action of thionyl chloride on benzoic acid. We obtained a 98% yield against one of 90% by the phosphorus pentachloride method. Meyer[6] has prepared by this method the p-nitrobenzoyl chloride after a long period of refluxing. We found that it was the most difficult of the three to prepare.

Phosphorus pentachloride cannot be used to prepare an acid chloride of an aminobenzoic acid since it attacks the amino group. We could find no references to the acid chlorides of the aminobenzoic acids. In the case of the o-aminobenzoic acid a vigorous reaction took place when it was first treated with the thionyl chloride and it was necessary to surround the flask with a freezing mixture. We were not able to isolate any definite products of the reaction. The *m*-aminobenzoyl chloride is a yellow oil distilling at 125° (15 mm.). Upon standing it passes into a solid of m. p. 42° and possesses a decided acid chloride odor. It reacts vigorously with

---

[4] Frankland and Garner, J. Chem. *Soc.*, 105, 1101 (1914).

[5] Heumann and Koechlin, Ber., 16, 1625 (1883).

[6] Hans Meyer, J. Chem. *Soc.*, 80, 1, 628 (1901); 82, 1, 31 (1902).

water, ammonia and alcohol. Analysis gave 22.72% of chlorine whereas the calculated value is 23.44%. The *p*-aminobenzoyl chloride is also a yellow oil distilling at 120° (12 mm.), solidifying upon standing to yellow crystals of m. p. 31°. These crystals possess the same properties as the meta compound and were found to contain 22.62% of chlorine.

The Hydroxybenzoic Acids

In only exceptional cases have the acid chlorides of the hydroxybenzoic acids been prepared by ordinary methods. When phosphorus pentachloride is used as a chlorinating agent, the OH group is also attacked. Meyer found that salicylic acid, m-hydroxybenzoic acid and *o*-and *m*-cresotinic acids readily formed the acid chlorides with thionyl chloride. We were able to obtain by using the free acid only a very small yield of the acid chloride of salicylic acid but a **36%** yield was obtained by using the sodium salt of the acid. The salicylyl chloride is a white, crystalline substance melting at 18° to a colorless, sirupy liquid which distils at 90° (11 mm.). No yield of the acid chloride could be obtained with m-hydroxybenzoic acid nor with o-and m-cresotinic acids as claimed by Meyer. We obtained only glassy solids of indefinite composition. The para acids do not react. Meyer states that an acid chloride is not formed if the acid has an OH group in the para position unless a second OH group is in the ortho position with respect to the first OH group.

The Phthalic Acids

The phthalic acids have been studied previously by Meyer, who found that phthalic acid formed an anhydride, isophthalic acid a dichloride and terephthalic acid was unattacked. Since no yields were recorded they were reinvestigated.

TABLE IV

THE PHTHALIC ACIDS

Acid	Amt. in g.	Time, hours	Product	% Yield
Phthalic	20	2	Phthalic anhydride	95
Isophthalic	10	12	Isophthalyl chloride	62
Terephthalic	15	72	None	..

Attempts to prepare phthalyl chloride were made by prolonged boiling of the anhydride with the thionyl chloride using aluminum chloride, iodine and pyridine as catalysts but without success. The isophthalyl chloride is a colorless oil distilling at 200° (15 mrn.). Catalyzers and various inert solvents were tried in the attempt to prepare terephthalyl chloride.

Summary

1. Thionyl chloride readily converts the acids of the fatty acid series into acid chlorides. Chloro-acetic acid is converted into an acid chloride while trichloro-acetic and amino-acetic acids are not.

2. Of the dibasic acids, oxalic is unattacked, while succinic and glutaric yield anhydrides and malonic, suberic and sebacic acids form dichlorides.

3. Tartaric acid is unattacked.

4. Of the unsaturated dibasic acids employed, maleic forms an anhydride and fumaric acid is unchanged.

5. Of the benzoic acids, the three nitrobenzoic acids all form the acid chlorides. The p-nitrobenzoyl chloride is formed only with difficulty due to the presence of the negative nitro group in the para position. Acid chlorides of m-and p-aminobenzoic acid can be prepared by this method. The ortho acid does not form an acid chloride.

6. Only by the use of thionyl chloride can the acid chlorides of some of the aromatic hydroxy acids be prepared. o-Hydroxybenzoic acid forms an acid chloride while the para acid does not. m-Hydroxybenzoic acid and the cresotinic acids gave products which could not be identified as acid chlorides as stated by Meyer.

7. Of the phthalic acids, the ortho acid forms an anhydride, the meta acid a dichloride and the para acid is not attacked by thionyl chloride.

8. The action of thionyl chloride on other organic acids is being continued in this Laboratory.

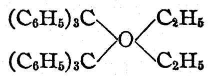
THE HEXAPHENYLETHANE ALKYL SULFIDE ADDITION COMPOUNDS[1]

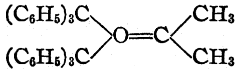
By Victor C. Rogers[2] and Gregg Dougherty

Received June 27, 1927 Published January 5, 1928

Introduction

Hexaphenylethane (triphenylmethyl) possesses the property of forming addition products with a great variety of organic substances.[3,4] The majority of these addition products have a composition corresponding to the ratio of one mole of hexaphenylethane to one mole of the substance added. In the case of the additions involving esters, ethers and ketones,[5] the oxonium theory is probably applicable, as follows





---

[1] This article is based upon a thesis submitted by Victor C. Rogers to the Faculty of the Graduate School of Princeton University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] DuPont Fellow in Chemistry.

However, the later discovery of addition products of hexaphenylethane with both olefin and saturated hydrocarbons,[6] in which the nature of the binding cannot be so explained, has led to some hesitation in suggesting structures for these complexes.

The alkyl sulfides are known to form a great number of complexes with both organic[7,8] and inorganic compounds.[9] The nature of some of these complexes has been interpreted by the use of the sulfonium theory, analogously to the conception of the oxygen linked complexes. One might expect then that hexaphenylethane with its remarkable additive tendency would form complexes with the alkyl sulfides. No mention of the formation of these substances is to be found in the literature, except for the statement by Schmidlin[10] that they have not been prepared. The preparation and a study of the properties of the methyl, ethyl and propyl sulfide addition products have been undertaken. The details of the preparation are found in the experimental part.

Properties of the Crystalline Addition Compounds

The crystals are colorless to light yellow in color. They are easily soluble in such solvents as benzene, ether, chloroform and the organic sulfides. The solutions are very sensitive to the action of the oxygen of the air; on standing in open vessels or when air or oxygen is passed through the solutions, the characteristic white peroxide is precipitated.'

We expected to find the sulfide addition compounds to be much more stable or inert than the analogous compounds involving oxygen linkage. Such is not the case. The strength of the bond between the sulfide and the hexaphenylethane appears to be of the same order as that in the complexes with ethers and esters. The sulfide is partially lost by washing the crystals with solvents of various kinds. The crystals also give up the alkyl sulfide when placed in a slow stream of carbon dioxide. This occurs to some extent even at room temperatures; a sample standing overnight lost about 20% of its sulfur content.

In the formation of the addition compounds of hexaphenylethane with esters, ketones, carbon disulfide, etc., Gomberg and Cone[11] found that although in general the ratio of the added substance to hexaphenylethane was one mole to one mole, varying results were obtained depending upon the temperature of preparation, nature of the solvent used to wash the crystals of the addition product and the amount of washing done. In the case of the ethyl sulfide addition product we obtained a consistently

[11] Gomberg and Cone, *Ber.*, 38, 1333, 2447,2451 (1905).

good ratio. With the methyl sulfide addition product greater irregularities of composition were encountered. However, there is no doubt that the figures (see experimental part) are of the magnitude demanded by the 1:1 ratio of the hexaphenylethane to the methyl sulfide. No satisfactory results were obtained with the crystals separating from the propyl sulfide. In this case careful drying resulted in a very low sulfur content, while less rigid drying gave a percentage somewhat above the theoretical value. It is interesting to note that the dipropyl ether compound with hexaphenylethane which Gomberg and Cone[12] prepared also gave no constant figure for the ether content.

Oxidation of the Alkyl Sulfide Addition Products

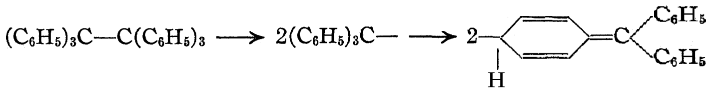
The absorption of oxygen by solutions of hexaphenylethane and related compounds has been shown by Gomberg and his co-workers[13] to be of the magnitude to warrant the equation

$$(C_6H_5)_3C\text{—}C(C_6H_5)_3 + O_2 \longrightarrow (C_6H_5)_3C\text{—}O\text{—}O\text{—}C(C_6H_5)_3$$

However, the reaction is clearly influenced by outside factors, for the yield of the triphenylmethyl peroxide may vary considerably according to the solvent used,[14] and also depending upon whether pure oxygen or air is used as the oxidizing agent.[15]

Now Moureu and Dufraisse[16] have pointed out the activity of sulfides, including the alkyl sulfides, in altering the rate of oxidation of auto-oxidizable substances, while Taylor[17] has pointed out the connection between catalysis of auto-oxidation and the property of addition complex formation.

It had been observed during the course of the work that the yellow color of the solutions of hexaphenylethane in pure alkyl sulfides was considerably deeper than when benzene or ether was used as the solvent. If the color is due to quinoxidation as proposed by Gomberg,[18] and Jacobson,[19] it would seem that the alkyl sulfides possess the property of shifting the equilibrium markedly toward the quinoid tautomer.



A test of this hypothesis could be made by studying the oxidation of hexaphenylethane in alkyl sulfide solutions, because it has been established

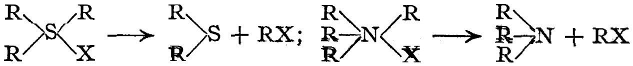
that the colored modification is rapidly transformed by air or oxygen into triphenylmethyl peroxide.[20]

Experiments were carried out to measure the rate of oxidation of hexaphenylethane in the presence of alkyl sulfides and also in the presence of other additive substances. The results as pictured by the curve in the experimental part show clearly that the presence of the alkyl sulfides has a marked accelerating effect. This may be explained by assuming that the sulfide increases the concentration of the quinoid or easily oxidized tautomer. Total absorption measurements showed this to be unaffected by the presence of the sulfides.

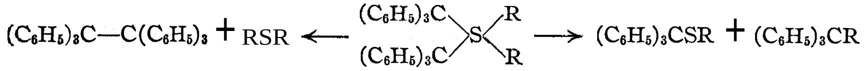
Thermal Decomposition of the Alkyl Sulfide Addition Products

When the alkyl sulfonium compounds and the quaternary ammonium compounds are heated, the following type of splitting occurs



$$\begin{matrix}R\\R\end{matrix}\!>\!S\!<\!\begin{matrix}R\\X\end{matrix} \longrightarrow \begin{matrix}R\\R\end{matrix}\!>\!S + RX;\quad \begin{matrix}R\\R\\R\end{matrix}\!\!\rightarrow\!N\!<\!\begin{matrix}R\\X\end{matrix} \longrightarrow \begin{matrix}R\\R\\R\end{matrix}\!\!\rightarrow\!N + RX$$

If the hexaphenylethane-alkyl sulfide complexes possess the sulfonium structure, an analogous splitting should occur and probably in two ways, as follows



$$(C_6H_5)_3C{-}C(C_6H_5)_3 + RSR \longleftarrow \begin{matrix}(C_6H_5)_3C\\(C_6H_5)_3C\end{matrix}\!>\!S\!<\!\begin{matrix}R\\R\end{matrix} \longrightarrow (C_6H_5)_3CSR + (C_6H_5)_3CR$$

so that we should find among the decomposition products mixed sulfides containing the triphenylmethyl group, and hydrocarbons of the a, a, α-triphenyl paraffin type.

It has been noticed that when the addition compounds of hexaphenylethane are warmed, they lose to a greater or less extent the added substance. In some cases this loss is nearly quantitative, but in other cases the result is below that corresponding to the one mole to one mole addition ratio. Furthermore, it has been observed frequently that the material left after driving off the added substance had not entirely the properties of hexaphenylethane. In the case of the sulfide additions, a positive test for sulfur in the residue indicated a decomposition in addition to the simple dissociation of the addition compound.

Attempts were made to retard the dissociation by heating in sealed tubes. Although complex, the resulting mixture could be separated into two classes—complex hydrocarbons of low volatility, probably of the α, a, a,-triphenyl paraffin type, and compounds containing sulfur and triphenylmethyl groups, also of low volatility. These results are explained most simply by the assumption of a sulfonium structure for the addition compound and a splitting in such a way that the two triphenylmethyl groups are separated to take part in the formation of two new molecules

$$[(C_6H_5)_3C]_2S(CH_3)_2 \longrightarrow (C_6H_5)_3C{-}S{-}CH_3 + CH_3C(C_6H_5)_3$$

Experimental Part

Preparation of the Addition Compounds.--The hexaphenylethane was prepared by treatment of a solution of triphenylmethyl chloride with mercury.[21] It was found most convenient to prepare the addition compounds by using the respective sulfides as the solvent in which to prepare the hexaphenylethane. The preparation was carried out in a large deformed "U"-tube. The limbs of the "U" were sealed and near the bend was affixed a small side arm. Through this arm the reactants were introduced into the far limb of the vessel. Two and seven-tenths g. of triphenylmethyl chloride, 1.7 cc. of mercury and 8–10 cc. of carefully dried alkyl sulfide were used in each preparation. The vessel was then evacuated until quiet boiling of the solvent displaced most of the air present. The side arm was then sealed and the vessel agitated in such a manner that the mixture was always confined to one arm of the "U."

After agitating for two or three days the vessel was supported vertically and the mixture allowed to settle, after which the clear, deep yellow solution of hexaphenylethane was decanted carefully into the opposite arm of the "U." By warming the limb containing the solution and cooling the other most of the solvent was distilled away from the hexaphenylethane. Upon standing, colorless or pale yellow crystals separated. After crystallization the mother liquor was decanted back into the opposite limb and then by cooling the limb containing the crystals pure solvent was condensed upon the crystals for washing them. When the crystals were washed sufficiently they were dried by warming them gently or by cooling the opposite limb in a cooling mixture. In this manner the crystals were prepared, washed and dried in an atmosphere free from oxygen. When the operation was completed, the limb of the vessel was circled with *a* file scratch and broken off in an atmosphere of carbon dioxide. The above method yielded from one to two grams of solid product from each preparation.

Analysis.—Qualitative examination of the crystals showed no mercury, a trace of chlorine and a strong test for sulfur.

An attempt was first made to analyze the compounds after the method of Gomberg and Cone[12] by heating them in a stream of carbon dioxide to 60–80° until constant weight was attained. The loss of alkyl sulfide was always below the theoretical amount and the residue gave a test for sulfur, indicating that all of the sulfide was not lost in this way.

Determination of the sulfur content of the crystals was carried out by first heating in a Carius tube at 200° for eight hours with fuming nitric acid and a drop or two of bromine. This was followed by a fusion with a mixture of potassium hydroxide and sodium peroxide. The sulfur was then determined in the usual manner as barium sulfate.

The results were as follows:

Ethyl sulfide-hexaphenylethane: Calcd.: S, 5.56. Found: 5.48, 5.42, 5.43. Methyl sulfide-hexaphenylethane: Calcd.: S, 5.83. Found: 6.02, 5.31, 5.28, 4.98, 4.80, 4.83. Propyl sulfide-hexaphenylethane: Calcd.: S, 5.31. Found: 2.90, 2.78, 2.28, 1.30, 6.56, 6.33, 5.96, 7.37.

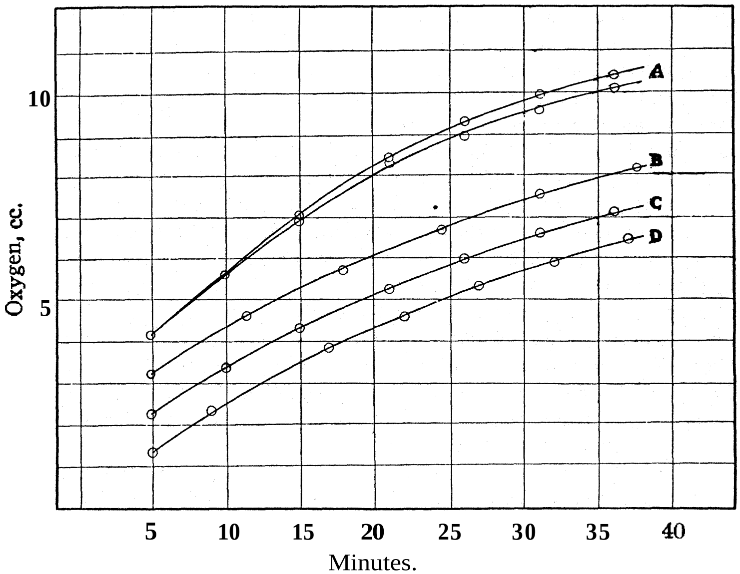
Oxidation Rate.—The alkyl sulfide-hexaphenylethane addition product was not isolated in the solid form for these experiments, but a solution resulting from the conversion of *a* definite amount of triphenylmethyl chloride in bromobenzene solution containing an equivalent of the additive substance was used. One-fourth of a gram of triphenylmethyl chloride, 0.5 cc, of mercury and 10 cc. of dry bromobenzene containing about four drops of the sulfide were sealed in an 11cc. thin-walled bulb which had been pre-

---

[21] Ref. 4, p. 30.

viously dried and swept out with nitrogen. This bulb was then agitated vigorously for eight hours, at which time all of the triphenylmethyl chloride had been converted to hexaphenylethane as shown by a total absorption. The bulb was then placed in a small vessel equipped with a manometer and a plunger for breaking the bulb. After the introduction of *a* few drops of bromobenzene the vessel was swept out with oxygen, closed and a few moments allowed for the saturation of the confined oxygen with bromobenzene vapor.

After recording the temperature, pressure and the position of the levels of the manometer tubes, the bulb containing the sample was completely crushed by striking the plunger in the vessel. As the oxygen in the vessel was absorbed, atmospheric pressure was maintained by continuous adjustment of the manometer levels. The position of the adjusted levels of the manometer was periodically recorded. The absorptions were carried out at 23.5°.



A, alkyl sulfide; B, acetone; C, carbon disulfide; D, bromobenzene.

Fig. 1.

The curves shown represent about two-thirds of the total absorption **taking** place over about forty minutes of time. The starting point of all of the curves is the same but the curves have **been** moved apart in order to emphasize the similarity of difference of slope. It is apparent from Curves II and III that the rate of oxidation is the same in the case of carbon disulfide and acetone and that it does not differ from the rate **when** bromobenzene alone is used. Curve I, on the other hand, representing the rate of oxidation in the presence of alkyl sulfides, has a much steeper slope than the other three, particularly during the first two-thirds of the reaction time.

Total Absorption.—Samples of hexaphenylethane in bromobenzene and in bromobenzene containing an equivalent amount of ethyl sulfide were prepared in the same manner as those used for the rate absorption measurements. These were placed in a glass-stoppered bottle which was connected to the mercury manometer of the previously used apparatus by means of a heavy-walled rubber tube. The bottle was shaken vigorously for five minutes. With the breaking of the sample tube the mercury rose immediately and at the end of five minutes the sample had absorbed from 11.2 to 11.3 cc. of oxygen, more than 10 cc. of this being absorbed in the first minute. At the end of the first minute the rate was very slow.

For three samples in bromobenzene only the absorption was: (a) 11.2, (b) 11.2, (c) 11.3; theoretical, 11.8. For three samples in bromobenzene containing ethyl sulfide: (a) 11.2, (b) 11.3, (c) 11.3.

Thermal Decomposition of the Addition Product.—A sample of hexaphenylethane dissolved in a large excess of methyl sulfide was heated in a sealed tube at 150° for eight hours. The resulting mixture was still yellow in color. Enough benzene was added to attain solution. Air was passed through the solution in order to convert any unchanged hexaphenylethane to the difficultly soluble peroxide. The small amount of solid resulting was separated by filtration. The filtrate was then evaporated and the solid residue was separated into several parts by fractional crystallization with petroleum ether and alcohol as solvents.

All of these fractions were solids or thick oils. Some contained sulfur and others did not. No attempt was made to carry out ultimate analyses since difficulties of purification and the probable slight variation in the composition of the hydrocarbons of high molecular weight made it extremely doubtful whether information could be obtained in this way. The fractions containing no sulfur showed, however, the general characteristics of hydrocarbons of the triphenyl paraffin class. They were extremely soluble in benzene, petroleum ether, chloroform, carbon tetrachloride, ether and acetone. They were slightly soluble in alcohol and could be recrystallized from this solvent. Concentrated solutions in benzene and petroleum ether showed a strong tendency to supercool and set to a hard, glassy mass without crystallizing. The solids were neither colored nor dissolved by concentrated cold sulfuric acid. Warm acid (80–90°) brought about partial solution and a slight coloring, but dilution of the mixture with water precipitated the substance unchanged.

The sulfur-containing solids were non-volatile and practically odorless; consequently the sulfur could not be present as originally in the molecule of the comparatively low-boiling alkyl sulfide. Attempts to recrystallize some of the sulfur-containing portions resulted in the appearance of the insoluble triphenylmethyl peroxide. This behavior is characteristic of sulfides and disulfides[22] containing triphenylmethyl groups. Also char-

---

[22] Blicke, This Journal, 45, 1965 (1923).

acteristic is the ready solubility and yellow to brown coloration in cold sulfuric acid. When the sulfuric acid solutions were warmed, alkyl mercaptans were evolved. The resulting solution when cooled, diluted and made alkaline yielded a solid precipitate which proved to be triphenylcarbinol.

$$(C_6H_5)_3C{-}S{-}R + H_2O\ (H_2SO_4) \longrightarrow (C_6H_5)_3C{-}OH + H{-}S{-}R$$

It seems certain, after consideration of the evidence, that our sulfur-containing products were of the triphenylmethyl alkyl sulfide class.[23]

The authors wish to express their appreciation for the suggestions offered by Professor L. W. Jones during the course of the investigation and also for the aid of the duPont Fellowship held by one of us during the latter part of the work.

Summary

1. Addition products of methyl, ethyl and propyl sulfides with hexaphenylethane have been prepared.
2. It has been found that the alkyl sulfides accelerate the rate of oxidation of hexaphenylethane in bromobenzene solution. This is apparently not so with carefully purified carbon disulfide and acetone, which also yield addition products with hexaphenylethane.
3. Observations have been made concerning the probable course of the thermal decomposition of the hexaphenylethane methyl sulfide addition product.

cases where the latter can be isolated, heating with acetic acid causes rearrangement. Auwers and Voss[4] isolated the hydrazones of cinnamic aldehyde and benzalacetone and found that they rearrange to the corresponding pyrazolines at higher temperatures or by heating with acetic acid. They concluded that phenylhydrazones from α,β-unsaturated ketones of the type R—CH=CH—CO—R′ can be isolated only when R is an aryl radical. Their failure to isolate the hydrazone of benzalacetophenone indicates that the stability of these products must be influenced also by the character of the radical R'. Its structure seems more important than its weight. When it is an aryl radical, hydroxyl and alkoxyl substituents favor rearrangement, while the nitro group stabilizes the hydrazone.[5] When halogen is present Straus[6] found that the closing of the pyrazoline ring occurs readily when the substituent is in either ketone or hydrazine residue. When both are substituted the hydrazone is quite stable and requires energetic treatment for rearrangement.

These conclusions are here questioned because the methods of preparation seem to be varied too much to permit a fair comparison of the products. In some cases the conditions were such that a hydrazone of this group might rearrange. In others the record does not include positive identification of the products.

In the present study the conclusion of Auwers and Voss that the "hydrazone of benzalacetophenone is so labile that it cannot be isolated, even at low temperature" was first tested. By conducting the experiment in glacial acetic acid solution at room temperature and also by following as carefully as possible the directions of Auwers and Voss, there was obtained a product that melted at 117–120°.[7] This substance was shown to be a hydrazone by examination of its reduction products,[8] and also by observing its direct rearrangement to 1,3,5-triphenylpyrazoline,[9] m. p. 135–136°.

To test the effect of substituents in the ketone and hydrazine residues, previously studied by Straus, and referred to above, attempts were made to prepare hydrazones containing some of the radicals mentioned by him. It will be shown below that in no instance was such a hydrazone isolated, but that in each of the five cases tested the corresponding pyrazoline was obtained.

Experimental Part

Methyl-3-bromo-4-acetylaminophenyl Ketone.—A solution of 2.6 cc. of bromine in 51.2 cc. of glacial acetic acid was dropped during twenty minutes into a solution of 5.12 g. of the acetylamino derivative in the volume of acid indicated above, to which an equal volume of water had been added,[10] while the whole was constantly shaken. After three and three-fourths hours this was poured with rapid stirring into 500 cc. of cold water containing about 1 g. of sodium bisulfite. Flocculent masses of fine needles separated and were removed. Addition of 100 cc. of concd. ammonia solution to the cold filtrate precipitated additional product; yield, 79%. Crystallization from alcohol gave leaflets; m. p. 138–138.5°.[11]

Anal. Subs., 0.5107, 0.2491: 19.79 cc. of 0.1 N $AgNO_3$, 12.4 cc. of N_2 at 20° and 746.5 mm. Calcd. for $C_{10}H_{10}O_2NBr$: Br, 31.25; N, 5.46. Found: 30.93, 5.63.

When the above-described product was refluxed for a few minutes with four times its weight of 6 *N* hydrochloric acid and the hot solution filtered through "Norit," crystals of the hydrochloride of the amino compound were deposited. These were suspended in water, an equal volume of ether was added and, after shaking, the lower layer made faintly alkaline, and extraction with ether completed. Treatment of the dried extract with hydrogen chloride precipitated nearly colorless needles; m. p. 155–156°.

Anal. Subs., 0.2500: 19.87 cc. of 0.1 N $AgNO_3$. Calcd. for $C_8H_9ONClBr$: halogen, 46.10. Found: 45.85.

Five g. of the above-described acetyl derivative was oxidized with potassium permanganate in the presence of magnesium sulfate, the mixture filtered, the filtrate evaporated to one-fourth its volume and acidified with concentrated hydrochloric acid. Crystals of 3-bromo-4-acetylaminobenzoic acid separated; yield, 83%. Crystallization from alcohol gave nearly colorless, long needles; m. p. 226–229°.

Anal. Subs., 0.5164: 20.08 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_9H_8O_3NBr$: Br. 31.00. Found: 31.06.

The same product was obtained in 70% yield by the oxidation of 3-bromo-4-acetylaminotoluene with potassium permanganate. Crystallization from alcohol gave long, colorless needles; m. p. 225–227°. Identity with the above-described product was proved by mixed melting point and analysis.[12]

Styryl-4-acetylaminophenyl Ketone.'—To a solution of 9.36 g. of methyl-4-acetylaminophenyl ketone in 100 cc. of alcohol there was added 5.84 cc. of benzaldehyde and then 11 cc. of 20% sodium hydroxide solution, with stirring. The mixture became orange colored and in ten minutes began to deposit flocculent masses of fine needles. Within two hours the mixture was nearly solid and after four and one-half hours the crystals were filtered off and washed with cold alcohol. When the filtrate was poured into 600 cc. of water a second portion of the product mixed with some resin sepa-

---

[10] Baeyer and Bloem [Ber., 17, 965 (1884)] obtained methyl-2-acetylamino-5-bromophenyl ketone by bromination in glacial or dilute acetic acid. With chloroform or sulfuric acid as solvent, bromine went into the methyl radical. In the present work an acetic acid solution of the 4-acetylamino derivative gave a good yield of methyl substituted product mixed with but small amounts of the nuclear compound.

[11] This product cannot possibly be identical with the isomeric bromo-aceto-acetanilide, m. p. 138°, reported by Knorr [*Ann.*, 236, 79 (1886)] and obtained by the action of bromine on the anilide of acetoacetic acid.

[12] It is of interest to note here that Friedländer, Bruckner and Deutsch, *Ann.*, 388, 30 (1912), found 224" for the melting point of 2-acetylamino-6-bromobenzoic acid. Our product cannot be identical with this.

rated.[13] Filtration of the hot alcoholic solution through "Norit," and cooling the filtrate gave yellow crystals; m. p. 160–161°.[14]

Anal. Subs., 0.5021: 18.77 cc. of 0.1 N HCl. Calcd. for $C_{17}H_{15}O_2N$: N, 5.28. Found: 5.23.

Styryl-3-bromo-4-aminophenyl Ketone.—To a mixture of 10 g. of the acetylaminobromophenyl ketone and 6.8 cc. (20% excess) of benzaldehyde in 100 cc. of alcohol, 10 cc, of 20% sodium hydroxide solution was added. The mixture became yellow immediately and red after standing a short time. After four hours the crystals that had formed were filtered off and the filtrate was treated as indicated above. The yield was nearly quantitative. Crystallization from alcohol gave fine, yellow needles; m. p. 146–147°.

Anal. Subs., 0.6807: 22.51 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{17}H_{14}O_2NBr$ and $C_{15}H_{12}ONBr$: Br, 23.22, 26.45. Found: 26.42.

Acetylation of the above product as directed by Sudborough[15] gave almost a quantitative yield of diacetyl derivative. Crystallization from alcohol gave colorless plates; m. p. 130–131°.

Anal. Subs., 0.6035: 15.77 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_{19}H_{16}O_3NBr$: Br, 20.72. Found: 20.87.

Styryl-3,5-dibromo-4-aminophenyl Ketone.—A solution of 2 g. of the required dibromo-amino-acetophenone[16] and 1.25 cc. (1.5 molecular proportions) of benzaldehyde in 175 cc. of alcohol was treated with 5 cc. of 20% sodium hydroxide solution and the mixture allowed to stand for twenty-four hours. After filtration to remove a small amount of flocculent material that had separated, a large amount of material crystallized promptly from the filtrate.[17] After an hour this was collected on a filter and the second filtrate diluted with 4 volumes of water as described above. The combined product was crystallized in cream-colored needles from a mixture of benzene and ligroin (60–70°); m. p. 133–134°.

Anal. Subs., 0.3734: 19.6 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{15}H_{11}ONBr_2$: Br. 41.99. Found: 41.94.

The above-described product was further identified by conversion into a diacetyl

---

[13] The total weight of material was more than that required by theory, and since the resin could not be separated alone, the yield of the ketone was not determined.

[14] Giua and Bagiellae, *Gazz. chim. ital.*, 51, II, 120 (1921), reported 154° as the melting point of this product in the crude form and 168° after crystallization. Although their analytical data agree with those required by this condensation product, the fact that they give 164–165° as the melting point of *p*-acetylaminoacetophenone, while the accepted value is 168°, suggests the possibility that the melting point they reported for the condensation product was actually made on the starting material. This explanation of the discrepancy is supported by their misinterpretation of the work of Rupe and Koschitz, Z. *Farben-ind.*, 5, 317 (1906), on the condensation of *p*-acetylaminobenzaldehyde with acetophenone and who reported 179° as the melting point of the product. Giua and Bagiellae objected to this on the erroneous assumption that the product had been obtained by the interaction of benzaldehyde and *p*-acetylaminoacetophenone.

[15] Sudborough, J. *Chem. Soc.*, 79, 533 (1901).

[16] Fuchs, *Monatsh.*, 36, 122 (1915).

[17] This behavior was noted in more than 20 different preparations of this material and seemed to be characteristic.

derivative in 90% yield by Blanksma's[18] method. Crystallization from alcohol gave yellow granules resembling sand; m. p. 173–174°.

Anal. Subs., 0.4209: 18.11 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{19}H_{15}O_3NBr_2$: Br, 34.40. Found: 34.37.

The Hydrazone of Styrylphenyl Ketone.—To a solution of 20 g. of benzalacetophenone in 100 cc. of glacial acetic acid, 9.5 cc. of phenylhydrazine was added gradually with shaking and the mixture allowed to stand. After about an hour[19] long, yellow crystals began to separate and for the next fifteen minutes crystallization was rapid; yield, 78%. Repeated crystallization from alcohol gave needles that melted at 117–120°.[20]

Anal. Subs., 0.2923: 19.52 cc. of 0.1 N HCl. Calcd. for $C_{21}H_{18}N_2$: N, 9.39. Found: 9.35.

Rearrangement to the Pyrazoline.[21]—Five g. of the hydrazone suspended in 25 cc. of glacial acetic was gently refluxed and the reddish-orange solution that resulted gradually faded to light yellow. After an hour, when the mixture was allowed to cool, it became an almost solid mass of yellow needles that melted at 135–136°.[22] Crystallization from alcohol caused no change; yield, 95%.

Reduction of the Hydrazone.—Ten g. of the hydrazone suspended in a mixture of 150 cc. of alcohol and 15 cc. of glacial acetic acid was reduced by sodium amalgam as directed by Tafel.[8] The resulting solution was poured off from the mercury, evaporated to half its volume, made strongly alkaline and distilled with steam. The distillate was rendered acid to methyl red and extracted with ether. From this extract aniline was isolated and identified as acetanilide. The aqueous residue was acidified with sulfuric acid and evaporated to dryness. The resulting solid was dissolved in water as far as possible, the liquid made alkaline and extracted with ether. From this dry extract gaseous hydrogen chloride precipitated α,γ-diphenyl-α-propylamine hydrochloride.[23] Crystallization from 6 *N* hydrochloric acid gave long, colorless needles; m. p. 195–195.5". It was further identified by the preparation of the picrate and the acid tartrate.[24]

This hydrazone was also obtained when the experiment was carried out as nearly as could be judged as directed by Auwers and Voss. Five g. of benzalacetophenone was dissolved in 40 cc. of alcohol; 2.38 cc. each of glacial acetic acid and phenylhydrazine were added and the mixture was allowed to stand at room temperature. After twenty-four hours an orange-colored oil had separated which crystallized in twenty-seven days. Filtration gave 2.3 g. of solid that, after recrystallization from alcohol, melted at 117–120°. This product was shown by mixed melting point to be identical with the hydrazone described above. Heating with acetic acid rearranged it to the pyrazoline; m. p. 135–136°.

---

[18] Blanksma, *Chem. Weekblad,* 6, 719 (1909).

[19] In this preparation it is necessary to remove the crystals within three hours after they begin to separate or they will be contaminated with the pyrazoline. The filtrate obtained at this point deposited a mixture of the hydrazone and pyrazoline.

[20] The failure to show a constant melting point suggests rearrangement as the heating proceeds.

[21] Though the pyrazoline had no noticeable effect on the skin, the hydrazone of benzalacetophenone exhibited severe vesicant action, producing chemical dermatitis.

[22] Knorr and Laubmann, ref. 9, found 134–135°.

[23] Excess of gas should be avoided since this appears to cause the hydrochloride of the amine to dissolve.

[24] Henrich, *Ann.,* 351, 180 (1907).

1,3-Diphenyl-5-(4-chlorophenyl)-pyrazoline.—To a solution of 20 g. of 4-chlorobenzalacetophenone[25] in 200 cc. of glacial acetic acid the theoretical amount of phenylhydrazine was added and the mixture allowed to stand for four days. The color darkened but no solid was deposited. The liquid was cooled until a part of the acid solidified, the mixture poured into a Büchner funnel and the acid allowed to melt and pass through the filter paper. No solid remained. Upon standing for an hour this filtrate deposited orange-colored needles; yield, 28% in eight hours. Crystallization from alcohol gave diamond-shaped plates; m. p. 129–130°.

Anal. Subs., 0.3587: 10.65 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_{21}H_{17}N_2Cl$: Cl, 10.67. Found: 10.54.

When 1.5 g. of the above-described material was boiled for one hour with 5 cc. of glacial acetic acid and the solution cooled, no crystals separated. Seeding caused deposition of 1.25 g. of unchanged starting material.

1,5-Diphenyl-3-(4-acetylaminophenyl)-pyrazoline.—Six cc. (20% excess) of phenylhydrazine was mixed gradually with a solution of 13.6 g. of styryl-4-acetylaminophenyl ketone in 75 cc. of glacial acetic acid and the mixture allowed to stand at room temperature for twenty-four hours. A reddish color was developed but no crystals were deposited. When the mixture was poured with stirring into 600 cc. of ice water, a yellow solid separated in nearly quantitative yield. Crystallization from alcohol gave fine, branched, hair-like, yellow needles; m. p. 241–242°. Separate portions boiled with acetic acid and treated with sodium amalgam, respectively, suffered no change.

Anal. Subs., 0.2323: 19.48 cc. of 0.1 N HCl. Calcd. for $C_{23}H_{21}ON_3$: N, 11.83. Found: 11.74.

1,5-Diphenyl-3-(3-bromo-4-aminophenyl)-pyrazoline.—Slightly more than the theoretical amount of phenylhydrazine was gradually added with shaking to a solution of 7.77 g. of the required ketone dissolved in 50 cc. of glacial acetic acid. After one and three-fourth hours "burrs" of crystals appeared on the surface of the liquid. During the next four hours 4.5 g. of orange-colored crystals deposited and were removed. On standing overnight, the filtrate deposited 2.6 g. more of the same material. Crystallization from alcohol gave cream-colored needles; m. p. 200.5°. The product was not affected by boiling acetic acid or by sodium amalgam.

Anal. Subs., 0.5221: 13.35 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{21}H_{18}N_3Br$: Br. 20.40. Found: 20.43.

1,5-Diphenyl-3-(3,5-dibromo-4-aminophenyl)-pyrazoline.—Ten g. of the required ketone dissolved in 25 cc. of acetic acid was treated with 2.8 cc. of phenylhydrazine and the mixture allowed to stand at room temperature. After two days 6.17 g. of orange-colored solid had separated. After removal of this the filtrate deposited more on standing; yield, 72%. Crystallization from alcohol or benzene gave orange needles; m. p. 180–181°. The product could be neither rearranged nor reduced.

Anal. Subs., 0.1716: 7.34 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{21}H_{17}N_3Br_2$: Br, 33.97. Found: 34.37.

---

[25] Obtained in 85% yield from Eastman's *p*-chlorobenzaldehyde by Walther and Raetze's method [*J. prakt. Chem.*, 65, 280 (1902)). The rate of this condensation was very rapid. Under the conditions, the action of unsubstituted benzaldehyde on acetophenone required two to three hours with efficient stirring; the p-chloro derivative condensed within one minute. The previous authors reported 103–104° as the melting point of the product, while 113–114° was found in this work. The purity of the material here in question was checked by analysis.

Anal. Subs., 0.4515: 18.55 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{15}H_{11}OCl$: Cl, 14.62. Found: 14.57.

1-(*p*-Bromophenyl)-3-phenyl-5-(p-chlorophenyl)-pyrazoline.—The theoretical amount of 4-bromophenylhydrazine in acetic acid was added to a warm solution of *p*-chlorobenzylidene-acetophenone. The crystals that separated during the first few hours turned out to be *p*-bromophenylhydrazine. The filtrate, which was nearly black by reflected light, gave a 31% yield of pyrazoline on standing for twenty-four hours longer. Fine, cream-colored crystals were obtained by crystallization from alcohol; m. p. 142–143°. The product was not affected by boiling acetic acid or by sodium amalgam, which indicated that it was not a hydrazone.

Anal. Subs., 0.4104: 19.85 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{21}H_{16}N_2ClBr$: halogen, 28.06. Found: 27.90.

Summary

1. A method has been described for the preparation of methyl-3-bromo-4-acetylaminophenylketone and its structure has been established.
2. A condensation product from phenylhydrazine and benzalacetophenone different from that reported by Auwers and Voss has been obtained. Its behavior toward sodium amalgam and its rearrangement when heated with acetic acid show that it is a hydrazone.
3. A number of new halogen substitution products of 1,3,5-triphenylpyrazoline have been obtained. In the preparation of these compounds we have been unable, thus far, to confirm Straus' conclusion that the presence of halogen substituents in all three of the phenyl radicals of the hydrazone of benzalacetophenone stabilizes the compound. Further study is in progress in which it is hoped to test the effect of molecular symmetry of the ketone in this rearrangement.

THE EFFECT OF CERTAIN BETA SUBSTITUENTS IN THE ALCOHOL UPON AFFINITY AND REACTIVITY IN ACETAL FORMATION

BY JOHN N. STREET AND HOMER ADKINS

RECEIVED AUGUST 13, 1927 PUBLISHED JANUARY 5, 1928

The study of the relations of the structure of the alcohol and aldehyde to the affinity and reactivity manifested in acetal formation has been continued by determining the location of the equilibrium point of the reaction of acetaldehyde with various alcohols which may be regarded as β substitution products of ethanol. The type reaction may be represented as follows

$$CH_3CHO + 2RCH_2CH_2OH \rightleftharpoons CH_3CH(OCH_2CH_2R)_2 + H_2O$$

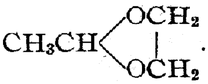
The β substituents used were the chloro, bromo, iodo, ethoxy, methoxy, methylene, carbethoxy, amine hydrochloride and nitro groups.

The methods of experimentation and the concentrations of reactants were essentially the same as those previously described.[1,2] The equilibrium points were determined from both sides in the case of the three halohydrins, phenylethanol and methoxy- and ethoxy-ethanols.

The Seyewetz-Bardin sulfite method was in most cases used for the determination of acetaldehyde. The hydrogen peroxide method was used in some instances. It was necessary to introduce a correction factor in the case of the halohydrins which hydrolyzed slowly during the titration.

In the case of amino-ethanol, acetal formation cannot **take** place in the usual way as the amino group reacts with the aldehyde. The acetal reaction must consequently be carried out with a salt of the amine. The hydrochloride is insoluble in most organic solvents so that the reaction must be allowed to occur in a water solution. The solution of the amine in water was made slightly acid with hydrogen chloride, the aldehyde added at 0° and the reaction allowed to proceed at room temperatures for a week. A sample of the reaction mixture was rendered just alkaline to phenolphthalein and then added to a sulfite solution and titrated in the usual way. The end-point is not clear. The hydrogen peroxide method was also used for the determination of the aldehyde. The results obtained were in good agreement with those obtained by the sulfite method. The reaction of ethanol and acetaldehyde was run under conditions similar to those used for amino-ethanol. The equilibrium constant found was 0.0618 instead of 0.0744 as found using 1 mole of alcohol and 0.091 mole of aldehyde.

An attempt was made to prepare β,β′-hydroxydiethylacetal, $CH_3CH(OCH_2CH_2OH)_2$, by the reaction of acetaldehyde and ethylene glycol. However, even when two moles of the glycol were used with one mole of acetaldehyde, there was a good yield of ethylene acetal



$$CH_3CH\left\langle\begin{array}{l}OCH_2\\ \;|\\ OCH_2\end{array}\right..$$

Attempts to use the sulfite, the hydrogen peroxide and the Hartung colorimetric method were alike unsuccessful in determining acetaldehyde or water in the presence of nitro-ethanol. The amount of acetal that could be isolated from a reaction mixture of two moles of nitro-ethanol and one of acetaldehyde was determined and the equilibrium constant calculated from this. A mixture of 1 mole of nitro-ethanol and 0.091 mole of acetaldehyde was made and allowed to stand for two weeks. A sample of the reaction mixture was poured into a solution of sodium ethoxide to prevent further acetal formation or hydrolysis. The aldehyde present was then removed by distillation, collected and titrated. An equilibrium constant was calculated on the basis of the amount found. This value (0.0403) was too high because it was impracticable to collect all-of

the aldehyde. The value calculated from the amount of nitro-ethyl acetal isolated (0.0119) was too low because of losses of the acetal. The true value lies between these limits.

The methods used in the preparation of the reagents and their boiling points are given in Table I and the footnotes. Five acetals not hitherto prepared were obtained using the standard methods of preparation. The boiling points and the analytical data for these compounds are given in Table II.

TABLE I

THE METHODS OF PREPARATION AND PURITY OF REAGENTS

Compound	Boiling point
Ethylene chlorohydrin[n]	43° (3–4 mm.)
Ethylene bromohydrin[b]	56–57° (20 mm.)
Ethylene iodohydrin[c]	86–87' (25 mm.)
β-Ethoxy-ethanol[d]	134' (740 mm.)
β-Methoxy-ethanol[d]	124° (740 mm.)
β-Phenylethanol[e]	99–100° (10 mm.)
Ethyl hydracrylate[f]	94–95° (22 mm.)
β-Amino-ethanol	121° (740 mm.)
β-Nitro-ethanol[g]	......
Propanol	96.0–96.1° (740 mm.)
Acetaldehyde[h]	21–22' (740 mm.)

[a] Commercial ethylene chlorohydrin was dried for several days over anhydrous potassium carbonate and distilled under a pressure of 3-4 mm. at 43°. The samples used for reaction with aldehyde gave no precipitate with a 10% solution of silver nitrate, no color with copper sulfate and only a trace of acidity.

[b] Read and Williams, *J. Chem. Soc.*, **111, 240 (1917)**; Read and Hook, *ibid.*, **117, 121 (1920).**

[c] Henry, *Bull. acad.* roy. *Belg.*, [3] *28*, **182 (1889)**; Wieland and Sakellarios, *Ber.*, **53B, 201 (1920).** It was found advantageous to cut the time of refluxing from 24 to 4 hours, a yield of 85–90% being obtained.

[d] Cretcher and Pittenger, THIS JOURNAL, **46,1505 (1924).**

[e] β-Phenylethanol from a commercial source was kept over solid oxalic acid for several days and then distilled. Later it was dried over lime and again distilled.

[f] Drushel and Holden, *Am. J. Sci.*, **40, 511 (1915).** Drushel and Holden report that the ester prepared from β-iodopropionic acid has a b. p. at 22 mm. of 95.5". The hydracrylic acid was prepared by the hydrolysis of ethylene cyanohydrin. [Erlenmeyer, *Ann.*, **191,268 (1878).**] After filtering off the ammonium chloride, the solution was neutralized with sodium hydroxide, evaporated to dryness and the sodium hydracrylate extracted with absolute alcohol. The salt was recrystallized once from alcohol, dissolved in alcohol and enough of an alcoholic solution of hydrogen chloride added to precipitate 90% of the sodium. The esterification was then carried out using copper sulfate (free of sulfur trioxide) as a catalyst.

		...	...[c]	(.0119)	2600

[a] 0.335 mole of amino-ethanol, 1.242 moles of water and 0.0955 mole of aldehyde showed 21.8% conversion to acetal in a volume of 54.25 cc.

[b] One mole of the alcohol and 0.091 mole of acetaldehyde showed the per cent. conversion indicated, in the volume given in the preceding column. The per cent. conversion given in the table is the average of from four to seven determinations, including in most cases synthetic and hydrolytic experiments. The individual determinations were within 0.5% of the average.

[c] 0.0505 mole of the acetal was isolated from 0.288 mole of nitro-ethanol and 0.273 mole of acetaldehyde.

stants and increasing values for —RT ln K. There have been included in the table for the sake of comparison the redetermined values for butanol, propanol, ethanol and phenylethanol. (The authors are indebted to Mr. A. E. Broderick for the values for butanol and ethanol.) It is believed that the values of —RT ln K given in the table are accurate to within plus or minus 50 units for all except the first and last alcohols given. Since it was necessary to treat the hydrochloride of β-amino-ethanol with acetaldehyde in a water solution the conditions of this reaction are not directly comparable with the others given in the table. The values given for P-nitro-ethanol are, at best, approximations.

Certain relations become obvious from a consideration of the values given in the table and a comparison of them with previously published values. The order of the halogens, when substituted in the beta position in ethanol, in decreasing affinity for the acetal reaction is the usual one of iodine, bromine and chlorine. However, iodine is more "positive" than is hydrogen in this case for the value of $-RT \ln K$ is 153 units less than for the unsubstituted ethanol. However, ethylene bromohydrin shows a decrease in affinity as compared with ethanol. Hartung showed that the substitution of bromine in acetaldehyde increased affinity for the acetal reaction. The substitution of ethyl, phenyl or methyl groups in the beta position in ethanol increases affinity for acetal formation. The ethoxy group increases affinity by 144 units while the methoxy group has little or no effect.

Hartung showed that the substitution of the methylene group in acetaldehyde (acrolein) decreased the affinity by about 1700 units. In contrast with this is the fact that the substitution of the methylene group in the alcohol (allyl alcohol) has relatively little effect, only lowering affinity by about 100 units.

The carbethoxy group is quite effective in decreasing affinity, the substitution of this group for a beta hydrogen in ethanol lowering affinity by 860 units.

In general it may be said that substitution in the beta position of ethanol has relatively little effect upon affinity for acetal formation. The effect is only a small fraction of what it would be if the substitution were made on the alpha carbon atom and is in the opposite direction in some cases, as, for example, in the case of phenyl and methyl substitution.

It was not possible to obtain any quantitative data upon the relative reactivities of the alcohols studied. In the case of the halohydrins and the ethyl hydracrylate the amount of catalyst present is modified by the small amount of hydrolysis that takes place. The purest samples of the halohydrins obtainable contain, or soon acquire, a concentration of halogen acid which is several times the very small amounts necessary to catalyze the acetal reaction. The methoxy-ethanol and ethylene chlorohydrin showed about 40% reaction of the acetaldehyde in thirty minutes while the n-propyl and phenylethyl alcohols showed a little less than 30% in the same interval. The reactions went from 85 to 90% to completion after several hours. Ethoxy-ethanol was a little slower, while allyl alcohol showed less than 20% reaction in the first thirty minutes. This is rather remarkable since the presence of a double bond in the aldehyde greatly increases reactivity. In general it may be said that the compounds whose **rates** were followed showed no great differences such as one would find in comparing acetaldehyde and benzaldehyde, for example. The greatest difference in reactivity was between the allyl alcohol and the others investigated.

summary

The equilibrium points in the reaction of 8-amino-ethanol, β-phenylethanol, ethylene iodohydrin, β-ethoxy-ethanol, β-methoxy-ethanol, allyl alcohol, ethylene bromohydrin, ethylene chlorohydrin, ethyl hydracrylate and 8-nitro-ethanol with acetaldehyde have been determined. Certain relationships have been pointed out as existing between the constitution of an alcohol and the affinity and reactivity that it manifests in acetal formation. Five acetals not hitherto prepared were obtained.

THE ELECTRON-SHARING ABILITY OF ORGANIC RADICALS—GLUCOSE AND OTHER POLY-ALCOHOLS

BY JAMES B. ALLISON WITH R. M. HIXON

RECEIVED AUGUST 20, 1927 PUBLISHED JANUARY 5, 1928

A preceding paper[1] pointed out that the physical properties of the polar groupings RNH_2, RCOOH, RCH_2COOH, RCH_2CH_2COOH and ROH could be expressed as an exponential function of "the electron-sharing ability" of "R." A strict interpretation of these data implies that the electron-sharing ability of the carbon radicals varies from a range more "positive" than hydrogen to a range more "negative" than chlorine, according to the substituents of the carbon under consideration. When the composition of the radicals is considered in the order of their "negativity," it is found that the typical aromatic groupings are intermediate to the most "positive" and most "negative" of the aliphatic radicals. In other words, we may expect to find carbons in "aliphatic" compounds with properties as negative, or even more negative, than those in "aromatic" structures.

In a previous paper[2] attention was called to the negative nature of the third carbon atom in diacetoneglucose on the following evidence.

1. The chlorine in 3-chlorodiacetoneglucose is relatively stable toward alkaline hydrolysis.

2. When diacetoneglucosetoluenesulfonate ester is treated with Grignard's reagent, *p*-tolylphenylsulfone is obtained in analogy with the aromatic sulfonate esters rather than the aliphatic esters.[3]

---

[1] Hixon and Johns, THIS JOURNAL, **49, 1786 (1927).**

[2] Allison and Hixon, *ibid.*, **48, 406** (1926).

[3] Gilman, Robinson and Beaber, *ibid.*, **48, 2715 (1926).**

3. When the sulfonate ester of diacetoneglucose is treated with hydrazine, dehydration as well as substitution takes place, which is analogous to the terpene sulfonate reaction.

The physical data presented in the following paper have been assembled in order to substantiate these qualitative observations and to correlate the chemical properties of the carbohydrate carbons with the properties of the more familiar "aliphatic" and "aromatic" carbons. These data indicate that the "electron-sharingability" of the carbons in the aliphatic poly-alcohols is intermediate to that of the alkyl and phenyl radical. This paper also indicates an experimental method of approach for the study of the affinity of particular carbons in complex structures such as glucose.

Acid dissociation constants for the hexoses have been measured by Osaka,[4] Madsen[5], Euler[6] and Michaelis and Rona[7] by the cryoscopic, saponification and electrode methods. These authors all agree in reporting values of a magnitude of $Ka = 10^{-13}$ for fructose, glucose and sucrose. The dissociation constant for ethyl alcohol is less than 10^{-15} and for phenol 10^{-11}. Madsen by means of the van't Hoff equation calculates the heat of neutralization for these three sugars and finds them to be respectively about 50, 35 and 25% that of the strong acids.

While these measurements are indicative of the semi-phenolic, semi-aliphatic nature of the carbohydrates they must be considered with the following two reservations.

(a) Values of the same magnitude have been reported for some of the aliphatic aldehydes and accordingly these values might be assigned to the hexose aldehydic or ketonic group. Such an explanation could not, however, be applied to sucrose.

(b) Since there are a large number of hydroxy groups, these values might be considered as the sum of many weaker dissociations.

The heat of the replacement of hydrogen by sodium in the general reaction

$$\mathrm{ROH} + \mathrm{Na} \longrightarrow \mathrm{RONa} + {}^1/_2\,\mathrm{H_2} + \text{heat}$$

may also be used as a comparative index of the degree of "acidity" of the hydrogen. Since R is the only variable in the reaction, this gradation must be explained as a function of the electron-sharing ability of R. A series of hydroxides is given in Table I in the order of the magnitude of the heat of this reaction, grading from the strong base sodium hydroxide to sulfuric acid. The values for the poly-alcohols have been taken from de Forcrand's[8] work; the other data are either taken directly or calculated from values given in Landolt-Börnstein.

TABLE I

HEAT OF REPLACEMENT OF HYDROGEN BY SODIUM

Sodium hydroxide	**2.0**	**Mannitol, average value**	**34.82**
Aluminum hydroxide	**27.0**	**Erythrite, average value**	**38 14**
Tertiary alcohol, average value	**27.89**	**Glycerol, average value**	**39.99**
Secondary alcohol, average value	**29.75**	**Phenol**	**39.10**
Primary alcohol, average value	**32.00**	**Acetic acid**	**50.17**
Water	**31.87**	**Sulfuric acid**	**68.00**

Attention should be called to the fact that these values indicate that the sugar alcohol groups and other poly-alcohols are almost as negative as phenol itself.

Dissociation Constant of **Glucosamine.**—The values given above cannot be localized for any particular carbon. From the variation in the reactivity of the various halides, it seems probable that there is a marked difference in the affinity of the various carbons in the glucose chain. It should be possible to measure the electron-sharing ability of any of these carbons by replacing the particular hydroxy group by more polar groups such as the amino or carboxy group. The conductivity of the free hydroxy groups is so small (10^{-13}) that it can be ignored for values of strongly polar groups. If trouble is encountered due to the hydroxy groups, they can be easily muzzled by methylation.

Vellinger[9] has reported the value $pK_b = 6.34$ for glucosamine, which gives the value 4.6×10^{-7} for the basic dissociation constant. This value was obtained by potentiometric measurements in connection with a study of the relationship of rotation to acidity of the solution. This value has been confirmed by conductivity measurements in this Laboratory.

Glucosamine was prepared from the hydrochloride salt by the method of Breuer.[10] It was recrystallized several times from methyl alcohol and checked for purity by Dumas nitrogen analysis and by direct titration. The melting point was indefinite, as reported in the literature, depending upon rate of heating. As the amine was repeatedly recrystallized the melting point was raised from 105–110° as reported to 125–130°. Conductivities of three separate preparations are reported in Table II. The value of μ_0 has been obtained by Washburn's[11] method of extrapolation and is an approximation at best.' A comparison of the basic properties of glucosamine with those of ammonia and hydrazine is shown graphically in Fig. I, data for the latter being taken from Bredig.[12]

When this value for the dissociation constant of glucosamine is compared with the list presented in the previous mathematical treatment,' it shows

that the "electron-sharing ability" of this particular carbon in the glucose chain is almost exactly intermediate to that of the methyl and phenyl radicals, respectively. As in the previous paper mechanical concepts of valence have been intentionally avoided. The conclusions rest on the assumption that, whatever the mechanistic cause of the conductance, the

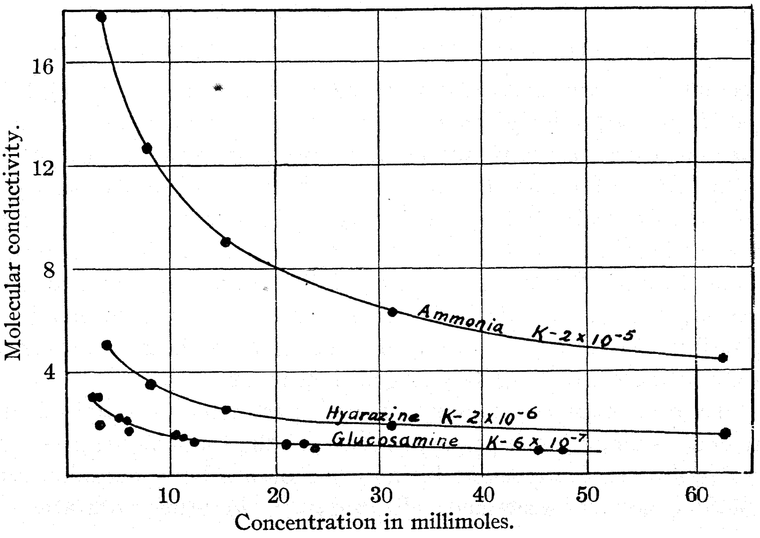

Fig. 1.—Molecular conductivities of ammonia, hydrazine and glucosamine.

magnitude is a function of the "electron-sharing ability" of the radical linked to the amine group.

Summary

It is pointed out that the electron-sharing ability of the aliphatic carbon radicals varies over a range extending from values more positive than hydrogen to values more negative than chlorine. The available physical data have been assembled to show the position of glucose (and other polyalcohols) among the more familiar aliphatic and aromatic radicals. These data agree in showing the intermediate position of this group of compounds as summarized in the following figures.

Nature of radical	Dissoc. const. of amine	Dissoc. of hydroxide	Heat replacement of H by Ma
Methyl-	5×10^{-4}	10^{-15}	32
2-Glucosyl-	6×10^{-7}	10^{-13}	37
Phenyl-	4×10^{-10}	10^{-11}	39

STUDIES ON THE PREPARATION OF THE HIGHER ACETYLENES. I. (PRELIMINARY PAPER.) DEHALOGENATION OF 1,1-DICHLOROHEPTANE IN THE VAPOR PHASE

BY ARTHUR J. HILL AND FLOYD TYSON

RECEIVED AUGUST 25, 1927 PUBLISHED JANUARY 5, 1928

Acetylenes, more particularly those of the normal, or alpha type, $RC\equiv CH$, are peculiarly reactive and in consequence may be used for the preparation of many interesting and important types of organic compounds. Unfortunately, however, their applicability in synthetic work is rather restricted because of the difficulty of preparing many of the a-acetylenes in quantity and in a state of purity. The usual methods of preparation involve dehalogenation of dihalides, or olefinic monohalides, with solid, aqueous or alcoholic alkalies, alcoholic sodium ethylate, metallic sodium, sodium amide and, in a few cases, soda lime,[1] magnesium,[2] zinc dust and alcohol[3a] and the Grignard Reagent.[3b]

Failure to obtain satisfactory yields, apart from incomplete removal of halogen, is usually due to one, at least, of the following causes, namely, *(a)* molecular rearrangement by aqueous or alcoholic alkaline reagents to diolefins and iso-acetylenes ($RC\equiv CR$); *(b)* ether formation, when alcoholic alkalies are employed; (c) polymerization. The use of sodium

---

[1] Peratoner, *Chem. Zentr.*, 1892, II, 737.

[2] Porcher, *Bull. soc. chim.*, [4] 31, 334 (1922).

[3] (a) Lespieau, *Compt. rend.*, 170, 1584 *(1920)*; (b) 171, 111 (1920).

amide[4] in dehalogenation practice constitutes an important advance in the preparation of a-acetylenes. Thus, like sodium, it is stated to effect the isomerization of an *iso-* to an a-acetylene; as a function of this property, a minimum of iso-acetylene is apparently produced when sodium amide is used to dehalogenate a given halide.

Vapor phase dehalogenation of dihalides has apparently received but little attention, except in connection with the preparation of certain 1,3-diolefins used in the preparation of synthetic rubber. The present investigation (the first of the series) has involved a study of the dehalogenation of 1,l-dichloroheptane[5] (I), $CH_3(CH_2)_5CHCl_2$, in the vapor phase. Halides of this type, in consideration of their constitution, should theoretically undergo dehalogenation with the formation of a larger amount of the a-acetylene and a smaller amount of diolefinic and iso-acetylenic isomers than 1,2-dihalides. Moreover, in view of the fact that dry alkalies are stated not to have the rearranging effect[6] of aqueous or alcoholic alkalies, dehalogenation of dichloroheptane in the vapor phase over soda lime should give a reaction product containing a preponderance of the normal acetylene, 1-heptine (11), ($CH_3(CH_2)_4C{\equiv}CH$).

The writers have passed dichloroheptane over soda lime in an electrically heated iron tube (see Fig. 1). Temperatures below 360° were found to be unsatisfactory because dehalogenation was incomplete, whereas above 430° extensive decomposition took place. The yield of normal heptine was never above 30% of the unsaturated compounds constituting the reaction product. The isomerization of α-heptine was apparently affected but slightly by temperature changes between 360 and 420°. At 420° the normal acetylene content of the reaction product was 28% (10% calculated from dichloroheptane), while at 360° the yield was 25% (6% calculated from dichloroheptane). Losses through decomposition and polymerization were also large. The fact that the a-acetylene constituted so small a portion of the unsaturated distillate indicated extensive molecular rearrangement, unless 1-heptine is far more susceptible to polymerization or decomposition than its isomers. Certainly the **P-**acetylene, and other unsaturated compounds derived from the initially formed a-acetylene, were decidedly in predominance in the reaction product.

Variations in the composition of the soda lime did not appreciably affect isomerization. This was decidedly advantageous in view of the fact that soda lime containing 25% of sodium hydroxide was less efficient as a dehalogenating agent than that containing 50% of the alkali. So

---

[4] Among others, see Bourguel, Ann. *chim.*, 10, 191,325 (1925).

[5] Dichloroheptane, rather than a lower homolog, was chosen for this preliminary investigation by reason of the accessibility of the corresponding aldehyde and the fact that the derived acetylenes, being oils, were easily handled.

[6] Faworsky, J. *prakt. Chem.*, 37,382,417,531 (1888).

far, then, as rearrangement phenomena are concerned, the vapor phase procedure does not appear to give results very different from those obtained by the employment of alkaline solutions.

A pyrogenetic dehalogenation of the dichloride at 470° over aluminum silicate effected almost complete decomposition and the yield of α-acetylene was very small—less than 2%.

Experimental Part

1,1-Dichloroheptane.—Although dichloroheptane has found fairly extensive use, there is insufficient detailed information regarding its preparation from heptaldehyde[7] and phosphorus pentachloride. In order that large quantities of the dichloride might be employed, and suitable technique developed for the preparation of other similarly constituted dihalides, a number of experiments were carried out to determine conditions most favorable for its preparation.

The chief loss in the preparation of dichloroheptane is due to polymerization of the aldehyde by the acidic reaction mixture. To obviate this effect to some degree, the writers found it necessary to use a solvent and stir rapidly in order to effect immediate dispersion of the aldehyde. The most favorable temperature was 20°; above this temperature the residual material, after distillation, increased very appreciably, and at 65° polymerization had increased to such an extent that the yield was approximately one quarter that obtained at 20°. Amounts of phosphorus pentachloride above or below $1-1^1/_4$ molecular equivalents were not as effective as the latter figures. Some loss is also incurred by the formation of chloroheptene.[8] A serious factor also to be reckoned with is the purity of the phosphorus pentachloride. Erratic and unsatisfactory results, characterized by excessive polymerization, were often obtained when other than fresh samples of phosphorus pentachloride were used. Although the best yield under optimum conditions was 70%, this was not as readily achieved when large quantities of the aldehyde were used.

Apparatus—A wide-mouthed flask equipped with dropping funnel, the stem of which reaches below the surface of the liquid; a thermometer with bulb in the reaction mixture, and a mercury-sealed stirrer capable of rapid rotation.

Procedure.—25 g. of heptaldehyde was added, during forty-five minutes, to a suspension of 45 g. of phosphorus pentachloride in 15 g. of benzene. The temperature was not allowed to rise above 20°. After addition of the aldehyde, the mixture stood at 25° for several hours (it may be allowed to stand overnight). Throughout the experiment the liquid remained light yellow in color. The phosphorus oxychloride was removed by adding ice to the reaction mixture and the dichloride extracted with benzene, washed with sodium carbonate, and dried over sodium sulfate. Distillation at 40 mm.

---

[7] The writers are greatly indebted to Dr. Herbert Guest of the J. B. Williams Company, Glastonbury, Conu., who kindly furnished the heptaldehyde used in this investigation.

[8] Cf. Bourguel, *Compt.* rend., 177, 823 (1923).

gave 28 g. of crude dichloroheptane boiling at 75–100° (b. p. 82–84" at 30 mm.). The residue was 11.2 g.

As stated in the introduction, the yields with larger quantities are liable to be lower. The following is a typical run in which 100 g. of heptaldehyde was used, Fraction 3 being practically pure dichloroheptane.

Fraction 1	50–70° (30 mm.)	= 5 g.
Fraction 2	70–80° (30 mm.)	= 5 g.
Fraction 3	80–100° (30 mm.)	= 73 g.
Fraction 4	100–115° (30 mm.)	= 5 g.
Fraction 5	115–140° (30 mm.)	= 11 g.

1-Heptine.—The soda lime used in these experiments was prepared by adding the desired amount of pulverized quicklime to molten sodium hydroxide at 900–1100°. The fused mass, after cooling, was crushed to 6 to 12 mesh.

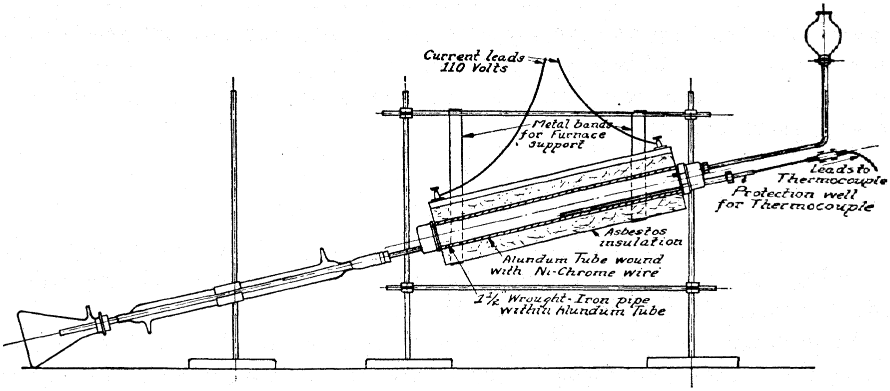

Fig. 1.—Electric furnace for dehalogenation experiments with soda lime.

The reactions were carried out in an electrically heated iron tube which is illustrated above (Fig. 1).

The accompanying chart gives a résumé of some typical experiments with this apparatus. Fresh soda lime was used in each experiment. This precaution appeared necessary for after each run, in which 100 g. or more of dichloroheptane was used, there was an appreciable deposit of carbon.

TABLE I

THE ACTION OF SODA LIME ON DICHLOROHEPTANE

Expt. no.	Dichloroheptane, g.	Soda lime, g.	Temp., °C.	Fraction to 116°, g.	1-Heptine in 116° fraction, %	Yield of 1-heptine calcd. from dichloroheptane, %
1	100	350 (50% NaOH)	360	11.3	30	6
2	150	300 (50% NaOH)	400	31.6	14	5
3	100	300 (50% NaOH)	420	21.0	28	10
4	30	250 (50% NaOH)	430	14.0	7	6
5	100	350 (25% NaOH)	410	13.4	25	6
6	100	300 (Aluminum silicate)	470	8.7	14	2

The conditions represented by Expt. 3 were found in general to be the most favorable. The distillation figures in experiments of this type were usually of the following order:

Fraction 1	80–90°	0.7 g.	Fraction 4	116–150°	4.7 g.
Fraction 2	90–100"	2.3 g.	Fraction 5	150–180°	16.2 g.
Fraction 3	100–116°	18.0 g.	**Residue**	....	3.5 g.

The isomeric heptines, alpha, or 1-heptine, and beta, or 2-heptine, boil at 99–100° and 111–113°, respectively. In consequence, the distillates up to 116° contained the isomeric acetylenes; these were analyzed for 1-heptine as described below. The acetylene distillates were halogen free, or at most contained but a trace of chlorine.

In Expt. 6 the furnace was charged with aluminum silicate in the form of porous cylindrical sticks, $^1/_2''$ long by $^1/_4''$ in diameter. Throughout this run copious fumes of hydrogen chloride issued from the furnace and decomposition was very pronounced. All fractions contained chlorine, hence the analyses were not wholly accurate. The data obtained, however, indicated very small amounts of 1-heptine. A typical distillation is given below:

Fraction 1	Up to 116°	8.7 g.
Fraction 2	116–150°	12.0 g.
Fraction 3	150–200°	9.4 g.

The experiment demonstrated the impracticability of pyrogenetic dehalogenation without the use of some acceptor for the hydrogen chloride resulting from the thermal dissociation.

Procedure for the Determination of **1-Heptine.**—In order to determine the a-acetylene formed in each experiment, two methods of analysis were employed, namely, (a) precipitation with ammoniacal cuprous chloride and (b) precipitation with an alcoholic silver nitrate solution. The former was carried out by agitating the heptine-containing oil with ammoniacal cuprous chloride for six hours. The yellow copper salt was filtered, washed with ether, and dried and weighed as $CuC\equiv C(CH_2)_4CH_3$. The rate of precipitation was slow and greatly affected by the concentration of ammonia. With strong solutions it was decidedly incomplete. The slowness of precipitation of the copper salt and the consequent inaccuracies led the writers to place greater reliance on the silver nitrate method.

Silver Nitrate Procedure.—This method, first introduced by Behal,[9] is based on the insolubility of the salts of the formula $RC\equiv CAg.AgNO_3$, formed in accordance with the following equation

$$CH_3(CH_2)_4C\equiv CH + 2AgNO_3 = CH_3(CH_2)_4C\equiv CAg.AgNO_3 + HNO_3$$

A *5%* solution of silver nitrate in 95% alcohol was used by the writers. A few preliminary experiments showed that a moderate excess of silver nitrate did not affect the analytical results.

---

[9] Behal, *Ann. chim. phys.*, [6] 15, 424 (1888).

To carry out an analysis, 0.5 g. of the heptine-containing oil was placed in an excess of the silver nitrate solution. Precipitation of the fine, white crystalline salt took place immediately, but the mixture was usually allowed to stand for six hours before filtration. At this point two procedures were followed. One method was to filter the precipitate upon a weighed Gooch crucible. It was then washed thoroughly with alcohol and dried at 60°. The other procedure consisted in titrating the nitric acid liberated by the formation of the silver salt. In this case the precipitate was first filtered and washed. The united filtrates were then diluted with water to about 300 cc. and the excess silver precipitated by the addition of pure sodium chloride. The nitric acid was then titrated with sodium hydroxide, phenolphthalein being used as an indicator. The titration procedure was utilized in this investigation, since the gravimetric method gave results 2–3% higher than the former method, probably because of adsorption of silver and the retention of moisture. The salt decomposed slowly above 100°, so that thorough drying at atmospheric pressures was impracticable.

Summary

1. Dichloroheptane has been passed over soda lime at various temperatures in an electrically heated tube and the 1-heptine content of the reaction products determined by the silver nitrate method.
2. The yield of 1-heptine was small on account of molecular rearrangement, polymerization reactions and decomposition resulting from the employment of high temperatures necessary to effect dehalogenation.
3. The extent of molecular rearrangement by this method, contrary to previous views on the effect of dry alkalies, is apparently quite comparable to that resulting from the use of alkali solutions.
4. A procedure for the preparation of 1,1-dichloroheptane is described.

NEW HAVEN, CONNECTICUT

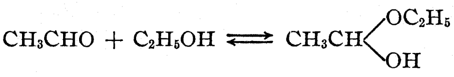
THE RATE OF SYNTHESIS AND HYDROLYSIS OF CERTAIN ACETALS

BY HOMER ADKINS AND A. E. BRODERICK

RECEIVED AUGUST 27, 1927 PUBLISHED JANUARY 5, 1928

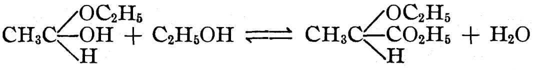
In a previous publication upon the relationship of the structure of alcohols and aldehydes to their reactivity in acetal formation,[1] a comparison of the rates of reaction was made upon the basis of "velocity constants" calculated according to the equation $k = \frac{2.302}{(a_e - b_e)t} \log \frac{(a_e - x)b_e}{(b_e - x)a_e}$, where a, and b_e represented the concentration of alcohol and aldehyde, respectively, at equilibrium and x the change in aldehyde concentration in time, t. As pointed out by the authors,[2] this empirical expression of Muller's has no justification except in the fact that for the first hour of the reaction fairly consistent "constants" are obtained, and that, apparently, by its use one may compare rates of reactions going to very different equilibrium points.

The treatment of the experimental results has been somewhat facilitated by the conclusion from the measurements of the refraction indices and densities of mixtures of certain alcohols and aldehydes,[3] that in some cases one molecule of alcohol reacts immediately with one molecule of aldehyde to form a hemiacetal.



$$CH_3CHO + C_2H_5OH \rightleftharpoons CH_3CH\begin{cases}OC_2H_5\\OH\end{cases}$$

The synthetic reaction whose rate is studied is then that of the hemiacetal with alcohol



$$CH_3C\begin{cases}OC_2H_5\\OH\\H\end{cases} + C_2H_5OH \rightleftharpoons CH_3C\begin{cases}OC_2H_5\\CO_2H_5\\H\end{cases} + H_2O$$

The reaction may then be treated as a bimolecular reversible reaction and the expression $dx/dt = k_1 (a - x)(b - x) - k_2X^2$ applied to the experimental results, where k_1 is the rate of the synthetic reaction, k_2 the rate of the reverse reaction, a and b the initial molar concentrations per liter of alcohol and hemiacetal, respectively, and x is the molar conversion of hemiacetal at time, t. k_1 or k_2 may be expressed in terms of the other and of the equilibrium constant, since $k_1/k_2 = K$, the value of K being calculated from the expression

$$K = \frac{\text{concn. acetal X concn. water}}{\text{concn. alcohol X concn. hemiacetal}}$$

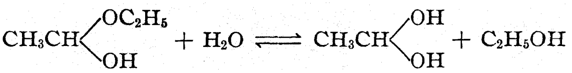
---

[1] Adkins and Adams, THIS JOURNAL, 47,1368 (1925).

[2] Ref. 1, p. 1378.

[3] Adkins and Broderick, THIS JOURNAL, 50, No. 2 or 3 (1928).

However, there is good reason for suspecting that hemiacetal reacts with water to form aldehydrol as well as with alcohol to give an acetal.



$$CH_3CH\begin{matrix}OC_2H_5\\OH\end{matrix} + H_2O \rightleftharpoons CH_3CH\begin{matrix}OH\\OH\end{matrix} + C_2H_5OH$$

A consideration of the three reactions shows that if the equilibrium point of the last reaction noted is quite far to the right, there will be no material reversal of the acetal reaction during the early stages of synthesis because little water will be present; and that the concentration of the aldehyde at any time, t, will not be $b - x$, but $b - 2x$, for every molecule of acetal formed means one molecule of water formed which would then convert a molecule of hemiacetal into aldehydrol. The concentration of the alcohol will remain constant, because every molecule of alcohol going to acetal will be replaced by a molecule of alcohol resulting from the hydrolysis of hemiacetal. The differential equation then becomes

$$dx = k_1' (a)(b - 2x)$$

or

$$k_1' = \frac{dx}{dt} \cdot \frac{1}{a(b - 2x)}$$

The rates of formation of methyl, ethyl, isopropyl and butyl acetals and the rate of hydrolysis of isopropyl acetal have been very carefully measured, using reagents of high purity, specially designed apparatus and a refined technique for analysis. The percentage of aldehyde (hemiacetal) found was plotted against time and a smooth curve drawn. Tangents were drawn to the curve at 2, 3, 6, 12, 18, 24, 30, 50, 75 and 100 minutes, and from the slopes of these tangents the values of dx/dt were calculated in molar concentration per minute. The values of k_1, k_2 and k_1' were obtained by substituting in the differential equation the values of dx/dt so found, the values of x as analytically determined and of a and b as calculated from the initial concentrations.

The data from which the curves were constructed represented in each case the results of several runs and on the average represented about 20 determinations. Very few of the experimental points were more than 1.0% off the curve representing the average. The concentration at equilibrium was checked after several days, although in general it was reached in from 24 to 36 hours. The values obtained during the first three or four minutes of the reaction are of doubtful reliability.

A summary of the numerical results is given in Table I. After the name of each acetal is given the per cent. conversion at equilibrium and the initial concentration in moles per liter of aldehyde and alcohol (or of acetal, alcohol and water in the hydrolytic reaction). The values of the tangents and the moles of aldehyde reacted are given for intervals from 2 to 100 minutes. The calculated value of k_1 or k_2 and k_1' are then given.

The values for the equilibrium constant, disregarding the formation of any hemiacetal, and the corresponding values of $-RT \ln K$ are as follows

Methyl acetal	$K = 0.1033$	$-RT \ln K = +1340$
Ethyl acetal	$K = .0744$	$-RT \ln K = 1540$
Butyl acetal	$K = .1850$	$-RT \ln K = 994$
*iso*Propyl acetal	$K = .00769$	$-RT \ln K = 2876$

TABLE I

THE RATE OF SYNTHESIS OF METHYL, ETHYL, *iso*PROPYL AND BUTYL ACETALS AND OF THE HYDROLYSIS OF *iso*PROPYL ACETAL[a]

[a] The concentration of the catalyst was 0.000465 g. of hydrogen chloride per mole of alcohol in the synthetic reactions and five times that amount in the hydrolysis of isopropyl acetal

The chief point of difference between the experimental results obtained by Adams and those described in this paper is with respect to the faster rate with which methanol reacts with acetaldehytle. However, this does not affect the validity of the conclusion that methanol has a lower reactivity during the initial stages of the reaction than does ethanol. However, it is greater than for butanol and isopropanol.

The method used in this paper for the evaluation of the reaction rates from the experimental results does change the conclusion reached by

Adkins and Adams that *isopropyl* alcohol is more reactive than the primary alcohols. The values of k_1 and k_1' given in the table must lead one to the conclusion that isopropyl alcohol is less reactive than the three primary alcohols studied, although the differences between the four alcohols are not great.

A consideration of the values of k_1 given in the table shows that they rapidly decrease as the synthetic reaction proceeds. The values of k_1' are very much more constant and after the first two or three time intervals are quite constant over a period of from 30 to 60 minutes. The assumption made in the calculation of k_1' is of course justifiable and approximates the truth only in the early stages of the reaction, as it ignores any hydrolysis of acetal and assumes that the active concentration of aldehyde is decreasing twice as fast as the formation of acetal. The limiting point of this assumption is the conversion of 50% of the aldehyde to acetal. The values of k_1' are seen to be constant for a much longer interval in the case of isopropyl acetal than for those acetals which reach an approximately 50% conversion in a shorter time. The values of k_1' lend support to the hypothesis outlined above with regard to aldehydrol formation. The rapid decreases in the values of the constants during the first few minutes are certainly due in a large part to the poisoning effect of water upon the catalyst. The values of k_1' reach a constant value more slowly in the case of isopropyl acetal than with the other acetals. This is understandable because any given concentration of water is reached more slowly in the synthesis of this acetal than with the others; so that the amount of change in k_2 during the period under consideration is relatively small and the value is fairly constant in the period from 24 to 100 minutes. It should be noted that while the values of k_2 for the hydrolytic reaction are roughly ten times those of the synthetic reaction, this is because the concentration of the catalyst is five times as great. With the same concentration of catalyst the rate of the hydrolytic reaction is a small fraction of that for the synthetic reaction. This is further evidence of the poisoning effect of water upon the catalyst.

An inspection of the curves showing percentage conversion of aldehyde against time, even more than an examination of the values given in the table, will lead one to the conclusion that the true reaction rates are individualistic and irregular. For example, if one notes the time required for the reaction to go half-way to equilibrium this is found to be about 50 minutes for methanol, an hour for ethanol and isopropanol, and two or three hours for butanol. Yet the one reaching this point the soonest (methanol) has a lower value k_1' than for ethanol, while butanol requires more than twice as long to reach the half-way point, this too in spite of the fact that the equilibrium points are quite close together. Four and a half minutes are required for 10% of the aldehyde to react with methanol, three minutes for ethanol and about six minutes for the isopropanol and butanol. A comparison of these figures leads to a somewhat different picture of the relative reactivities.

The authors do not believe that the lack of conformity of the experimental curves representing the aldehyde conversion to any precise mathematical pattern is due to impurity of reagents or errors in procedure or analysis. The results have been repeatedly checked by using different sets of reagents under different conditions, using a technique that can be demonstrated to be very accurate.

Experimental

The alcohols were repeatedly dried over fresh lime until the last portion of lime showed no visible crumbling effect at the end of 24 hours' refluxing. (Some ethanol thus dried was refluxed with aluminum ethoxide for 24 hours, but showed no precipitate of aluminum hydroxide. The alcohol so dried was identical in reactivity with that dried over lime only.) The final distillation was performed very carefully, a 46cm. Vigreux column used, the first and last 500 cc. of a 3000cc. lot being discarded and the product protected at all times by guard tubes. The boiling point range was always less than 0.2°.

Acetaldehyde was fractionated from a commercial product through a 46cm. Vigreux condenser surrounded by a water jacket. The vapors before condensation were passed through a 22cm. horizontal column of calcium chloride. Ice water was circulated through the condensers and about the column. All connections were made with paraffined corks. The distillation was discontinued when the temperature of the vapors rose above 21°. The process was repeated three times, the final product being sealed in 5cc. portions in test tubes.

Di-*iso*Propyl Acetal.—In a 2.5 liter bottle were placed 1100 *g*. of *iso*propyl alcohol of commercial grade and 200 g. of specially prepared calcium chloride. The whole was then shaken mechanically for several hours until most of the calcium chloride was dissolved. The mixture was then cooled to near 0° and 425 *g*. of acetaldehyde of commercial grade was added slowly so as to prevent immediate mixing. The bottle was then securely stoppered to resist pressure and the contents were thoroughly shaken. Considerable heat was evolved. The mixture was allowed to stand for twenty-four hours with occasional shaking. At the end of this time no aqueous layer was observed to have formed. The material was filtered through dry potassium carbonate into a flask. It was then distilled under diminished pressure. No very definite fractions could be collected at this time but it was divided into two parts, of which the lower contained most of the alcohol and some aldehyde while the higher was richer in the acetal. The temperature was never allowed to rise above 50°. The average pressure maintained was 25 mm. of mercury. A large quantity of solid material. 200–300 *g*., remained as residue. The two fractions of liquid collected were then fractionated several times. A fraction boiling at 125.5 to 126.5° was collected as di-*iso*propyl acetal. This weighed 251 g. and represented a yield of 18.7%. By making a wider cut the yield could have been increased 3 to 4%, but a less pure product would have been obtained. The pure material was found to have a specific gravity of 0.8128 (25°).

The calcium chloride was prepared by treating the commercial grade with dry hydrogen chloride at 250 to 300'. A flask containing the material was placed in an oil-bath and kept at that temperature. Hydrogen chloride was passed through for five to six hours. It was then swept clear of any excess by carbon dioxide. This gave the normal salt, whereas the commercial grade is often slightly alkaline, Catalyst.—Hydrogen chloride generated by adding concentrated sulfuric acid to moist sodium chloride was conducted through a sulfuric acid gas-washing bottle into a bottle containing **150** to **200** cc. of the alcohol for which the catalyst was intended. The alcohol used had been purified in the manner described above. After a considerable quantity had bubbled through, it was allowed to come to room temperature. It was then analyzed for chlorine content by the Volhard method. Having determined the concentration of hydrogen chloride in this way, a quantity was diluted up to the proper concentration for the reaction. For convenience, the concentration was so chosen that on adding **1.0** cc. of the catalyst for the reaction mixture, the final concentration was **0.000465** g. of hydrogen chloride per mole of alcohol present. This was the concentration used by Adams. The bottle containing the catalyst thus prepared was protected from the light by covering with glazed paper. It was then inserted into the apparatus as illustrated in Fig. **1.**

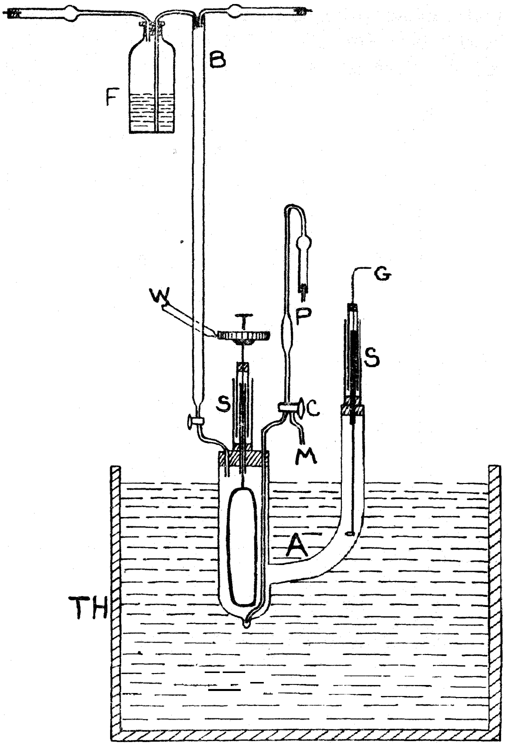

Fig. 1.

It was found that the catalyst diminishes in value as time goes on, if exposed to light, and it seems probable that it does so to a slight extent even when protected. For this reason, the catalyst was always used within a few days after making up. **A** sample unprotected from the light, which contained **0.21107** g. of hydrogen chloride per **10** cc., was found at the end of six weeks of exposure to contain **0.19198** g. per 10 cc. The depreciation, therefore, was about 10% for that period of time. Very probably some of the hydrogen chloride was converted to the alkyl chloride.

The reaction **flask A** in Fig. **1** was kept in the thermostat TH but may be removed independently of the remaining apparatus should accidental breaking of the stirrer T occur or should mercury from either of the seals gain entrance. The stirrer T was propelled by a current of air W working against a fan which **was** attached at the outer end. The **flask A** was washed with three **75cc.** portions of anhydrous alcohol after each experiment. This was introduced through the side arm of A, from which the mercury seal S had been temporarily removed, and was withdrawn through the pipet P into a trap. This procedure was then repeated using 75 cc. portions of anhydrous ether. The pipet P was then connected to a source of air under pressure, the air having been previously passed through a sulfuric acid gas-washing bottle. The air was allowed to pass through at a moderate rate for fifteen to twenty minutes when all of the ether vapors had been removed and the flask was completely dry and filled with an atmosphere of dry air. The aldehyde sample was then put in place in the side arm of A with the finely drawn tip going through the loop of *G*. It was allowed to rest in this position until the alcohol was added. The connection of the mercury seal with the arm was carefully made with collodion. The required quantity of alcohol was forced into the buret B from the flask F by means of an aspirator connected to the drying tube. That part of the buret below its stopcock was filled from the previous experiment. The rubber connections to the drying tubes were shut off by pinchcocks when not in use in order to prevent the action of any vapor from the bottle F upon the calcium chloride in the drying tubes. An identical arrangement for introducing the catalyst was used but is not illustrated by Fig. 1. The alcohol was allowed to flow into the flask. The aldehyde was then released by raising the support G and allowing the tube to fall against the bottom of the arm, thus breaking the capillary tip. The stirrer was working vigorously, meanwhile, so that it was immediately mixed with the alcohol as it flowed into A. In this way the effect of the vapor pressure of the aldehyde on the mercury seals was rapidly diminished. The temperature was allowed to come to 25°. A 5.0cc. sample was then withdrawn into the pipet P through the three-way stopcock C. The sample was allowed to flow into the titration flask F, Fig. 2, through M, Figs 1 and 2.

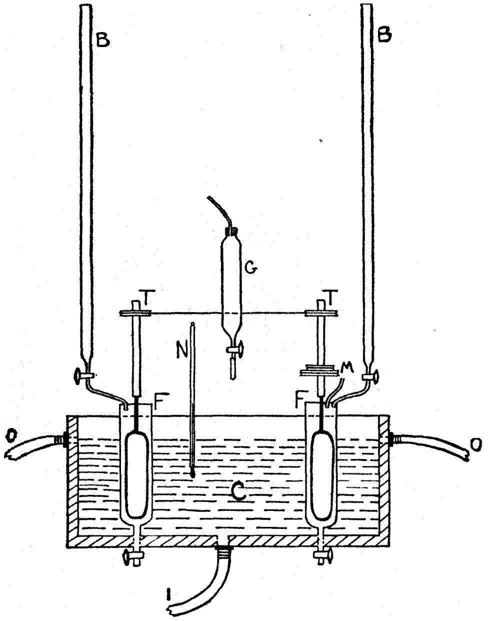

Fig. 2.

The titration flask F, Fig. 2 contained 40 cc. of 10% sodium sulfite maintained at 2 to 3° by a circulating bath C through which ice water was passed in through I and out at O. The aldehyde was determined by titrating the alkalinity developed. This is the Seyewetz-Bardin method described by Child. The amount of alkali formed is equivalent in moles to the available aldehyde and hemiacetal in the sample. The titration flask F on the left was for holding the blank. The stirrers T were operated by a motor at such a speed that good mixing was obtained. The buret G was for measuring out quantities of sodium sulfite from a stock solution immersed in an ice-salt water-bath. The titration must be performed slowly. The acid was allowed to run from the buret B at an average rate of 4 cc. per minute. The volume of liquid in the two flasks was equalized by adding distilled water gradually to the blank so that the temperatures and volumes were identical at the end-point. When the color of the liquid in the two flasks had reached the same degree of intensity when compared by observation against a light background behind the bath C, whose rear and forward faces are of transparent glass, the end-point had been reached and the reading on the buret B on the right was taken.

When the titration for the original concentration had been completed, the catalyst was added through a buret B which was graduated accurately to 0.01 cc. The stirrer T was working vigorously, meanwhile, to insure rapid and thorough mixing. Only 1 cc. of the catalyst was added so that the time consumed never exceeded thirty seconds. The mid-point of this period of time was taken as the initial time in all calculations of the rate. The time was carefully noted by means of a stopwatch with a second hand. Samples were withdrawn at the desired intervals of time and titrated in a manner identical with that described above. The time at which the meniscus of the sample passed a given point on the pipet P, Fig. 1, in discharging, was chosen as the time the sample was taken. Since a titration at the beginning requires ten to fifteen minutes, it was necessary to combine the results of several runs in order to obtain sufficient data for the first hour or so.

The concentrations at the beginning of the reaction were always so regulated that 0.091 mole of aldehyde and 0.000465 g. of hydrogen chloride were present for each mole of alcohol.

It is essential that the reaction mixture be free from mercury. It has been found that mercury diminishes the rate very appreciably.

Summary

The rate of reaction of acetaldehyde with methyl, ethyl, *iso*propyl and *n*-butyl alcohols has been very accurately determined using reagents of very high purity. The curve representing the disappearance of aldehyde is in each case somewhat different for each alcohol so that the quantitative differences between reactivities are somewhat dependent upon the method of comparison. There are, however, no very large differences in the reactivities of the four alcohols for acetal formation.

The values of the reaction velocity constant have been calculated upon the assumption that the reaction under investigation is a bimolecular reversible reaction in which a molecule of hemiacetal reacts with a molecule of alcohol to form a molecule of acetal and of water. The values of k_1 so calculated fall off steadily in the period from 2 to 100 minutes, in some cases to one-tenth of their first value.

The values of the reaction velocity constants have also been calculated upon the assumption that the water formed in the acetal reaction is largely consumed in the hydrolysis of hemiacetal. The constants so obtained are quite consistent after the first few minutes of reaction and a study of them lends confirmation to the assumptions upon which they are based.

The values of the reaction velocity constant for the hydrolytic reaction increase somewhat as the reaction proceeds, but are fairly consistent during the period of 24 to 100 minutes. When the concentration of catalyst used in the hydrolytic reaction is the same as in the synthesis, the reaction rate is very much slower.

The decrease in the velocity constant as the synthesis proceeds, the increase as the hydrolysis proceeds and the lowered rate of hydrolysis as compared with rate of synthesis (in the early stages of each) are all three believed to be due to the poisoning effect of water.

OXIDATION IN THE BENZENE SERIES BY GASEOUS OXYGEN III. OXIDATION OF ALPHA PHENYL CARBINOLS

BY H. N. STEPHENS

RECEIVED SEPTEMBER 2, 1927 PUBLISHED JANUARY 6, 1928

In studying the oxidation of alkyl benzenes by gaseous oxygen,[1] the writer has found that methylbenzenes yield as the only identifiable products mono-aldehydes and the corresponding acids, while hydrocarbons containing two or more carbon atoms in the side chain were found to be attacked only at the alpha carbon atom, the products being ketones. In the case of hydrocarbons with secondary alkyl groups, for example, cumene, the reaction involves loss of a methyl group together with the alpha hydrogen. Although a careful search was made in many instances no trace of an alcohol was detected in the oxidation products.

The mere absence of alcohols in the products of oxidation does not, of course, preclude the possibility of their being formed in the reactions, as it might be expected that the oxidation of hydrocarbon to alcohol would require a higher potential than the oxidation of alcohol to aldehyde or ketone. In this event the alcohol would be destroyed as rapidly as it was formed. Preliminary to an attempt to find out whether or not the alcohol stage is an intermediate one in the production of aldehydes and ketones, it was considered desirable to study the oxidation of some α-phenylcarbinols under the same conditions that were employed in the oxidation of hydrocarbons. In this connection an investigation has been made of the oxidation of methyl-, ethyl-, dimethyl-, n-propyl- and isopropylphenylcarbinols.

In examining the products formed from the above alcohols, it was discovered, to our surprise, that no less than three concurrent reactions took place under the conditions employed. Only one of these is a direct oxidation while the other two appear to be thermal dehydrations. These latter will be reported on more fully at a later date, so it will be sufficient for our present purpose merely to mention that one of them involves the elimination of one molecule of water from two molecules of alcohol while the other involves the loss of a molecule of water from each molecule of alcohol. The structural nature of the products of the first type of dehydration is not yet fully established but in the second type unsaturated hydrocarbons are produced.

Oxidation Products

All the secondary alcohols employed, with the exception of isopropylphenylcarbinol, underwent direct oxidation to a very limited extent, yielding small amounts of the corresponding ketones. Ethylphenyl- and

---

[1] Stephens, THIS JOURNAL, 48, 1824, 2920 (1926).

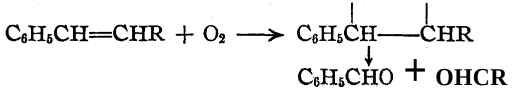
n-propylphenylcarbinols were found to be the most readily oxidized, methylphenylcarbinol was attacked very much less and, strange to say, isopropylphenylcarbinol was unaffected at the temperature used.

Although in the oxidation of the secondary alcohols a simple oxidation of the —CHOH— group to —CO— may take place, when tertiary alcohols are concerned (for example, dimethylphenylcarbinol) an alkyl group must be destroyed before a ketone can be formed. As acetophenone is a product in the oxidation of dimethylphenylcarbinol, this is probably what takes place, the oxidation being analogous to that of cumene,[1] the corresponding hydrocarbon, which also yields acetophenone. However, on account of there being another way (see below) in which acetophenone may be formed from dimethylphenylcarbinol, it is impossible to determine to what extent direct oxidation takes place or, indeed, whether it **takes** place at all.

Secondary Oxidations

It has been mentioned that unsaturated hydrocarbons were produced by dehydration of the carbinols under the conditions employed. With the exception of one instance, that of the production of *iso*propenylbenzene from dimethylphenylcarbinol, no hydrocarbons were detected in the final products as they were destroyed by oxidation as rapidly as they were formed. The fact that they are actually formed from the secondary alcohols, as well as from dimethylphenylcarbinol, was demonstrated by heating a sample of ethylphenylcarbinol in an atmosphere of carbon dioxide at 102–104° for ten days, at the end of which time quite an appreciable amount of unsaturated hydrocarbon was detected. In the case of dimethylphenylcarbinol, the speed of dehydration was evidently much greater than the speed of oxidation of the product; consequently a considerable amount of hydrocarbon survived.

It is well known that in some cases auto-oxidation of substances containing the ethylenic linkage involves scission of the molecule at the double bond and by assuming this type of reaction to take place, **all** oxidation products isolated in the oxidation of carbinols can be satisfactorily accounted for. Considering the hydrocarbons that would result from the dehydration of the secondary carbinols, the following general equations would represent the oxidations that could take place



$$C_6H_5CH{=}CHR + O_2 \longrightarrow \overset{\qquad\quad O\text{———}O}{C_6H_5CH\text{———}CHR}$$
$$\downarrow$$
$$C_6H_5CHO + OHCR$$

and

$$2C_6H_5CHO + O_2 \longrightarrow 2C_6H_5COOH$$

Benzaldehyde was actually isolated in only one oxidation, that of ethylphenylcarbinol, but its oxidation product, benzoic acid, was isolated in the oxidation of ethylphenyl-, n-propylphenyl- and *iso*propylphenylcarbinols. A small amount of solid acid was also obtained from methylphenylcarbinol but this was insufficient for purification. The second aldehyde which would be expected from scission of the peroxide was never isolated, as it was probably lost by volatilization or, in the case of formaldehyde, by oxidation,[2] under the conditions of the experiments.

On the above basis isopropenylbenzene (from dimethylphenylcarbinol) would be expected to yield, as oxidation products, acetophenone and formaldehyde. On oxidation of the hydrocarbon alone at 102–104°, acetophenone was formed, while the formaldehyde was lost by volatilization. On account of the fact that acetophenone is formed from the dehydration product of dimethylphenylcarbinol and is also probably a product of the direct oxidation of the alcohol, it is impossible to determine the extent of direct oxidation, if it takes place at all.

The Inhibitory Action of Water

In the presence of excess water all three reactions mentioned above are completely inhibited. In view of the fact that each reaction involves the elimination of water, the most obvious explanation of this surprising inhibitory effect might lie in the assumption that all are reversible. In the two dehydrations which take place, it is not difficult to understand how the elimination of water might be a strictly reversible reaction, but in the case of direct oxidation of the alcohol, the way is not so clear. In the earlier papers on the oxidation of hydrocarbons to aldehydes or ketones, it has been assumed that oxidation consists of more than one stage, one of these being a reversible reaction involving the elimination of the elements of water. In the oxidation of carbinols it seems necessary to make a similar assumption.

Further work on the mechanism of these reactions is in progress and an investigation of the reversibility of the two dehydrations of carbinols is also planned.

Experimental Part

Materials.—The carbinols employed in the research were all synthesized by means of the Grignard reaction. The secondary carbinols were prepared from benzaldehyde with methylmagnesium iodide, ethylmagnesium bromide and n-propyl- and isopropylmagnesium chlorides. Dimethylphenylcarbinol was prepared from phenylmagnesium bromide and acetone.

In purifying the secondary carbinols the unchanged benzaldehyde was first carefully removed by allowing the product to stand over saturated bisulfite solution. This was repeated with fresh portions of bisulfite until no precipitate formed on standing for twenty-four hours. After washing the residual liquid with several small portions of the solution and finally

---

[2] Ref. 1, p. 2921.

with potassium carbonate solution, it was dried over anhydrous potassium carbonate and fractionated under reduced pressure. Distillations were repeated until a product was obtained which boiled within 1°. The first two or three drops of each final distillate gave no test for carbonyl compounds with semicarbazide hydrochloride and potassium acetate in aqueous alcohol solution.

Procedure.—The crude product of oxidation was in each case examined for benzaldehyde, benzoic acid and a ketone. The benzaldehyde was removed by allowing the liquid to stand for at least forty-eight hours over a small portion of saturated sodium bisulfite solution. Only in the case of ethylphenylcarbinol was a precipitate of addition compound obtained and this was decomposed with sodium carbonate and the aldehyde characterized as the semicarbazone. When no precipitate was obtained the bisulfite was neutralized with sodium carbonate, partially distilled and the distillate treated with semicarbazide hydrochloride and potassium acetate, but no semicarbazone was detected in any of these instances.

Benzoic acid was removed by treating the residue from the bisulfite treatment with sodium bicarbonate solution and later acidifying with dilute hydrochloric acid. Finally, the liquid was dried over anhydrous potassium carbonate and submitted to fractional distillation under reduced pressure. As ketones always boil at a lower temperature than the corresponding alcohols, the lower fractions were collected and these treated with semicarbazide hydrochloride and potassium acetate in aqueous alcohol solution.

Methylphenylcarbinol

I. Twenty-five g. of methylcarbinol, b. p. 85–86' (7 mm.), treated with dry oxygen for ten days at 102–104° yielded 2.1 g. of a liquid, b. p. 132–136' (7 mm.), and a very small amount of acetophenone, isolated as the semicarbazone (m. p. 201°[3]), m. p. 201°.

II. Twenty-five g. of methylphenylcarbinol, oxidized for eleven days at 122–124°, yielded about 8 g. of liquid, b. p. 132–136° (7 mm.), 0.85 g. of acetophenone and a trace of a solid acid, presumably benzoic.

Action of Water.—Twenty-five g. of methylphenylcarbinol and 25 g. of water, treated at the boiling point with oxygen for twelve days, yielded no reaction product.

Ethylphenylcarbinol

Twenty-five g. of ethylphenylcarbinol, b. p. 105–106° (17 mm.) oxidized for ten days at 102–104°, yielded 10 g. of a liquid, b. p. 158–160° (12 mm.), 0.21 g. of benzoic acid, m. p. 121°, 0.34 g. of ethylphenyl ketone, isolated as semicarbazone,' and a very small amount of benzaldehyde, identified as its semicarbazone by the mixed melting point method.

Action of Heat in an Inert Atmosphere.—Twenty-five g. of ethylphenylcarbinol heated to 102–104° in an atmosphere of carbon dixoide, yielded a considerable amount of

---

[3] Klages, Ber., 37, 2306 (1904).

[4] The melting points given in the literature for the semicarbazone of ethylphenyl ketone vary from 173–175° to 182°. The writer has found that rate of heating influences the melting point considerably. The highest melting point obtained was 179°.

unsaturated hydrocarbon and 9.5 g. of an oil, b. p. 158–160° (12 mm.). Assuming the hydrocarbon to be propenylbenzene, the absorption of bromine in carbon tetrachloride solution would indicate its presence to the extent of approximately 0.25 g.

Action of Water.—Forty g. of ethylphenylcarbinol plus 40 g. of water yielded no reaction product in detectable quantity.

Dimethylphenylcarbinol

Forty g. of dimethylphenylcarbinol, b. p. 79–80° (7 mm.), oxidized for ten days at 102–104" yielded 3.2 g. of an unsaturated hydrocarbon, b. p. 159–161°, 12 g. of a high-boiling liquid, b. p. 158–162° (8 mm.), and a very small amount of acetophenone, identified as semicarbazone, m. p. 201'. The unsaturated hydrocarbon, oxidized alone at 102–104°, yielded acetophenone as a product. It is, therefore, *iso*propenylbenzene, b. p. 161–162°.[5] The other product, formaldehyde, which would be expected from the oxidation of this hydrocarbon, could not be detected, as it would be volatilized under the conditions employed.

Action of Water.—Twenty-two g. of dimethylphenylcarbinol plus 22 g. of water, treated with oxygen for twelve days at the boiling point, yielded no reaction product.

n-Propylphenylcarbinol

Twenty-five g. of n-propylphenylcarbinol, b. p. 107–108° (8.5 mm.), oxidized for ten days at 102–104° yielded 10.5 g. of a liquid b. p. 173–175° (12 mm.), a small amount of benzoic acid, m. p. 120–120.5°, and 0.76 g. of n-propylphenyl ketone, isolated as semicarbazone (m. p. 188.5°[6]), m. p. 188".

Action of Water.—Fifteen g. of n-propylphenylcarbinol plus 15 g. of water, treated with oxygen for ten days at the boiling point, yielded no product.

*iso*Propylphenylcarbinol

Twenty-five g. of isopropylphenylcarbinol, b. p. 97.5–98.5° (9 mm.), oxidized for ten days at 102–104° yielded 9 g. of a liquid, b. p. 163–164" (12 mm.), and a very small amount of benzoic acid, m. p. 119–120° (recrystallized once), but no ketone.

Summary

The oxidation by gaseous oxygen of several a-phenylcarbinols has been studied and it has been found that only a very small proportion of the substances undergo direct oxidation to ketones.

Two other reactions take place under the conditions employed, both of which appear to be thermal dehydrations. One of these results in the formation of high-boiling liquids, which correspond to two molecules of carbinol minus one molecule of water. This latter is the main type of reaction that takes place. The other dehydration yields unsaturated hydrocarbons.

All three types of reactions are completely inhibited in the presence of excess water.

Work on the mechanism of these reactions is being continued in this Laboratory.

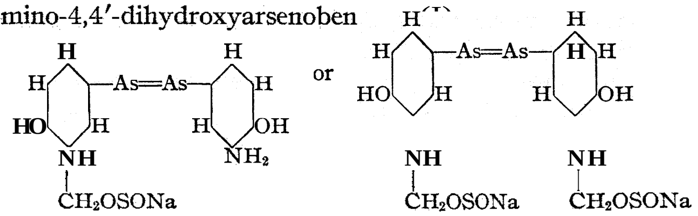
STUDIES ON THE ANALYSIS AND CHEMISTRY OF NEOARSPHENAMINE[1]

BY ALFRED E. JURIST AND WALTER G. CHRISTIANSEN

RECEIVED SEPTEMBER 15, 1927 PUBLISHED JANUARY 5, 1928

Weoarsphenamine is officially described as a condensation product of 3,3'-diamino-4,4'-dihydroxyarsenoben



I

and sodium formaldehyde sulfoxylate. Since it is not a pure crystalline substance but a complex mixture of varying composition, an accurate method of analysis is important in making a synthetic study. Investigation of the available methods showed that of Elvove[1a] most satisfactory. However, it was found necessary to make two modifications, and as a result of these two modifications of Elvove's method it is possible to gain a clearer insight into the composition and chemistry of neoarsphenamine than has been possible hitherto.

The Elvove method of analysis is based on a differential sulfur determination, chiefly on the assumption that the combined and free sodium formaldehyde sulfoxylate differ in their reaction to iodine in neutral[2] solution in that the free sulfoxylate only reduces iodine in neutral solution whereas both the free and combined sulfoxylate reduce iodine in alkaline solution. Freedman[3] calls attention to the fact that this is not correct and we have found that the combined sulfoxylate as well as the free sulfoxylate reduces iodine in neutral solution. This can be demonstrated by oxidizing neoarsphenamine with an excess of iodine, reducing the excess iodine with sodium arsenite, acidifying the solution and then precipitating the sulfur as barium sulfate instead of titrating the excess iodine with sodium thiosulfate as in the Elvove method. The sulfur thus determined directly as barium sulfate is usually greater than that calculated by the Elvove method.

Free sodium formaldehyde sulfoxylate reduces 4 atoms of iodine, whereas combined sodium formaldehyde sulfoxylate reduces only 2 atoms of iodine.

---

[1] This paper was presented before the American Chemical Society, Section on Chemistry of Mechanical Products, at Detroit, in September, 1927.

[1a] Elvove, *U. S. Pub. Health S. Repts.*, *40*, 1235 (1925).

[2] The P_H of neoarsphenamine solutions varies from 5.8 to 9.0.

[3] Freedman, *J. Lab. Clin. Med.*, *11*, 6 (1926).

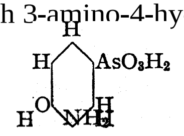
By applying these facts and the results obtained by the method just described, which we shall call the arsenite method to distinguish it from the Elvove direct titration, along with the Mvove titration two simultaneous equations may be set up, as follows

$$x + y = A; \frac{x}{0.8} + \frac{y}{1.6} = B$$

where x is the free sulfoxylate sulfur, y the combined sulfoxylate sulfur, A the sulfur found by the arsenite method less the free sulfate sulfur and B the iodine titration in neutral solution corrected for the arseno group iodine equivalent. These equations give directly both the free and combined sulfoxylate sulfur.

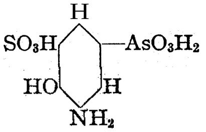
In addition to the free and combined sulfoxylate sulfur determinations, Elvove uses a free sulfate sulfur determination and a total sulfur determination. The difference between the total sulfur and the sulfur oxidizable by iodine in alkaline solution, the total sulfoxylate sulfur, is then considered to be sulfur present as sulfarsphenamine. It has been found that this sulfur difference represents not sulfarsphenamine but nuclear sulfur introduced in the preparation of the arsphenamine base from which the neoarsphenamine was prepared.

In order to demonstrate this, two preparations of arsphenamine base were made in which great care was taken to avoid the introduction of nuclear sulfur by starting with 3-amino-4-hydroxyphenylarsonic acid (II),



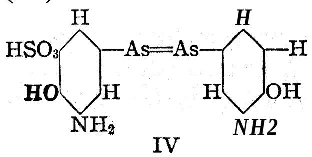
II

which has been shown by Christiansen[4] to yield a base low in nuclear sulfur, but in one of these preparations 10% of 3-amino-4-hydroxy-5-sulfophenylarsonic acid (III)



III

was substituted for the "amino" acid, yielding a base containing 10% of the sulfonic acid derivative (IV)



IV

---

[4] (a) Christiansen, This journal, 43, 2202 (1921); 44, 2334 (1922).

The two bases so obtained were analyzed for sulfur and arsenic and then converted into neoarsphenamines, using formaldehyde sulfoxylate which was known to be free from formaldehyde bisulfite. The neoarsphenamines were than also analyzed for total sulfur and sulfur oxidizable by iodine in alkaline solution. The results of the sulfur analyses of the neoarsphenamines and the bases from which they were made are as follows:

Sulfur content of base made free from sulfonic acid . . .	1.51%
Sulfur content of base with 10% of sulfonic acid	2.31%
Calculated sulfur due to sulfonic acid.	0.77%
Sulfonic acid sulfur found.	.80%
Nuclear sulfur content of neoarsphenamine made from base free from sulfonic acid.	.06%
Calculated sulfur content of neoarsphenamine made from base with 10% sulfonic acid.	.53%
Found sulfur content of neoarsphenamine made from base with 10% sulfonic acid.	.57%

These results serve to demonstrate conclusively the fact that the "sulfarsphenamine sulfur" of Elvove is actually nuclear sulfur.

A further addition to the methods given here permits the determination of the percentage composition of neoarsphenamine by utilizing the results of the differential sulfur determinations, the arsenic content and several factors as follows:

The per cent. of sulfoxylate sulfur × 3.69 = % of free sulfoxylate
The per cent. of combined sulfoxylate sulfur as mono-substituted arsenical ÷ 6.87 = % of mono-substituted arsenical
The per cent. of combined sulfoxylatesulfur as di-substituted arsenical ÷ 11.31 = % of di-substituted arsenical
(The per cent. of arsenic—the per cent. of arsenic as substituted arsenical) × 2.44 = % of free base
The per cent. of free sulfate sulfur × 4.44 = % of sodium sulfate

A large number of neoarsphenamines have been analyzed by the foregoing methods and the results so obtained are given in the following table, showing examples of some of the different types observed.

The results given here show a great difference between the results given by the Elvove method and by the arsenite method for determining free and combined sulfoxylate sulfur. In types A and B, the free sulfoxylate sulfur is always less by the arsenite method than by the Elvove method and the combined sulfoxylate sulfur always greater. In certain cases, namely, type C, the amount of combined sulfoxylate sulfur is small by the Elvove method, but still less by the arsenite method, there being none in two instances. This latter result is not a fault, however, in the method but rather an indication of the existence of a type of combination between arsphenamine base and sulfoxylate differing from that usually described, a probability which must be assumed since the Elvove and arsenite methods both

[a] P = commercial product, = experimental product.

sometimes give results for the combined sulfoxylate which are almost impossibly low.

The directly detectable difference between the two types of combined sulfoxylate sulfur is their reaction to iodine in neutral solution in which the usual or N-methylene type of combined sulfoxylate reduces but two atoms of iodine whereas the second type of combined sulfoxylate reacts in the same manner as free sulfoxylate and reduces four atoms of iodine. This latter type of combined sulfoxylate can be explained on the basis of a double salt of arsphenamine base and sulfoxylate similar to the metallic compounds of arsphenamine, such as the silver compound, due, perhaps, to reactions of secondary valences of the arseno linkage or the amino group. While this possibility has previously been expressed verbally to one of us, this is the first evidence presented to support this view and the results also show the possibility of the existence of both types of combined sulfoxylate in one product.

In addition to the differences between the amounts of free and combined sulfoxylate sulfur given by the Elvove method and the arsenite method, the latter shows the presence in neoarsphenamine of a type of sulfur hitherto unrecorded. This is here called the non-sulfoxylate sulfur and varies in these analyses from 0.19 to 1.27%. No information is available as to the nature of this sulfur but it probably has its origin in decomposition or reaction with the benzene ring of the sulfoxylate used in the preparation of neoarsphenamine. However, several preparations which were exposed to air contained large amounts of non-sulfoxylate sulfur, indicating that it may be an oxidation product. While the nature of this sulfur is not clearly indicated, it can be oxidized to sulfate by iodine in alkaline solution but not in neutral solution so that the amount can be determined by subtracting the total arsenite sulfur from the sulfur oxidized to sulfate in alkaline iodine solution.

In the foregoing data it will be noted that there is a wide range of variation in the nuclear sulfur from zero to 1.05%. This indicates clearly to what extent the variation in nuclear sulfur can occur with slight variations in the base, but in only four instances is this nuclear sulfur present in amounts greater than 0.31%.

The data showing the compositions of the neoarsphenamines illustrated disclose a wide range of variation in composition from products which have no sulfoxylate directly condensed on the amino group to products which contain more di-substituted arsenical than mono-substituted arsenical. The free sulfoxylate varies from zero to 25.00% and many of the products examined contain at least small amounts of arsphenamine base. All neoarsphenamines examined contain a small amount of sodium sulfate introduced as an impurity in the sulfoxylate used in their preparation.

Summary

The method of analysis given here leads to a fairly complete knowledge of the composition of neoarsphenamine and it has been found:

1. That the arsenite method of analysis gives a more accurate distribution of the sulfur in neoarsphenamine than has been previously possible.
2. That the so-called "sulfarsphenamine sulfur" is, in fact, nuclear sulfur.
3. That there are probably two types of combination between arsphenamine base and sodium formaldehyde sulfoxylate, one being of the N-methylene type, and the other resembling a double salt formation.
4. That there is a type of sulfur present in neoarsphenamine which owes its origin to some reaction or decomposition of sodium formaldehyde sulfoxylate but it is no longer present as sulfoxylate.

THE DIBROMIDES OF METHYLCOUMARIC AND METHYLCOUMARINIC ACIDS

BY MARIE REIMER AND MARION HOWARD

RECEIVED SEPTEMBER 28, 1927 PUBLISHED JANUARY 5, 1928

In connection with a study of o-methoxybenzalpyruvic acid it became necessary, for purposes of identification, to prepare α-bromo-*o*-methoxycinnamic acid (169–171°). As reactions for the preparation of this substance by the action of a 50% aqueous solution of potassium hydroxide on methylcoumaric acid dibromide, according to the directions of Perkin,[1] failed to give the substance he described, we have made a study of the action of bromine on methylcoumaric and methylcoumarinic acids and of the elimination of hydrogen bromide from the resulting compounds. Perkin[1] described two isomeric dibromo addition products, neither of which, however, he prepared in the pure condition. Fittig and Ebert[2] questioned Perkin's results, as they were able to obtain but one dibromo compound. Later investigators[3,4,5] were also unable to identify two products of the reaction, although Stoermer mentions an "impure methylcourmarinic dibromide" left in the filtrates. We find that the product of addition of bromine to methylcoumaric and methylcoumarinic acids is in each case a mixture of isomers which we have succeeded in separating and purifying; a dibromo acid melting, with vigorous decomposition, at 177° and, in smaller quantity, an isomeric acid melting, with very slight de-

---

[5] Biilmann and Lund, *Ann. chim.*, [9] 18, 263 (1922).

composition, at 134° and changing above this temperature to the higher-melting isomer.

The isomeric dibromo acids differ markedly in solubility and in their behavior toward alkaline reagents. The higher-melting acid reacts rapidly with 50% aqueous potassium hydroxide, the chief product of the reaction being an oil which was proved to be a-bromo-o-methoxystyrene. This was accompanied by a very small amount of the potassium salt of an acid melting when pure at 136°, instead of a large percentage of acid melting at 169–171° as was expected from Perkin's description of this experiment. This low-melting acid was the chief product of the reaction when alcoholic instead of aqueous potassium hydroxide solution was used with the dibromo acid (177°). The dibromo acid (134°), treated with 50% aqueous potassium hydroxide, reacted slowly in the cold to give an almost quantitative yield of an acid melting at 171°, the same α-bromo-*o*-methoxycinnamic acid as described by Perkin (169–171°). That this acid is the geometrical isomer of that melting at 136° is proved by the ready conversion of the latter into the acid (171°) by exposure of its aqueous solution to the sunlight.

Since it was found possible to prepare the two dibromo acids in pure condition and since they differ so markedly toward alkaline reagents, it seemed of interest to carry out with both acids certain of the reactions previously studied by other investigators with the higher melting of the two. The products of the reactions of the two dibromo acids with water and with an aqueous solution of bromine were the same. With methyl alcohol isomeric compounds have been obtained.

Experimental Part

Preparation of Methylcoumaric and Methylcoumarinic Acids

Since coumarin is the least expensive of the substances from which these compounds can be prepared and dimethyl sulfate, for the same reason, is to be preferred to methyl iodide, a modification of the method of Stoermer and Friemel was used instead of that of Reychler[6] which gives better yields.

Fifty grams of coumarin was dissolved by warming with a solution of 30 g. of sodium hydroxide in 150 cc. of water. To the cooled solution 100 g. of dimethyl sulfate was added, the mixture shaken repeatedly and allowed to stand at room temperature for about three days. At the end of this time an oil, the methyl ester of methylcoumarinic acid, had separated. Water was added until the ester formed the lower layer; it was drawn off, the ethereal extract of the aqueous residue added to it, the ethereal solution washed repeatedly, dried over calcium chloride, and the ether distilled off. The clear oil remaining was hydrolyzed by boiling with 30% potassium hydroxide solution if methylcoumarinic acid was to be prepared or distilled

---

[6] Reychler, *Bull. soc. chim.*, [4] 3, 551 (1908).

and then hydrolyzed to obtain methylcoumaric acid. The change of the methyl ester of methylcoumarinic acid to that of methylcoumaric acid on distillation was not complete but a fair yield of the latter could be obtained by rapid and repeated distillation. Although a boiling point of 275" is given as that of the methyl ester of methylcoumarinic acid, hydrolysis of the fraction distilled carefully at this temperature gives a mixture of the two acids. This agrees with the results of Biilmann. By rapid distillation the boiling point rises to 293°, that of methylcoumaric acid methyl ester. The yield of methylcoumarinic acid (m. p. 92–93") obtained by hydrolysis of the undistilled ester was 78% calculated from the coumarin used; that of methylcoumaric acid (m. p. 182") obtained from the ester two or three times distilled was 40 to 50%.

Action of Bromine on Methylcoumarinic and on Methylcoumaric Acids

Methylcoumarinic acid was dissolved in carbon disulfide, the calculated amount of bromine added slowly to the cooled solution and the solvent evaporated completely in a current of air. The pure white dibromo addition product, formed in quantitative yield, softened slightly at 120 to 130° and melted with decomposition at about 165". Twenty-two grams of this product was treated with 25 cc. of toluene and the mixture thoroughly heated with stirring in boiling water. The liquid was drawn off, the undissolved residue extracted again at 100° with 25 cc. of toluene and a third time with 20 cc. The undissolved portion melted at 174–175°; on crystallization from boiling toluene it separated in compact clumps, melting with vigorous decomposition at 177°. The crystals that separated from the three toluene extracts were those of the impure, low-melting dibromide. They were purified by treatment at 100° with a quantity of toluene insufficient for complete solution; the portion undissolved was impure, high-melting dibromide. The crystals separating from the solution were again treated in the same way until after four or five recrystallizations the substance had a constant behavior on melting. The pure, low-melting dibromide melts to a clear liquid at 134" and immediately resolidifies; this solid begins to give off a gas at 169° and clears and decomposes vigorously at 170°. The melting at 134° is accompanied by slight decomposition, so that the final melting point is never as high as that of the pure high-melting isomer. That this behavior in the melting point tube is due to a transformation to the high-melting isomer was proved by heating a considerable quantity of the low-melting acid for about ten minutes to 136°. The cooled product, slightly brown, after washing with warm toluene melted at 177° and at the same temperature when mixed with the pure, high-melting dibromo acid.

Anal. (Subs. 134°.) Subs., 0.1794, 0.1446: CO_2, 0.2326, 0.1888; H_2O, 0.0523, 0.0396. Calcd. for $C_{10}H_{10}O_3Br_2$: C, 35.52; H, 2.96. Found: C, 35.36, 35.59; H, 3.23, 3.03. Subs. 7.628 mg.: AgBr, 8.588 mg. Calcd.: Br, 47.33. Found: 47.84 (micro-Carius). Subs. 8.434 mg.: AgI, 5.820 mg. Calcd.: OCH_3, 9.17. Found. 9.22 (micro-Zeisel).

The quantity of pure acid (134') isolated from the reaction of bromine on methylcoumarinic acid was 18 to 20% of the crude product; by the action of bromine on methylcoumaric acid no more than 9 to 10% was obtained. The substance crystallizes from toluene in clumps of branching needles which separate on the surface of the solution and "creep" up the sides of the beaker, a behavior characteristic of this isomer as distinguished from that of the other. In fact it is possible to make a rough separation of the isomers by allowing a toluene solution of the mixture to stand until the solvent has completely evaporated. The crystals on the sides and over the top of the beaker are slightly impure, low-melting acid; the compact crystals on the bottom, the high-melting form. The low-melting acid is not as stable as its isomer but takes on a brown coloration on exposure to light and air.

The solubilities of the two dibromo acids in the solvents which have been used by other investigators of this bromination reaction are given in the following table.

Table I

Solubilities

Substance	G. of subs. in 100 g. solvent			
	CS_2 (20°)	$CHCl_3$ (20°)	Toluene (209	Toluene (100°)
177°	0.33	3.73	2.08	**6.91**
134°	1.54	14.50	4.88	**45.91**

It is evident that for the separation of these isomers toluene at 100° is the best solvent. The compound (134°) can be heated in toluene at **100°** for many hours without isomerization. In boiling toluene, however, it gradually changes to the high-melting form. This fact, together with the decidedly greater solubility of the 134" acid, evidently accounts for the failure of other investigators to isolate the compound.

Reaction of Alkalies on the Dibromo Acids

a-Bromo-o-methoxycinnamic Acid, 2-$CH_3OC_6H_4CH{=}CBrCOOH$ (171°).—When finely ground crystals of the acid (134") were stirred in an excess of a 50% aqueous solution of potassium hydroxide, the crystals became opaque and slowly went into solution; after standing for twenty-four hours an almost solid mass of a colorless potassium salt had separated. This was filtered out and dissolved in water. **A** faint cloudiness due to the oil, α-bromo-*o*-methoxystyrene, was removed by filtration. Addition of hydrochloric acid precipitated a colorless acid which separated from boiling water in long, fine needles melting at 171°. The acid is in all respects like that described by Perkin as melting at 169–171°. From the solution left after filtration of the potassium salt, more of the same acid was precipitated. The yield was practically quantitative. By boiling the acid with 10% aqueous potassium hydroxide solution, a second molecule of hydrogen bromide was eliminated readily and *o*-methoxyphenylpropiolic acid (124–125°) formed, as described by Perkin.

α-Bromo-*o*-methoxycinnamic Acid (136°).—The dibromo acid melting at 177° was subjected to the same treatment as that described above. After twenty-four hours, the solution was clear except for a few crystals of a potassium salt. These, on solution and acidification, gave a trace of an acid melting at about 130°. On acidification of the potassium hydroxide solution, an oil separated. It was taken up with ether, the ethereal solution washed with sodium carbonate, dried, the ether distilled off and the residue, a pale yellow, fragrant oil, analyzed.

Anal. Subs. 0.1112; CO_2, 0.2069; H_2O, 0.0405. Calcd. for C_9H_9OBr: C, 50.70; H, 4.22. Found: C, 50.74; H, 4.04.

The substance on oxidation with potassium permanganate in the cold yields o-methoxybenzoic acid. It is, therefore, a-bromo-o-methoxystyrene, 2-$CH_3OC_6H_4CH{=}CHBr$.

In the hope of getting a larger quantity of the low-melting acid, the dibromo acid (177°) was treated with potassium hydroxide in alcoholic solution; **3** g. of the finely powdered acid was covered with a saturated solution of potassium hydroxide in methyl alcohol and the mixture stirred vigorously. Soft, white crystals began to separate immediately and after three minutes there was a nearly solid mass of this substance. The solid, a potassium salt, was at once filtered and dissolved in water, a trace of bromostyrene filtered out and the cooled solution acidified. The mixture, at first cloudy, rapidly deposited pale yellow needles of an acid which was purified by crystallization from hot benzene It separates in stiff, pale yellow needles melting at 136'; from hot water it separates in a pasty condition and slowly solidifies.

Anal. Subs. 0.1577, 0.1690; CO_2, 0.2692, 0.2897; H_2O, 0.0531, 0.0553. Calcd. for $C_{10}H_9O_3Br$: C, 46.68, H, 3.50. Found: C, 46.49, 46.66; H, 3.75, 3.63.

The yield of this acid was 80–90% of that calculated. From the aqueous filtrates a small amount of a higher-melting, colorless acid separated slowly. This was formed by the action of light on the solution of the yellow acid (136°) as was proved by subjecting a saturated aqueous solution of the latter in a quartz test-tube to bright sunlight. After two hours the liquid was filled with a mass of fine, white needles. This substance crystallized from hot water in long, stiff needles melting at 171°. A mixed melting point determination proved it to be identical with the a-bromo-o-methoxycinnamlc acid (171°) previously described. This transformation shows that the new, more soluble yellow acid (136°) is the geometrical isomer of the slightly soluble, colorless acid (171°). The same transformation can be brought about in benzene solution.

The methyl ester of the acid (136°) could not be prepared by allowing the acid to stand in contact with methyl alcohol saturated with hydrogen chloride; almost the whole amount of the acid was recovered unchanged after many hours. The pure ester, a lemon-yellow, mobile oil, was prepared in quantitative yield by the action of diazomethane on the purified acid.

Anal. Subs. 0.1311; CO_2, 0.2342; H_2O, 0.0499. Calcd. for $C_{11}H_{11}O_3Br$: C, 48.70; H, 4.05. Found: C, 48.64; H, 4.23.

Elimination of hydrogen bromide from the acid (136°) was much more difficult than from the isomeric acid. After boiling a solution of the acid in 10% potassium hydroxide solution for thirty minutes, practically the entire amount was recovered unchanged. After boiling the solution for two hours, the acetylenic acid was precipitated from the acidified solution together with a considerable quantity of methoxybromostyrene.

The differences in properties of the two isomeric acids might indicate that the acid (136°) is the cis, the acid (171") the trans isomer but no conclusion can be.drawn without direct experimental evidence.

Reaction of Aqueous Bromine Solution on the Two Dibromo Acids

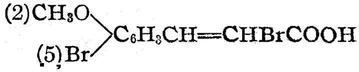
5-Bromo-2-methoxycinnamic Acid Dibromide, 
$$\left.\begin{matrix}(2)CH_3O\\(5)Br\end{matrix}\right\rangle C_6H_3CHBrCHBrCOOH$$

(201").—The dibromo acid (177") on treatment with an aqueous solution of bromine, according to the directions of Biilmann,[5] gave a practically quantitative yield of a product with a bromine atom in the ring. After crystallization from benzene it melted at 201". (M. p. given by Biilmann, 198°; Perkin, 188°.)

The dibromo acid (134°), subjected to the same treatment, became pasty and even on vigorous shaking could not be made to react completely with the bromine solution. The only product isolated melted at about 184" and was shown by analysis to be a mixture of a tribromo and a dibromo compound. By repeated recrystallization of this mixture a small amount of the tribromo acid (201°) was obtained in pure condition.

By the action of hot aqueous potassium hydroxide solution on this tribromo acid, Perkin obtained 5-bromo-2-methoxyphenylpropiolic acid. By a less strenuous method we have prepared two isomeric ethylenic acids.

α-Bromo-5-bromo-2-methoxycinnamic Acid,



$$\left.\begin{matrix}(2)\mathrm{CH_3O}\\(5)\mathrm{Br}\end{matrix}\right>\mathrm{C_6H_3CH{=}CHBrCOOH}$$

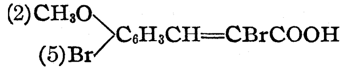
(163–164°).—Two grams of the tribromo acid was covered with a saturated solution of potassium hydroxide in methyl alcohol and the mixture stirred. The tribromo acid dissolved at once and a very few crystals of a potassium salt separated. After five minutes, addition of water produced no cloudiness, indicating that there had been no formation of a styrene derivative as was the case with the acids in which there was no bromine in the ring. Acidification of the solution gave a pasty precipitate which slowly solidified after cooling and vigorous stirring. The substance, obtained in practically quantitative yield, separates from boiling benzene in fine, pale yellow needles, melting at 163–164°.

Anal. Subs. 0.1554; CO_2, 0.2052; H_2O, 0.0380. Calcd. for $C_{10}H_8O_3Br_2$: C, 35.71; H, 2.38. Found: C, 36.01; H, 2.66.

The methyl ester was obtained in small quantity when the acid was treated with a saturated solution of hydrogen chloride in methyl alcohol but about one-half of the acid was recovered unchanged. A quantitative yield of the ester separated from the ethereal solution in lustrous, pure white needles when the acid was treated with diazomethane. It crystallizes from a small volume of methyl alcohol in fine, soft needles melting at 94°.

Anal. Subs. 0.1488; CO_2, 0.2079; H_2O, 0.0427. Calcd. for $C_{11}H_{10}O_3Br_2$: C, 37.71; H, 2.85. Found: C, 38.10; H, 3.19.

α-Bromo-5-bromo-2-methoxycinnamic Acid,



$$\left.\begin{matrix}(2)\mathrm{CH_3O}\\(5)\mathrm{Br}\end{matrix}\right>\mathrm{C_6H_3CH{=}CBrCOOH}$$

(221").——This acid separated slowly from the benzene filtrates of the yellow acid (163–164°) just described. After repeated crystallization from benzene it was obtained in the form of fine, pure white needles melting at 221°. The high-melting point led to the belief that the substance might be a polymer of the acid (163–164") formed by the action of light on the benzene solution of the latter. A molecular weight determination, however, and the fact that the substance readily decolorizes a solution of potassium permanganate in the cold to form 2-methoxy-5-bromobenzoic acid proved it to be an isomeric, not a polymeric, form of that acid.

Anal. Subs. 2.692 mg ; CO_2, 3.560 mg.; H_2O, 0.540 mg. Calcd. for $C_{10}H_8O_3Br_2$: C, 35.71; H, 2.38. Found: C, 36.07; H, 2.24. Mol. wt. (Rast method). Subs. 0.570 mg.: camphor, 7.596 mg. *At* 9°. Calcd.: 336. Found: 333.5.

It was found possible to prepare this acid in quantity by exposing a saturated benzene solution of the yellow acid (163–164°) to bright sunlight. The first crystals to separate on spontaneous evaporation of the benzene, after two or three days' exposure, were those of the high-melting, colorless acid which is considerably less soluble in benzene than its isomer. By repeated exposures good yields of the acid (221°) were obtained.

The methyl ester of the acid (221°) may be formed in quantitative yield by the reaction of methyl alcohol saturated with hydrogen chloride or by diazomethane. It separates from methyl alcohol in firm, stiff needles, melting at 106–107°.

Anal. Subs. 0.1342; CO_2, 0.1856; H_2O, 0.0364. Calcd. for $C_{11}H_{10}O_3Br_2$: C, 37.71; H, 2.85. Found: C, 37.71; H, 3.01.

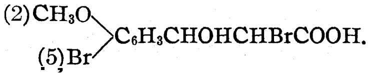
By treatment of both the acids (163–164°) and (221°) with a boiling 10% aqueous solution of potassium hydroxide a molecule of hydrogen bromide was readilv eliminated from each and 5-bromo-2-methoxyphenylpropiolic acid formed; it was crystallized from boiling benzene. The substance turns bright yellow and effervesces violently at 174°; it is evidently Perkin's acetylenic acid "melting with decomposition at about 168°."

Anal. Subs. 0.1244; CO_2, 0.2134; H_2O, 0.0317. Calcd. for $C_{10}H_7O_3Br$: C, 47.06; H, 2.74. Found: C, 46.98; H, 2.83.

Reaction of Water on the Two Dibromo Acids

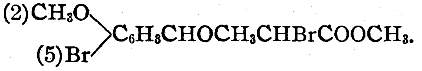
α-Bromo-β-hydroxy-*o*-methoxyhydrocinnamic Acid, $2\text{-}CH_3OC_6H_4CHOHCHBrCOOH$ (134°).—Biilmann prepared this hydroxy acid by shaking the high-melting dibromo acid with water. The low-melting dibromo acid (134°) gives the same substance under the same treatment.

By reaction of the hydroxy acid with an aqueous bromine solution Biilmann prepared α-bromo-β-hydroxy-5-bromo-2-methoxyhydrocinnamic acid,



$$\begin{matrix}(2)CH_3O\\(5)Br\end{matrix}\!\!>C_6H_3CHOHCHBrCOOH.$$

The acid melted at 137°, solidified and melted again at 154°. This behavior and especially the fact that after he had prepared the 154" substance he was not able to obtain the compound (137') in the same laboratory led Biilmann to conclude that the acids were dimorphic not isomeric. The behavior of the compound (137°) on melting is so like that of our dibromo acid (134") that the question of possible isomerism in the case of the two hydroxy acids arose. To test the point we have prepared the two hydroxy acids and treated both with an ethereal solution of diazomethane. From both solutions an oil separated which solidified completely. The solid, in each case, was crystallized from boiling ligroin from which it separated in firm clumps of crystals melting at 93–95°. A mixed melting point determination showed that the two were identical. The substance is the methyl ester of α-bromo-β-methoxy-5-bromo-2-methoxyhydrocinnamic acid



$$\begin{matrix}(2)CH_3O\\(5)Br\end{matrix}\!\!>C_6H_3CHOCH_3CHBrCOOCH_3.$$

Anal. Subs. 0.1559; CO_2, 0.2131; H_2O, 0.0517. Calcd. for $C_{12}H_{14}O_4Br_2$: C, 37.69; H, 3.66. Found: C, 37.29; H, 3.71.

The formation of the same compound by the action of diazomethane on the two hydroxy acids is an argument for their dimorphism rather than isomerism.

Reaction of Methyl Alcohol on the Two Dibromo Acids

α-Bromo-β-methoxy-2-methoxyhydrocinnamic Acid, $2\text{-}CH_3OC_6H_4CHOCH_3CHBrCOOH$ (118°).—Werner[7] prepared the methyl ester (m. p. 64") of this acid by warming the impure high-melting dibromo acid with methyl alcohol and hydrogen chloride; on hydrolysis of this ester the acid (m. p. 118") was obtained. We have prepared this acid, in good yield, by shaking the pure dibromo acid (177°) with an excess of cold methyl alcohol for nine hours.

α-Bromo-β-methoxy-2-methoxyhydrocinnamic Acid (136') .—On repeating Werner's experiment we obtained not only the acid described by him, melting at 118°, but in very small quantity an isomeric acid melting at 136°. The ester (64") formed by the action of methyl alcohol saturated with hydrogen chloride on the high-melting dibromo acid gives, on hydrolysis with alcoholic potassium hydroxide, a heavy deposit of the potassium salt of the acid (118"). On acidifying the alkaline filtrate from the separation of the potassium salt, a small amount of an acid separates slowly in fine, shining needles melting, after recrystallization from water, at 136". Analysis proves it to be isomeric with Werner's acid (118°).

Anal. Subs., 5.207 mg.: CO_2, 8.680 mg.; H_2O, 2.160 mg. Calcd. for $C_{11}H_{13}O_4Br$ C, 45.67; H, 4.53. Found: C, 45.46; H, 4.64.

---

[7] Werner, *Ber.,* 39, 27 (1906).

When the low-melting dibromo acid (134°) was shaken with an excess of cold methyl alcohol, this methoxy acid (136°) was the sole product of the reaction.

Summary

Two isomeric dibromo acids have been prepared in the pure condition by the action of bromine on methylcoumaric and on methylcoumarinic acids.

The reactions of these acids with potassium hydroxide, water, an aqueous solution of bromine and methyl alcohol have been studied.

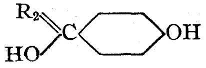
TAUTOMERISM OF HYDROXYTRIARYLCARBINOLS

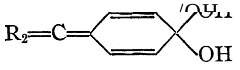
BY L. C. ANDERSON AND M. GOMBERG

RECEIVED SEPTEMBER 30, 1927 PUBLISHED JANUARY 5, 1928

It has been shown[1] that when p-hydroxytriphenylcarbinol is crystallized from 50% acetic acid, the product obtained is yellow in color, melts at 139–140°, and when warmed it loses a molecule of water in a comparatively short time, forming fuchsone (III). On the other hand, when this carbinol is crystallized from alcohol containing a trace of ammonia, it is obtained colorless, melts at 157–159°, and when warmed loses a molecule of water at a very slow rate, fuchsone being the product. It has been demonstrated that neither of the modifications contains water of crystallization and that they are not simply two different crystalline forms of the same material. One modification can be changed into the other by the proper choice of solvent; heat or light favors the colored form. Structures (I) and (II) have been assigned to these forms:



I. Benzenoid (colorless)



II. Quinonoid (colored)

III. Fuchsone

It has been our purpose to study these tautomeric forms by means of the quantitative absorption spectra of their solutions. The present paper deals with p-hydroxytriphenylcarbinol and with o-cresyldiphenylcarbinol (3-methyl-4-hydroxytriphenylcarbinol). Work on other carbinols will appear in subsequent papers.

Procedure.—For the measurement of absorption spectra in the ultraviolet, we used a Judd-Lewis sector photometer (Hilger)[2] and a Hilger quartz spectrograph, Size C. The source of light was a condensed spark between tungsten electrodes under distilled water and, when photo-

[2] Adam Hilger, Ltd., London, Catalog No. H-40.

graphed through the photometer, its spectrum was continuous and intense to a frequency of about 4350. The electrical set-up was patterned after the one used for similar purposes at the Bureau of Standards[3] Some of the curves where absorption was in the visible region of the spectrum were checked by the use of a Nutting photometer and Hilger wave-length spectrometer with a Pointolite lamp as the source of light.

About 0.1 g. of the material under investigation was weighed into a 25 or 50cc. volumetric flask and the flask filled with the solvent. A one centimeter absorption tube filled with this solution was inserted in one section of the photometer and a similar tube filled with the solvent was placed in the other. The sector in the beam of light passing through the solvent was set at extinction coefficient values of 0.1, 0.2, etc., up to 1.2 and the two spectra were photographed at each setting. Five cc. of the solution was then diluted to 25 cc. and a new series of exposures taken on another plate. Further dilutions were made until the peaks of the absorption bands had been photographed. When this procedure is followed, the first one or two exposures taken of a diluted solution coincides with the last exposures taken of the solution before diluting. The overlapping sections of the curves assisted us materially in checking our dilutions and in obtaining continuous curves. At least two and sometimes six or seven samples of a substance have been used before a quantitative absorption curve was considered to have been obtained.

The points at which the comparison beam and the beam which had passed through the solution were of equal intensity were determined under a low power lens in a comparator similar to the one used at the Bureau of Standards. The scale of the comparator was fitted with a vernier reading to a tenth of a millimeter. A curve showing the relationship between the comparator readings and frequencies was made by means of the spectrum of the copper spark.

As regards the choice of suitable solvents, very few are transparent to the shorter ultraviolet rays. Of these methyl alcohol and ethyl alcohol, although transparent, are of necessity eliminated, since in solutions of the hydroxytriarylcarbinols in alcohols, an equilibrium is established between the two tautomers.[4] Water cannot be used for two reasons: first, the insolubility of the carbinols in it and, second, the possibility of its reaction with the solutes. Ether has been found very satisfactory and, in every case studied thus far, the absorption spectrum of the ether solution that has been standing for several weeks has been found to be identical with that of the fresh solution.

Purification of Materials.—The compounds discussed in this paper were purified until their quantitative absorption spectra remained constant.

p-Hydroxytriphenylmethane[5] obtained from the carbinol by reduction with zinc dust and acetic acid was recrystallized from ether; m. p. 110°.

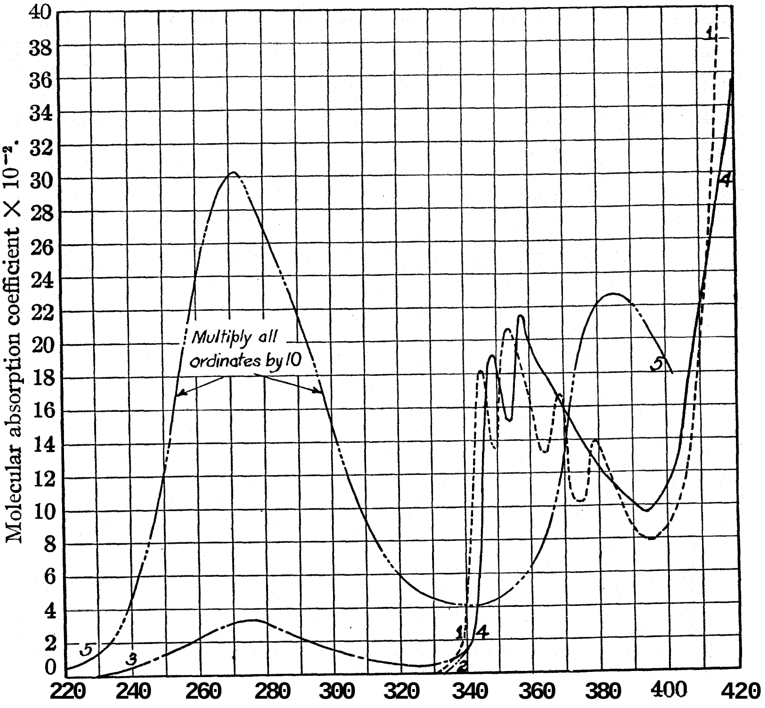
[4] (a) Ref. 1a, p. 1037; (b) Omdorff, Gibbs, McNulty and Shapiro, THIS JOURNAL. 49, 1545 (1927).

[5] Bistrzycki and Herbst, *Ber.*, 35, 3137 (1902).

p-Hydroxytriphenylcarbinol, benzenoid tautomer, was recrystallized three times from alcohol containing a trace of ammonia. It was filtered in an atmosphere which was free from acid fumes and the substance dried over soda lime. The crystals acquired a very pale greenish-yellow color; m. p. 159–160°.

p-Hydroxytriphenylcarbinol, quinonoid tautomer, was recrystallized from water solutions of acetic acid containing 50, 60 and 70% of acid, and from solutions containing 50 and 60% of propionic acid. The crystals were allowed to stand in contact with the mother liquor for from twenty-four to forty-eight hours and were washed on the filter plate with a small quantity of solvent. They were dried to constant weight in a desiccator which contained a saturated solution of potassium hydroxide and in which the pressure was reduced to 3–4 mm.; m. p. 139–140°.



1. ----Methane. 2. ———Benzenoid form of the carbinol. 3. ———Quinonoid form of the carbinol. 4. ————Both forms—benzenoid and quinonoid carbinols. 5. —————Fuchsone of the carbinol.

Fig. 1.—*p*-Hydroxytriphenylmethane and its derivatives.

Diphenylquinomethane, or the fuchsone of *p*-hydroxytriphenylcarbinol, was obtained by the dehydration of the carbinol. It was recrystallized twice from ether; m. p. 168'.

3-Methyl-4-hydroxytriphenylmethane[6] was prepared by reducing *o*-cresyldiphenylcarbinol with zinc dust and acetic acid. It was recrystallized from ether; m. p. 100°.

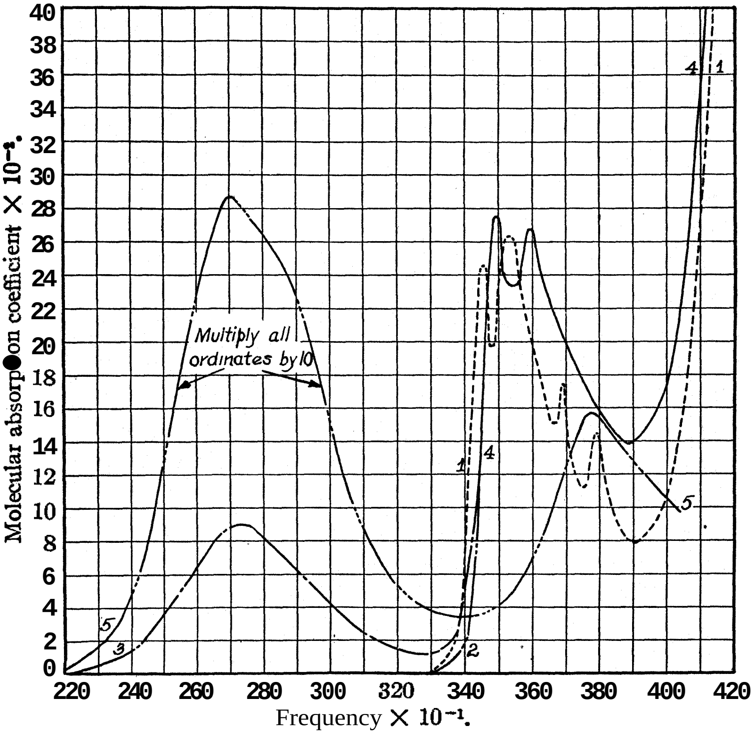
3-Methyl-4-hydroxytriphenylcarbinol, benzenoid tautomer, was obtained when

---

[6] Bistrzycki and Zurbriggen, *Ber.* 36, 3561 (1903).

carbon dioxide was passed into an alkaline solution of the fuchsone. The colorless crystals were recrystallized from ether; m. p. 151°.

3-Methyl-4-hydroxytriphenylcarbinol, quinonoid tautomer, was obtained when either the colorless modification of the carbinol, or the corresponding fuchsone, was crystallized from 50, 60 or 70% aqueous solutions of acetic acid, or 50 or 60% aqueous solutions of propionic acid. The crystals were washed with pure solvent and dried in an evacuated desiccator containing soda lime. The literature[7] records 108–109° as the melting point of this modification. All samples prepared by us melted at 138–139°. The color of the crystals obtained varied with the acid concentration but by means of quantitative absorption spectra we have been able to show that this difference in color is due to the size of the crystals; the finely divided material from the 50% acetic acid solution having a lighter yellow and the larger crystals from the 70% acid having a deeper yellow color than the material from the 60% acid; a similar relationship held true for the material crystallized from the propionic acid solutions. Ether solutions of all these samples, however, have identical quantitative absorption spectra.



1. - - - - -Methane. 2. — - - —Benzenoid form of the carbinol. 3. — - —Quinonoid form of the carbinol. 4. ———Both forms—benzenoid and quinonoid carbinols. 5. — - - - —Fuchsone of the carbinol.

Fig. 2.—*o*-Cresyldiphenylmethane and its derivatives.

3-Methyl-4-hydroxyquinodiphenylmethane was prepared by heating *o*-cresyldi-

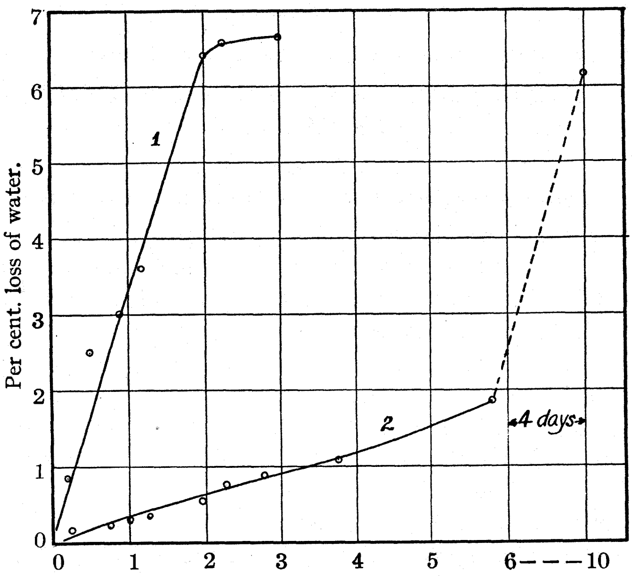
[7] Ref. 1c, p. 1585; ref. 6, p. 3558.

phenylcarbinol at 75° until it had reached constant weight. It was crystallized from ether; m. p. 176°.

Further proof has been obtained that the quinonoid modification of o-cresyldiphenylcarbinol is not a mixture of the benzenoid form and the fuchsone. By the application of Beer's law we calculated that the intensity of the absorption band of the quinonoid form of o-cresyldiphenylcarbinol at frequency 2730 is equal to that of a mixture composed of 3.17% of fuchsone and 96.83% of the benzenoid form. Mixtures of approximately this composition were made and the absorption spectrum of these mixtures was found to be very similar to that of the quinonoid carbinol. When the melting point of this mixture was determined, however, it was observed that the mixture began to soften several degrees below the temperature at which it melted, whereas the melting point of the quinonoid modification is always quite sharp. Moreover, the mixture made by us loses water when placed in a current of warm air at a rate quite different from the rate of loss by the true quinonoid carbinol (Diagram I).



Time in days. Temp. = 75°.

Curve 1 = Quinoid form of *o*-cresyldiphenylcarbinol.
Curve 2 = 3.16% of fuchsone + 96.84% of benzenoid form of *o*-cresyldiphenylcarbinol.

Fig. 3.

We therefore conclude that within a fairly wide range of acid concentration only a single product, namely, the quinonoid tautomer, is formed when either the *p*-hydroxytriphenylcarbinol or *o*-cresyldiphenylcarbinol is recrystallized from dilute acetic or propionic acid.

Summary

The quantitative absorption curves of ether solutions of the methane, the benzenoid carbinol, the quinonoid carbinol and the fuchsone of each—the *p*-hydroxytriphenylcarbinol and o-cresyldiphenylcarbinol—have been carefully determined. The spectroscopic results constitute further evidence that *p*-hydroxytriphenylcarbinol and *o*-cresyldiphenylcarbinol exist each in two tautomeric forms, a quinonoid and a benzenoid,

THE ABSORPTION SPECTRA OF SOME TRIPHENYLMETHANE DERIVATIVES

BY L. C. ANDERSON

RECEIVED SEPTEMBER 30, 1927 PUBLISHED JANUARY 5, 1928

The curves which we have obtained for the quantitative absorption of ultraviolet light by solutions of triphenylmethane and some of its derivatives differ in many respects from those which other investigators have recorded. These differences are due partly to variations in equipment and procedures used at different laboratories but partly, however, to the fact that in some of the recently published work no account was taken of the fact that reaction between the solute and the solvent had given rise to compounds which differed from the original solute and which consequently possessed different absorption spectra.

As previously mentioned,[1] we have found ether to be a very satisfactory solvent to use in this type of work. We have examined layers of pure ethyl ether as thick as two centimeters and in no case has the pure liquid shown selective absorption[2] in the spectrum included by our equipment,[1] which allows measurements to be made at frequencies from 4550 mm.^{-1} to the visible.

The ultraviolet absorption spectra of solutions of triphenylmethane and triphenylcarbinol have been described by Hartley,[3] Baker[4] and Hantzsch[5] who give curves which show absorption only in broad bands. Orndorff, Gibbs, McNulty and Shapiro[6] have given curves which show the quantitative absorption of ultraviolet light by absolute ethyl alcohol solutions of these compounds. They report ten peaks for the solution of triphenylmethane and seven for triphenylcarbinol between 3700 and

---

[1] Anderson and Gomberg, THIS JOURNAL, 50, 203 (1928).

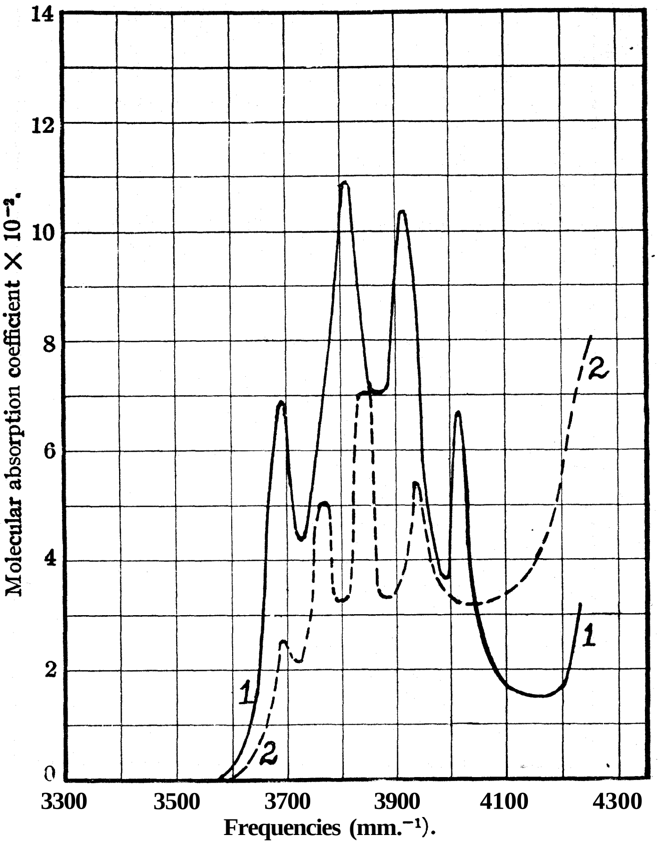
4200 mm^{-1}. Using ether solutions we have located only the four prominent peaks of each compound between the above frequencies. A careful examination of our plates has not given any indication of several of the absorption peaks which the latter investigators have found in alcohol solutions.

The quantitative absorption spectra of solutions of the ethyl ether of triphenylcarbinol, whether in ethyl ether or absolute ethyl alcohol, differ only in intensity; the position of the bands at frequencies 3690, 3760, 3840 and 3930 are virtually unchanged by the change of solvent.



1. ——— = Triphenylmethane; 2. ---- = Triphenylcarbinol.

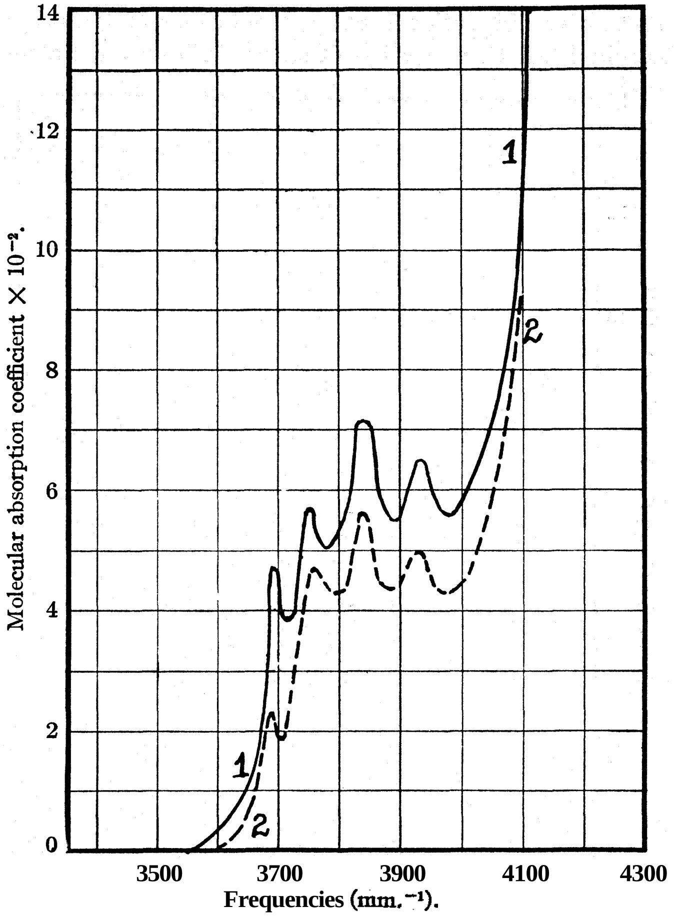
Fig. 1.

It is known that triphenylchloromethane reacts with hot ethyl alcohol to form the ethyl ether of triphenylcarbinol,[7] and we have found that even in the cold the conversion of the chloride to the ether by alcohol is almost

---

[7] (a) Hemilian, Ber., 7, 1208 (1874); (b) Friedel and Crafts, Ann. *chim., phys.* [6] 1, 502 (1884); (c) Frey, Bar., 28, 2518 (1895).

quantitative. A solution of triphenylchloromethane in ether has absorption bands at frequencies 3660, 3740, 3830 and 3920 mm^{-1}. When, however, the chloride is dissolved in absolute ethyl alcohol (neutral), the frequencies of the absorption peaks become practically identical with those of the pure ethyl ether of triphenylcarbinol, there being only a slight difference in the intensity of the peaks. We conclude that the quantitative absorption curve of a solution of triphenylchloromethane in absolute ethyl alcohol as described by Orndorff, Gibbs, McNulty and Shapiro is not due to triphenylchloromethane but is due to the ethyl ether of triphenylcarbinol.

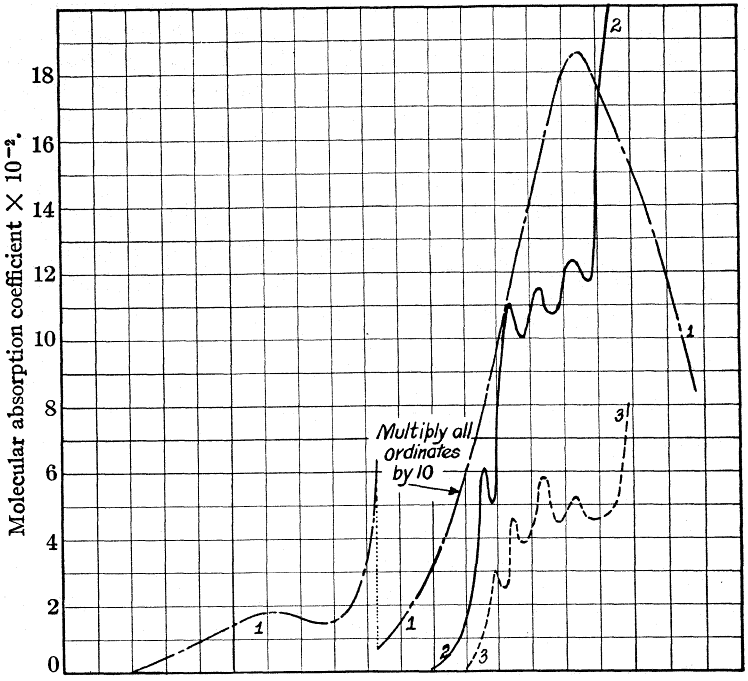


1. ——— = Solution in ether; 2. ‐ ‐ ‐ ‐ = Solution in neutral absolute ethyl alcohol.

Fig. 2.—Ethyl ether of triphenylcarbinol.

Purification of Compounds.—Benzophenone was distilled under reduced pressure and, after three repeated crystallizations from alcohol, it was recrystallized from ether; m. p. 47°. It was used by us to check our curves with data that have been given in the literature. Our results agree very well with those of the most recent investigator.[8]

Triphenylmethane was prepared by the reduction of triphenylcarbinol with zinc dust and acetic acid. It was recrystallized from benzene and then twice from ether; m. p. 92°.



1. — - — = Benzophenone in alcohol; 2. ——— = Triphenylchloromethane in ether; 3. - - - - = Solution obtained by dissolving triphenylchloromethane in neutral absolute ethyl alcohol.

Fig. 3.

Triphenylcarbinol, made from bmzophenone by the Grignard reaction with phenylmagnesium bromide, was recrystallized once from benzene and then twice from ether; m. p. 162°.

Triphenylchloromethane was made by the reaction between a benzene solution of triphenylcarbinol and dry hydrogen chloride in the presence of anhydrous calcium chloride. It was recrystallized from absolute ether just prior to being used; m. p. 111–112".

The ethyl ether of triphenylcarbinol was prepared by adding pure triphenylchloromethane to an alcohol solution of sodium ethylate. After it was crystallized twice from ether, it melted at 83°. The ethoxy compound was also made by allowing a solu-

---

[8] Scheibe. *Ber.*, 59, 2626 (1926).

tion of pure triphenylchloromethane in neutral absolute ethyl alcohol to stand at room temperature overnight. The solvent was evaporated under reduced pressure in a desiccator which contained fused calcium chloride. Samples of the dried residue melted at 81–82° and the melting point of mixtures of this residue and the purified ether, which was prepared as first described, showed that the residue was practically pure ethyl ether of triphenylcarbinol.

The absolute ethyl alcohol which was used as solvent was obtained by a careful fractionation of 99.5% ethyl alcohol which had been distilled from anhydrous potassium hydroxide. A two centimeter layer of the liquid was perfectly transparent at all frequencies within the limit of our equipment. The ether that was used as solvent was in most cases a product obtained on the market as "Reagent Ether Anhydrous." This ether, without further purification, was optically clear and was without effect upon the solute; however, for some of the work, it was distilled from fresh metallic sodium.

Summary

1. Curves are presented which show the quantitative absorption spectra in the ultraviolet of ether solutions of triphenylmethane, triphenylcarbinol, triphenylchloromethane and the ethyl ether of triphenylcarbinol; also curves which show the absorption of absolute ethyl alcohol solutions of benzophenone and the ethyl ether of triphenylcarbinol.

2. It has been shown that the curve obtained from a solution of triphenylchloromomethane in neutral absolute ethyl alcohol is in reality the absorption curve of the alcohol solution of the ethyl ether of triphenylcarbinol.

THE REACTION OF ISOPROPYL IODIDE WITH MERCURIC CHLORIDE

BY BEN H. NICOLET AND WILLIAM McDANIEL POTTS[1]

RECEIVED SEPTEMBER 30, 1927 PUBLISHED JANUARY 5, 1928

Conant and others[2] have recently studied the reaction RCl + KI = RI + KCl (R representing a considerable variety of alkyl and other radicals) in some detail. With the simpler alkyl chlorides, it took place some 60 times more rapidly for primary than for secondary chlorides. They found the reaction quite strictly of the second order, and so slightly reversible that the opposing reaction (if any) did not need to be considered in the calculation of velocity constants.

Nevertheless, Oppenheim[3] in 1860 reported that ethyl chloride and amyl chloride could be obtained by the action of mercuric chloride on the

---

[1] The material here presented was used by William McDaniel Potts in partial satisfaction of the requirements for the degree of Master of Science, at the University of Chicago, 1927.

[3] Oppenheim. *Ann.*, **140**, 207 (1860).

respective iodides. By a similar process, Maumene[4] made $ClCH_2CH_2I$ and $C_2H_4Cl_2$ from $C_2H_4I_2$. Later, Linnemann[5] prepared butyl chloride in 70% yield by the action of mercuric chloride on butyl iodide at 120–130°.

This reaction[6] thus has the appearance of being an effective reversal of the conversion of chlorides to iodides as studied by Conant and his collaborators. Such a reversal might be explained as due to the fact that the concentration of iodide ion in mercuric iodide solutions is excessively small, even in comparison with the chloride-ion concentration in solutions of mercuric chloride.

On the grounds suggested, the reaction of isopropyl iodide with mercuric chloride in dry ether was studied, and found to take place at a rate proportional to the concentrations of these two substances, and also to the concentration of the mercuric iodide. In the calculation of velocity constants, it was found possible to neglect the reverse reaction. *Iso*propyl iodide was chosen after it had been found that n-propyl iodide reacted at least 50 times more slowly. This ratio again favors the idea that the reaction is really a reversal of that studied by Gonant.

Experimental Part

Choice of a Solvent.—It has already been shown[7] that alcohol is not a suitable solvent for the study contemplated, as in it the chief reaction would be one of alcoholysis, catalyzed by the mercuric halide. A suitable solvent would be one which did not react with mercuric salts, which contained no hydroxyl group and which dissolved mercuric iodide to a considerable extent. As the simplest compromise, absolute ether was selected, although it dissolved so little mercuric iodide that, at convenient concentrations of the reacting substances, it was possible to follow the reaction only to 25–50% completion; beyond this, mercuric iodide separated.

Procedure.—The reacting substances were dissolved in absolute ether in the desired proportions, the solution was made up to 200 cc. and the whole kept in a thermostat at 25°. Samples of 10 cc. were withdrawn at suitable intervals and analyzed for inorganic iodine as follows:

The sample was placed in a 150cc. flask and dry air drawn through until the ether and organic iodide were completely evaporated. Blank determinations showed that less than 0.5% of the organically combined iodine was converted to mercuric iodide under these conditions. The dry residue was covered with water, made acid with sul-

[6] We have also found that when solid mercuric chloride is covered with a moderate excess of ethyl iodide in a closed flask, which is allowed to stand for some days, remarkably good crystals of mercuric iodide separate. This is, in fact, an excellent method of growing such crystals. It might be predicted that isopropyl iodide would give more rapid results, but it is not clear whether this would be an advantage in the formation of such crystals.

[7] Nicolet and Stevens, THIS JOURNAL, 50, 135 (1928).

furic acid and mossy zinc added. The solution was allowed to stand until the mercury was completely precipitated. The iodine was then liberated with nitrosylsulfuric acid, extracted with carbon disulfide, and the extract titrated with standard thiosulfate solution.

Typical results are given in Table I. At all the concentrations listed, mercuric iodide was still completely dissolved. Each run was discontinued when the iodide began to separate.

[a] Values for Case A calcd. for successive intervals from Equation 2.

[b] Values for Case B calcd. for successive intervals from Equation 1.

[c] Values for Case C calcd. from Equation 3.

Calculation of Velocity Constants

The reaction is obviously autocatalytic. In the equation

$$\underset{(a)}{HgCl_2} + \underset{(b)}{2(CH_3)_2CHI} = \underset{(d)}{HgI_2} + 2(CH_3)_2CHCl$$

the initial concentration of each substance present may be represented by the letter beneath its formula. The values of K in Table I were calculated, for Case B, from the formula

$$\frac{dx}{dt} = \frac{K}{4}(2a - x)\,(b - x)x \qquad (1)$$

It is apparent that, at the time t, the concentrations of mercuric chloride and iodide may be represented by $(2a - x)/2$ and $x/2$, respectively, x representing moles of iodide transformed. For Case A (in which $2a = b$), this becomes

$$\frac{dx}{dt} = \frac{K}{4}(b - x)^2x \qquad (2)$$

Finally, in Case C, mercuric iodide was added at the beginning to confirm the assumption that it was responsible for the catalytic effect observed. As for simplicity concentrations were so chosen that $2a = b$, the corresponding equation was

$$\frac{dx}{dt} = \frac{K}{[illegible]}(b - [illegible])\,[illegible]\,(d\ x) \qquad (3)$$

A possible interpretation of the reaction mechanism which would be consistent with the equations used would be the following. Isopropyl iodide reacts extremely slowly with mercuric chloride, but with mercuric iodide it forms a complex $(CH_3)_2CHI{\cdot}HgI_2$ which reacts (in the molecular ratio 1:1) with mercuric chloride (or perhaps with chloride ion) at a considerably greater rate. This complex is relatively rapidly formed in reversible reaction, so that its concentration (probably small) is proportional to $x(b - x)/2$.

Discussion of Results

In Cases A and B, the nature of the integrated equation requires that the constants be calculated between intervals and not from zero time. To save space in presentation, these calculations have been made between successive intervals, which magnifies the errors of individual determinations. The values of K are, however, sufficiently consistent in each series to indicate agreement with the type of equation used. The variation in the average values for the different series still requires explanation.

While the data presented give a fairly satisfactory account of the reaction under discussion, there is a definite logical defect in the equations used in the calculations given. It is not strictly possible that the entire reaction velocity should be proportional to the concentration of a product of the reaction not initially present.

It must be assumed, therefore, that the observed velocity is really made up of the sum of the velocity represented in accordance with the equations used and the velocity of the (evidently much slower) reaction of isopropyl iodide with mercuric chloride alone. Using the same symbols as before, the true equation would probably have one of the following forms

$$\frac{dx}{dt} = \frac{K}{4}(2a - x)(b - x)x + \frac{K'}{2}(2a - x)(b - x) \tag{4}$$

$$\frac{dx}{dt} = \frac{K}{4}(2a - x)(b - x)x + \frac{K'}{4}(2a - x)^2(b - x) \tag{5}$$

In Equation 4, the slow reaction is represented as being the simplest possible. Equation 5 represents the assumption that the slow reaction is catalyzed by mercuric chloride in the same way that the main reaction is catalyzed by mercuric iodide.

Calculations of constants based on both these equations have been made but, as might have been expected from the figures already presented, the "slow component" of the reaction is so very slow, and makes such a slight contribution to the total "K," that a decision between the mechanisms suggested in these two equations would be quite impossible with the present data.

Further work is planned to determine more definitely whether the present reaction actually constitutes a true reversal of the reaction studied by Conant. If it does, there is every reason to believe that the latter reaction should also be powerfully catalyzed by mercuric iodide. It is apparent that this test cannot be applied experimentally, since the catalyst (HgI_2) is incompatible with one of the reactants (iodide ion). While obviously no contradiction is here involved, the apparent paradox is interesting.

Summary

1. The reaction of isopropyl iodide (and presumably of other iodides) with mercuric chloride (measured in ether at 25°) takes place at a rate proportional to the product of the concentrations of these two substances and of the mercuric iodide formed. The reaction evidently goes practically to completion.

2. This reaction is pictured as a reversal of that of alkyl (and other) chlorides with iodide ion. which also goes practically to completion.

[CONTRIBUTION FROM CENTRAL ILLINOIS TESTING LABORATORIES]

DIRECT NESSLERIZATION OF KJELDAHL DIGESTIONS

BY H. M. CHILES

RECEIVED OCTOBER 4, 1927 PUBLISHED JANUARY 5, 1928

The method outlined here is the outgrowth of a study started in the summer of 1922 as one step in the simplification of the methods of Folin-Wu and of Benedict for blood analysis to make them more suitable as routine tests for use by technicians of limited basic training. The work was started in the pathological laboratory of the St. John's Hospital, Springfield, Illinois, and continued at the present location since that time.

The Nesslerization of ammonia in the presence of considerable quantities of inorganic salts is an old problem. The published methods to date seem to be confined to limiting the amount or the nature of the salts present. It seems strange that so little apparent effort has been made to attack the problem by the use of protective colloids. Folin and Denis[1] have developed a method for the direct Nesslerization of micro Kjeldahl digestions by the substitution of phosphoric acid for a large part of the sulfuric acid and omitting the alkali sulfate generally used. This digestion mixture has the serious fault of attacking the glassware, leaving a considerable amount of insoluble sediment; moreover, only low concentrations of ammonia can be Nesslerized, limiting the method to micro determinations.

By the use of a protective colloid to prevent precipitation of the color in the Nesslerized solutions as here described it is possible to Nesslerize directly any of the commonly used Kjeldahl digestion mixtures. Moreover, it is thus possible to Nesslerize a much higher concentration of ammonia in the presence of relatively large amounts of alkali sulfates than by the usual methods even in the absence of any extraneous salts. A number of colloids have been tried for this purpose but by far the most satisfactory one found to date is a specially prepared gum arabic solution. By the use of this material it is possible to successfully Nesslerize concentrations of ammonia as high as 20 mg. of nitrogen per 100 cc. of final solution and this in the presence of from 5 to 8 g. of anhydrous sodium or potassium sulfate. Such solutions develop their maximum color rapidly and do not start to precipitate for a considerable time; in fact, aliquot portions of Kjeldahl digestions containing in the Nesslerized solution 5 mg. of ammonia nitrogen per 100 cc. have been retained without noticeable precipitation for as long as two weeks. Satisfactory Nesslerizations have even been carried out in solutions saturated with sodium sulfate.

The method has been tried in comparison with the usual Kjeldahl methods both macro and micro on the following materials: blood, blood

filtrates, urine, milk, grain feeds, tankage, and cottonseed meal. The following table shows some of the comparative results.

TABLE I

In the above comparative determinations, digestions were made in the usual manner, the digested solutions were made up to a definite volume and proper aliquots used for each method. In some of the digestions copper was used and in some mercury. For products of low nitrogen content the result is calculated from one careful reading at the colorimeter. For materials of high nitrogen content the result is calculated from the average of five distinct readings; the results calculated from the highest and the lowest readings are also reported. A study of the comparative results will show only the differences to be expected due to the inherent inaccuracy of colorimetric determinations.

Since one of the principal advantages of this method is the saving of time, we have found it expedient to use it in combination with the sulfuric-perchloric acid decomposition method of Mears and Hussey.[2] This we have found very satisfactory for many materials although the results are usually somewhat low for urine and for this reason we prefer to omit the perchloric acid in this case. For micro determinations we have found the following digesting mixture to be very convenient: concentrated sulfuric acid 70 cc., water 50 cc., 20% perchloric acid 20 cc., anhydrous sodium sulfate 15 g. and copper sulfate 1 g.

---

[2] **Mears and Hussey, J.** *Ind. Eng. Cham.*, 13, **1054** (1921).

For micro analysis blood, urine, milk and similar liquid materials are suitably diluted and such aliquots as will normally give from 2 to 5 mg. of ammonia nitrogen are taken and digested with 1 or 2 cc. of the above digestion mixture in the usual manner, heating for at least two minutes after the solutions are colorless. If desired, particularly for urine, the perchloric acid may be omitted. The mixture after digestion is cooled, transferred to a volumetric flask and 5 cc. of colloid solution is then added for each 100 cc. of final volume; two or three drops of Nessler solution are added to serve as indicator and the solution neutralized with 10% sodium hydroxide solution. The solution is then diluted and the Nessler solution, to which the colloid has been added, is run in to the amount of from 10 to 25 cc., according to the nitrogen content of the solution, for each 100 cc. of final solution. No care need be taken as to the manner of addition of the Nessler solution except to note its volume, which must be the same as for the preparation of the standard for comparison. After the addition of the Nessler solution, the flask is filled to the mark, shaken and compared with Nesslerized standard prepared in the same manner.

For analysis of feeds and other dry materials it is best to make the usual macro digestion using either copper sulfate or mercury for catalyst. In general copper is preferable as it is easier to get crystal clear Nesslerization when it is used than in the case of mercury. When mercury is used as a catalyst somewhat more protective colloid should be added to the solution before neutralization; also the solution should be diluted as much as possible before neutralizing. The turbidity due to mercuric oxide formed in neutralizing when a slight excess of alkali is added usually, however, entirely clears after Nesslerization. By the use of the colloid as described it is possible to add the solution to be Nesslerized to the diluted Nessler and colloid solutions and in this way it is unnecessary to make several standards, as an acid mixture corresponding to the digested mixture may be neutralized and the Nessler solution added and then the standard ammonia solution until it approximately matches the unknown. It is, of course, very necessary to use an accurate buret for the measurement of the concentrated standard solution.

For routine work we have found it desirable to use definite amounts and dilutions and obtain results from a prepared chart referred to colorimeter scale readings.

Preparation of Protective Colloid Solution

While many samples of gum arabic may be used without special preparation, all samples which we have examined give considerable color with Nessler solution as well as an appreciable reduction to free mercury upon standing for some time. All of the ammonia and most of the other interfering substances can be easily removed by treatment of the solution with Permutit powder.

Ten grams of powdered gum arabic are slowly added with vigorous stirring to 190 cc. of ammonia-free water and the mixture stirred until the gum is entirely dispersed. The solution is transferred to a flask and approximately 4 g. of Permutit powder as prepared for ammonia determinations is added and the mixture shaken at intervals for ten minutes. Upon standing for a few minutes the Permutit powder settles and the slightly turbid supernatant liquid is decanted. This liquid should at most give only a faint coloration with Nessler solution; if a test portion gives an appreciable coloration with Nessler solution, the treatment with a fresh portion of Permutit powder is repeated. The solution as prepared is somewhat turbid but the insoluble material will settle out on standing for some hours. The turbidity in the freshly prepared solution, however, usually does not interfere and the solution may be used at once. Some samples of gum arabic treated as above have considerable reducing action on the Nessler solution; such solutions may be oxidized by the addition of small amounts of sodium peroxide, allowing the solution to stand until the evolution of oxygen has ceased; but as there appears to be no satisfactory indication as to the proper amount of sodium peroxide to be added, resulting in solutions which are not uniformly satisfactory, we have found the following method of oxidation to be more satisfactory.

The colloid solution from which the ammonia has been removed by treatment with Permutit as described above is treated with about one-tenth its volume of Nessler solution, the mixture allowed to stand until clear and the clear solution decanted when it is ready for use.

This colloid solution may be added in amounts to suit the particular case in hand, but the addition of 3 cc. of this solution to 15 cc. of Nessler solution we have found suitable for nearly all cases met in practice. Apparently any of the various modifications of Nessler solution may be used, but we have found it desirable to follow Folin's directions with the exception of making more concentrated, so that after the addition of the colloid solution the final concentration of alkali and mercury will be that given by Folin and Wu.[3]

Standard ammonia solutions for the preparation of Nesslerized standards may be made by suitable dilution of a macro digestion of a material whose nitrogen content has been accurately determined by the usual distillation and titration procedure or from an accurately weighed portion of pure, dry ammonium sulfate. Care must be taken, however, that the standard and unknown solutions when Nesslerized contain as nearly as possible the same concentration of salts. This would seem to be particularly true when iron is present in appreciable amount, as the colloid will hold considerable ferric hydroxide in the colloidal state and this will undoubtably affect the readings, although to what extent we have not as yet determined.

---

[3] Folin and Wu, J. Biol. Chem., 38, 81 (1919).

Further work on the method is in progress but owing to the very limited time available for this work it was thought advisable to publish the progress at this time.

Summary

1. A protective colloid prepared from gum arabic has been utilized in the Nesslerization of ammonia in the presence of alkali sulfates.

2. By this method a higher concentration of ammonia nitrogen can be Nesslerized in an ordinary Kjeldahl digestion solution than by previous methods even in the absence of any extraneous salts.

3. The limit of accuracy for the colorimetric determination of nitrogen by this method appears to be the accuracy of the colorimeter readings.

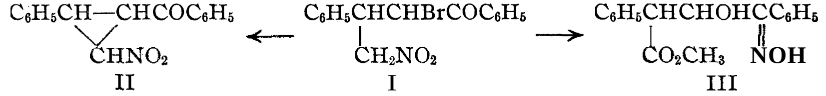
ISOXAZOLINE OXIDES. VIII

BY E. P. KOHLER

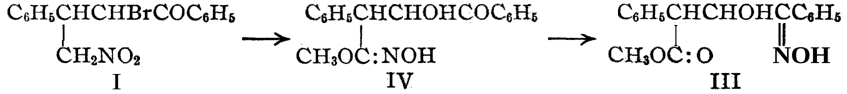
RECEIVED OCTOBER 5, 1927 PUBLISHED JANUARY 5, 1928

It has been shown that cold methyl alcoholic potassium acetate transforms certain α-bromo-γ-nitro ketones into cyclopropane derivatives and hydroxy oximido esters.[1] The oximido esters were unexpected



products. Their discovery led to an investigation of the mechanism by which substances so remotely related are formed from the nitro ketones. The mechanism has not been established completely, but a significant intermediate has been isolated, and the facts which have been accumulated provide a basis for a reasonable explanation.

The method of investigation was based on the fact that no compounds corresponding to the hydroxy oximido esters are formed from bromonitro ketones in which the nitro group is attached to a secondary carbon atom. This observation led to the inference that the oximido esters are formed by rearrangement of some hydroxamic acid derivative because the formation of such derivatives is peculiar to primary nitro compounds. A plausible series of steps would be



For the purpose of testing this hypothesis, methyl alcoholic potassium acetate-was unsuitable because the solution steadily increases in acidity

---

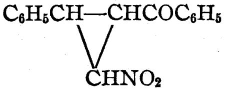
[1] (a) Kohler and Shohan, THIS JOURNAL, 48, 2425 (1926); (b) Kohler and Goodwin, *ibid.*, 49, 219 (1927).

as the reaction progresses. In place of it was used a buffered solution prepared by suspending a large excess of sodium carbonate and sodium bicarbonate in dry methyl alcohol. Towards this solution the two stereomeric bromine compounds represented by I behaved quite differently: the lower-melting isomer gave, mainly, three of the four possible cyclopropane derivatives, while the higher-melting compound yielded, along with cyclopropane derivatives, a substance isomeric with the hydroxy oximido ester. This proved to be the hydroxamic ether represented by IV.

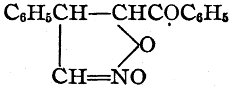
When the hydroxamic ether is shaken or warmed with a methyl alcoholic solution of potassium acetate and acetic acid it passes rapidly and almost quantitatively into the hydroxy oximido ester. It, therefore, doubtless is a real intermediate in the process by which the bromo nitro ketone is converted into the oximido ester. Two problems still remain: to account for the formation of the hydroxamic ether, and to explain the transposition of the oximido group.

With respect to the first problem it is well known that while primary nitro compounds are readily transformed into hydroxamic acids, this occurs only in the presence of acids; bases either form salts of aci-nitro forms or, if too dilute, have no action on the nitro group. Direct experiment showed, moreover, that beyond developing a feeble yellow color, neither potassium acetate nor methyl alcoholic sodium carbonate has any action on the unbrominated nitro ketone. The bromine in the α position, therefore, plays an important part in the process.

In order to provide a proper role for the α bromine atom, and also to account for the fact that the hydroxamic ether is much more readily formed from one of the stereo-isomeric bromine compounds than from the other, one inevitably turns to cyclic intermediates. Two types of cyclic compounds have been obtained by eliminating hydrogen bromide from α-bromo-γ-nitro ketones: nitro cyclopropane derivatives[2] and isoxazoline oxides.[3] In the case under consideration these cyclic products would be represented by II and V.



II



V

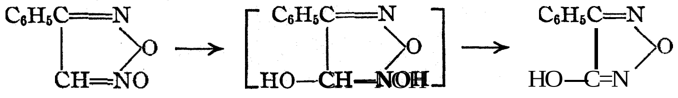
Three of the four possible cyclopropane derivatives are in hand. As they are quite insensitive to methyl alcoholic sodium carbonate they cannot be involved in the formation of the hydroxamic ether. All efforts to prepare the oxide V were fruitless, but from the behavior of known oxides and that of analogously constituted furoxanes it is possible to

---

[2] Kohler and Engelbrecht, THIS JOURNAL, 41, 1379 (1919).

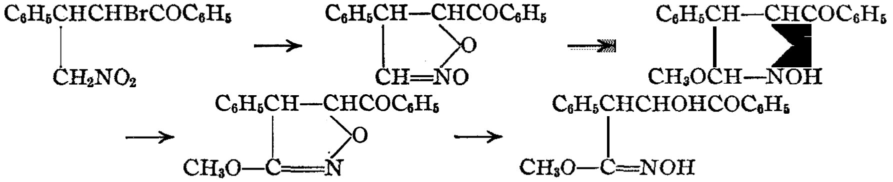
[3] Kohler and Barrett, *ibid.*, **48**, 1770 (1926).

foresee that this oxide would be exceedingly sensitive and that it would be rearranged into more stable substances both by acids and by bases. Its nearest relative, phenylfuroxane VI, in the presence of bases rapidly changes to the hydroxy furazane V11[4]



VI VII

In accordance with this behavior methyl alcoholic sodium carbonate would first transform the isoxazoline oxide into a methoxy isoxazolidine, but since isoxazoline rings are readily opened by bases, the final product would be the hydroxamic ether. The most probable mechanism is, therefore



Inasmuch as acids hydrolyze hydroxamic ethers to esters, and hydroxy ketones readily form oximes in acid solution, the transition from the hydroxamic ether to the oximido ester could be adequately explained by successive hydrolysis and oxime formation. But no free hydroxylamine can be detected at any stage of the process and none can be caught by allowing the reaction to take place in the presence of a large quantity of an aldehyde. It seems at least as probable therefore that the transposition of the oximido group occurs by way of cyclic intermediates. There is at present no experimental evidence on this point.

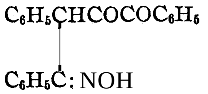
As a result of this and earlier investigations it now appears certain that whenever hydrogen bromide is eliminated from a-bromo-y-nitro ketones the two possible primary products are nitro cyclopropane derivatives and isoxazoline oxides. Since these nitro cyclopropane derivatives are not attacked either by dilute bases or acids, they can almost invariably be isolated. All isoxazoline oxides are sensitive both to bases and acids; they can consequently be isolated only in favorable cases; usually secondary products appear in place of the isoxazoline oxides. The nature of these secondary products depends on that of the nitro ketone and on the medium in which hydrogen bromide is eliminated. In a basic medium bromo ketones which contain a primary nitro group give either a hydroxamic acid or its ether

$$\underset{\text{HOC:NOH}}{C_6H_5CHCHOHCOC_6H_5} \qquad \underset{CH_3OC\text{:NOH}}{C_6H_5CHCHOHCOC_6H_5}$$

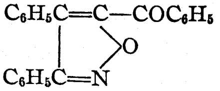
---

[4] Wieland and Semper, *Ann.*, **358**, 47 (1907).

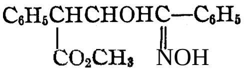
Secondary nitro compounds, under the same conditions, yield either monoximes of triketones or isoxazole derivatives



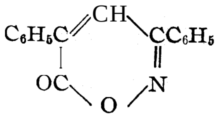
$C_6H_5\underset{C_6H_5C:NOH}{\underset{|}{C}H}COCOC_6H_5$



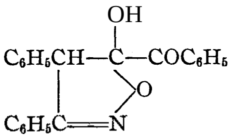
In an acid medium the products from the primary nitro compounds are oximido esters or oxazine derivatives

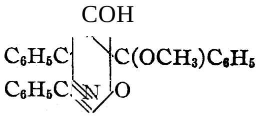


$C_6H_5\underset{CO_2CH_3}{\underset{|}{C}H}CHOH\underset{NOH}{\underset{\|}{C}}-C_6H_5$



The corresponding products from secondary nitro compounds are hydroxy isoxazolines or oxyazines of a different type.

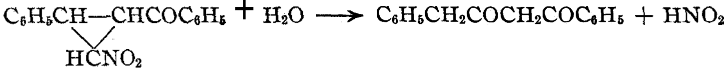




Experimental Part

The reagent used in this investigation—a suspension of anhydrous sodium carbonate in dry methyl alcohol—was first tried separately with each of the stereo-isomeric bromonitro ketones. Both reacted rapidly when the mixture was shaken sufficiently vigorously and both gave a number of products, all of which contained nitrogen.

The methyl alcoholic solution obtained from the lower-melting isomer, when concentrated, readily deposited a large quantity of a solid which was identified as the known cyclopropane derivative melting at 95°. The filtrate left an oil which slowly solidified and from which two additional products melting at 88 and 140° were ultimately isolated. These with cold concentrated sodium alcoholate gave the characteristic reaction of nitro cyclopropane ketones[6]



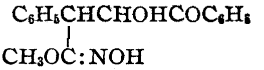
The solution obtained from the higher-melting isomer likewise first deposited the known cyclopropane derivative but the filtrates from this slowly deposited a much higher-melting solid which was exceedingly difficult to handle until it was discovered that from solutions containing acetone it crystallizes fairly well in tables containing acetone of crystallization.

Analyses and a molecular weight determination showed that this new product is isomeric with the oximido ester. A methoxyl determination proved the presence of one such group and a quantitative examination

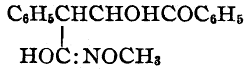
---

[6] Kohler and Engelbrecht, THIS JOURNAL, 41, 1379 (1919).

of its behavior towards methyl magnesium iodide showed that it consumed three moles of reagent and liberated two moles of methane gas. These analytical results show that the substance contains a methoxyl group, two active hydrogen atoms presumably present as hydroxyl and one group capable of combining with methyl magnesium iodide—probably carbonyl. Unlike the oximido ester, it does not form a copper derivative when its ethereal solution is shaken with copper acetate; it, therefore, does not contain the system —C(OH)C(NOH)—. In combination with the known origin of the substance, these facts leave only two possible formulas

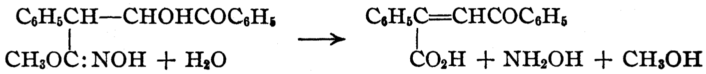


$$\begin{array}{l}C_6H_5CHCHOHCOC_6H_5\\ \qquad\quad |\\ CH_3OC{:}NOH\end{array}$$



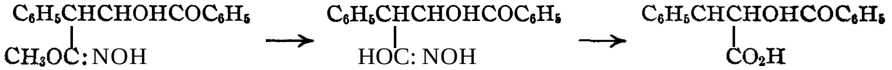
$$\begin{array}{l}C_6H_5CHCHOHCOC_6H_5\\ \qquad\quad |\\ HOC{:}NOCH_3\end{array}$$

The first formula is confirmed, the second excluded, by the following transformations. Acetic acid and dilute solutions of mineral acids in methyl alcohol convert the substance into the oximido ester **III,** while concentrated hydrochloric acid in methyl alcohol both hydrolyzes and eliminates water, leaving *trans*-α-phenyl-β-benzoyl acrylic acid.



$$\begin{array}{l}C_6H_5CH{-}CHOHCOC_6H_5\\ \qquad\quad |\\ CH_3OC{:}NOH + H_2O\end{array} \longrightarrow \begin{array}{l}C_6H_5C{=}CHCOC_6H_5\\ \qquad\quad |\\ CO_2H + NH_2OH + CH_3OH\end{array}$$

The substance, while indifferent to weak and dilute bases, dissolves readily in strong alkaline solutions and is reprecipitated by carbon dioxide and other acids. This typical behavior of oximes excludes the second formula. If the alkaline solutions are allowed to stand for some hours before acidification, the result is an acid which gives the characteristic reactions of hydroxamic acids and which can be further hydrolyzed to an hydroxy acid of known structure



$$\begin{array}{l}C_6H_5CHCHOHCOC_6H_5\\ \qquad\quad |\\ CH_3OC{:}NOH\end{array} \longrightarrow \begin{array}{l}C_6H_5CHCHOHCOC_6H_5\\ \qquad\quad |\\ HOC{:}NOH\end{array} \longrightarrow \begin{array}{l}C_6H_5CHCHOHCOC_6H_5\\ \qquad\quad |\\ \qquad CO_2H\end{array}$$

After a sample of the hydroxamic ether had become available for inoculation it was possible to get the substance by starting with the mixture of stereomeric bromine compounds and, since the separation of this mixture is an exceedingly laborious operation, most of the substance was prepared in this manner. The procedure was as follows.

Fifty grams each of the mixed bromo compounds and anhydrous sodium carbonate were suspended in 300 cc. of dry methyl alcohol. The mixture was vigorously shaken on a mechanical shaker for four hours, then poured into a liter of water. This precipitated a yellow oil which was suspended in a faintly yellow aqueous solution. Four lots were poured together and extracted with ether. The water solution contained only a minute amount of organic material. The ethereal layer was thoroughly washed with water to remove methyl alcohol, then dried over calcium chloride and freed from ether. This left 140–150 g. of bromine-free yellow oil.

The oil was dissolved in 200 cc. of acetone, the solution diluted with 275–300 cc.

of petroleum ether, then inoculated with a sample of the hydroxamic ether which had been recently recrystallized from acetone-petroleum ether and set aside. In the course of twenty-four hours it gradually deposited 24–26 g. of fairly pure ether in well-formed tables, and 3-4 g. more of less pure substance separated in the course of a week. After purification by recrystallization from the same mixture of solvents the total yield was 21 g.

The filtrate from the hydroxamic ether was freed from acetone and petroleum ether, the oil dissolved in 300 cc. of warm methyl alcohol, the solution inoculated with the cyclopropane derivative melting at 95°, then gradually cooled, finally to —20". It deposited 75–100 g. of almost pure product. The filtrate from this, when allowed to evaporate very slowly in covered beakers, finally turned into a pasty mush. By draining off the liquid at a low temperature with a pump and patiently recrystallizing the solid from ether-petroleum ether this was finally separated. It yielded 3 substances, the known cyclopropane derivative melting at 95°, and two new cyclopropane derivatives melting, respectively, at 88° and 140–142°.

The Cyclopropane Derivatives

The new cyclopropane derivatives crystallize in fine needles. They resemble each other so closely that it is impossible to distinguish them except by melting point and solubility.

Anal. Calcd. for $C_{16}H_{13}O_3N$: C, 71.9, H, 5.0 Found: I (88°): C, 71.9; H, 5.2; II (140°): C, 72.0; H, 4.9.

Each of these substances was dissolved in concentrated sodium methylate as directed in an earlier paper.[6] The lower-melting compound gave 3.5, the higher-melting 3.1 g., of the copper derivative of benzoyl phenacetyl methane—proving that these substances are stereo-isomers of the known benzoyl phenyl nitro cyclopropane.

The Hydroxamic Ether. IV

The ether crystallizes from acetone in transparent tables containing one molecule of acetone which is slowly given off at the ordinary temperature.

Anal. Calcd. for $C_{17}H_{17}O_4NC_3H_6O$: C, 67.6; H, 6.9. Found: C, 67.4; H, 7.1.

When the substance is pure, it can be recrystallized from ether and petroleum ether from which it separates in small, thick plates which are free from solvent.

Anal. Calcd. for $C_{17}H_{17}O_4N$: C, 68.2; H, 5.8; OCH_3, 10.2. Found: C, 68.4; H, 6.0; OCH_3, 10.2.

The ether is extremely soluble in alcohol and in acetone, moderately soluble in ether, insoluble in petroleum ether. It melts with decomposition at about 190°.

Behavior **toward** Bases.—The hydroxamic ether dissolves readily in excess of cold 20% aqueous sodium hydroxide. If the resulting pale yellow solution is immediately acidified all of the ester is recovered; if it is shaken with acetic anhydride it deposits a mono-acetate of the ester; and if it is kept for some hours and then acidified the product is the corresponding hydroxamic acid.

---

[6] Kohler and Engelbrecht, THIS JOURNAL, 41, **1383** (1919).

The Acetate.—The acetate is most readily made by dissolving the ether in acetic anhydride, warming the solution for a few minutes on a steam-bath and then pouring it into ice water. It crystallizes from ether and from methyl alcohol in stout needles, from ether-petroleum ether in prisms. It melts with effervescence at about 185°.

Anal. Calcd. for $C_{19}H_{19}O_5N$: C, 66.9; H, 5.6; OCH_3, 9.1. Found: C, 66.8; H, 5.7; OCH_3, 8.4.

The Hydroxamic **Acid.—A** solution of 10 g. of the hydroxamic ether in excess of 10% aqueous sodium hydroxide was kept for five hours at the ordinary temperature, then extracted with ether. This removed 0.4 g. of unchanged hydroxamic ether. The alkaline solution was cooled in ice water, covered with 25 cc. of ether and acidified with iced dilute sulfuric acid. The ethereal layer promptly began to deposit colorless needles melting with decomposition at about 160". The aqueous layer, even though it had been extracted with ether five times, deposited another gram of the same acid in the course of a week; total yield of crude product, 7.2 g.

The acid is extremely difficult to purify because in solution it gradually changes to a more soluble acid. From a mixture of ether and petroleum ether it occasionally separated in well-formed tables.

Anal. **Calcd.** for $C_{16}H_{15}O_4N$: C, 67.3; H, 5.3. Found: C, 67.1; H, 5.1:

The acid is readily soluble in alcohol, moderately soluble in ether, sparingly soluble in water. It forms a khaki-colored copper compound both when its ethereal and when its aqueous solution is shaken with copper acetate. Both ethereal and aqueous solutions also give blood-red solutions when they are added to methyl alcoholic ferric chloride. In polar solvents the hydroxamic acid apparently undergoes a spontaneous rearrangement into the isomeric oximido ester. Thus in an attempt at recrystallization a solution of 2 g. of the acid in methyl alcohol was diluted with water until it was definitely turbid. In the course of a few days the turbidity disappeared and the solution then gave a vivid green instead of a khaki-colored copper compound. Upon inoculation it deposited 1.4 g. of the isomeric oximido acid melting at 168°.[1b]

Behavior of the **Hydroxamic** Ether toward Acids.—The sole action of acids on the hydroxamic ether appears to be its rearrangement to the isomeric oximido ester, for while other products can be obtained by vigorous treatment with mineral acids, all of these are also formed by similar treatment of the oximido ester. The rearrangement can be brought about almost quantitatively with methyl alcoholic potassium acetate and acetic acid. Thus a solution of 2 g. of the ether, 2 g. of the acetate and 5 cc. of acetic acid in 20 cc. of dry methyl alcohol was boiled for half an hour, then cooled and poured into ether and water. The ethereal layer was shaken with sodium carbonate, washed with water, dried and concentrated. It gave 1.72 g. of pure oximido ester and a small quantity of a contaminated product.

Trans-α-phenyl-β-benzoyl Acrylic Acid

The unsaturated ketonic acid is the final product in the degradation of the hydroxamic ether by acids. It is formed when the ether itself, the hydroxamic acid, the oximido ester, the oximido acid or the ketonic acid is heated with methyl alcoholic hydrochloric acid. This was established by heating each of these substances for several hours with a mixture of equal volumes of methyl alcohol and concentrated hydrochloric acid. The best yield (80%) was obtained from the oximido ester. The acid is readily soluble in acetone and alcohol, sparingly in ether. It was purified by crystallization from a mixture of acetone and petroleum ether, from which it separates in small, lustrous tables melting without decomposition at 202°.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.2; H, 4.8. Pound: C, 76.5; H, 4.8.

Structure.—An aqueous solution of permanganate was dropped into *a* cold and rapidly stirred solution of 2 g. of the acid in sodium bicarbonate until the permanganate color persisted for fifteen minutes. The oxide of manganese was dissolved by adding sulfur dioxide, the solution strongly acidified and extracted with ether. The dried ethereal solution, on evaporation, left a residue weighing 2.18 g. With phenylhydrazine this gave 3.05 g. of a phenylhydrazone melting at 161–162°, and identified as the hydrazone of phenyl glyoxylic acid by comparison with *a* sample on hand. Oxidation with permanganate, therefore, ends in two molecules of phenyl glyoxylic acid.

Synthesis.—Although the result of oxidation left no doubt as to the structure of the unsaturated acid it seemed best to synthesize it because it does not, like the isomer described in an earlier paper,[7] give an oxazine when treated with hydroxylamine. The synthesis by way of α-phenyl-β-benzoyl propionic acid presents no difficulties. When this ketonic acid is brominated it gives two isomeric β-bromo derivatives melting, respectively, at 195 and 208°, both with decomposition. The lower-melting compound crystallizes from ether in large prisms containing ether of crystallization which is lost at the ordinary temperatures.

Anal. Calcd. for $C_{16}H_{13}O_3Br$: C, 57.7; H, 3.9. Found: C, 57.5; H, 4.0.

This bromo compound readily dissolves in an equivalent quantity of normal aqueous sodium carbonate, but it soon becomes cloudy and in the course of a week it deposits a considerable quantity of crystalline material composed of the acid and an indifferent compound which will be described elsewhere. The mixture was easily separated by extraction with sodium carbonate. The acid obtained in this manner was the same as that formed by the hydrolysis of the hydroxamic acid.

Summary

An investigation of the process by which methyl alcoholic potassium acetate transforms certain a-bromo-y-nitro ketones into β-hydroxy-γ-oximido esters leads to the conclusion that the primary product of the reaction is an isoxazoline oxide. Potassium acetate first transforms this into an hydroxamic ether, which was isolated, and the acetic acid formed in the reaction rearranges the hydroxamic ether to the oximido ester.

5-BROMO-2,4-DIMETHOXYBENZOYLACRYLIC ACID AND ITS ESTERS

BY GRACE POTTER RICE

RECEIVED OCTOBER 19, 1927 PUBLISHED JANUARY 5, 1928

The work described in this paper was begun with the intention of studying a dimethoxy substituted benzoylacrylic acid and its esters but the method used in the attempt to prepare them from dimethoxybenzoylpropionic acid gave unsaturated substances with a bromine atom in the ring; the methyl ester has been shown to be methyl-5-bromo-2,4-dimethoxybenzoylacrylate.[1] The fact that the acid as well as its methyl and ethyl esters have melting points much higher than those of the various unsaturated ketonic acids and esters previously investigated in this Laboratory[2] suggested that they might be desirable substances for evidence of any possible relationship between the melting point of a solid which is sensitive to light and its tendency to isomerize or polymerize. No evidence on this point is obtained from the study of 5-bromo-2,4-dimethoxybenzoylacrylic acid (208") and its methyl ester (129°), for they do not polymerize or isomerize in the sunlight. The ethyl ester, however, is extremely sensitive to light and since a low-melting substance on exposure to light usually isomerizes like a substance in solution because it melts and behaves in the molten condition as though it were in solution,[3] this ethyl ester, with its melting point of 115.5°, would not be expected to isomerize but to polymerize as is usually the case with solids in the dry condition. It has been found that the ethyl ester is rapidly changed to a polymer which is probably a cyclobutane derivative; it is the only unsaturated ketonic ethyl ester of the five investigated to form a polymer and the only one with a melting point above 55°.

The tendency of a bromine atom in the ring to favor the formation of crystalline substances has made possible the investigation of reactions with this ketonic acid which could not be studied with benzoylacrylic acid and its simpler substitution products. Such a reaction is that which the methyl ester of 5-bromo-2,4-dimethoxybenzoylacrylic acid undergoes in methyl alcohol solution containing a trace of potassium hydroxide. Two structural isomers are possible which are a result of 1:4 addition to the two conjugated systems of double linkages in the ester, $(CH_3O)_2C_6H_2Br\underset{1}{O}\underset{2}{C}\overset{4}{\underset{3}{C}}H=$

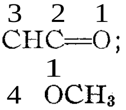
[1] Rice, THIS JOURNAL, 48, 3125 (1926).

[2] Rice, *ibid.*, 45, 222 (1923); 46, 214, 2319 (1924); 48,269 (1926).

[3] (a) Stobbe, *Ber.*, 52, 666 (1919); (b) Stobbe and Steinberger, *Ber.*, 55, 2225 (1922); (c) Stobbe and Lehfeldt, *Ber.*, 58, 2415 (1925).



$\overset{3}{\mathrm{C}}\mathrm{H}\underset{\substack{1\\ \mathrm{OCH_3}}}{\overset{2}{\mathrm{C}}}=\overset{1}{\mathrm{O}}$ (4); if the $(COOCH_3)$ determines the addition, the product would be a β-methoxy ester, $(CH_3O)_2C_6H_2BrCOCHOCH_3CH_2CO_2CH_3$, but if the (CO) determines the addition, the product would be an a-methoxy ester, $(CH_3O)_2C_6H_2BrCOCH_2CHOCH_3CO_2CH_3$. The proof that the latter is the case rests on the fact that the β-methoxy ester was prepared in a way which left no doubt as to its structure and it was found to be not identical but isomeric with the methoxy ester formed in the addition reaction. The results of further study of the bromodimethoxy acid and its esters will be reported later.

Experimental Part

2,4-Dimethoxybenzoylpropionic acid[4] was prepared from resorcinol dimethyl ether and succinic anhydride by the Friedel and Crafts reaction. After the dark red solid addition product had been decomposed with water, steam was forced through the mixture until the carbon disulfide and resorcinol dimethyl ether were removed. The colorless product which crystallized from the hot aqueous solution was a mixture of acids and a mixture was always obtained though the conditions of carrying out the reaction were varied in an attempt to find the factors favoring the formation of pure dimethoxy acid. The crude product—75 to 85%—was separated partially after several recrystallizations from 50% acetic acid to give a yield of 65–75% of pure dimethoxy acid. The residue was still a mixture which was shown to contain 2-hydroxy-4methoxybenzoylpropionic acid by isolation of the methyl ester of this acid melting at 87°[4] on esterification of the residue; the acid itself was not separated.

Anal. Calcd. for $C_{12}H_{14}O_5$: C, 60.50; H, 5.88. Found: C, 60.28; H, 5.95.

β-Bromo-5-bromo-2,4-dimethoxybenzoylpropionic Acid, $(CH_3O)_2C_6H_2BrCOCHBrCH_2CO_2H$.—The bromo acid is formed when the dimethoxy acid is suspended in chloroform and treated with bromine; on evaporation of the chloroform it was left as a solid which was purified by recrystallizing it first from glacial acetic acid and then from methyl alcohol. It separates from both solvents in colorless needles melting at 165° with decomposition. When the crude acid was recrystallized from methyl alcohol it was changed completely into its methyl ester, esterification apparently being brought about by the hydrogen bromide held by the solid.

Anal. Calcd. for $C_{12}H_{12}O_5Br_2$: C, 36.36; H, 3.03. Found: C, 36.54; H, 3.59.

5-Bromo-2,4-dimethoxybenzoylacrylic Acid, $(CH_3O)_2C_6H_2BrCOCH{=}CHCO_2H$.—The unsaturated acid was prepared by heating a concentrated glacial acetic acid solution of the bromo acid with potassium acetate in a boiling water-bath for two hour-,. It crystallized as the solution cooled, was filtered off, washed with water and dried; it is sparingly soluble in boiling water, soluble in boiling methyl alcohol, acetone, benzene, chloroform and glacial acetic acid and almost insoluble in ether. It was purified with

[4] Perkin and Robinson, J. *Chem. Soc.*, 93, 506 (1908).

both benzene and glacial acetic acid as solvents—yield 95–99% calculated from the saturated acid. The bright yellow needles melt at 208°.

Anal. Calcd. for $C_{12}H_{11}O_5Br$: C, 45.71; H, 3.49. Found: C, 46.10; H, 3.52.

The unsaturated acid can be prepared most readily by brominating a glacial acetic acid solution of the saturated acid and heating this solution of the bromo acid in boiling water for two hours with potassium acetate. The acid which separates on adding a few drops of concd. hydrochloric acid and cooling the solution in an ice-bath melts at 205–208° and the yield is practically quantitative.

5-Bromo-2,4-dimethoxybenzoylpropionic Acid, $(CH_3O)_2C_6H_2BrCOCH_2CH_2COOH$.—This acid was obtained in 75% yield by treating a suspension of unsaturated acid cooled in ice with an aqueous solution of sodium hydrosulfite. The solid which separated on diluting and acidifying the solution was pure and melted at 187° after two recrystallizations from methyl alcohol.

Anal. Calcd. for $C_{12}H_{13}O_5Br$: C, 45.42; H, 4.10. Found: C, 45.62; H, 4.20.

The unsaturated acid is so sparingly soluble in cold ether and benzene that it is not practical to study the action of sunlight on the acid in these solvents; a solution of it in glacial acetic acid was exposed for three months but there was no change in the substance except for a slight amount of decomposition. After exposure for the same length of time, the powdered unsaturated acid was still yellow; a change in melting point of the solid, however, may indicate a very slow formation of a polymer but such a substance was not isolated.

The methyl ester of dimethoxybenzoylpropionic acid was obtained in quantitative yield by heating a methyl alcohol solution of the pure acid for two hours with concd. sulfuric acid; the solution was poured onto cracked ice, powdered sodium carbonate was added as long as solid ester continued to separate and the ester was filtered off, washed with ice water and dried. It can be used without recrystallization for preparation of the unsaturated ester. It separates from methyl alcohol with solvent of crystallization in heavy, transparent needles melting at 49°; they become opaque after several hours and melt at 58–59°, the melting point given by Perkin and Robinson.[4]

When this ester was treated in chloroform solution with one molecular equivalent of bromine under most carefully regulated conditions for bromination, the residue, after removal of the solvent, was an oil which failed to crystallize and which gave an untractable mixture on treatment with potassium acetate. The only unsaturated substance separated from the mixture held a bromine atom, so after the reaction had been repeated several times with the same results, it was deemed useless to try to prevent a bromine atom from entering the ring. Therefore, in subsequent work with this ester, as well as with the ethyl ester and the acid, two molecular equivalents of bromine were used for bromination.

Methyl-β-bromo-5-bromo-2,4-dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_2BrCOCHBrCH_2CO_2CH_3$.—A chloroform solution of the ester of the dimethoxy acid, cooled in an ice-bath, was treated with two molecular equivalents of bromine and the solvent removed by drawing dry air through the solution. The residue was a cake of crystalline solid which melted at 103° after two recrystallizations from methyl alcohol.

Anal. Calcd. for $C_{13}H_{14}O_5Br_2$: C, 38.05; H, 3.41. Found: C, 38.10; H, 3.54.

Methyl-5-bromo-2,4-dimethoxybenzoylacrylate, $(CH_3O)_2C_6H_2BrCOCH{=}CHCO_2CH_3$.—The methyl alcohol solution of the bromo ester, 20 g. in 200 cc. of methyl alcohol, was boiled for two hours with 10 g. of potassium acetate. The yellow unsaturated ester which separated in long needles as the solution cooled was filtered off, washed with ice water and dried; yield, 97%. After removal of the chloroform, the bromo ester can be used without purification for the preparation of the unsaturated ester; yield, 95–98%. The ester is soluble in boiling benzene, methyl alcohol, acetone, chloroform and glacial acetic acid and all of these solvents can be used for recrystallizing it. On melting it behaves like a substance holding solvent of crystallization; the solid after recrystallization from methyl alcohol softens at 129° and melts at 138°, solidifies on cooling and melts sharply at 129°. The point where the ester softens varies somewhat with specimens recrystallized from different solvents but the melting point of the re-solidified substance is always 129°.

Anal. Calcd. for $C_{13}H_{13}O_5Br$: C, 47.41; H, 3.95. Found: C, 47.11; H, 4.03.

The unsaturated ester is hydrolyzed extremely slowly by boiling with 10% sodium carbonate solution but more readily by boiling with dilute hydrochloric acid to give the unsaturated acid.

Methyl-5-**bromo-2,4-**dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_2BrCOCH_2CH_2CO_2CH_3$.—This substance was formed when an ice-cold methyl alcohol solution of the ester was treated with sodium hydrosulfite; the solid which was precipitated when the solution was diluted with ice water separated from methyl alcohol in fine, colorless needles melting at 117°.

Anal. Calcd. for $C_{13}H_{15}O_5Br$: C, 47.13; H, 4.53. Found: C, 47.10; H, 4.45.

Hydrolysis of this ester gave the corresponding acid melting at 187'.

The yellow, unsaturated ester was recovered unchanged from its benzene solution which had been exposed to the sunlight; when it was exposed as a powdered solid 70% was recovered unchanged and the rest was a brown, amorphous mass from which no crystalline substance could be separated.

Ethyl-2,4-dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_3COCH_2CH_2CO_2C_2H_5$.—An absolute alcohol solution of dimethoxybenzoylpropionic acid containing concd. sulfuric acid was refluxed for two hours; the solid ester which separated when the solution was poured onto ice was filtered off and washed with ice water. On recrystallization from alcohol large, transparent crystals were obtained which melted at 44°, slowly became opaque, and melted at 68.5"; yield, 94%.

Anal. Calcd. for $C_{14}H_{18}O_5$: C, 63.15; H, 6.76. Found: C, 63.14; H, 6.89.

Ethyl-β-bromo-5-bromo-2,4-dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_2BrCOCHBrCH_2CO_2C_2H_5$.—A chloroform solution of the ester was treated with two molecular equivalents of bromine, the solvent removed and the solid recrystallized once from alcohol. It separated in thick needles melting at 114.5'; yield, 97%.

Anal. Calcd. for $C_{14}H_{16}O_5Br_2$: C, 39.62; H, 3.77. Found: C, 39.77; H, 4.07.

Ethyl-5-**bromo-2,4-dimethoxybenzoylacrylate,** $(CH_3O)_2C_6H_2BrCOCH{=}CHCO_2C_2H_5$.—The unsaturated ester is formed when the bromo ester is refluxed for two hours with potassium acetate. The ester which crystallized as the solution cooled was filtered off and washed with ice water; it is soluble in boiling organic solvents and crystallizes from benzene and alcohol in firm, yellow plates melting at 115.5'; yield of pure product 96%.

Anal. Calcd. for $C_{14}H_{15}O_5Br$: C, 48.97; H, 4.37. Found: C, 48.79; H, 4.25.

In subsequent preparations, the bromo ester was used without recrystallization for making the unsaturated ester.

Action of Sunlight on **Ethyl-5-bromo-2,4-dimethoxybenzoylacrylate**

The yellow ethyl ester undergoes a remarkably rapid change when powdered and exposed to the sunlight. The colorless solid formed was boiled with several portions of alcohol which left undissolved a substance melting at 265° and practically insoluble in all the common organic solvents; from **6.1** g. of ester, **5.3** g. was obtained (87%). **It** is soluble in boiling nitrobenzene and separates completely from a saturated solution in transparent plates melting at **266°**; its molecular weight was determined in nitrobenzene with the use of a Woods metal bath to insure regular boiling of the solvent.

Anal. Calcd. for $(C_{14}H_{15}O_5Br)_2$: C, 48.97; H, 4.37; mol. wt., 686. Found: C, 48.64; H, **4.27;** mol. wt., 713.

The polymer is stable in the dark but it gradually turns yellow when left in diffused daylight.

From the alcohol a small quantity of substance (129–130°) was separated which did not react with bromine and was stable to light in benzene solution in the presence of iodine; a molecular weight determination by the Rast method indicated that the substance has twice the molecular weight of the unsaturated ester. Its behavior, however, was irregular, for the camphor solution was yellow after the solid mixture had been melted several times and each successive melting point of this yellow solid was lower, showing that depolymerization was taking place. Evidently this polymer is not stable at the melting point of camphor, 178°.

Anal. Calcd. for $(C_{14}H_{15}O_5Br)_2$: C, 48.97; H, 4.37. Found: C, 49.11; H, 4.59.

Reaction of Unsaturated Methyl Ester in Methyl Alcohol Solution Containing a Trace of Potassium Hydroxide

Methyl-α-methoxy-5-bromo-2,4-dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_2BrCOCH_2CHOCH_3CO_2CH_3$, and **α-Methoxy-5-bromo-2,4-dimethoxybenzoylpropionic** Acid, $(CH_3O)_2C_6H_2BrCOCH_2CHOCH_3CO_2H$.—A mixture of these substances is obtained when a methyl alcohol solution of methyl-5-bromo-2,4-dimethoxybenzoylacryle, cooled in a freezing mixture, is stirred vigorously for three minutes with a few drops of potassium hydroxide solution (2:3). If sufficient solvent was used to keep the unsaturated ester in solution at the low temperature of the reaction, the methoxy acid was the chief product formed; if a suspension of the unsaturated ester was used, the methoxy ester separated at once and could be filtered off, but it was mixed with unsaturated ester which had escaped reaction, and if stirring was continued, in this case, until the yellow ester had reacted completely considerable hydrolysis of the methoxy ester took place and both the methoxy acid and ester were contaminated with sticky yellow decomposition products. The reaction can be carried out with the speed necessary for its success if the unsaturated ester (3 g.) is dissolved in hot methyl alcohol (150 cc.) and enough chloroform added to prevent the ester from crystallizing when the solution is cooled. After stirring for three minutes with a few drops of potassium hydroxide solution, the mixture was acidified with concd. hydrochloric acid, the lower chloroform layer drawn off and the upper layer extracted once with chloroform. Evaporation of the solvent left 3.3 g. of solid which gave, after four recrystallizations from methyl alcohol, 2.9 g. of methoxy ester (117°) and **0.3** g. of methoxy acid (189°), a quantitative yield. The ester is soluble in cold chloroform, hot ether, benzene and methyl alcohol; it crystallizes from benzene and methyl alcohol in fine, colorless needles. The acid is sparingly soluble in ether, benzene and hot chloroform and extremely soluble in methyl alcohol; it is purified most readily by recrystallization from a mixture of methyl alcohol and chloroform.

Anal. (117°). Calcd. for $C_{14}H_{17}O_6Br$: C, 46.53; H, 4.70; mol. wt., 361. Found: C, 46.57; H, 4.83; mol. wt., 357.

Anal. (189°). Calcd. for $C_{13}H_{15}O_6Br$: C, 44.95; H, 4.32. Found: C, 44.92; H, 4.30.

The methoxy acid was also obtained when β-bromo-5-bromo-2,4-dimethoxybenzoylpropionic acid was treated cautiously in ice-cold methyl alcohol solution with sodium methylate. The methoxy acid can be changed into its methyl ester by the usual esterification methods and the ester can be hydrolyzed by very cautious treatment with alkali to give the methoxy acid. When the methoxy ester was heated for two hours on a water bath with dil. hydrochloric acid (1:2) about equal parts of unsaturated acid and unsaturated methyl ester were obtained.

Synthesis of α- and β-Hydroxy Acids

α-Hydroxy-5-bromo-2,4-dimethoxybenzoylpropionic Acid, $(CH_3O)_2C_6H_2BrCOCH_2CHOHCO_2H$.—This acid was formed when the unsaturated acid and its methyl ester were boiled with dilute hydrochloric acid for many hours, but even after repeated attempts an amount of it sufficient for preparation of the ester of its ether was not accumulated. It is readily soluble in water, alcohol and hot chloroform; from chloroform it separates in fine needles melting at 172°.

Anal. Calcd. for $C_{12}H_{13}O_6Br$: C, 43.24; H, 3.90. Found: C, 43.84; H, 3.86.

β-Hydroxy-5-bromo-2,4-dimethoxybenzoylpropionic Acid, $(CH_3O)_2C_6H_2BrCOCHOHCH_2COOH$.—Since the α-hydroxy acid could not be obtained in quantity, the β-hydroxy acid was prepared in order to compare the ester of its ether with the methoxy ester (117°). A mixture of 14 g. of β-bromo-5-bromo-2,4-dimethoxybenzoylpropionic acid and 1000 cc. of 10% sodium carbonate solution was shaken in a machine for three hours; on acidification a solid was precipitated which crystallized from methyl alcohol and from water in colorless needles melting at 179° with decomposition; yield of pure acid 80%.

Anal. Calcd. for $C_{12}H_{13}O_6Br$: C, 43.24; H, 3.90. Found: C, 43.32; H, 3.76.

Methyl-β-methoxy-5-bromo-2,4-dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_2BrCOCHOCH_3CH_2CO_2CH_3$.—This substance was formed when a methyl alcohol solution of the β-hydroxy acid was heated for eleven hours on a water-bath with methyl iodide and silver oxide; it crystallizes from methyl alcohol in needles melting at 134.5°.

Anal. Calcd. for $C_{14}H_{17}O_6Br$: C, 46.53; H, 4.70. Found: C, 46.71; H, 4.77.

Since this is the methyl ether of the β-hydroxy ester, the methoxy ester melting at 117° must have its methoxy group in the α position.

Reaction of Unsaturated Ethyl Ester in Alcohol Solution Containing a Trace of Potassium Hydroxide

Ethyl-α-ethoxy-5-bromo-2,4-dimethoxybenzoylpropionate, $(CH_3O)_2C_6H_2BrCOCH_2CHOC_2H_5CO_2C_2H_5$ and **α-Ethoxy-5-bromo-2,4-dimethoxybenzoylpropionic Acid** $(CH_3O)_2C_6H_2BrCOCH_2CHOC_2H_5CO_2H$.—These substances are formed when an absolute alcohol solution of the unsaturated ethyl ester is treated with alkali in the manner described in the reaction with the unsaturated methyl ester. The ethoxy ester is readily soluble in ether, chloroform and hot methyl and ethyl alcohols; it crystallizes from alcohol in needles melting at 97°.

Anal. Calcd. for $C_{16}H_{21}O_6Br$: C, 49.35; H, 5.39. Found: C, 49.52; H, 5.52.

The ethoxy acid (139–140°) is soluble in alcohol, chloroform and boiling benzene, sparingly soluble in ether and petroleum ether; it can be recrystallized from benzene, from alcohol and from a mixture of chloroform and petroleum ether.

Anal. Calcd. for $C_{14}H_{17}O_6Br$: C, 46.53; H, 4.70. Found: C, 46.47; H, 4.65.

The ethoxy acid was obtained in 50% yield by cautious hydrolysis of the ethoxy ester with alcoholic potassium hydroxide and was separated from the unsaturated acid which is also formed by taking advantage of the lack of solubility of the latter in cold chloroform.

When the unsaturated ethyl ester was treated with potassium hydroxide in the presence of methyl alcohol in the way described for the unsaturated methyl ester, a 69% yield of the methyl ester of the methoxy acid was formed; likewise the unsaturated methyl ester in the presence of ethyl alcohol gave an 80% yield of the ethyl ester of the ethoxy acid. In neither reaction was a second substance found; the poorer yields than were obtained when the reaction was carried out with an ester in the presence of the corresponding alcohol are accounted for by the formation, in both cases, of a considerable amount of yellow decomposition product.

Summary

5-Bromo-2,4-dimethoxybenzoylacrylic acid and its methyl ester are not isomerized or polymerized in the sunlight; the ethyl ester is stable to light in benzene solution but it is rapidly polymerized when exposed as a solid. Hydrolysis of the esters with sodium carbonate solution is extremely slow and incomplete; the methyl ester gives the unsaturated acid and *a* trace of a-hydroxy-5-bromo-2,4-dimethoxybenzoylpropionic acid on boiling for many hours with dilute hydrochloric acid. These esters react in methyl and ethyl alcohol solution in the presence of a few drops of potassium hydroxide solution to give α-alkoxyl addition products which are a result of 1:4 addition to one of the two conjugated systems of double linkages present in the esters.

THE RELATION OF THE STRUCTURE OF KETONES TO THEIR REACTIVITY AND AFFINITY IN ACETAL FORMATION

BY HARRY E. CARSWELL AND HOMER ADKINS

RECEIVED OCTOBER 20, 1927 PUBLISHED JANUARY 5, 1928

The reaction of ketones with alcohols to form acetals analogous to the reaction of aldehydes with alcohols proceeds to so slight an extent, if at all, that the reaction is of no importance. In order to form the acetal of the ketones it is necessary to react the ketones with an ortho ester according to the equation $R_2C{=}O + HC(OR')_3 \qquad R_2C(OR')_2 + HCO_2R'$. The reaction like that of aldehydes with alcohols is a reversible one and hence may be used for the evaluation of the relation of the structure of a ketone to the strength of the linkage between oxygen and carbon in the acetal.[1,2,3] To this end the extent of the reaction of eight ketones

with orthoformic ester has been determined. The ketones whose. reactions have been investigated include five methyl ketones in which the second radical was methyl, ethyl, *n*-hexyl, phenyl or tertiary butyl, besides diethyl, diphenyl and propylphenyl ketones.

The reaction of the ketone with orthoformic ester did not proceed in a toluene or xylene solution containing hydrogen chloride, but proceeded smoothly in an alcoholic solution containing hydrogen chloride as a catalyst. It is apparently necessary to have a considerable proportion of alcohol in the solution, at least in some cases, for 0.1 mole of phenylpropyl ketone did not react with 0.12 mole of orthoformic ester in the presence of 4 cc. of ethanol but the reaction proceeded readily with 14 cc. of alcohol, the amount of hydrogen chloride being constant.

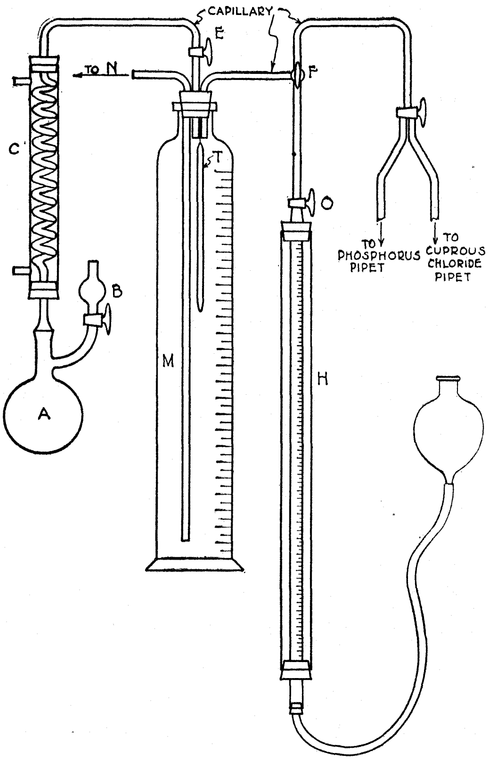

Fig. 1.—Apparatus for analysis for ethyl formate.

A typical procedure for an experiment was as follows. One-tenth of a mole (7.35 cc.) of acetone was run from a standard buret into a Pyrex test-tube (25 X 3.5 cm.). Twenty cubic centimeters or 0.1268 of a mole of orthoformic ester was added, followed by 11.65 cc. of absolute alcohol. A sampling device similar to that described by Child[4] was connected to the test-tube and the test-tube placed in a thermostat at 25°. After allowing the contents of the tube to come to the temperature of the thermostat, 1 cc. of alcohol containing 0.0136 g. of hydrogen chloride was added through the sampling device and thoroughly mixed with the contents of the tube by several times drawing the liquid up into the sampling device and allowing it to run back into the test-tube. After 48 to 60 hours a 5cc. sample was withdrawn and analyzed for ethyl formate. The time interval was chosen after it had been ascertained by experiment that the reaction had gone to completion in that time.

The retrograde reactions were run upon the diethyl acetals of acetone, acetophenone, diethyl ketone and methyl-n-hexyl ketone. Again, acetone diethyl acetal is given as typical. One-tenth of a mole of the diethyl acetal of acetone was put into a Pyrex test-tube, 0.1 mole of ethyl formate was added, together with sufficient alcohol to make the volume of the reaction mixture the same as that in the synthetic reaction. The test-tube was placed in a thermostat and, when the contents had reached 25°, 1 cc. of ab-

solute alcohol containing 0.0136 g. of hydrogen chloride was added through the sampling device. After standing 48–60 hours a 5cc. sample was withdrawn and analyzed.

The method for the determination of ethyl formate was developed by making use of Geuther's observation that sodium ethoxide catalyzes the decomposition of the ester into carbon monoxide and alcohol.[5] An apparatus, a diagram of which is shown in Fig. 1, was developed in which ethyl formate was decomposed by sodium ethoxide and the evolved gas collected and analyzed for carbon monoxide. Such an analysis was conducted in the following manner.

One-half of a gram of sodium ethoxide was placed in the 50cc. flask (A) connected to a 20cm. spiral condenser (C) by a rubber stopper sealed in with collodion. The sample was run into the side-arm bulb (B) from which it was allowed to run into the flask through a stopcock. Ice water was placed about the flask in order to absorb the heat generated at the beginning of the reaction; otherwise the temperature in the flask would rise so rapidly that some of the ethyl formate would volatilize and condense on the cooler portions of the flask and condenser before reacting with the sodium ethoxide. Two cc. of dry toluene was poured down the sides of the side arm and bulb to wash down any of the ester which might be adhering to the sides of the glass. The evolved gas passed up through the condenser and replaced the saturated salt solution in the graduated container (M), the replaced liquid passing into a second graduated container (N). The level of the liquid in (N) was maintained slightly lower than that of the liquid in (M), so that no back pressure would be set up. After five minutes the ice-bath was replaced by a paraffin oil-bath which was gradually heated until it attained a temperature of 110–115° and this temperature was maintained for about one hour. All of the gas in the flask, condenser coils and connecting capillary tubing was forced into (M) by passing a saturated salt solution into the system through the side arm (B). The three-way stopcock (E) was closed and the container (N) was adjusted so that the level of the solution in it was the same as that in (M). The volume of gas in (M) was recorded and the temperature of the gas was obtained from the thermometer (T) which was immersed in it. The barometric pressure was recorded. A thorough mixing of the gas in (M) was accomplished by drawing a portion of it into the volumetric buret (H) and then passing it back into (M) eight or ten times until, finally, a 100cc. portion was confined in (H) by closing the three-way stopcock (F). This aliquot was analyzed for carbon monoxide, after removing the oxygen over phosphorus. The carbon monoxide was absorbed in acid cuprous chloride. The time required to decompose the ethyl formate and analyze the resulting gas was from one and three-quarters to two hours.

The presence of ethyl alcohol was found by Geuther to inhibit the decomposition of ethyl formate. This difficulty was overcome by adding a small piece of sodium, in slight excess of the amount necessary to react with all the alcohol formed. The presence of toluene and orthoformic ester did not affect the amount of carbon monoxide evolved. It was found that the amount of sodium ethoxide used to decompose ethyl formate did not influence the amount of carbon monoxide evolved, in most experiments 0.5 g. of sodium ethoxide being used. The analysis of nineteen samples of known and varying ethyl formate content showed that the amount of carbon monoxide formed was 64.6% ± 1.5% of that required by the equation given by Geuther, $HCO_2C_2H_5 \rightleftarrows CO + C_2H_5OH$. The course of this reaction will be considered later; suffice it for the present

---

[5] Geuther, *Chem. Cent.*, **39**, 632 (1868).

to say that apparently approximately three molecules of the ester yield two molecules of carbon monoxide. Not a trace of carbon dioxide was detected when over three liters of the evolved gas was passed through a solution of barium hydroxide.

The ratio of carbon monoxide to ethyl formate was found to vary slightly, depending on the amount and kind of ketone present in the reaction mixture. Presumably this discrepancy is due to the condensation of ethyl formate with the ketone according to the Claisen reaction. A concentration of 0.0125 mole of acetone in the reaction so affected the decomposition that only 33.8% of ethyl formate was accounted for. If the concentration was decreased to 0.00085 mole of acetone, which was about that in the samples analyzed in the equilibrium-point determinations, the amount of carbon monoxide formed was 66.6% of the ethyl formate known to be present. This conversion factor was used in calculating the percentage conversion of ketone to acetal. The conversion factors for the other ketones used were obtained by analyses of four or mare samples in which the concentration of ketone was approximately that in the samples of equilibrium mixtures analyzed. These factors ±1.5% were: acetophenone 62.5%; diethyl ketone 63.4%; phenylpropyl ketone 65.2%; methylethyl ketone 66.0%; methylhexyl ketone 65.6%; methyl-*tert.*-butyl ketone 59.4% and benzophenone 66.8%.

TABLE I

SUMMARY OF DATA ON PERCENTAGE CONVERSION OF VARIOUS KETONES INTO ACETALS BY ORTHOFORMIC ESTER

Ketone	Per cent. conversion Retrograde	Synthetic	Ketone	Per cent. conversion Retrograde	Synthetic
$CH_3C{=}OCH_3$	92.62	89.87	$CH_3C{=}OC_6H_5$	67.45	66.87
$CH_3C{=}OC_2H_5$	...	87.73	$C_3H_7C{=}OC_6H_5$	...	64.25
$C_2H_5C{=}OC_2H_5$	86.16	87.49	$C_6H_5C{=}OC_6H_5$	...	31.55
$CH_3C{=}OC_6H_{13}$	85.82	84.91	*tert.*-$C_4H_9C{=}OCH_3$	...	12.48

A summary of the percentage of ethyl orthoformate found as ethyl formate is shown in the table for the synthesis of the acetal of eight ketones and for the retrograde reaction on four of the acetals. An inspection of the values given in the table shows that replacement of one or both of the methyl groups in acetone with higher straight-chain alkyl radicals results in a slight lowering of the percentage conversion to the acetal. A hexyl group has a rather marked effect. The substitution of a phenyl group for a methyl group in acetone lowers the percentage conversion by over 20%, while a second phenyl group causes a further lowering of over 30%. The negative effect of the higher as contrasted with the lower alkyl groups is again shown by the fact that the percentage conversion of phenylpropyl ketone is lower than that of phenylmethyl ketone.

The similarity of the tertiary alkyl radicals to the aryl radicals has been previously noted,[6] but it is surprising to find that methyl tertiary butyl ketone shows a lower conversion than methylphenyl ketone and even lower than diphenyl ketone. The number of ketones for which data are now available is too small to justify any attempt at a theoretical treatment of the subject.'

Preparation and Purification of Reagents

Orthoformic Ester was prepared in the usual way.[8]

Fourteen preparations each involving the use of 250 *g.* of sodium and 400 *g.* of chloroform averaged 375 g. of orthoformic ester boiling at 144–146' at 740 mm. after two fractionations. The 5250 g. of ester so obtained was reduced to 2500 g. by three fractionations through a 20cm. Vigreux column, the product boiling at 145–146° under atmospheric pressure and at 45–46° under 15 mm. This product was further fractionated just before use. The pure ester as used in this work had a density of d_{25}^{25} = 0.9385. The density given in the critical tables[g] is 0.8964.

Ketones.—Acetone was fractionated from a commercial product and purified as by Conant and Kirner;[10] b. p. 56.2–56.7' (740 mm.); $d_{25}^{25} = 0.7964$.

Methylethyl ketone, diethyl ketone, methyl-n-hexyl ketone, acetophenone and phenylpropyl ketone were supplied by the Eastman Kodak Co. Each ketone was dried over anhydrous potassium carbonate and then distilled from a Claisen flask carrying a Vigreux distilling column 20 cm. in length. The products used had the following constants: methylethyl ketone, b. p. 79–81" (760 mm.), & = 0.8072; diethyl ketone, b. p. 101–102" (corr.), sp. gr. 0.8156 (25/25); methyl-n-hexyl ketone, b. p. 173–175" (760 mm.), $d_{25}^{25} = 0.8360$; acetophenone, b. p. 200–202° (760 mm.), $d_{25}^{25} = 1.030$; and phenylpropyl ketone, b. p. 228–229.5° (760 mm.), $d_{25}^{25} = 0.9967$.

Benzophenone was an Eastman Kodak Co. product which had a melting point of 47.5–48°. Methyl-*tert.*-butyl ketone was prepared from pinacol by the pinacoline rearrangement as described in "Organic Syntheses."[11] The boiling point of this product was 103–105° (uncorr.) and its specific gravity was 0.7250(25/25).

Ethyl formate was obtained from the Eastman Kodak Co., and after standing over anhydrous potassium carbonate was freshly distilled before using. The boiling point of this reagent was 54° and its specific gravity was 0.9250 (25/25).

Acetals.—The diethyl acetal of acetone was prepared by a method described by

[7] Without further experimental work it does not seem advisable to use these determinations on the amount of ethyl formate formed, for the calculation of the equilibrium constant for the reaction of the orthoformic ester with the ketones, because in some cases it is possible that small amounts of the ethyl formate reacted with ketone according to the Claisen reaction and were therefore not found in the analytical determination. It is anticipated that further work will be done on the extent of the Claisen reaction under the conditions used in this work so that the values given in this paper may be more quantitatively interpreted.

Claisen,[12] with the exception that 0.0136 g. of dry hydrogen chloride was used as a catalyst in place of 1 g. of ammonium chloride; b. p. (15 mm.) 24–25.5°; d_{25}^{25} = 0.8714.

Diethyl acetal of acetophenone was prepared by the method described by Claisen,[13] with the exception that 0.0136 g. of dry hydrogen chloride was used as a catalyst instead of 0.15 cc. of aqueous hydrochloric acid; b. p. (12 mm.) 110–112°; d_{25}^{25} = 1.0012.

The other diethyl acetals synthesized were prepared in the same manner as was that of acetophenone and possessed the following constants: diethyl acetal of diethyl ketone, b. p. (15 mm.) 51–53', d_{25}^{25} = 0.8810; diethyl acetal of methylethyl ketone, b. p. (16 mm.) 40–41°, d_{25}^{25} = 0.8787; diethyl acetal of methyl-n-hexyl ketone, b. p. (16 mm.) 101–103°, d_{25}^{25} = 0.8798; and diethyl acetal of phenylpropyl ketone, b. p. (15 mm.) 118–120°, d_{25}^{25} = 0.9406.

The preparation of methyl-n-hexyl acetal and phenylpropyl acetal are not described in the literature.

Anal. Calcd. for $(CH_3)(C_6H_{13})C(OC_2H_5)_2$: C, 71.28; H, 12.87. Found: 71.48, 13.11.

Anal. Calcd. for $(C_3H_7)(C_6H_5)C(OC_2H_5)_2$: C, 75.67; H, 9.90. Found: 75.90, 10.12.

Catalyst.—The catalyst used was made up as described by Adkins and Adams,[1] so that a concentration of 0.0136 g. of hydrogen chloride per cubic centimeter of ethyl alcohol was obtained.

Sodium Ethoxide.—Fifty grams of sodium was added to 150 cc. of absolute alcohol in a flask of 500cc. capacity. The flask was connected to a reflux condenser to the top of which was attached a calcium chloride tube. As soon as all of the sodium had reacted, the alcohol was distilled off from an oil-bath in an atmosphere of dry hydrogen. The hydrogen was dried by passing it through concentrated sulfuric acid. The temperature of the sodium ethoxide in the flask was maintained at 180–200° for at least an hour. A pure white product was obtained which turned slightly yellow after a week's time.

Summary

A method has been developed for the quantitative estimation of ethyl formate in the presence of alcohol, orthoformic ester, a ketone and its acetal, which consists in partially converting ethyl formate into carbon monoxide using sodium ethoxide as a catalyst. The percentage of ethyl formate converted into carbon monoxide varied somewhat with the amount and kind of ketone present.

The method of analysis for ethyl formate has been used to determine the extent of the reaction of orthoformic ester with eight ketones: dimethyl, methylethyl, diethyl, methyl-n-hexyl, methylphenyl, phenylpropyl, diphenyl and methyl-*tert.*-butyl ketones. Certain conclusions have been drawn with respect to the relation of the structure of a ketone to the affinity manifested in acetal formation.

The reaction of orthoformic ester with ketones does not proceed in a xylene or toluene solution. The true catalyst would then appear to be a compound of alcohol and hydrogen chloride. Acetophenone reacts much more rapidly than does acetone.

ALKYL AMINO-ETHANOL AND PROPANOLS[1]

BY J. STANTON PIERCE

RECEIVED OCTOBER 24, 1927 PUBLISHED JANUARY 5, 1928

Many naturally occurring compounds of therapeutic importance contain the grouping alkyl-N-C-C-0 or alkyl-N-C-C-C-O. Among these compounds are cocaine, quinine, strychnine, hydrastine, hyoscine, atropine and adrenaline. Also, many synthetic medicinals, as procaine, stovaine, alypine, apothesin, butyn and homatropine contain one of these groups.

Since the linkages referred to above are prevalent in so many compounds of marked physiological action, a good method for the preparation of simple substances containing these groupings should be of considerable value in the synthesis of more complex compounds, as those mentioned above. A large number of alkyl amino-ethanols have been prepared by Matthes[2] by the action of ethylene oxide on the monoalkyl amines, but there was usually obtained as by-product the corresponding alkyl dihydroxyethylamine. The latter compounds were difficult to separate from the desired product. A similar method was used by Knorr and Matthes[3] and Knorr and Schmidt.[4] Knorr[5] also condensed aqueous methylamine with ethylene chlorohydrin to form methylamino-ethanol.

This paper deals with the preparation of alkyl amino-ethanol and alkyl aminopropanols by the method used by Otto[6] and Adarns and Segur[7] for aryl amino-ethanols and Pierce with Adams[8] for aryl-aminopropanols. By this method there are no by-products of tertiary amines and in most cases the yield of pure product is fair.

Discussion of Results

The condensation of the alkyl amines with β-chloro-ethylchloroformate and with γ-chloropropylchloroformate took place readily, as was the case

---

[1] The author wishes to express his thanks to Professor Roger Adarns, of the University of Illinois, for his valuable suggestions at the outset of this work. Also, acknowledgment is made to the Chemical Department of the University of South Dakota, at which place part of this work was done.

of the aryl amines.[7,8] The reaction of β-chloro-ethylallyl carbamate and γ-chloropropylalkyl carbamates with alcoholic potash was much more vigorous than that of the corresponding aromatic compounds. The addition of alcoholic potash to each of the carbamates mentioned in this paper caused the precipitation of potassium chloride and potassium carbonate, indicating the splitting out of hydrochloric acid and carbon dioxide. In all cases the reaction took place without the application of heat and with β-chloro-ethylallyl carbamate the reaction took place almost spontaneously, the heat given off being sufficient to boil the alcohol within a few seconds after the carbamate and potash were mixed.

3-Allyl-2-oxazolidone was obtained by refluxing an alcoholic solution of β-chloro-ethylallyl carbamate with 1.75 moles of potassium hydroxide and vacuum distilling the product. Attempts were made to prepare pure 3-alkyl tetrahydro-1,3,2-oxazones by ring closure of the γ-chloropropyl alkyl carbamates with alcoholic potash and vacuum distilling the products, but constant-boiling products were not obtained.

When the alkyl carbamates mentioned above were refluxed in alcohol solution with 4 moles of potassium hydroxide, no oxazolidone nor oxazones but amino alcohols were isolated. This indicates that, as in the aromatic series,[7,8] these ring nitrogen compounds are decomposed by excess of alcoholic potash. β-Chloro-ethylallyl carbamate yielded β-allylamino-ethanol and the γ-chloropropyl alkyl carbamates yielded the corresponding γ-alkyl amino-propanols.

Experimental Part

β-Chloro-ethyl and γ-Chloropropyl Alkyl Carbamates.—These compounds were prepared by the method described by Pierce with Adams[8] for the preparation of γ-chloropropyl aryl carbamates, sodium carbonate being used as a condensing agent, and the reaction mixtures being kept cool by the addition of ice. As these carbamates are much more soluble in water than the aryl carbamates, the aqueous layers were extracted with ether. The crude carbamates, which were obtained in yields of 84–92%, were purified by vacuum distillation. The yield of pure product was usually about 85% of the crude product. However, for the preparation of the oxazolidone, oxazones and amino alcohols, usually the crude products were used.

All of the carbamates prepared were soluble in alcohol, ether, ethyl acetate, chloroform, carbon disulfide and benzene. In water, β-chloro-ethylallyl carbamate and γ-chloropropylmethyl carbamate were slightly soluble, and the solubility decreased with increase in molecular weight until γ-chloropropylamyl carbamate was practically insoluble.

3-Allyl-2-oxazolidone.—3-Allyl-2-oxazolidone was prepared by refluxing for two hours β-chloro-ethylallyl carbamate, in 2 3 volumes of alcohol, with 1.75 moles of potassium hydroxide. The reaction mixture was cooled, the alcoholic solution decanted from the inorganic residue, the residue extracted with alcohol and the combined alcoholic extract evaporated on a hot-plate at a temperature of 125°. The solution was cooled, filtered into a Ladenburg flask and fractionated *in vacuo*. A very poor yield of pure product was obtained as three fractionations were necessary to separate the ring compound from the amino alcohol and unchanged carbamate present.

The pure product was soluble in water, alcohol, ether, benzene, chloroform, acetone and ethyl acetate, and slightly soluble in carbon disulfide and petroleum ether.

Alkyl Tetrahydro-1,3,2-oxazones.—Several attempts were made to purify by fractional distillation the crude products obtained by refluxing the γ-chloropropyl alkyl carbamates with about 1.5 moles of potassium hydroxide in alcohol. Constant-boiling products were never obtained but the products formed usually had a boiling point, at the pressure used, about 15° above that of the corresponding carbamate. Usually the products had about 0.7% less nitrogen than the pure oxazone would have and they contained a trace of chlorine, indicating the presence of some unchanged carbamate. As it has been shown definitely, in the aromatic series, that 3-aryl tetrahydro-1,3,2-oxazones are intermediates[S] in the preparation of arylaminopropanols, from the corresponding y-chloropropyl aryl carbamates, the high-boiling products referred to above are doubtless 3-alkyl tetrahydro-1,3,2-oxazones.

β-Allylamino-ethanol and γ-Alkyl Aminopropanols.—Allylamino-ethanol and the alkyl aminopropanols were prepared as were the corresponding aryl amino-ethanols[7] and propanols.[8] However, due to the greater solubilities of the alkyl compounds, the method of isolation and purification was modified somewhat.

Two methods were used for the isolation of allylamino-ethanol and the alkyl aminopropanols. In one method potassium carbonate was added in considerable excess to the alcoholic solution of the amino alcohol and, after the mixture had stood for two hours, the solution was filtered, the alcohol evaporated and the residual liquid vacuum distilled. The other method consisted of steam distilling the reaction mixture, acidifying the distillate, evaporating to low volume, neutralizing the acid with sodium hydroxide, salting out the amino alcohol with potassium carbonate and vacuum distilling the prod-

uct. The latter method worked very well with γ-allylaminopropanol and γ-amylaminopropanol but was not very good for γ-methylaminopropanol and β-allylamino-ethanol, due to their great solubility in water. In all cases better yields would be obtained by working with larger amounts.

All of the amino alcohols were colorless liquids when freshly prepared but darkened on standing. All had a characteristic odor. All were soluble in water, alcohol, ether, chloroform, ethyl acetate and acetone. The solubility in water decreased with increase in molecular weight, for, although all dissolved readily, amylaminopropanol was salted out readily with potassium carbonate, allylaminopropanol was salted out a little less readily and methylaminopropanol and allylamino-ethanol could scarcely be salted out. In carbon disulfide and petroleum ether amylaminopropanol was readily soluble, while the lower molecular weight amino alcohols went into solution with difficulty.

Summary

1. Allylamine was condensed with β-chloro-ethylchloroformate to yield β-chloro-ethylallyl carbamate. The latter compound, refluxed with 1.5 moles of alcoholic potash, yielded 3-allyl-2-oxazolidone, and with 4 moles of alcoholic potash, yielded β-allylamino-ethanol.
2. Allyl-, methyl-, and n-amylamines condensed with γ-chloropropylchloroformate to yield the corresponding γ-chloropropyl alkyl carbamates. These carbamates, refluxed with 4 moles of alcoholic potash, yielded the corresponding γ-alkyl aminopropanols.

THE PREPARATION OF 2-BROMO-*p*-CRESOL FROM p-NITROTOLUENE

BY HOWARD J. LUCAS AND NATHAN F. SCUDDER

RECEIVED OCTOBER 26, 1927 PUBLISHED JANUARY 5, 1928

The usefulness of 2-bromo-p-cresol in standardizing bromide-bromate solutions[1] makes desirable a convenient method of preparation. It has been obtained from 2-amino-*p*-cresol through the diazo reaction[2] and its use as a dye intermediate has been suggested.[3]

In this work it has been found that the desired compound may be conveniently obtained in satisfactory yield from *p*-nitrotoluene by the following operations.

---

[1] Buxton and Lucas, THIS JOURNAL, 50, 249 (1928).

Bromination of p-Nitrotoluene

In the usual method of brominating p-nitrotoluene[4] the materials, including iron bromide, are sealed in a tube and heated to 170° We have found that, using iron filings as the source of the iron bromide, the reaction proceeds with moderate rapidity at 50–60° and, although some bromine is lost in the process, the yield obtained is satisfactory.

To 300 g. (2.2 moles) of p-nitrotoluene (Eastman) and 10 g. of iron filings in a flask fitted with a return cooler is slowly added 370 g. (2.3 moles) of cold bromine. The flask is surrounded by an ice-bath in order to moderate the reaction, which is quite rapid at first and continues vigorously for about one hour. The next day it is slowly heated by means of a warm water-bath and finally to 150° by means of an oil-bath until the evolution of hydrogen bromide ceases. This requires about three hours.

The mass, after cooling, is shaken with an aqueous solution of sodium bisulfite, in order to remove hydrogen bromide and unchanged bromine, and then leached out with cold alcohol in order to remove any unchanged nitrotoluene. Crystallization from hot alcohol gave 358 g. of 2-bromo-4-nitrotoluene (76% yield). Although the yield is lower than that obtained by Scheufelen,[4] the superiority of this method lies in the greater convenience and saving of time.[5]

Reduction of 2-Bromo-4-Nitrotoluene

Although 2-bromo-4-aminotoluene has been prepared in other ways,[5,6] the reduction of the corresponding nitro compound seems to be the most practicable. Neville and Winther[7] reduced with tin and hydrochloric acid, while Blanksma[5] reduced with sodium bisulfide in alcohol solution, obtaining not only the expected bromotoluidine but also 2-bromo-4-aminobenzaldehyde. In this work ammonium sulfide in alcohol was used as the reducing agent and gave a satisfactory yield (85%) of the expected amine, which was easily purified from a small amount of another substance which may have been the compound observed by Blanksma. The following method was employed. An alcoholic solution of ammonium sulfide was prepared by passing anhydrous ammonia into 1 liter of alcohol until the gain in weight was 108 g. (6.35 moles), followed by hydrogen sulfide until no more was absorbed, 90 g. (2.65 moles). When about half of the hydrogen sulfide had been added, white plate-like crystals came

---

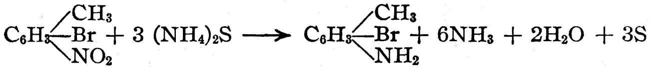
[4] Scheufelen, *Ann.*, 231, 171 (1885); Cohen and Dutt, J. *Chem. Soc.*, 105, 505 (1914); a 94% yield is claimed.

[5] The desired compound may also be obtained from 2-amino-4-nitrotoluene by the Sandmeyer method, Blanksma, *Chem. Weekblad,* 6, 899 (1909).

[6] Hafner, *Ber.*, **22,** 2903 (1899), obtained 2-bromo-4-aminotoluene along with some of the 3-isomer by brominating the sulfate of p-toluidine.

[7] Neville and Winther, *ibid.*, 14, 418 (1891). No yield is given.

down and by the time saturation was reached the mixture had become mushy due to the separation of ammonium sulfide. The amount of 2-bromo-4-nitrotoluene, 150 g. (0.66 mole), was so chosen that there would be about 30% excess[8] of ammonium sulfide needed for the reduction according to the equation



$$C_6H_3\begin{cases}CH_3\\ Br\\ NO_2\end{cases} + 3\ (NH_4)_2S \longrightarrow C_6H_3\begin{cases}CH_3\\ Br\\ NH_2\end{cases} + 6NH_3 + 2H_2O + 3S$$

The unchanged ammonium sulfide (30%) would react with the sulfur to form the poly-sulfide, as follows

$$(NH_4)_2S + 3S \longrightarrow (NH_4)_2S_4$$

The characteristic brown color of the polysulfide which develops as the operation proceeds is useful in indicating the extent of the reaction. Soon after mixing there was a small heating effect which was taken care of by placing the flask in an ice-bath. At first the color of the solution was unaffected but later on it changed rapidly from yellow to red-brown. After standing overnight the flask was heated on a steam-bath under a reflux condenser in order to drive out the ammonium sulfide, which was absorbed by another portion of alcohol preparatory for a subsequent run. By passing a slow stream of air through the system the troublesome condensation of solid ammonium sulfide in the condenser could be avoided. After heating for some hours, the ammonium sulfide was largely removed from the alcoholic liquid, which had lost all but a trace of the brown color and was mixed with much precipitated sulfur. The liquid was filtered hot to remove sulfur and then the alcohol was evaporated on the steam-bath to small volume, leaving a brown oil.[9] The oil was heated with sufficient 6 N hydrochloric acid to dissolve it hot; the resulting solution was filtered from a small amount of sulfur and allowed to cool. Long, slender crystals having a pale brown tint separated, weight 130 g. Evaporation of the filtrate to small volume and cooling gave a small amount of yellow amorphous solid but no crystals. The yield of the hydrochloride of 2-bromo-4-aminotoluene is 84%.

This salt was obtained in fine, snow-white needles by crystallizing 25 g. from hot absolute alcohol (300 cc.) in which dry hydrogen chloride was dissolved. After washing with absolute alcohol, the crystals were dried for thirty-six hours in a vacuum desiccator containing both concentrated sulfuric acid and solid sodium hydroxide. Two analyses for chloride ion by precipitation as silver chloride gave 15.95 and 15.97%; the theoretical is 15.94%. The melting point in a sealed tube was 271°.

Treatment of the purified salt with concentrated ammonium hydroxide

---

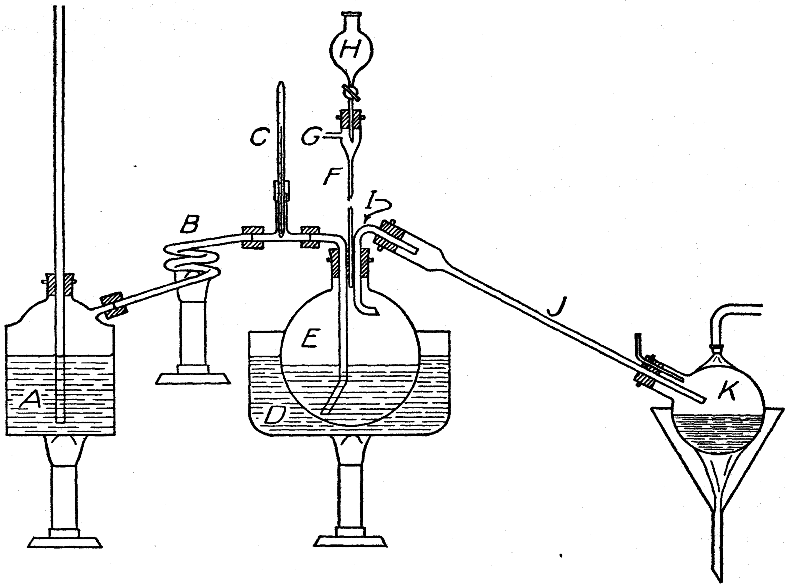
[8] With 100% excess of ammonium sulfide the yield was much lower (56%).

[9] A more convenient method of working up the reaction mixture would consist in distilling off alcohol and ammonium sulfide together, leaving behind the crude amine.

gave the free base, which after drying over solid sodium hydroxide was slightly brown in color and melted at 27.3–27.5° (corr.).

2-Bromo-p-Cresol from the Amine

Attempts to convert the amine into the corresponding hydroxyl compound by the usual method of heating the diazotized solution of the amine led to the formation of much tar, from which only small amounts of the cresol could be extracted. However, by heating the diazo solution rapidly and distilling out the product as soon as it formed, a satisfactory yield was obtained. This was accomplished in the apparatus shown in the figure by the following method. The hydrochloride of the amine, 90 g. (0.4 mole), was dissolved in a hot solution of 55 cc. of concentrated hydrochloric acid and 350 cc. of water. This was cooled to 2–3° and diazotized with a solution of 31 g. of sodium nitrate (5% excess) in 120 cc. of water in the usual way. To the diazotized solution, now about 500 cc., was added 150 cc. of cold, dilute sulfuric acid (approximately 65%, from equal volumes of acid and water), keeping the temperature at all times below 8°. This cold, diazotized solution was placed in the dropping funnel H, and introduced rapidly in portions of 10–15 cc. into the flask



A, Steam generator; B, steam heater; C, thermometer; D, oil-bath, 130–140°; E, balloon flask, 3 liter; F, tube, internal diameter 2 mm., length 30–40 cm.; G, side arm for compressed air; H, container for diazotized amine; I, exit tube, internal diameter 10–12 mm.; J, condenser tube, length 60 cm.; K, flask, 2 liter, cooled by water.

Fig. 1.—Apparatus for converting diazotized bromotoluidine into bromocresol.

E which contained a hot mixture of 750 g. of anhydrous sodium sulfate, 300 cc. of concentrated sulfuric acid and 300 cc. of 6 N sulfuric acid,[10] and was heated by the oil-bath D kept at 130–140°. Steam heated to 160–180° in the heating coil B was passed into the flask, thus removing the cresol as soon as it formed and preventing a coupling reaction between it and the diazonium salt.

By adding the diazo solution rapidly and blowing off the last few drops from the tube F by a jet of air through G, it cannot become warm and undergo reaction before it enters the flask. The distillate of approximately 600 cc. was shaken twice with about 200 cc. of benzene and the benzene solution then extracted with 1000 cc. of 2 N sodium hydroxide. The alkaline solution after filtering and acidifying with sulfuric acid gave an oil which solidified in the ice box overnight. The crude 2-bromo-*p*-cresol was filtered off and after drying in a vacuum desiccator over sulfuric acid weighed 91 g. (yield, 80.5%).

The bromocresol was purified by washing with some cold redistilled petroleum ether, b. p. 40–63°, to remove most of the colored impurity, and then crystallized from another portion, b. p. 40–75°, giving white, silky, slender needles. Since the temperature coefficient of solubility is high, slow cooling was necessary in order to avoid excessive supersaturation and the formation of a liquid instead of the desired solid phase. The first crop when dissolved in petroleum ether gave an almost colorless solution and crystallized out as before. The recrystallized material melted at 55.2–55.4° (corr.) to a colorless liquid.[11] By proper evaporation of the filtrate the greater part of the 2-bromo-*p*-cresol is recovered. Thus from a total of 142 g. of crude material there was obtained 131 g. (92% recovery) of the purified cresol. On this basis the best yield of purified 2-bromo-*p*-cresol calculated back to nitrotoluene is 47% for the three operations, whereas that obtained by Plummer[2] from 2-amino-*p*-cresol through the diazo reaction in one operation was 18.5%.

Analyzed for bromine by the Carius method, 0.2031 g. of 2-bromo-*p*-cresol gave 0.2066 g. of AgBr, and 0.2447 g. gave 0.2457 g. of AgBr, equivalent to 43.3 and 42.7% of bromine, compared to the calculated value of 42.7%.

The cresol is exceedingly soluble in benzene and in methyl, ethyl and propyl alcohols and does not crystallize readily from these solvents. It is readily soluble in ligroin, from which it separates as a liquid phase. Petroleum ether, b. p. 40–75°, is the most satisfactory solvent for purification purposes.

The Benzoate of 2-bromo-*p*-cresol.—This compound was easily obtained from the cresol by the Schotten-Baumann reaction. After treatment with sodium hydroxide solution, followed by two crystallizations from absolute alcohol, it separates in the form of large, white needles melting at 74.6–75.1° (corr.), a value unchanged by further crystallization.

Summary

Starting with *p*-nitrotoluene, 2-bromo-*p*-cresol has been obtained in yields of 47% by the operations of bromination, reduction and replacement of the diazonium group.

---

[10] A mixture of this composition, which is in reality largely sodium acid sulfate with smaller amounts of sulfuric acid and water, has a boiling point of 135°.

[11] Previous observers, Plummer, ref. 2, gave 54–55°, and D. R. P., ref. 3, 55–56°.

Replacement of the diazonium group by hydroxyl is best accomplished by running the diazotized amine into a solution of sulfuric acid and sodium sulfate at 130–140°, and continually distilling out the cresol with superheated steam.

THE ANALYSIS OF BROMINATED CRESOLS

BY JOHN BUXTON AND HOWARD J. LUCAS

RECEIVED OCTOBER 26, 1927 PUBLISHED JANUARY 5, 1928

Previously described methods which were being employed for analyzing mixtures of brominated cresols were found to be troublesome enough to justify further investigation in the hope that improvements could be made. In the bromide-bromate titration method of Francis and Hill[1] there is, after acidification, a slow reaction between the standard solution and the alcohol used as solvent. In the method of halogen determination proposed by Robertson[2] the end-point of the final titration is difficult to determine because hydrogen peroxide present in the solution reacts with the thiocyanate.

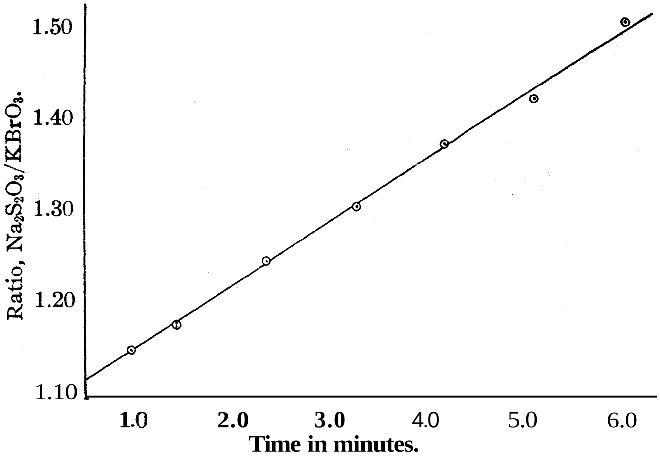

Fig. 1.—Effect of alcohol upon standard bromate solution in 1 N H_2SO_4.

The Bromide-Bromate Titration.—In the method of Francis and Hill it was found that the reaction between alcohol and bromate in acid solution decreased the amount of thiosulfate required for back titrations. Fig. 1 shows how the ratio of 0.1005 N thiosulfate to 0.091 N bromate changes

---

[1] Francis and Hill, THIS JOURNAL, 46, 2499 (1924).

[2] Robertson, J. Chem. *Soc.*, 107, 902 (1912).

with time when 15.00 cc. of standard bromide-bromate solution stands with 50 cc. of water, 15 cc. of alcohol and 5 cc. of 18 *N* sulfuric acid. This reaction may not ordinarily be bothersome in the procedure recommended by Francis and Hill since the solution is not made acid until all of the bromate is introduced. However, any variations in time, temperature or concentration from the standard conditions might introduce errors. It has been found that by substituting glacial acetic acid for alcohol the undesirable side reaction between the solvent and the bromate solution is eliminated.

The following is the method finally adopted: approximately 0.10 to 0.15 g. of the phenol or substituted phenol is dissolved in 25 cc. of glacial acetic acid in a glass-stoppered conical flask and diluted with 50 cc. of water. Standard bromide-bromate solution of about 0.1 normality is introduced slowly until there is an excess of 2 to 4 cc., as shown by the development of the bromine color. This liberation of free bromine when the bromate is in excess is a convenience since it is not necessary to know in advance the bromine requirement of the sample. The solution is shaken thoroughly and allowed to stand for about one minute, at which time approximately 0.5 g. of potassium iodide is added and the liberated iodine is titrated with standard thiosulfate. The method was checked against pure 2-bromo-*p*-cresol, m. p. 55.2–55.4,[3] with the following results.

Wt. of 2-bromo-*p*-cresol taken, g.	Cc. of 0.100 N bromate	Wt. found, g.	Percentage error
0.1254	26.79	0.1252	0.16
.1698	36.03	.1684	.82

A sample of 3-bromo-p-cresol which distilled at 104–105.5' under 20 mm. on a second distillation gave the following results on analysis.

Wt. of sample taken, g.	Cc. of 0.0986 N bromate	Wt. found, g.	Percentage error
0.1715	18.68	0.1721	0.35
.2047	22.10	.2037	.49

Mixtures of known amounts of 2-bromo- and 3-bromo-p-cresol gave

Wt. of 2-bromo-, g.	Wt. of 3-bromo-, g.	Cc. of 0.0986 N bromate	% of 3-bromo-	
			Present	Found
0.0317	0.1732	26.02	84.5	83.0
.0253	.2188	28.98	89.6	90.6
.1018	.1683	40.14	62.3	63.0

The per cent. of each isomer was calculated according to the following equations

$$x = \frac{9.35\,nc}{w} - 100 \quad \text{and } y = 200 - \frac{9.35\,nc}{w}$$

where x and y are the per cent. of 2-bromo and 3-bromo-p-cresol, respectively, w = weight of sample, *n* = normality of the bromate solution

---

[3] Lucas and Scudder, THIS JOURNAL, 50, 244 (1928).

and c = number of cc. used. Since 2-bromo-*p*-cresol may be obtained quite pure by the method described elsewhere[3] its use as a means of standardizing the bromide-bromate solution is here suggested.

The Determination of Total Bromine.—In Robertson's[2] method of halogen determination the end-point of ferric thiocyanate fades rapidly due to the presence of hydrogen peroxide. To one who has developed considerable familiarity with the titration the fading may not be bothersome, but to one who is using the method for a short time only this complication may give much trouble. The removal of the hydrogen peroxide may be accomplished by boiling the solution while still alkaline with some of the iron salt which is needed for the end-point, for under these conditions the peroxide decomposes completely. If more than 1 cc. of 1 N ferric nitrate solution is added before boiling, the ferric hydroxide dissolves very slowly after acidifying.

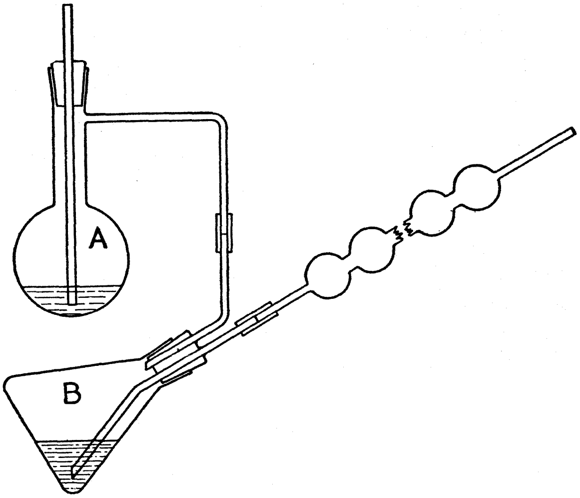

Fig. 2.—Absorption apparatus for bromine determination.

The apparatus of Robertson, Pig. 2, was modified for the sake of convenience by building it in separate units which could be joined together by heavy pieces of rubber tubing well lubricated with sirupy phosphoric acid. The modified method follows: sufficient sample to give the equivalent of 9 cc. of 0.1 *N* silver nitrate is weighed into the reaction flask A and covered with 30 cc. of cold concentrated sulfuric acid which should be free from chloride. The acid is added by means of a funnel while the flask is kept surrounded by an ice-salt bath. After the sample has dissolved and the temperature of the contents has dropped to zero, 10 g. of c. p. chromic anhydride is added and the connection is made to the absorption flask B, which should contain 40 cc. of 1 *N* sodium hydroxide and

20 cc. of 3% hydrogen peroxide, both free of halides. Heat is applied slowly to flask A, care being taken not to increase the temperature rapidly, otherwise the reaction may become too vigorous and lead to the production of smoke, the presence of which should be avoided since low results invariably accompany it. After the end of the reaction, which usually requires about forty-five minutes, a slow stream of air is passed through the apparatus in order to sweep the vapors of bromine and hydrogen bromide over into the absorption apparatus and at the same time the mixture is heated more strongly so as to decompose most of the excess chromic acid. After about fifteen minutes longer the apparatus is disconnected, the solution is washed out of the absorption tube into the flask and 1 cc. of 1 N ferric nitrate is added to the solution. It is boiled for ten minutes in order to decompose the hydrogen peroxide and after cooling is acidified with 20 cc. of 6 *N* nitric acid. In order to have a good end-point, 9 cc. more of ferric nitrate is added. The titration is made by adding 10 cc. of 0.1 N silver nitrate, filtering, washing the precipitate and back titrating the filtrate and washings with 0.1 N potassium thiocyanate.

The reliability of the method is indicated by the results obtained with a pure specimen of 2-bromo-*p*-cresol,[3] for which the bromine content was found to be 42.95 and 43.02%, compared to the calculated value of 42.50%.

Summary

The bromide-bromate titration method of Francis and Hill as applied to brominated cresols is best carried out in water-acetic acid solution.

A procedure has been suggested for obtaining a better end-point when determining bromine in brominated cresols by the method of Robertson.

PASADENA, CALIFORNIA

NOTE

Improved Lighting Source for Melting-Point Apparatus.—A melting point determination, when taken on a dull day or at night under artificial light, is both difficult to accomplish and a strain on the eyes. If a light is placed directly above or behind the melting-point apparatus, considerable reflection from the glass surface results, and the intensity of light directed at the melting point tube is very small. In order to avoid these obstacles, a simple device has been developed.

A short length of tube or rod of any clear glass, fused quartz being desirable but not essential, will transmit practically the entire intensity of light with very little loss of light transversely, and this property is utilized in an apparatus constructed as follows. A small box built of aluminum, or of wood lined with tin foil, holds an electric light bulb (about 100 watts). In the wall opposite the bulb is a hole through which a piece of quartz tube, 8 mm. in diameter and 4 cm. long, is projected. This box is placed so that the beam of intense light coming through the end of the quartz tube projects on the material in the melting point tube, allowing the observer to follow the fusion of the substance easily, with the added advantage that none of the light is directed at the observer's eyes. To prevent overheating it is preferable to provide breathing holes in the bottom and top of the box.

NEW BOOKS

Kolloidchemie: Ein Lehrbuch. (Colloid Chemistry: A Textbook.) BY DR. RICHARD ZSIGMONDY, Professor at the University of Göttingen. II. Fifth, enlarged and completely revised edition. Otto Spamer, Leipzig, Germany. 1927. x + 256 pp. 16 figs. 25 × 17.5 cm. Price, unbound, Rm. 14; bound, Rm. 16.

The author speaks of this book as a textbook. It is really more of a handbook; particularly this second volume, in which the author takes up *seriatim* all the various colloids which have been prepared and studied. The inorganic colloids occupy about two-thirds, the organic colloids about one-third of the volume.

Under each colloid are given the methods used for its preparation, its properties and behavior, its occurrence and uses. The volume affords a valuable and, so far as I know, unique handbook of what might be called descriptive colloid chemistry.

The treatment is clear and succinct. However, references to the earlier editions are perplexingly numerous so that one really needs to have them at hand.

Professor Handovsky and Dr. Thiessen, both of the University of Göttingen, wrote the chapters entitled, respectively, "Colloidal Albumins" and "Soaps."

ARTHUR B. LAMB

An Introduction to Organic Chemistry. By ROGER J. WILLIAMS, Ph.D., Associate Professor of Chemistry, University of Oregon. D. Van Nostrand Company, Inc., 8 Warren Street, New York City, 1927. ix + 565 pp. 8 figs. 22 X 14 cm. Price, $3.75.

The author has been refreshingly successful in his attempt to bring organic chemistry into consonance with the modern treatment of descriptive inorganic chemistry which precedes it in the student's course of study. The selection of descriptive material and the order of its presentation obviates reference to pages further on in the story whose subject matter as a whole has not been studied and excerpts from which are so often misunderstood or entirely misleading. Infractions of this rule occur so late in the text that they are not so annoying and harmful. Some consideration of atomic structure in a textbook for beginners was long overdue. However, the appearance in such a book of equations showing the production of oxygen and hydrogen available for oxidation or reduction processes might well be a subject for adverse criticism.

The attentive student of this text will be ever mindful that the criterion of the soundness of theory is its conformation to facts. In its pages he will find sound treatment of fundamentals and enough illustrative application of them to inspire him to further study of larger works and literature.

Perhaps a little too exhaustive consideration is given to the proteins, but on the whole the book is well balanced. It is handy in form and attractive in appearance. Without question it shows distinct progress from a pedagogical standpoint and merits most careful consideration.

C. E. BOLSER

Organic Syntheses. An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. VII. Edited by FRANK C. WHITMORE, WITH ROGER ADAMS, H. T. CLARKE, J. B. CONANT, HENRY GILMAN AND C. S. MARVEL. John Wiley and Sons, Inc., 440 Fourth Avenue, New York City, 1927. 105 pp. 1 fig. 23.5 X 15.5 cm. Price $1.50.

The seventh volume of Organic Syntheses is at hand, with a new Editor-in-Chief but with the same Editorial Board, and without any change in the essential features of earlier volumes. The reviewer notes with pleasure that nearly all of the thirty preparations have been supplied by contributors, of whom more than half appear for the first time in this volume. Since the editorial board, on principle, assumes the burden of checking all directions, we others have no better way of showing our gratitude for this large and steadily increasing number of carefully developed preparations than by contributing our bit.

The present volume contains directions for the following preparations: anhydro-2-hydroxymercuri-3-nitrobenzoic acid, *p*-arsonophenoxyacetic acid, benzanilide, β-bromo-ethylphthalimide, 2-bromo-3-nitrobenzoic acid, chloro-acetamide, *p*-chloromercuribenzoic acid, α-cyano-β-phenylacrylic acid, p-dimethylaminobenzophenone, 3,5-dinitro-anisole, diphenic acid, ethyl bromomalonate, ethyl n-butylacetoacetate, furan, furfuralacetone, 2-furylmethyl acetate, guanidine nitrate, hydrogen cyanide (anhydrous), β-hydroxypropionic acid, β-iodobenzoic acid, methyl n-amyl ketone, α-methyl mannoside, nitroguanidine, 3-nitrophthalic acid, 3-nitrophthalic anhydride, pentene-2, phthalimidomalonic ester, triphenyl stibine, xanthone, xanthydrol.

BY WILLIAM B. HOLTON[1] WITH B. S. HOPKINS

RECEIVED FEBRUARY 10, 1927 PUBLISHED FEBRUARY 4, 1928

Considerable interest has attached to the question of the possible presence of element number 72 in rare earth minerals, and especially in the more soluble fractions of the yttrium group, because of the assertion of Urbain that the element celtium was found in such material. This investigation was undertaken for the purpose of furnishing more information pertaining to this interesting question.

Inasmuch as both zirconium and thorium, the two most closely related homologs of element number 72, are often found in varying percentages in rare earth minerals, it seems reasonable to suppose that element number 72, which comes between zirconium and thorium, should likewise be present. It is a well-known fact that the usual procedures employed for the separation of the rare earths concentrate the thorium and zirconium content in the most soluble fractions of the series. Wherefore, it is not improbable that element number 72 might also be present in these same fractions.

X-Ray Analysis

With this possibility in mind, an x-ray analysis[2] was made of the oxide material prepared from the most soluble fractions of two different crystallization series of the yttrium group. The L-series spectra in the region of the $L\alpha_1\alpha_2$ doublet for element number 72 was photographed but the most intense $L\alpha_1$ line was not visible on the plates. This would indicate that if this element were present, its concentration must be less than one part in one thousand, which we believe is the limiting concentration detectable by our method of x-ray analysis.

Arc Spectrum Analysis

The arc spectrum lines in the ultraviolet region are already well known for element number 72.[3] Using an E-1 model Hilger quartz prism spectrograph, we have measured the wave lengths of twenty-five of the most prominent and easily recognized lines of this element in order that they may be used for comparison. These selected lines are free from coincidence with all but a very few of the minor arc spectrum lines of the rare earths, zirconium, thorium and other probable interfering elements.[4] The material used to obtain this arc spectrogram was a mixture of the oxides of zirconium and element number 72, containing approximately 30% of the latter element.[5]

The wave lengths which we measured and the intensities as we observed them are given in the first column of the accompanying table, while the corresponding values as noted by Hansen and Werner are listed in the second column.

The arc spectrograms of eight rare earth preparations were examined, not only for these lines of element number 72, but also for the major lines of both zirconium and thorium. The first, second, third and fourth preparations were materials obtained at various steps in the working up of some original gadolinite from Hittero, Norway. The presence of most of the rare earth elements and thorium was readily established. No evidence was obtained for the presence of either zirconium or element number 72.

The fifth and sixth preparations were phosphate precipitates obtained from the soluble end fractions of the two yttrium group series which were used in the x-ray analysis. The seventh preparation was a similar precipitate obtained from the soluble end fractions of a cerium group series. In these three materials thorium was found present but the presence of zirconium and element number 72 could not be established.

Preparation No. 8 was a solution of nitrates obtained from some potassium double sulfate residues. This rare earth–potassium double sulfate residue was the accumulation of many years' work, obtained by treating the most soluble fractions of various yttrium group series with potassium sulfate to remove the cerium elements along with zirconium and thorium. The arc spectrogram of this material revealed the presence of much thorium and no zirconium. The evidence with regard to element number 72 is presented in the third column of the accompanying table. The intensity symbols used in this connection have the following meanings: ab—absent; 0—a faint, yet distinctly perceptible line; and the other

Summary

1. The method of x-ray analysis failed to show the presence of element number 72 in the most soluble fractions of rare earth elements of the yttrium group.

2. Arc spectrum analysis showed the presence of thorium and failed to show the presence of zirconium (1) in gadolinite from Hitterö, Norway, (2) in the most soluble fractions of rare earth elements from both the yttrium and cerium groups, **(3)** in an accumulation of potassium double sulfate residues obtained from the soluble end fractions of various yttrium group series.

3. Arc spectrum analysis failed to show the presence of element number 72 in any of the aforementioned rare earth materials except the last.

4. Arc spectrum analysis indicated the probable presence of element number. 72 in the potassium double sulfate residues from the yttrium group.

REACTIONS IN LIQUID HYDROGEN SULFIDE. III
THIOHYDROLYSIS OF CHLORIDES[1]

BY A. W. RALSTON AND J. A. WILKINSON

RECEIVED APRIL 14, 1927 PUBLISHED FEBRUARY 4, 1928

In the two previous papers from this Laboratory concerning liquid hydrogen sulfide as a reaction medium[2,3] it has been shown that while liquid hydrogen sulfide has, in many ways, more the properties of an organic solvent than water has, nevertheless there are some reactions that bring out its close relationship with water. One of these is its reaction with chlorides, especially those of the elements of the fifth group in the periodic table. This reaction, which corresponds to hydrolysis in water systems and ammonolysis in ammonia systems, has been designated as thiohydrolysis. While the above mentioned chlorides are the most reactive, other chlorides have been studied in order to make the series complete.

Most of the truly metallic chlorides, except $AlCl_3$, $FeCl_3$, $HgCl_2$ and $ZnCl_2$, are quite insoluble and non-reactive, but the more non-metallic chlorides are not only very soluble but many of them are quite reactive. An attempt has been made to bring about these reactions and to examine the products formed to show how complete is the thiohydrolysis.

Experimental

The liquid hydrogen sulfide was prepared in an apparatus very similar to that used by Quam.[2] The chlorides, after careful purification, were placed in heavy-walled, well-annealed glass tubes of about 10cc. capacity which had been dried by washing with alcohol and ether and then heating in an oven while passing a current of dry air through them. The liquid hydrogen sulfide was transferred directly from the generator to these after they had been cooled in a freezing mixture of ether and solid carbon dioxide contained in Dewar bulbs.

The reactions were allowed to take place at that temperature (about −77°) and at the same time other tubes were sealed at this temperature and then permitted to come to room temperature at which they were kept for a week or more, if necessary. for any slow reaction to take place. After the reaction had taken place at either temperature the excess of liquid hydrogen sulfide and any volatile substances were permitted to evaporate

---

[2] Quam, THIS JOURNAL, 47, 103 (1925).

[3] Quam and Wilkinson, *ibid.*, 47, 989 (1925).

and the residue was examined by analysis to find whether any reaction had taken place and if so what products had been formed.

The samples for analysis were weighed in small glass capsules which were broken beneath the surface of a concentrated solution of potassium hydroxide contained in a stoppered vessel. This prevented any loss of hydrogen sulfide. This solution was used for analyses.

Data

The chlorides of the alkali metals and of the alkali earth metals, $CuCl_2$, $CdCl_2$, $MnCl_2$, $CoCl_2$, $FeCl_2$ and $CrCl_3$ (both the green and violet forms) are insoluble and non-reactive in liquid hydrogen sulfide both at low temperature and at room temperature. Cuprous chloride and silver chloride react with liquid hydrogen sulfide, the former blackening immediately and the latter reacting more slowly to form a flocculent, yellow solid which turns black on exposure to the air. Hydrogen chloride is liberated, showing that some thiohydrolysis has taken place.

Zinc chloride is slightly soluble at the low temperature and more soluble at room temperature, although it is non-reactive at all temperatures. The halides of mercury where the valence is two are soluble but non-reactive at the low temperature, the iodide being the most soluble and the chloride the least. The solubility increases with rise of temperature and at room temperature the chloride is thiohydrolyzed to the black sulfide, which later turns to the red form. The iodide is not thiohydrolyzed but on the evaporation of the liquid hydrogen sulfide the iodide crystallizes out as the yellow form which later turns to the stable red form.

Mercurous chloride is insoluble in liquid hydrogen sulfide but reacts even at the low temperature to form a brown, flocculent, gelatinous mass which on analysis was found to contain 85.81% of Hg and 13.65% of S, which is very close to the composition of HgSH (85.85% of Hg and 13.72% of S). It cannot be mercurous sulfide (92.6% of Hg and 7.4% of S) and it is unlikely that it is a mixture of mercuric sulfide and mercury, not only from the brown color but also because hydrogen sulfide is shown to be a strong reducing agent with other elements such as titanium, selenium and tellurium and so it would hardly be expected to permit the oxidation of the HgSH to mercuric sulfide.

Boron trichloride and aluminum chloride are both quite soluble in liquid hydrogen sulfide. The former reacts very vigorously, even at the temperature of the ether and solid carbon dioxide mixture, forming a white, crystalline compound. As the temperature is raised, this compound melts to a clear liquid at $-47°$ from which the crystals again separate on cooling. Due to its low melting point and to its instability it was impossible to get a weighed sample for analysis to find the per cent. and the formula. However, by adding an unweighed quantity of the crystals to a solution of potassium hydroxide and analyzing aliquot portions of this for the weights of boron, chlorine and sulfur, the formula of the solid may be calculated. The chlorine was determined by the Volhard titration with silver nitrate and ammonium thiocyanate and the sulfur by distilling, after acidifying with hydrochloric acid, into ammoniacal cadmium chloride and titrating with standard iodine solution. The boron was determined by distilling it as methyl borate, saponifying with lime and weighing as boron trioxide. Two hundred cc. of such a solution showed 0.0344 g. of boron trioxide and other 200cc. portions required 48.4 and 48.32 cc. of silver nitrate solution, one cc. of which is equivalent to 0.00217 g. of chlorine. Twenty-five-cc. portions were used to determine the sulfur and they required 29.57 cc. and 29.68 cc. of an iodine solution, one cc. of which is equivalent to 0.001585 g. of sulfur. This shows that there was present in the unweighed sample 0.0344 g. of boron trioxide or 0.01069 g. of boron, 0.10503 and 0.10485 g. of chlorine and 0.37495 and 0.37632 g. of sulfur. Calculating the formula from these results shows quite clearly that the formula for the compound is $BCl_3.12H_2O$.

This calculation is made by dividing the weight of each element by its respective atomic weight and finding the ratios of these quotients which will give the relative number of atoms that are present in the compound.

Aluminum chloride shows solubility but no thiohydrolysis, and no thiohydrates were found to crystallize out on evaporation although Biltz[4] has shown the existence of thiohydrates of aluminum choride by vapor pressure measurements. Quam reported aluminum choride as insoluble and non-reactive but there is definite evidence of the fact that it dissolves as shown in the conductance of the solution, which will be discussed later.

In the fourth group of the periodic table where the elements become more non-metallic the solubility of the chlorides in liquid hydrogen sulfide becomes quite marked. Carbon tetrachloride and silicon tetrachloride are miscible with liquid hydrogen sulfide in all proportions and show practically no thiohydrolysis. However, when silicon tetrachloride was kept at room temperature with hydrogen sulfide for several weeks a small amount of brown silicon disulfide was formed. Stannic chloride, which freezes at $-33°$ is insoluble and non-reactive at the low temperatures but at room temperature the two liquids are miscible. After standing for two weeks at this temperature a small amount of yellow stannic sulfide was formed. Biltz[4] has shown that plumbic chloride is reduced to plumbous chloride. This group of chlorides which are so easily hydrolyzed in water are very inert in liquid hydrogen sulfide. It should, therefore, be an excellent medium in which to study the reactions of these compounds.

Titanium tetrachloride at very low temperatures forms a yellow crystalline body, the composition of which is shown by analysis to be $2TiCl_4.H_2S$.

---

[4] Biltz, *Z. anorg. allgem. Chem.*, **147, 171 (1925).**

This compound is very unstable and decomposes into titanium tetrachloride and hydrogen sulfide as the temperature is slowly raised. If it is rapidly warmed to room temperature the decomposition takes place almost explosively. It is therefore impossible to get a weighed portion of this addition product, due to its instability. By allowing the excess of hydrogen sulfide to evaporate off at $-77°$ and taking an unweighed portion of the residue and dissolving in potassium hydroxide solution, as was done with the boron compound, the formula may be determined. The following values were obtained.

Titanium. 0.0378 g. of $TiO_2 = 0.0378/80.1 = 0.000472$ atom $= 2 \times 0.000233$.
Chlorine. 0.2674 g. of $AgCl = 0.2674/143.3 = 0.001866$ atom $= 8 \times 0.000233$.
Sulfur. 0.0544 g. of $BaSO_4 = 0.0544/233.4 = 0.000233$ atom $\approx 1 \times 0.000233$.

This shows that the formula for the compound is $2TiCl_4.H_2S$.

Biltz[4] reported only two thiohydrates of $TiCl_4$, $TiCl_4.2H_2S$ and $TiCl_4.H_2S$.

At room temperature the reaction between liquid hydrogen sulfide and titanium tetrachloride is very vigorous. A brown solid is first formed which is soluble in the liquid hydrogen sulfide giving a red solution. Later a layer of black solid mixed with a yellow one forms. When this mass is extracted for a long time with carbon disulfide, the yellow dissolves and is found to be sulfur, showing that some reduction has taken place. The black residue was analyzed and found to be titanous chloride. The brown solid which is first formed is soluble in alcohol, giving a solution with a decided mercaptan odor. Pfordten[5] prepared similar compounds by the action of dry hydrogen sulfide gas on titanium tetrachloride. Titanium tetrachloride seems to be one of few chlorides studied where it is possible that the thiohydrolysis first gives an SH body corresponding to the OH in hydrolysis. Further work is being done on the reaction between hydrogen sulfide and titanium tetrachloride.

Phosphorus trichloride is partly miscible but non-reactive at low temperatures with liquid hydrogen sulfide but P_2S_3 is formed immediately on mixing at room temperature. Phosphorus pentachloride immediately forms the insoluble $PSCl_3$ at all temperatures. This resembles the similar reaction with water except that there the hydrolysis is completed forming the soluble hydroxide or acid.

Arsenic trichloride gives the sulfide, As_2S_3, immediately at all temperatures. This also differs from the similar reaction in water where the soluble hydroxide or acid is formed. Antimony trichloride shows that the element is more metallic than arsenic in that it does not dissolve or react with the hydrogen sulfide at low temperature as does arsenic trichloride. It is very soluble but non-reactive at room temperature. In either case, however, when the liquid hydrogen sulfide is evaporated off, the antimony

---

[5] Pfordten, *Ann.*, 234, 257 (1886).

trichloride reacts with the vapor of hydrogen sulfide to form lemon-yellow crystals and hydrogen chloride is evolved. These crystals were analyzed and found to be $SbSCl.7SbCl_3$. The data obtained are as follows.

Anal. **Calcd.: Sb, 54.21; Cl, 43.98; S, 1.81. Found: Sb, 54.12; Cl, 43.86; Cl, 1.87.**

This same compound has been prepared by Schneider[6] by the action of dry hydrogen sulfide gas on dry antimony trichloride at reduced temperatures.

Antimony pentachloride reacts similarly to phosphorus in hydrogen sulfide forming the $SbSCl_3$. It is more thiohydrolyzed in hydrogen sulfide than it is hydrolyzed in water since the antimony chloride is hydrolyzed only in warm water. Bismuth trichloride reacts immediately, even at low temperatures, with liquid hydrogen sulfide forming an orange-red solid. This solid slowly gave off hydrogen chloride but after standing in a desiccator over sulfuric acid for several days it arrived at constant weight and an analysis showed it to be Bi_2SCl_4 or $BiSCl.BiCl_3$.

Anal. **Calcd. for Bi_2SCl_4: Bi, 70.62; Cl, 23.96; S, 5.42. Found: Bi, 70.49; Cl, 23.91; Cl, 5.52.**

It seems therefore that an addition product or thiohydrate is first formed which slowly loses hydrogen chloride in the air, forming the basic salt. This corresponds to the action of hydrogen sulfide on titanium tetrachloride except that in the case of bismuth trichloride the addition product is more stable. The formation of the insoluble addition product accounts for the fact that Quam and Wilkinson[3] found that a mixture of bismuth trichloride and hydrogen sulfide did not conduct an electric current in spite of the fact that a visible reaction had taken place. The same body is formed with bismuth trichloride at room temperature.

Selenium tetrachloride at low temperatures reacts slowly with liquid hydrogen sulfide until all of it has disappeared. After boiling off the excess of hydrogen sulfide, a yellow solid remains. When the temperature is raised, this solid melts to a red-brown liquid which has sulfur suspended in it. An analysis of this liquid showed it to be Se_2Cl_2. At room temperature selenium tetrachloride reacts rapidly with hydrogen sulfide and is reduced to red selenium. This can be separated from the sulfur mixed with it by means of the greater solubility of the selenium in carbon disulfide compared to the sulfur.

Tellurium tetrachloride in the cold is reduced immediately to tellurium dichloride and sulfur, the former being insoluble in carbon disulfide while the latter dissolves slowly. At room temperature the tellurium tetrachloride, like selenium tetrachloride, is completely reduced to the element.

Chromium trichloride, either the green or violet form, is insoluble and does not react with hydrogen sulfide at any temperature. This is a little

---

[6] Schneider, *Pogg. Ann. phys. Chem.*, **108,407 (1859).**

unusual considering that the trivalent chlorides, aluminum chloride and ferric chloride, are both soluble. Manganous chloride and cobalt chloride are insoluble and non-reactive at low temperature although cobalt chloride will turn black on long standing at room temperature.

Ferric chloride dissolves to a yellow liquid from which, at low temperatures, a white precipitate of ferrous chloride slowly separates. At room temperature the same reaction takes place very rapidly.

Conductance of Chloride Solutions in Liquid Hydrogen Sulfide

In order to check the conclusions as to whether or not the chlorides dissolved in the liquid hydrogen sulfide, the conductances of the solutions were determined after they had stood until equilibrium had been reached. The cells used were similar to those described by Quarn and Wilkinson[3] and the conductance was measured at the temperature of the mixture of ether and solid carbon dioxide.

Potassium, strontium, barium, cadmium, chromic (green and violet forms), manganous and cobalt chlorides all showed non-conductance.[7] Silver, cuprous and mercurous chlorides all show some conductance after standing, due to the hydrogen chloride liberated by the thiohydrolysis. The specific conductances for solutions of the other chlorides are given in the following table.

TABLE I

CONDUCTANCES OF SATURATED SOLUTIONS OF CHLORIDES IN LIQUID HYDROGEN SULFIDE

Pure H_2S, λ = (1×10^{-11})		Pure H_2S, λ = (1×10^{-11})	
Salt	$\lambda \times 10^6$	Salt	$\lambda \times 10^6$
$HgCl_2$	0.031	$AlCl_3$	2.092
$SnCl_4$	.106	$HgBr_2$	5.16
$SiCl_4$	.129	HgI_2	9.99
$ZnCl_2$	.634	$FeCl_3$	209.9
HCl	.881	$SbCl_3$	424
$AsCl_3$	1.15		

Conclusions

A study of the chlorides in different parts of the periodic table shows that the chlorides of the metallic elements are mostly insoluble in liquid hydrogen sulfide except zinc, mercuric, aluminum and ferric chlorides. The univalent chlorides of silver, copper and mercury are insoluble but thiohydrolyze to insoluble hydrosulfides or sulfides.

The chlorides of the non-metallic elements which are easily hydrolyzed in water forming the hydroxides are, in many cases, soluble in liquid hydrogen sulfide in all proportions and show no thiohydrolysis. In other cases they form thiohydrates, addition products and sulfides but there

---

[7] In the paper by Quam and Wilkinson (ref. 3) the statement is made that the specific conductance of pure liquid hydrogen sulfide is half that of water. This is obviously an error as the figures which are given show that it is one hundred thousandth as much.

is little evidence that any of them form a thio-acid such as H_3AsS_3, except possibly $TiCl_4$.

The reducing action of hydrogen sulfide accounts for many of the differences encountered in comparing these reactions with similar ones in water, for example, with $TeCl_4$, $SeCl_4$, $TiCl_4$ and $FeCl_3$.

AMES, IOWA

[FROM THE DEPARTMENT OF INORGANIC CHEMISTRY, BEDFORD COLLEGE, UNIVERSITY OF LONDON]

THE POSITION OF THE ELEMENTS OF THE RARE EARTHS IN THE PERIODIC SYSTEM

BY J. F. SPENCER

RECEIVED MAY 2, 1927 PUBLISHED FEBRUARY 4, 1928

From the time when Mendeléeff enunciated the principles of the periodic system, many attempts have been made to include the elements of the rare earths in the classification. Previous to 1870 the rare earth elements were regarded as divalent, chiefly because of the strongly basic character of their oxides. Mendeléeff, finding difficulty in placing the then known elements of the rare earths in Group II of his system, contended that the metals are tervalent. He, therefore, assigned to yttrium, didymium and erbium positions in Group III and to cerium and lanthanum positions in Group IV. The work done on the rare earths since 1870 has confirmed Mendeléeff's view of the tervalency of these elements and at the same time it has increased their number from five to seventeen. There are included in this remarkable series of elements, scandium, yttrium, lanthanum, cerium, praseodymium, neodymium, illinium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium and lutecium. The order given above is that of ascending atomic number.

The element illinium (atomic number 61) has recently been recognized by Lapp, Rogers and Hopkins[1] by means of x-ray analysis of rare earth fractions, and thus a complete series of elements of atomic numbers 57 to 71 is made up. In order of atomic number lanthanum (57) follows barium (56) and hafnium (72) follows lutecium (71). Consequently it may be taken that the series of rare earths is complete.

Since the time of Mendeléeff many attempts have been made to arrange these elements either in Mendeléeff's system, in modifications of Mendeléeff's system or in geometrical systems by Brauner, R. J. Meyer, Retgers, Benedicks, Soddy, Stefan Meyer, Steele, Werner, Vogel, Rydberg, Aston, Bohr and others. The arrangements in Mendeléeff's system have failed because of an apparent lack of accommodation and because valencies have been assigned to certain of the elements which could not be sub-

---

[1] Lapp, Rogers and Hopkins, *Phys. Rev.*, 25, 106 (1925).

stantiated. The arrangements in modified forms of the Mendeléeff system have destroyed the symmetry, simplicity and usefulness of the periodic classification, and the arrangement in geometrical systems, whilst often useful, is not necessarily an arrangement in the periodic system.

What follows is an attempt to place these elements in the Mendeléeff system in its original form. Hence, without considering any of the previous attempts in detail, the present attempt may be put forward.

From a consideration of the whole of the elements from the point of view of the ease with which they may be separated from one another it becomes evident that they may be sub-divided into four groups thus: (I) elements which are readily separable from each other, that is, elements like sodium, silver, oxygen, chlorine, etc., (II) elements which are difficult to separate from each other; this group comprises the triads of Group VIII of Mendeléeff's system: iron, cobalt, nickel; ruthenium, rhodium, palladium; osmium, iridium, platinum; (III) elements which are very difficult to separate, this group includes the rare earths; and (IV) elements which, for practical purposes, are inseparable, the isotopes. Each of the elements of the first group occupies alone a place in the Mendeléeff system; the elements of the second group are placed three in a single place of the system and the elements of the fourth group, the isotopes, are placed many in a single space; thus there are at least eleven isotopes of lead, five of bismuth, four of zinc, seven of xenon and six of thorium. The isotopes of a given element have the same atomic number and properties and they are therefore all placed in the same place of the periodic system. Furthermore, this in no way destroys the Mendeléeff system nor impairs its symmetry and usefulness to the chemist.

The tervalency of the elements of the rare earths has been established beyond all doubt from (I) the specific heat of the metals, (II) the molecular weight of the anhydrous chlorides in absolute alcohol solution, (III) the molecular weight of the acetyl acetonates in carbon disulfide solution, (IV) the isomorphism of the octahydrates of the sulfates and (V) the equivalent conductance of aqueous solutions of the chlorides and sulfates. Consequently all of the seventeen elements yield an oxide M_2O_3 and a chloride MCl_3.

In addition, cerium, neodymium, praseodymium and terbium yield a dioxide MO_2, whilst europium and samarium yield a dichloride MCl_2. The two elements of smallest atomic number, scandium and yttrium, find places in the periodic system without difficulty; they fall naturally following the order of atomic numbers into Group III, Series 4 and 6, respectively. This leaves fifteen elements which form *a* complete series, lanthanum (57)—lutecium (71), to be placed between barium *(56)* and hafnium (72). Since these elements are basic, show no marked acidic properties and are all tervalent, they must all be accommodated in the six places of the periodic system, in Groups III and IV, Series 8, 9 and 10. Here it is that the difficulty of the problem becomes apparent; any one of these elements with the exception of cerium might from its chemical properties go into Group III, Series 8, and cerium would naturally go into Group IV, Series 8.

It has been shown by Weiss,[2] from measurements of the ionic magnetic moment, made by Cabrera and Stefan Meyer with the octahydrates of the sulfates of these elements, that when the ionic magnetic moments are plotted as abscissas against the number of electrons in the cations, a double curve is obtained (Fig. 1) which divides these elements into two groups, (I) lanthanum, cerium, neodymium, praseodymium and samarium, (II) europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium and lutecium.

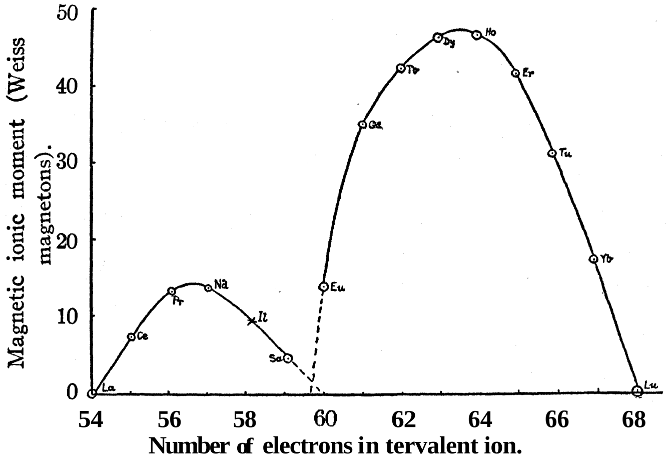

Fig. 1.

The element illinium (61) must be taken to come between neodymium and samarium. These two groups are practically identical with the two groups which may be made from the order of the solubility of the sulfates of the rare earths in saturated solutions of alkali sulfates; (I) practically insoluble, lanthanum, cerium, praseodymium, neodymium and samarium; (II) europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium and lutecium; the first three members of the second group are sparingly soluble and the remainder are more soluble than in water. The first three elements of the second group, that is, the terbium earths, fall on the ascending branch of the second half of Weiss' curve and the others on the descending branch.

From the above facts and the general chemical characteristics of the

---

[2] *Journ. de Phys.*, 1925, Bull., 218, 86 S.

rare earth elements it appears that they may be placed in the periodic system as shown below.

TABLE I

	II		III		IV		V	
	A	B	A	B	A	B	A	B
4	Ca		Sc		Ti		V	
5		Zn		Ga		Ge		As
6	Sr		Yt		Zr		Nb	
7		Cd		In		Sn		Sb
8	Ba		La		Ce, Pr, Nd, Il		. . .	
9	. . .			Sa, Eu, Gd		Tb	. . .	
10	. . .		Dy, Ho, Er, Tu, Yb, Lu		Hf		Ta	

Leaving samarium out of account for the moment, the elements on the first half of Weiss' curve (the cerium earths) fall into Series 8; those on the rising branch of the second half of the curve (the terbium earths) fall into Series 9 and those on the falling branch of the second half of the curve fall into Series 10 (yttrium earths). Samarium sulfate may be equally well regarded as the most soluble of the insoluble cerium earth sulfates in saturated alkali sulfate solutions or as the least soluble of the sparingly soluble sulfates. That is, the solubility series given above may be written (I) insoluble: lanthanum, cerium, neodymium, praseodymium; (II) sparingly soluble: samarium, europium, gadolinium, terbium; (III) soluble: dysprosium, holmium, erbium, thulium, ytterbium, lutecium. The solubility sub-division is now the same as that in the periodic system.

Lanthanum is put in Group 111 A, Series 8, because its oxide is the strongest base of the rare earths and naturally follows barium; cerium, praseodymium and neodymium are placed in order of atomic number in Group IV A, Series 8, since they all form dioxides and sesquioxides, as also do titanium and zirconium, which precede them in Group IV A. The new element illinium must also be placed there because its ionic magnetic moment will undoubtedly fall between the moments of neodymium and samarium on the Weiss curve; samarium, europium and gadolinium are placed in Group III B, Series 9; of these europium and samarium form dichlorides, a type of compound also formed by the other members of Group III B, gallium, indium and thallium. A dichloride is unknown in the case of gadolinium but in the present state of our knowledge of gadolinium compounds this is no reason for stating that such a compound cannot exist; further, gadolinium is very like europium and samarium in its general behavior, so much so that gadolinium and samarium were separated together from Mosander's didymium by Delafontaine,[3] and for a time regarded as a single element, decipium. The

---

[3] Delafontaine, *Compt. rend.*, **87, 559, 634 (1878).**

six elements dysprosium, holmium, erbium, thulium, ytterbium and lutecium come in order of atomic number into Group III A, Series 10. These metals are typically tervalent and each of them could be placed in this position. If the reasons given above be accepted, these six elements must all go into this position. Between lutecium (71) and tantalum (73) in Series 10, there is still a vacant place in group IV A into which hafnium (72) naturally goes. The scheme presented places the whole of the elements of the rare earth group into Mendeléeff's periodic system without destroying its symmetry or impairing its utility in the slightest. It is difficult to submit the scheme to a rigorous test because many essential data are lacking; but a broad line taken through the existing chemical and physical data confirms, in general, the present arrangement.

SIMPLE BIMETALLIC ELECTRODE SYSTEMS FOR POTENTIOMETRIC TITRATIONS. I. THE APPLICATION OF THE PLATINUM-GOLD AMALGAM SYSTEM TO CERTAIN OXIDATION-REDUCTION TITRATIONS

By N. Howell Furman

Received June 17, 1927 Published February 4, 1928

Introduction

Hostetter and Roberts[1] suggested the possibility of substituting a palladium wire for the calomel half-cell that is generally used as a reference electrode in potentiometric titrations. Willard and Fenwick[2] have studied a large number of possible systems that consist of two dissimilar metallic electrodes. They did not, however, study amalgamated electrodes.

This investigation grew out of a study of certain platinum electrodes that were unintentionally "poisoned" with mercury. These electrodes behaved temporarily like mercury electrodes. It has not thus far been found possible to prepare amalgamated platinum electrodes that serve over long periods of time as mercury electrodes.

Amalgamated gold electrodes were found to behave like calomel electrodes in solutions that contained chloride and like mercurous sulfate electrodes in solutions that contained sulfate. During the course of most oxidation-reduction titrations the concentration of chloride or sulfate varies. Nevertheless, an amalgamated gold electrode will serve as a satisfactory reference electrode for such titrations. The reducing action of the minute quantity of mercury or gold that is in contact with

---

[1] Hostetter and Roberts, This Journal, 41, 1343 (1919).

[2] Willard and Fenwick, *ibid.*, 44, 2504 (1922).

the solution does not occasion any systematic error when the reagents are as dilute as 0.05 N.

Experimental

Electrodes.—The gold amalgam electrodes were of the construction indicated in Fig. 1. The Bakelite block, e (6 × 3 × 0.5 cm. drilled with 6 holes of 0.45 cm. diameter), was found to be a very convenient support that permitted ready interchange of electrodes. Gold of C. P. grade from two sources (foil 0.23 mm. thick from the United States Mint and wire of 0.33 mm. diameter (28 gage B. and S.) from Baker and Co., Inc., Newark, N. J.) was used. A momentary immersion of the exposed gold tip in pure mercury effected the amalgamation. It was not found advisable to put a drop of mercury within the tube because of leakage of mercury through the gold. Molten paraffin was poured into the glass tubes (see Fig. 1) as a safeguard against leakage. (A number of electrodes served satisfactorily for long periods without the paraffin seal.) The amalgamated tip is immersed in dilute hydrochloric acid when the electrode is not in use. Electrodes that dry in air become sluggish. They may be reactivated by wiping the amalgamated tip and dipping it anew in mercury.

It was found by heating portions of the tips of a number of electrodes that the initial percentage of mercury was between 15 and 20. It was anticipated that the reducing action of the mercury might be objectionable. McCay and Anderson[3] have shown that ferric iron, chromic acid, vanadic acid and other oxidizing agents are reduced quantitatively to lower states of oxidation when shaken with a large excess of mercury in the presence of a suitable amount of chloride. The tips of the electrodes that dipped into the solutions contained at most 2 mg. of mercury—a quantity capable of reducing only 10^{-5} g. equivalent, or 0.01 cc. of N solution. Only a small part of the 2 mg. or less of mercury is actually in contact with the solution. After a large number of titrations mercury is still visible in the electrodes.

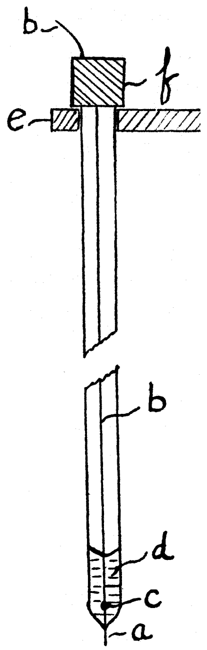

Fig. 1.—Amalgamated gold electrode. (a) Amalgamated tip of a gold wire that is sealed through the glass. Soft glass was used and care was taken not to fuse the gold. (b) Copper wire fused to gold at point (c). The upper end of (b) is wrapped around the glass tube and is held in position by rubber tubing (f). The shaded portion (d) represents paraffin.

There was a relatively large unintentional variation in the total time of titration. In a few instances that were noted as long as twenty minutes elapsed between the time that the solution was first stirred in contact with the electrodes and the start of the titration with ferrous sulfate. In a number of other instances interruptions occurred after a titration had proceeded a short distance. It was not necessary to reject any determinations that were interrupted nor was any definite trend due to this cause noted.

Thus far no tests have been made of the effectiveness of the Pt-Hg(Au) system with reagents more dilute than 0.05 N.

---

[3] McCay and Anderson, THIS JOURNAL, 43, 2372 (1921); 44, 1018 (1922).

Apparatus.—A Leeds and Northrup Co. students' type potentiometer and a portable galvanometer (type 2320 d) of 0.5 micro-ampere sensitivity were used.[4] All volumetric apparatus had been carefully calibrated.

Procedure.—Tenth or 0.05 N solutions of oxidizing and reducing agents were standardized potentiometrically. Anhydrous sodium oxalate of known purity was the primary standard. Bichromate and permanganate solutions were compared by as nearly as possible simultaneous potentiometric titrations of portions of a solution of Mohr's salt.

Titrations with the usual system[5] were interspersed with those made with the Pt-Hg(Au) combination. No attempt was made to free the solutions from dissolved air by working in an inert atmosphere. This may affect the accuracy of the results with the 0.05 N solutions but should not affect the precision of the comparison of the two electrode systems because both sets of titrations were made under as nearly as possible identical conditions.

The Bichromate-Ferrous Iron Reaction.—The average of at least three concordant determinations by the usual potentiometric method was assumed to be correct. The volume was 100 cc. at the start of each titration. The general conditions that were employed will be evident from Table I.

TABLE I

TITRATION OF APPROXIMATELY 0.1 *N* POTASSIUM BICHROMATE WITH FERROUS SULFATE

		1	2	3	4	5	6
I. Cc. of $FeSO_4$ (Pt-N. C. E.)		10.00	10.00	25.01	25.01	25.01	25.01
II. Cc. of $FeSO_4$ (Pt-Hg(Au))		10.04	10.04	24.98	25.00	24.98	24.96
Difference (II–I)		+0.04	+0.04	−0.03	−0.01	−0.03	−0.05
Acid present, cc.	12 *N* HCl	15	15	15	15	...	...
	6 *N* H_2SO_4	...	...	...	...	25	25

The reverse titration was then studied, varying the experimental conditions in a similar manner. The differences in quantities of bichromate that were found by using the two systems were: +0.07, +0.02, +0.03, −0.04, +0.02, −0.03, −0.05 and +0.02 cc. of 0.1 N potassium bichromate.

Further comparisons of the two systems were made with 0.05 *N* solutions; differences found: cc. of 0.05 *N* $FeSO_4$: +0.01, +0.02, —0.03, —0.02, +0.01 and —0.05; and in the reverse titration the differences were cc. of 0.05 N $K_2Cr_2O_7$: —0.07, —0.04, +0.02, —0.06, —0.02, +0.04 and +0.01.

The values in Table I, and the paragraphs that follow it, have been

---

[4] For further details of the apparatus, see Furman, J. Chem. Education, 3, 936 (1926).

[5] Hereafter designated as Pt-N. C. E. When necessary a salt bridge of N potassium sulfate solution was interposed between the normal calomel electrode and the titration beaker.

calculated to cc. of exactly 0.1 or 0.05 N solution. The actual normalities of the bichromate solutions were 0.1000 and 0.05098. The substitution of the amalgamated gold electrode for the N calomel electrode does not cause any systematic error. The average deviation of the values from the mean is practically the same with both systems.

Graphs that are constructed from the titration data show some interesting features. When the solutions contain chloride, the curves (Pt-Hg(Au) system) are very similar to those that are obtained with the Pt-N.C.E. system. They are merely displaced upward on the e.m.f. axis (see Fig. 2) because the chloride concentration is usually greater than N.

In solutions that contain sulfuric acid and sulfates, the curves resemble closely those obtained with Pt-N potassium sulfate-N mercurous sulfate system. When the surface of the electrode becomes depleted of mercury by long use, the curves representing the titration of bichromate with ferrous sulfate show a pronounced sweep upward before the end-point. This is characteristic of the Pt-Au system.[6]

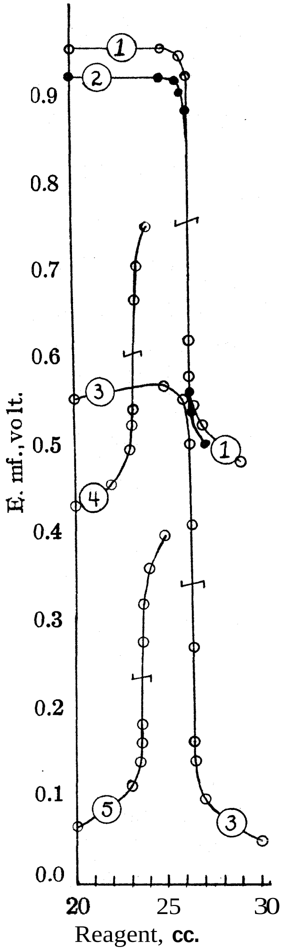

Fig. 2.—Typical plots of titration data. Curves 1, 2 and 3 represent the titration of 25 cc. portions of 0.1000 *N* $K_2Cr_2O_7$ with an approximately 0.1 *N* ferrous sulfate solution, first with Pt-Hg(Au) system, second with Pt-N. C. E., both in HCl solution, and the third with the Pt-Hg(Au) system in H_2SO_4 solution. Curve (4) represents titration of 25 cc. of approximately 0.05 *N* $FeSO_4$ in HCl solution and (5) titration of 25 cc. of approximately 0.1 N $FeSO_4$ in H_2SO_4 solution with the Pt-Hg (Au) system. Bichromate was the oxidant in both cases.

The Permanganate-Ferrous Iron Reaction.—The permanganate solutions were 0.0518 and 0.0510 N, respectively. The values found have been calculated to cc. of exactly 0.05 N solutions. A salt bridge of N potassium sulfate solution was interposed between the N calomel cell and the titration beaker.

In the titration of ferrous sulfate with permanganate the differences, expressed in cc. of 0.05 *N* potassium permanganate, were: +0.01, −0.03, −0.06, −0.05, −0.03 and ±0.00.

---

[6] A detailed study of the Pt-Au system is presented in the second paper of this series, THIS JOURNAL, 50, 273 (1928).

The data for the reverse titration are presented in Table II.

TABLE II

TITRATION OF APPROXIMATELY 0.05 N PERMANGANATE WITH FERROUS SULFATE

	1	2	3	4	5
I. Cc. of $FeSO_4$ (Pt-N. C. E.)	25.50	25.50	25.50	10.20	10.20
II. Cc. of $FeSO_4$ (Pt-Hg(Au))	25.51	25.51	25.44	10.18	10.21
Difference (II − I)	+0.01	+0.01	−0.06	−0.02	\$0.01

In each instance the initial volume was 50 cc., containing 25 cc. of 6 *N* H_2SO_4.

The potentiometric titration of permanganate with ferrous sulfate must be carried out under the conditions that were established by Miiller and Möllering.[7] They found that the acid concentration must be sufficiently high and that the ferrous sulfate must be added rapidly until the end-point is closely approached. The permanganate color disappears a few drops before the end-point is reached. The work of Miiller and Möllering explains this fact in terms of the reactions

$$Mn^{VII} + 3Fe^{II} = Mn^{IV} + 3Fe^{III}, \text{ and} \qquad (1)$$
$$Mn^{IV} + 2Fe^{II} = Mn^{II} + 2Fe^{III} \qquad (2)$$

that occur simultaneously. The author's experience is entirely in accord with these views. It was found, for example, that slow addition of ferrous sulfate to 25 cc. of 0.05 N permanganate in a volume of 100 cc. containing 25 cc. of 6 *N* sulfuric acid caused a very considerable separation of manganese dioxide (Equation 1). All determinations in which there was any visible precipitation of manganese dioxide were inaccurate.

The **Vanadic** Acid-Ferrous Sulfate Reaction.—The normality of the vanadic acid solution was established by titration with ferrous sulfate that had been titrated potentiometrically with standard permanganate solution. Found: vanadic acid 0.05596 N (average) by the potentiometric method, and 0.05597 N (average) when diphenylamine was used as indicator.[8,9]

TABLE III

TITRATION OF 0.05597 *N* VANADIC ACID WITH 0.0488 *N* FERROUS SULFATE

	1	2	3	4	5
Cc. of vanadic acid	25	25	25	25	10
$FeSO_4$ calcd., cc.	28.67	28.67	28.67	28.67	11.46
$FeSO_4$ found, cc.	28.62	28.68	28.70	28.66	11.50
Error, cc.	−0.05	+0.01	+0.03	−0.01	+0.04

In nos. 1–2, 15 cc. of concd. HCl (sp. gr. 1.2), and in nos. 3–5, 25 cc. of 6 N sulfuric acid were present. The initial volume was 50 cc. in each determination.

The graphs of the titration data present no unusual features.

Discussion

A number of incidental observations have been made upon the use of the amalgamated gold electrode in other oxidation-reduction reactions. The results were satisfactory in all instances. Six different electrodes, three of foil and three of gold wire, were used in the progress of the work. All served satisfactorily. The especial advantages of these electrodes are their simplicity and the fact- that in solutions that contain chloride the voltage readings are very close to those that are obtained with the familiar Pt-N. C. E. system.

Preliminary observations have shown that the amalgamated gold electrode may be used in following neutralizations of hydrochloric or sulfuric acid; also that such electrodes serve as indicator electrodes for certain precipitation reactions, for instance, precipitation of halides with silver, or vice versa, It is planned to make a detailed study of some of these possible applications of gold amalgam as an indicator electrode.

Summary

A small amalgamated gold electrode has been shown to be a suitable reference electrode for several kinds of potentiometric oxidation-reduction titrations with reagents as dilute as 0.05 N.

SIMPLE BIMETALLIC ELECTRODE SYSTEMS FOR POTENTIOMETRIC TITRATIONS. II. NOTES ON THE USE OF THE PLATINUM-GOLD ELECTRODE SYSTEM

BY N. HOWELL FURMAN

RECEIVED JUNE 17, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

A knowledge of the platinum-gold system was found to be desirable in connection with a study of the platinum-gold amalgam electrode system that has been described in the former communication.[1] The construction of electrodes, electrical apparatus, and mode of procedure were there described.

Experimental

Titration of Permanganate with Ferrous Sulfate.—The general form of the graph of the titration data is indicated in Fig. 1. There is always a sharp rise to a "peak" in e.m.f. just before the end-point. The position of this peak is extremely variable (see Table I). The drop in voltage at the end-point is unmistakable.

---

[1] Furman, THIS JOURNAL, 50, 268 (1928).

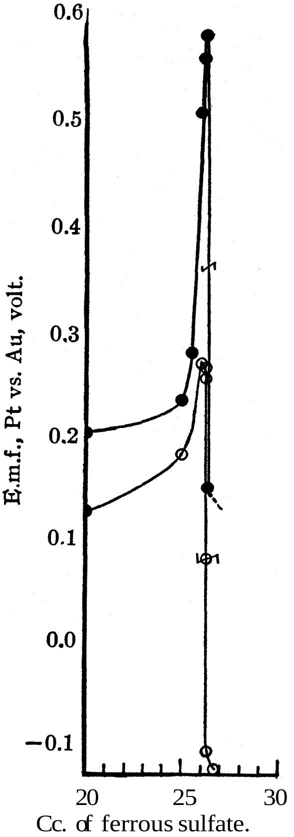

Fig. 1,— Characteristic curves, permanganate-ferrous sulfate reaction, followed by Pt-Au system, showing variability of peak of e.m.f.

TABLE I

TITRATION OF APPROXIMATELY 0.05 *N* PERMANGANATE WITH FERROUS SULFATE

No.	FeSO$_4$ calcd., cc.	FeSO$_4$ found. cc.	Error, cc.	Difference in voltage, Pt vs. Au		
				(a) Initial	(b) Maximum	(c) Break at end-point (1 or 2 drops)
1	26.32	26.30	−0.02	0.180	0.671	0.496 (1 drop) FeSO$_4$
2	26.32	26.28	− .04	.153	.622	.482 FeSO$_4$
3	26.32	26.26	− .06	.175	.330	.454 FeSO$_4$
4	26.32	26.33	+ .01	.150	.279	386 { 0.186 1st drop .200 2nd drop
5	10.52	10.46	− .06	.169	.424	.482 { .305 1st drop .177 2nd drop
6	10.52	10.58	+ .06	.177	.392	.486 1 drop
7	10.52	10.53	+ .01	.186	.340	.455 1 drop

The initial volume was 50 cc. in each case, with 25 cc. of 6 N sulfuric acid present.

The precautions noted by Miiller and Möllering[2] were carefully followed in order to avoid formation of any appreciable amount of manganese dioxide.

The Bichromate–Ferrous Iron Reaction.—The ferrous sulfate solutions were frequently restandardized by potentiometric titration with potassium bichromate. The results of the titrations using the Pt-Au electrode system are presented in Tables II–IV.

TABLE II

TITRATION OF APPROXIMATELY 0.05 *N* BICHROMATE WITH FERROUS SULFATE

No.	Calcd., cc.	Ferrous sulfate Found, cc.	Error, cc.	E.m.f. difference, Pt vs. Au (a) Initial	(b) Maximum	(c) Break per 1 drop of $FeSO_4$
1	26.16	26.11	−0.05	0.144	0.176	0.187
2	26.16	26.11	− .05	.246	.315	.200
3	26.16	26.13	− .03	.241	.332	.211
4	26.16	26.19	+ .03	.218	.427	.270
5	26.16	26.17	+ .01	.207	.368	.122

In determinations 1, 4 and 5, 5 cc. of concd. sulfuric acid (sp. gr. 1.84) and in nos. 2 and 3, 10 cc. of hydrochloric acid of sp. gr. 1.2 were present. The initial volume was 50 cc.

The determinations in Tables III and IV were made by Mr. H. H. Carspecken, to whom the author wishes to express his indebtedness.

TABLE III

TITRATION OF APPROXIMATELY 0.1 *N* FERROUS SULFATE WITH BICHROMATE

No.	Calcd., cc.	Bichromate Found. cc.	Error, cc.	H_2SO_4 of sp. gr. 1.84, cc.	Initial volume, cc.	Voltage break per 1 drop of reagent
1	48.26	48.25	−0.01	10	100	0.091
2	9.66	9.65	− .01	2	40	.175
3	9.66	9.65	− .01	2	40	.169
4	24.13	24.18	+ .05	5	50	.050
5	24.13	24.15	+ .02	5	50	.108

TABLE IV

TITRATION OF APPROXIMATELY 0.1 *N* BICHROMATE WITH FERROUS SULPATE

No.	Calcd., cc.	Ferrous sulfate Found, cc.	Error, cc.	E.m.f. difference, Pt vs. Au (a) Initial voltage	(b) Maximum voltage	(c) Break per drop of reagent at end-point
1	51.84	51.80	−0.04	0.203	0.495	0.287
2	25.92	26.00	+ .08	.220	.560	.340
3	10.36	10.35	− .01	.300	.505	.315
4	10.36	10.35	− .01	.293	.503	.313

From 2–10 cc. of sulfuric acid (sp. gr. 1.84) was present. Initial volume 100 cc. in no. 1 and 50 cc. in nos. 2 4.

Discussion

The **Pt-Au** system appears to be capable of use in solutions that are as dilute as 0.05 N.

---

[2] Müller and Möllering, *Z. anorg. allgem. Chem.*, *141*, 111 (1924).

The general features of the graphs of the titration data are shown in Fig. 2. It will be noted that there is no pronounced peak in the curve for the titration of bichromate in hydrochloric acid solution, The very marked rise that is observed with sulfuric acid solutions appears to be a composite of the usual anomalous rise in potential at the Pt electrode[3] and the fall at the gold electrode. This was found to be true by following the changes at each electrode with the aid of an auxiliary reference electrode (see curves 3, 4 and 5, Fig. 2).

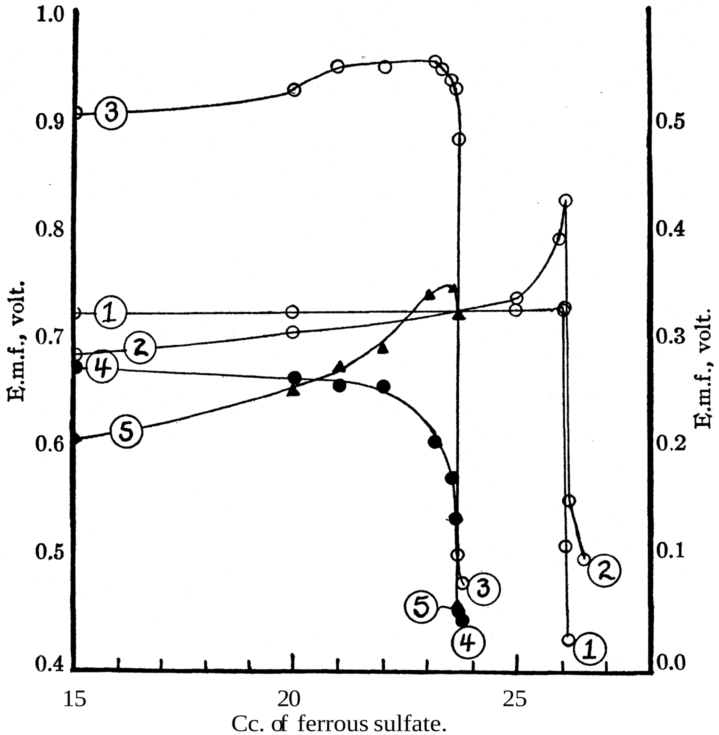

Fig. 2.—Titration of bichromate with ferrous sulfate (Pt-Au system). (Ordinates for 1, 2 and 5 at right; 3 and 4 at left.) Curve (1) 25 cc. of approximately 0.05 N bichromate titrated in hydrochloric acid solution. Curve (2) similar to (1) except that sulfuric acid was present. Curves (3, 4, 5) are from data of a single titration of 0.1 N bichromate with ferrous sulfate. (3) Pt-N. C. E. system. (4) Au-N. C. E. (5) Pt-Au system; (5) is a composite of (3) and (4).

The chief disadvantage of the Pt-Au system is the variable nature of the readings. The initial and maximum voltages show wide variations in magnitude for the same type of titration, so that it is difficult to judge

---

[3] Forbes and Bartlett, THIS JOURNAL, 35, 1527 (1913).

the approach of the end-point or to predict the voltage range in which the end-point change will occur in any given case.

Summary

A brief study of the use of the Pt-Au electrode system has shown that it gives a sharp change in e.m.f. at the end-points of some oxidation-reduction reactions in 0.1 or 0.05 N solutions.

A SIMPLE CONTINUOUS READING METHOD OF ELECTROMETRIC TITRATION WITH BIMETALLIC ELECTRODES

BY N. HOWELL FURMAN AND E. B. WILSON, JR.

RECEIVED JUNE 18, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

Electrometric methods of determining the end-points of volumetric oxidation-reduction reactions are accurate and convenient. Many varieties of systems have been developed to follow changes in the e.m.f. of a suitable pair of electrodes during the progress of a titration,[1] but not all of them possess the advantages of simplicity, economy of apparatus and speed. The system that is described in this paper combines these advantages and is, in addition, continuous reading.

Experimental

Apparatus.—The electrical system consists of a platinum electrode, a tungsten electrode,[2] a galvanometer and a high resistance that can be varied. The electrical connections are shown diagrammatically in Fig. 1. The platinum electrode was a wire of 0.33 mm. diameter (No. 28 B. and S. gage) and of 6–8 cm. length. The wire was soldered to a copper wire with gold; the platinum was sealed through the end of a glass tube (see Fig. 1). The end of the tungsten wire (No. 28 B. and S. gage; actual diameter 0.32 mm.) was dipped into the solution to a depth of 2–3 cm. The dimensions of the electrodes seem to have no very marked effect upon the behavior of the apparatus. A platinum wire of the size given seems somewhat more reliable than one of very small surface. The

---

[1] For a review of these systems, see E. Müller, "Die Elektrometrische Massanalyse," 4th ed., Steinkopf, Dresden, 1926; I. M. Kolthoff and N. Howell Furman, "Potentiometric Titrations," John Wiley and Sons, Inc., New York, 1926.

[2] Qualitative studies have been made using tantalum, platinized platinum, copper or gold instead of tungsten. The Pt-Au system was the best of these combinations. It gave excellent end-point indications in the reaction between permanganate and ferrous sulfate but was, in general, far less sensitive than the Pt-W system.

electrodes must be clean. The solution should be effectively stirred (motor stirrer).

A handy resistance unit was assembled from inexpensive radio grid-leak mountings. The resistances were of the cartridge type, and were rated at 10,000, 18,000, 20,000 and 100,000 ohms.[3] By making one or two interchanges of resistors it is possible to vary the resistance in steps of about 10,000 ohms each up to 160,000 ohms. A resistance of about 50,000 ohms served for most titrations.

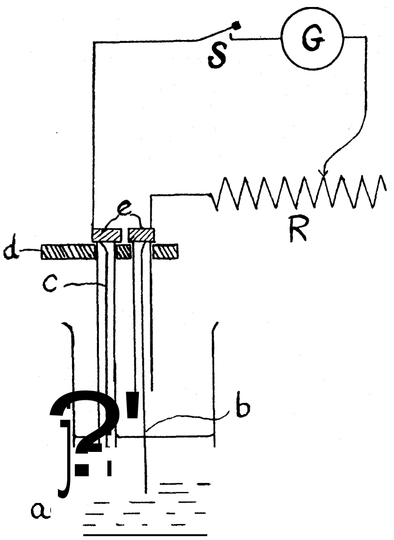

Fig. 1.—Apparatus. (a) Platinum electrode; (b) tungsten electrode; (c) copper wire. The copper and tungsten wires are wrapped around the glass tubes and held in place by the rubber tubes at (e); (d) is a Bakelite support for the electrodes. S, switch; G, galvanometer; R, variable high resistance.

The galvanometer was a Leeds and Northrup Company portable instrument (Type 2320D) of current sensitivity 0.5 micro-ampere. Any galvanometer of approximately similar characteristics should serve.

End-points.—Operation of the apparatus is very simple. The end-point is the largest single permanent deflection (usually 2–10 divisions) of the galvanometer that is produced by a single drop of the reagent, for all of the reactions that we have studied (ferrous sulfate-permanganate; ferrous sulfate-vanadic acid; ferrous sulfate-bichromate; iodine-thiosulfate). The galvanometer usually reads zero, or a low value, on the reducing side. As oxidizing agent is added, there is a slight increase in the galvanometer deflection. As the end-point is approached the needle gives temporary deflections that serve as convenient warnings. At the end-point there is a maximum permanent shift (2–10) divisions per unit volume of reagent. Further addition of oxidant produces relatively slight changes.

In the reverse titration there is a high initial galvanometer deflection, a maximum permanent downward shift in reading at the end-point and little further deflection on the addition of excess of reducing agent. Occasionally the end-point deflection is divided into two nearly equal parts. The maximum change per unit volume of reagent corresponds to the end-

---

[3] The resistances were "Aerovox Lavite" resistors (Aerovox Wireless Corp., New York). A suitable unit can be assembled at a cost of $3 to $5. It was found that the resistors were in some cases as much as 10% higher than rated. We are indebted to Mr. W. S. Niederhauser for the resistance measurements.

point, as is the case in potentiometric procedures. Graphs with galvanometer readings as ordinates and cc. of reagent as abscissas are analogous to those obtained potentiometrically. In any case the end-point is definitely determinable by a slightly experienced operator.

Accuracy.—Approximately 0.1 or 0.05 *N* solutions of the reagents were prepared and standardized. Starch indicator was used in the iodine–thiosulfate reaction. In other cases the potentiometric method was employed. A large number of quantitative determinations were made for the ferrous sulfate–dichromate, ferrous sulfate–vanadic acid and iodine–thiosulfate reactions. In many of these titrations simultaneous observations were made by the potentiometric method and the new "galvanometric" method. The outstanding fact of such determinations was that in every instance the end-point determined with the galvanometer checked exactly with the potentiometer end-point; that is, the same drop of reagent produced the greatest relative change with both systems.

In order to determine whether the presence of the Pt-W system caused any change in the position of the end-point, determinations were made with the standard (Pt-N calomel) method alone. The errors thus found were no greater than the natural experimental errors; in fact, deviations from the average were as great for the standard method as for the galvanometer method.

Permanganate-Ferrous Sulfate Reaction

A preliminary orientation study showed that the Pt-W system gave excellent results. The galvanometer deflections at the end-points were large. There was, in every case, agreement with the usual potentiometric end-point.

Bichromate-Ferrous Sulfate

The solutions that were titrated contained 10–15 cc. of 12 *N* hydrochloric acid or 25 cc. of 6 *N* sulfuric acid in a total volume of 45–75 cc. Assuming that the average values obtained with the Pt-N calomel system were correct the errors found in the titration of 0.1 *N* bichromate were: +0.07, ±0.00, +0.04, +0.05, +0.06 cc. of 0.1 N ferrous sulfate. In these and subsequent determinations the amounts of solution that were pipetted out ranged from 10 to 50 cc.; the resistance was approximately 70,000 ohms. The end-point deflections per 0.05 cc. of reagent were 7–9 galvanometer divisions in hydrochloric and 3–5 divisions in sulfuric acid solution. In the reverse titration the errors found were: –0.04, +0.02, –0.06, ±0.00, ±0.00 cc. of 0.1 N bichromate. The end-point breaks were less pronounced than in the reverse titrations, being about 5 divisions in hydrochloric and about 4 in sulfuric acid solutions. The calculated cc. of bichromate are the average of three concordant determinations (Pt-N calomel).

The data for more dilute (0.05 *N*) solutions are presented in Tables I and II.

TABLE I

TITRATION OF FERROUS SULFATE WITH APPROXIMATELY 0.05 *N* BICHROMATE

	1	2	3	4	6	6	7
Bichromate, calcd. cc.	23.07	23.07	23.07	23.07	23.07	9.22	46.14
Bichromate found, cc.	23.10	23.03	23.09	23.09	23.11	9.27	46 18
Error, cc.	$0.03	−0.04	+0.02	+0.02	+0.04	+0.05	$0.04
Resistance, 1000-ohm units	58	58	40	100	50	58	58
Galvanometer defl. div. at end-point per 0.05 cc.	4.9	3.1	3.0	1.5	3	**3.9**	1.5

Acid present: Nos. 1, 2, 25 cc. of 6 N H_2SO_4; Nos. 3–7, 10–15 cc. of 12 *N* HCl. Initial volume, 50–65 cc.

Large variations in the resistance, therefore, do not change the order of magnitude of the sensitivity of the method.

TABLE II

TITRATION OF BICHROMATE WITH APPROXIMATELY 0.05 N FERROUS SULFATE

	1	2	3	4	5	6
Ferrous sulfate found (Pt-W), cc.	27.17	27.14	10.94	37.94	27.16	37.98
Ferrous sulfate found (Pt-N calomel)	27.17	27.14	...	...	...	...
Ferrous sulfate calcd.	...	...	10.86	37.99	27.16	37.99
Error, cc.	...	...	+0.08	−0.05	$0.00	−0.01

The general conditions were those of Table I except that the resistance was 58,000 ohms.

Unfortunately no independent comparisons of the bichromate and ferrous sulfate by the usual potentiometric method had been made within several hours of the time when these determinations were carried out. One of us (F.) made up solutions Nos. 3–6, and the other (W.) made the titrations without any knowledge as to the relative strengths of the solutions.

The Iodine-Thiosulfate Reaction.—The solutions were approximately 0.1 N.

TABLE III

TITRATION OF THIOSULFATE WITH IODINE (APPROXIMATELY 0.1 *N*)

	1	2	3	4
Iodine calcd., cc.	26.69	26.69	26.69	26.69
Iodine found, cc.	26.68	26.64	26.69	26.70
Error, cc.	−0.01	−0.05	±0.00	+0.01

The calculated values are the average of several concordant determinations with starch as indicator. The resistance was 86,000 ohms. The reverse titration was studied by simultaneous determinations with Pt-W, Pt-N calomel and starch. All three methods gave the same end-point within 0.05 cc. It is perhaps worth noting that in a few instances the electrical end-point by either system was a distinct fraction of a drop different from the color end-point. It appears that minute traces of iodine loosely combined with starch do not affect the electrodes as would free iodine. There appeared to be no immediate diffusion of iodine out of the complex, because the color remained faint blue while the potential was decidedly on the reducing side. The galvanometer deflections, per fraction of a drop of reagent at the end-point, were very large. Occasionally the change was distributed over two drops of reagent. The maximum rate of change per drop invariably checked with the potentiometer.

The Vanadic Acid-Ferrous Sulfate Reaction.—A 0.05597 N vanadic acid solution that had been standardized potentiometrically was used. The solution contained 30 cc. of sulfuric acid sp. gr. 1.84, per liter. In instances marked with an asterisk (*) the quantity of vanadic acid was unknown to the operator.

TABLE IV

TITRATION OF 0.05597 N VANADIC ACID WITH FERROUS SULFATE

	1	2	3	4*	5*	6*	7*
$FeSO_4$ calcd., cc.	28.76	28.76	28.76	28.76	11.61	11.61	11.61
$FeSO_4$ found, cc.	28.77	28.72	28.70	28.75	11.50	11.62	11.61
Error, cc.	+0.01	−0.04	−0.06	−0.01	−0.11	+0.01	±0.00

NOTE.—Some time elapsed between determinations No. 4 and 5, and the ferrous sulfate was restandardized. The resistance was 58,000 or 30,000 ohms. The initial volumes ranged from 35–50 cc., with either 6–10 cc. of concd. HCl, or 25 cc. of 6 *N* H_2SO_4 present.

The galvanometer deflections were the smallest per drop of reagent at the end-point of any case thus far investigated. The sensitivity was somewhat increased by dropping the resistance to 30,000 ohms.

Discussion

The chief possible source of error in this method seems to be the continuous production of current, which must occur at the expense of some reaction in the solution. Assuming that all of the current drawn is produced by the reduction of the oxidant (and this is not necessarily the sole source of current), and assuming that 10 galvanometer divisions represent 5 micro-amperes, it appears that this deflection could be maintained for one hour at the expense of about 0.05 cc. of 0.1 N reagent. Only a few minutes are required for the titration.

The relation of the potential difference between Pt-W and the difference between each wire and a N-calomel electrode is shown for a typical instance in Fig. 2. The slight current that is drawn does not affect the graph of the readings Pt vs. N calomel to any very considerable extent.

The authors have not thus far attempted to secure new evidence to establish the theoretical basis of the method. Analogous phenomena (persistent differences in oxidation potential) have been reported.[4] The gen-

---

eral characteristics of the Pt-W systems have been previously studied.[5] It is planned to study the behavior of the Pt-W system further to see how far polarization effects account for the phenomena observed, and to study this and other systems in conjunction with vacuum tube amplifiers. Preliminary experiment has shown that polarization effects due to grid current may play an important role in its application.

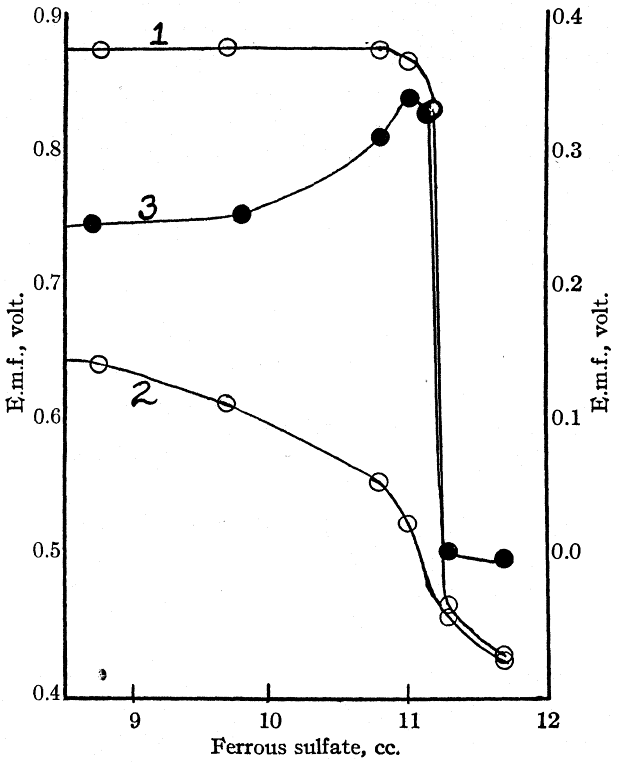

Fig. 2.—Titration of 0.1 *N* bichromate with ferrous sulfate. Ordinates for (1) and (2) at left. (1) Curve for Pt-N calomel, (2) for W-N calomel and (3) for Pt-W system, showing the sharp break at the end-point (ordinates of (3) at right of figure).

In the interactions between substances that are sufficiently far removed in the oxidation potential scale, there is a very close superficial analogy between the end-point indication in the present method and the excellent indication that is given by the method of Foulk and Bawden.[6] In the latter method, however, the high galvanometer readings are not always on the oxidizing side of the end-point.

The authors intend to study the application of the "Galvanometric" method to other reactions than those studied.

Summary

This paper describes a simple, direct reading and inexpensive system for determining end-points of oxidation-reduction reactions. The method depends upon the sudden change at the end-point in the potential difference between a platinum and a tungsten electrode which are immersed in the solution.

THEORY OF THE SORET EFFECT

BY E. D. EASTMAN

RECEIVED JUNE 22. 1927 PUBLISHED FEBRUARY 4, 1928

In a previous paper[1] a thermodynamic theory of the reversible Soret effect was given. It was there shown that the effect is related in magnitude to the heat of transfer of the constituents of the solutions in which it is manifested. Consideration of the nature of the latter quantity leads to a number of conclusions concerning general questions not yet experimentally settled. These inferences, and the views on which they are based, render intelligible many obscure features in this very uncertain field and offer guidance to further progress in it. They will, therefore, be outlined in this paper.

Definitions and Thermodynamic Relations

When a portion of one of the constituents of a solution is transferred by diffusion, or in the case of ions by an applied electric field, from one region to another within the solution, there is in general an accompanying absorption of heat from the surroundings of one region and evolution in those of the other. The quantity of heat absorbed from the surroundings of the region (of infinite extent) from which one mole of constituent **A** is transferred will be denoted by Q^*_A.[2] The entropy lost by the surroundings of the region from which the transfer is made is then $Q^*_A/T = S^*_A$. These quantities will be referred to as the heat and entropy of transfer, respectively. Their nature will be discussed in detail later.

In the former paper it was shown that in a binary solution placed in a temperature gradient the equilibrium compositions due to reversible effects are governed by the equation

$$(\partial \overline{F}_A/\partial N_A)_T\, dN_A = -\, S^*_A\, dT \tag{1a}$$

or

$$(\partial \overline{F}_A/\partial \ln N_A)_T\, d\ln N_A = -\, S^*_A\, dT \tag{1b}$$

---

[1] Eastman, THIS JOURNAL, 48, 1482 (1926).

[2] In the previous paper, ref. 1, $\overline{Q}_A$ was used as the symbol for the heat of transfer. To avoid confusion with the partial molal quantities in the case of entropy it seems better to adopt the symbols above.

Here $\overline{F}$ and N represent partial molal free energy and mole fraction, respectively. These equations are correct if the composition change is the only effect produced by the gradient in temperature.

The first members of Equations 1 are each equal to the change in partial molal free energy of constituent A corresponding to an isothermal composition change of the same magnitude as that produced by the temperature gradient. It was this quantity which it was found desirable to use in defining a Soret coefficient for use in theoretical work. Calling the latter s_A, and writing $\mathrm{d}\overline{F}^*_A$ in place of the first member of (1) a defining equation may be written

$$s_A = \mathrm{d}\overline{F}^*_A/\mathrm{d}T = -\overline{S}^*_A \qquad (2)$$

In numerical comparisons of the effect in different solutions it is also desirable to employ where possible the coefficient defined by (2) rather than the ordinary ones (d ln $N_A/\mathrm{d}T$ or d ln $c_A/\mathrm{d}T$) resulting from direct determinations. The latter coefficients are proportional to the former in sufficiently dilute solutions, but in more concentrated imperfect solutions this proportionality fails. The magnitude of the composition change is then of lessened significance. As an extreme illustration of this the case of a metal, regarded as a "solution" of ions and electrons, may be cited. Ordinary temperature gradients can scarcely produce appreciable composition changes in such systems. Yet it would be a mistake to assume the Soret effect to be negligible, since an appreciable potential gradient and free energy difference are still possible. This is an example in which a large rate of change of free energy with composition is coupled with a small actual or fractional change in concentration. The reverse of this might be illustrated by substances forming a two-phase mixture. A solution near one of the equilibrium compositions would show very small values of $(\partial\overline{F}/\partial N)$ and correspondingly large values of $\mathrm{d}N$, even though the free energy change and therefore the true Soret effect were small.

To illustrate the difference in the two coefficients in solutions of some representative electrolytes, the following examples may be given. According to Arrhenius[3] d ln $c/\mathrm{d}T$ in 0.05 M copper sulfate is -2.2×10^{-3}, and in 0.5 M -9.3×10^{-3} deg.$^{-1}$ Using Lewis and Randall's[4] activity data, the corresponding values of s (Equation 2) are found to be -1.5 and -4.6, cal./deg., respectively. Chipman[5] gives -2.1×10^{-3} and -0.33×10^{-3} for the ordinary coefficient in 0.1 M and 10 M hydrochloric acid, while the values of s are 2.3 and 1.4 cal./deg. For most strong electrolytes in concentrations up to 0.1 M, however, the relative values of the two coefficients are constant within the present rather wide limits of error.

One further point concerning the application of Equation 2 to solutions

[5] Chipman, THIS JOURNAL, 48, 2577 (1926).

of electrolytes should be mentioned at this stage. Solutions of binary electrolytes are really to be regarded in the present connection as systems of three components. This follows because of the partially independent distribution of the ions in the temperature gradient which manifests itself in the accompanying potential gradient[6] in the solution. It might, therefore, be supposed that the total Soret effect should be considered in two parts. These parts would be associated, respectively, with the free energy change due to the concentration gradient and that due to the electrical gradient. The latter part of the effect may, however, be seen to be negligible compared to the first. Owing to the very strong forces between ions of opposite charges, the gradient in ionic composition must be extremely small. The number of equivalents of positive ion transferred in establishing equilibrium, or in returning to the normal condition after removal of the temperature gradient, is therefore almost exactly the same as that of the negative ion. The free energy difference per mole of either ion transferred in such diffusion, which is the product of the difference in number of equivalents of oppositely charged ions, and the potential difference between which they are moved, must be negligibly small even though the potential difference itself is not. This being the case, the Soret free energy difference is due mainly to the concentration difference of the electrolyte and is governed by an equation like *(2)* in which the entropy term is the sum of the entropies of transfer of the ions corresponding to one mole of electrolyte. That is, the system may still be treated as one of two components.

The Nature of Heats of Transfer in Solutions of Electrolytes

For the purposes of the present discussion the space in the vicinity of an ion in an undissociated polar solvent may be divided, roughly, into three concentric regions of gradually differing properties. First, there is the "ion-cavity,"[7] within which there are no solvent molecules. This space varies in size from case to case and appears to be large compared to the volumes defined by the outer electron orbits of the ion. Immediately outside of the ion cavity the (polar) molecules of solvent are strongly attracted and oriented. The inner layers of solvent molecules in this second region, and those extending out from it to varying distances in different cases, are held so strongly by the central ion as to form a complex with it, acting in processes of diffusion, as a single molecule. The third region comprises all the rest of the outer space. In this sphere the solvent molecules are still subject to forces of compression and orientation, diminishing with distance from the center of the complex, and not sufficiently strong to bind these molecules to the ion. The second and third

---

[6] Potential gradients of this kind are discussed in the paper following this.

[7] Webb, THIS JOURNAL, 48, 2689 (1926).

of these regions obviously merge into each other in such a way as to prevent sharp boundaries from being drawn between them.

When a solvated ion of the kind described is transferred by diffusion from one region to another of the solvent, the aggregate comprising the first and second regions above remains mostly intact and takes part in no internal energy or entropy changes. But as the ion moves it leaves behind material which had been under its influence in the third sphere, and brings under its influence solvent molecules not previously so strongly affected. A relaxation occurs, therefore, in the region from which it goes, with an attendant increase in entropy and absorption of heat. The reverse effects appear in the region into which it moves. It is, therefore, these changes in the third sphere that give rise to the heats of transfer that determine the reversible Soret effects in solutions of ionized substances.

The conception of solvated ions outlined above takes into account only the electrical effects produced by the charge of the ion upon the molecules of the solvent regarded as electric dipoles. The mechanism of the heat of transfer dependent upon it holds strictly therefore only in the simpler cases. Several factors that were neglected in its discussion may be of importance in certain cases. Any sort of chemical bonding in the ion aggregate may greatly affect the spheres of influence about the central charge, and so alter the heat effects attending its diffusion. This kind of thing may differentiate, for example, between positive and negative ions in their orienting and bonding effects on water molecules. The hydrogen nuclei of the solvent may form a sort of hydrogen bond[8] with electrons of the outer shell of negative ions, a type which is not possible between the oxygen atoms and most positive ions. The effect of such bonds, if extensively formed, would be to increase region two at the expense of three, with consequent lessening of the heat of transfer. The possibility that either ion of the solvent may be transferred, in effect, by a chain mechanism, must also be considered in solutions of acids and bases. For if this occurs, not only the energy represented in the third sphere above, but that of the second as well, a very much larger quantity, would be involved in the heat of transfer.

The simple mechanism pictured above would appear to afford a basis for quantitative theoretical treatment. The entropy effects in region three about the ion depend upon the degree of compression and orientation of the solvent molecules in it. Both are approximately calculable in any element of volume at a given distance from an ionic center by methods like those of Webb.' The dependence of the entropy of the solvent upon pressure is measurable, and the entropy change due to orientation might be calculated from the relative probabilities of the axial distributions

[8] Rodebush and Latimer, THIS JOURNAL, 42, **1419 (1920).**

of the dipoles in the field of the ion and without it by methods like those of Langevin. Volume integrations throughout the sphere should result in the desired entropy. One of the limits in the integration is obviously infinity. The other, which is the boundary between regions two and three, is somewhat indefinite and variable from one ion to another. It could probably be fixed with enough exactness as the radius at which the equipartition amount of kinetic energy would be just sufficient to carry a solvent molecule against the force of attraction of the ion (known as a function of distance) to infinity. This would be, on the average, the dividing line between the "bound" and "unbound" solvent molecules, and would serve to define the third region above for the purpose of integration. The calculation outlined therefore appears theoretically feasible. Practically, however, several obstacles are encountered. Thus some of the essential data required in it, such as the electric moment of solvent molecules, are known only very inaccurately at present. Further refinements, taking into account the ion cavity, in calculations of the force field about ions, and some indication as to the influence of other factors than the purely electrostatic ones, are no doubt also necessary. This is particularly true since the effect in question is of the second order, as compared with the entire "entropy of solvation" of the ions. The actual application must therefore await these developments. It is, however, possible to draw a number of conclusions and suggest correlations from these ideas. Before proceeding to their discussion it is desired to present in the next section a comparison of certain indirectly measured entropies of transfer with those corresponding to measured Soret effects.

Comparison of Directly and Indirectly Determined Soret Effects

In the paper following this, approximate values are calculated for the entropy of transfer of the ions of a number of substances for which Soret coefficients have also been measured. The Soret coefficients corresponding to these, together with the experimentally determined values by several investigators, are shown in Table I.

TABLE I

SORET COEFFICIENTS, IN CALORIES PER DEGREE PER MOLE, OF CERTAIN ELECTROLYTES IN WATER

Observer	Av. temp., °C.	Av. concn., *M*	HCl	LiCl	NaCl	KCl	NH_4Cl
Soret[g]	47	±1.0	...	−0.10	−0.67	−1.1	..

---

[9] Soret, *Ann. chim. phys.*, [5] 22, 293 (1881).

[10] Wereide, *Ann. Physik*, 2, 55 (1914).

The calculated values in the last line of Table I are approximate in character and subject to revision when more reliable measurements of the electromotive forces from which they were obtained are available. They are, however, thought not to be seriously in error. In comparing them with the experimental Soret coefficients of the table it is seen that they agree fairly well with the older determinations, but are much higher than the more recent results of Chipman. It should be borne in mind in this connection that for stable substances all of the systematic errors of measurement render the observed values too low. There is, moreover, much evidence that some unstudied source of error is present in some, at least, of the measurements. Thus, two observers of the same quantity seldom agree. Duplicate determinations by one observer ,show differences much larger than the apparent errors in either observation. The occasional occurrence of curves of Type C in Chipman's[5] observations of the approach to equilibrium points to the presence of convection, the effects of which may have been present but masked in his other experiments. The relative values obtained by a single observer for a series of substances are probably approximately correct. It is only to such relative values that much weight is given in the following discussion, since it appears to the writer that few actual magnitudes for individual substances are known at present with any degree of certainty. It is also thought that the indirect method of determination is capable of greater accuracy than the direct.

Effect of Concentration on Magnitude of Soret Coefficients

The mechanism outlined in the second section to explain the heat of transfer of ions obviously requires a finite value of this quantity for every ion at infinite dilution. As has been previously assumed, and will be discussed later, in strong electrolytes the total effect is the sum of the effects of the constituent ions. For this class of substance it follows that the Soret coefficient approaches a constant finite value with dilution.[11] The form of the curve chosen by Chipman[5] to represent his results for hydrochloric acid at small concentrations is therefore correct.

The heat and entropy of transfer have many of the properties of partial molal quantities. It is easy to show, for example, that for both quantities equations of the following type are valid.

$$N_A S_A^* + N_B S_B^* + \ldots\ldots. = 0 \qquad (3)$$

It follows, therefore, that in the infinitely dilute solution the Soret effect (defined by Equation 2) is zero for the solvent though it is not for the solute; and dN/dT becomes zero for both.

In solutions of electrolytes each ion is surrounded mainly by ions of

---

[11] **This corrects a statement in the earlier paper. See also in this connection Rodebush, THIS JOURNAL, 49, 792 (1927), and Eastman, *ibid.*, 49, 794 (1927).**

opposite sign. The decrease in average distance between oppositely charged ions produced by increasing concentration from infinite dilution will, up to a certain limit at least, increase the field acting on the intervening molecules of the solvent and therefore increase the heat of transfer and Soret coefficient. With further approach of the oppositely charged centers, conditions become more complex and it is difficult to be sure without exact analysis how the third zone of the ions will be affected. If there is appreciable formation of ion pairs, with partial neutralization of the external fields of the ions, a decrease in heat of transfer may be looked for. This would lead to a maximum in the Soret coefficient at higher concentrations. In certain cases, as is pointed out in the following section, continued increase in concentration may lead to a reversal of sign of the effect, with the possibility of a minimum as well as maximum.

The Sign of the Soret Effect

As long as the charge of the ion is chiefly responsible for its solvation, the entropy of transfer of strong electrolytes predicted on the basis of the above mechanism will always be such as to produce an increased concentration of solute in the colder portions of the solution. This is found experimentally to be the case.

It would appear possible, however, to find solutions in which the role of ionized solute and polar (un-ionized) solvent might be reversed at different concentrations. For example, a small amount of water in hydrogen chloride might be ionized and solvated by the halide molecules. It should then be the water which would show increased concentration at the lower temperature. It might, of course, in this instance be necessary to go to very great dilution to secure much ionization of the water. Two constituents of more nearly equal ease of ionization in solution, and still ionized but little when pure, might more readily show this behavior.

Additivity of Soret Coefficients of Ions

The present theory requires, as does almost any other, that individual values be assignable to the Soret coefficients of all ions at infinite dilution, irrespective of the particular combination, and this idea has been used throughout. The theory also indicates many specific effects (such as the possibility of different geometrical packing of ions of different size ratios) which might destroy the additivity in more concentrated solutions. None of these effects would be thought, however, to be of great importance below about 0.1 *M*. That the additivity rule has not been approximately established experimentally at these concentrations is a further indication of uncertainty in the magnitude of the experimental values.

Correspondence with Mobilities of Ions

The total entropy of hydration of ions is known[12] to be an approximately linear function of the inverse of the radius of the ion. The entropy located in the outer sphere of unbound solvent molecules probably is a similar function of the radius of the ion complex (second sphere). The mobility of the ion may also be expected to be a similar function of the latter quantity. If it is, the Soret coefficient of ions should form a series having about the same order as the mobilities. The experimental values again are too uncertain to permit sure conclusions. Yet it appears that in certain series of similar ions, alkalies and halides, the order is actually the same. Apparently the generalization cannot be extended to ions of dissimilar type. For example, ammonium ion and, if the calculations of the following paper are correct, chloride ion appear to have much lower Soret coefficients than potassium ion, though the mobilities are not greatly different. The former both belong to the class of ions in which the electrical effects are perhaps not the only ones determining the size of the ion complex, which may account for the discrepancy.

Effects in Solutions of Non-electrolytes

In considering non-electrolytes in the light of the discussion in the second section, it is apparent that any kind of a molecule that can influence the neighboring molecules of the solvent must give rise to a finite Soret effect, even at infinite dilution. The fields of molecules of non-electrolytes are very much more nearly closed or saturated than are those of ions. The reversible Soret coefficients of non-electrolytes in general should then be very much smaller than those of ions. Even in the latter the effect is often small. With all non-polar substances and many non-electrolytes the coefficient may then be expected to be in general very close to zero. This is found experimentally by Wereide[10] and others to be true for a number of typical substances. Those for which the values appeared not to be zero are almost without exception of an unstable type in which some reaction occurring at different speeds at different temperatures might cause spurious effects. As an example, the fermentation of unsterilized sugar solutions may be mentioned. It is, of course, possible that extremely polar molecules may give rise to effects comparable with actually dissociated ions. In the absence of such polar bonds the conclusion seems fairly sure that only very small reversible Soret coefficients are possible.

Reversibility of the Effect

In the former paper the question of the relative magnitude of the reversible and irreversible Soret coefficients was left open. It now seems

---

[12] Latimer and Buffington, THIS JOURNAL, 48, 2297 (1926).

likely that in liquid solutions only the reversible effect is of importance. The conditions favorable to a large irreversible effect would appear to have been met in several of the solutions of non-electrolytes which have been studied. The failure to obtain measurable effects (in cases where the source of error mentioned above was precluded) indicates that no large irreversible effect exists in these solutions.

Summary

In this paper the thermodynamic properties of the entropy of transfer of dissolved substances are discussed. This quantity is also considered in its relation to the effect on the solvent of the charge of the ions of electrolytic solutes. A comparison of indirectly determined entropies of transfer is made with measured Soret coefficients for certain substances. From these three sources a number of conclusions, often to be regarded as predictions for the guidance of further experimental investigation but all of a high degree of probability, are drawn. The following ideas are in this way developed.

Soret coefficients are best expressed, when possible, in terms of entropies of transfer. A solution of an electrolyte may be considered from the standpoint of the Soret effect as a two-component system in spite of the partial separation of positive and negative ions in the temperature gradient. Some unknown source of error probably affects seriously many of the existing measurements of Soret coefficients, and indirect determinations may prove more reliable. The Soret coefficient of the solute in imperfect solutions is finite at zero concentration and nearly constant over a certain range from zero. At higher concentrations of strong electrolytes an increase in magnitude of the effect is normally expected. The possibility, in some instances, of a change in sign with both a maximum and minimum in the curve against composition is indicated. The coefficients for all strong electrolytes at small concentrations in water are negative in sign. The Soret coefficients of ions are additive. There is a limited correspondence between the mobility of ions and their Soret coefficients. The Soret coefficient in solutions of non-polar substances is negligibly small, as is also the irreversible Soret effect in all liquid solutions.

ELECTROMOTIVE FORCE OF ELECTROLYTIC THERMOCOUPLES AND THERMOCELLS AND THE ENTROPY OF TRANSFER AND ABSOLUTE ENTROPY OF IONS

BY E. D. EASTMAN

RECEIVED JUNE 22, 1927 PUBLISHED FEBRUARY 4, 1928

Systems of the type represented schematically as follows **are** often referred to as electrolytic thermocouples

$$\underset{T_1}{\text{Electrode}},\ \underset{T_1}{\text{Solution I}},\ \underset{T_2}{\text{Solution II}},\ \underset{T_1}{\text{Solution I}},\ \text{Electrode} \qquad \text{(I)}$$

The two electrodes in this arrangement are identical and are kept at the same temperature. Solutions I and II, the junctions of which are at different temperatures, may contain the same electrolyte at different concentrations, or different electrolytes.

Other arrangements consisting of two similar electrodes, at different temperatures, and a single solution in which the temperature gradient lies, are also occasionally given this name. The latter type may be represented as follows:

$$\underset{T_2}{\text{Electrode}},\ \text{Solution},\ \underset{T_1}{\text{Electrode}} \qquad \text{(II)}$$

In a previous paper[1] arrangements like (II) were referred to as thermocells. To distinguish them from the first class, this designation will be continued here.

The electromotive force of these cells is related to the entropy of transfer[2] and partial molal entropy of the ions of the electrolytes. Of the latter quantities, the first is of interest in connection with the Soret effect and the second is capable of many applications in the thermodynamics of solutions. It is the purpose in this paper to show the thermodynamic relations between these quantities and to employ certain of the existing data in illustrative calculations in order to determine to what extent it may prove possible to utilize these methods in numerical evaluations.

Thermodynamic Relations

Electrolytic Thermocouples.—The cells of Type I to be utilized in the later calculations all involve solutions of uni-univalent electrolytes having a common anion. The theory outlined will, therefore, be restricted to this case, though it is readily generalized. It is also convenient to consider cells in which the temperature difference is infinitesimal, T_1 and T_2 of Arrangement I being replaced by T and $T + dT$.

When one faraday of electricity is passed through systems of this kind, the direction of positive current being from left to right through the cell,

---

[1] Eastman, THIS JOURNAL, 48, 1482 (1926).

[2] For a discussion of this quantity, see the preceding paper.

the change in state produced may be considered in the following parts: A, the electrode reaction at the first electrode, occurring at temperature T; B, the change, or "reaction' at the liquid junction, at T; C (1), the transfer of t_{C_2} equivalent of the cation of solution II from T to $T + dT$ and (2) the corresponding transfer at t_{A_2} equivalent of anion from $T +$ dT to T (t with the appropriate subscripts being used to represent the transference numbers of the ions in the two solutions); D, the reaction at the liquid junction at T + dT; E (1), the transfer of t_{C_1} equivalent of positive ion in Solution I from T + dT to T; and (2), the transfer of t_{A_1} equivalent of negative ion from T to T + dT; F, the electrode reaction, reversing (A) above, at T.

The electromotive force, dE, corresponding to this series of changes, may be shown by the methods of the earlier paper to depend upon the heat transferred by reversible absorption at the upper temperature and evolution at the lower. The relation is

$$FdE/dT = L/T = AS \tag{1}$$

Here F is the equivalent of electricity, and L and A S are the heat absorbed from and entropy lost by the surroundings of the system at the upper temperature and transferred to the lower when one faraday is passed reversibly from left to right through the cell.

Regarded from the standpoint of heat transfer in the cell processes, it is obvious that the electrode reactions, items A and F above, are without effect. The liquid boundary reactions, B and D, do, however, produce a heat transfer. The attendant entropy effect (loss by surroundings or gain by system due to the reaction at the upper temperature) will be called ΔS_B.

There is also an entropy effect due to the transfer (items C and E) of the ions between the two temperatures. The net entropy of transfer of the ions (loss of entropy by the surroundings at T + dT and gain at T) will be called AS*.

Considering the two effects above, Equation 1 may be rewritten as

$$FdE/dT = \Delta S_B + AS^* \tag{2}$$

The temperature coefficient of the whole cell as given by (2) may therefore be considered in the separate parts indicated. The part which may be designated $dE_B/dT = \Delta S_B/F$, due to the liquid junctions, may be calculated (exactly at infinite dilution and approximately at finite concentrations) by the methods due to Nernst and Planck. The remaining part, $dE^*/dT = \Delta S^*/F$, due to the transfer of the ions between different temperatures, may then be obtained from the measured e.m.f. of the cell and the calculated change in junction potential. This corrected e.m.f. may then be related to the entropies of transfer of the individual ions, since ΔS^* is expressible in terms of them. Thus, if S^* is the molal entropy of transfer of a single ion,

$$\Delta S^* = t_{C_1}S^*_{C_1} - t_{C_2}S^*_{C_2} + (t_{A_2} - t_{A_1})S^*_A \tag{3}$$

It will also be observed that $\mathrm{d}E^*/\mathrm{d}T$ is the potential gradient accompanying the thermal one, and is due no doubt to partial separation of positive and negative ions in the solution lying in the temperature gradient, as first suggested by Nernst.[3]

Throughout the preceding discussion the composition of the electrolytes in the temperature gradient has been assumed to be uniform. Equations 1, 2 and **3** are exactly valid only if this condition is fulfilled, and do not apply, therefore, to cells in which Soret equilibrium has been established. Other equations covering the latter case can be deduced. The Soret equilibrium is, however, established very slowly as compared with the other cell processes, and it is possible therefore to avoid its effects by proper experimental precautions. It is then permissible to apply the equations in the forms given above.

Thermocells.—Cells of Type II were specifically treated in the former paper.[1] The entropy of transfer of the ions was neglected, however, in the development given there. When this is included, the equation (19 of the former paper) becomes

$$F\mathrm{d}E/\mathrm{d}T = \Delta S_R + AS^* \tag{4}$$

In this equation ΔS_R is the entropy gained by the system at the higher temperature in the electrode reaction caused by one faraday passing from left to right through the cell. AS*, again the net entropy of transfer of ions, is now given by

$$AS^* = t_C S^*_C - t_A S^*_A \tag{5}$$

The Soret effect is again neglected, since the measurements may be made so as to exclude its influence in the solution, and it is assumed to be negligible for the electrons in the wire in the temperature gradient.

By opposing two cells of this second type having the same electrodes, and electrolytes with a common negative ion but with different positive ions, a change in state is produced on operation which is the same as that in the Type I cells, except for the liquid junction reactions. These combinations without liquid junction obviously offer many advantages over the first type for the determination of entropy sums such as that in Equation **3.**

Approximate Calculation of Entropy of Transfer of Ions

Of the existing data applicable in Equations 2 and **3** for the determination of entropy of transfer of ions, the most satisfactory are those of Podzus,[4] since they relate to dilute solutions and were obtained under conditions designed to eliminate the effect of the Soret phenomenon. The observations to be used here were obtained from a series of cells of Type I (and a few combinations of Type II) in which the first and second electrolytes

---

[3] **Nernst,** *Z. physik. Chem.*, **4**, 129 (1889).

[4] **Podzus,** Ann. *Physik*, [4] **27,** 859 (1908).

were different members of a group comprising the chlorides of hydrogen, ammonium and four of the alkali metals. They may be cast in the form of five independent equations, based upon Equation 3, as follows

$$
\begin{array}{lr}
0.497\,S^*_{\mathrm{K}^+} - 0.822\,S^*_{\mathrm{H}^+} - 0.325\,S^*_{\mathrm{Cl}^-} = -7.15 \pm 0.15 & (6)\ \mathrm{a} \\
0.497\,S^*_{\mathrm{K}^+} - 0.343\,S^*_{\mathrm{Li}^+} + 0.154\,S^*_{\mathrm{Cl}^-} = 0.57 \pm 0.15 & \mathrm{b} \\
0.497\,S^*_{\mathrm{K}^+} - 0.402\,S^*_{\mathrm{Na}^+} + 0.095\,S^*_{\mathrm{Cl}^-} = 0.08 \pm 0.1 & \mathrm{c} \\
0.497\,S^*_{\mathrm{K}^+} - 0.508\,S^*_{\mathrm{Rb}^+} - 0.011\,S^*_{\mathrm{Cl}^-} = -0.07 & \mathrm{d} \\
0.497\,S^*_{\mathrm{K}^+} - 0.498\,S^*_{\mathrm{NH}_4^+} - 0.001\,S^*_{\mathrm{Cl}^-} = 0.60 \pm 0.1 & \mathrm{e}
\end{array}
$$

The directly observed data upon which these equations depend are average temperature coefficients of electromotive force, dE/dT, over intervals of about 20°, the mid-point being 25°. The concentration of the solutions was 0.02 N. Podzus' calculations from the Planck equation of the junction e.m.f.'s were used to correct the direct observations to give the values of ΔS^*. The numerical values of ΔS^* in Equations 6 are averages obtained from several combinations. The average deviation of separate values from the mean is indicated in the equation when more than one value is obtainable.

From thermodynamics alone these relations are all that can be obtained. To calculate the entropies of transfer of the individual ions some further relation between them is required. At the present time no such relation is known. In the paper preceding, however, certain general deductions of a qualitative character were made concerning the magnitudes of these quantities. Thus it was concluded that they are independent of each other in dilute solution and that they are always positive in sign. It also appears probable that in a series of closely related ions, such as those of the alkali metals, the entropies of transfer vary in the same order as the mobilities. Utilizing these ideas in connection with Equations 6, the magnitudes may be roughly fixed for each ion. Thus from Equation 6e the minimum value of $S^*_{\mathrm{K}^+}$ is determined to be about 1.2 ± 0.2, since neither $S^*_{\mathrm{NH}_4^+}$ nor $S^*_{\mathrm{Cl}^-}$ may be less than 0. From Equation 6c, the maximum value of $S^*_{\mathrm{K}^+}$ is fixed as 0.9 ± 1, since $S^*_{\mathrm{Na}^+}$ cannot (according to the above ideas), exceed $S^*_{\mathrm{K}^+}$ and $S^*_{\mathrm{Cl}^-}$ cannot be less than 0. Adopting 1.0 as a probable value of $S^*_{\mathrm{K}^+}$, that for $S^*_{\mathrm{Cl}^-}$ must be about 0.0 if Na^+ is to fall between Li^+ and K^+ in the series. With these values fixed, the others follow from the equations. The experimental errors in ΔS^+ in Equation 6 are large enough to render these values rather uncertain. Within the limits of error, however, the values shown in Table I agree with the experimental data, and with the general properties enumerated above, and no large changes in them are possible without some departure from this agreement.

TABLE I

ENTROPY OF TRANSFER, IN CALORIES PER DEGREE PER MOLE, OF IONS IN 0.02 N SOLUTIONS AT 25°

Ion	H^+	Li^+	Na^+	K^+	Rb^+	NH_4^+	Cl^-
Entropy of transfer	9.3	0.1	0.9	1.0	1.1	0.0	0.0

The values in Table I can scarcely be said to have been calculated. Rather, they have been selected to agree with the known data and probable laws. Nevertheless, they can hardly fail to be correct in order of magnitude and the probability is high that the relative and absolute values are roughly correct also. Due in part to experimental uncertainties and partly to the approximate character of the assumptions made, nothing more than this rough correspondence can be claimed. The results of these estimates make it appear probable that experiments more expressly designed for the purpose would lead to a fairly close limitation of the values of the entropies of transfer, even though a sufficient number of quantitative relations for their exact determination be not available.

The results of the application of the values in Table I to the calculation of Soret coefficients are discussed in the preceding paper.

Partial Molal **Entropy of** Chloride Ion

Richards[5] measured dE/dT in cells of Type II exemplified by

$$\underset{T_2}{Hg},\ \underset{T_2}{HgCl},\ HCI(O.l\ M),\ \underset{T_1}{HgCl},\ \underset{T_1}{Hg}$$

Applying Equation 4 to this cell, it is seen that ΔS_R is the entropy change in the reaction

$$Hg + C1^-(0.1\ M) = HgCl + E^-_{(Hg)}$$

Further

$$AS^* = t_H S_H^* - t_{Cl} S_{Cl}^* \qquad (7)$$

Using the measured values of dE/dT, with the entropy of transfer of H^+ and Cl^- from Table I, the entropy change in the calomel electrode half reaction may be calculated. From the known entropy of calomel and mercury that of chloride ion may then be obtained.

Richards's best experiments were made with the chlorides of hydrogen, lithium, sodium and potassium as electrolytes. Data pertaining to each of these cells are collected in Table II. The total entropy change of the cells as calculated from dE/dT is shown in the second column of the table. The temperature to which it corresponds is 15°, and the concentration of electrolyte is 0.01 M. The third column gives AS^* as calculated by Equation 7 from the data of Table I. The latter apply to 0.02 M solution at 25°. In calculating ΔS_R in the fourth column, the errors due to these differences in concentration and temperature are assumed to be no larger than the other errors. It is also assumed that the Soret equilibrium was not established in the cells, though this assumption is difficult to verify from Richards's descriptions. The entropies of Hg and HgCl used, with ΔS_R, in calculating $\overline{S}_{Cl^-}$ in the fifth column of the table are 17.8 and 23.2, respectively.[6]

TABLE II

PARTIAL MOLAL ENTROPY, IN CALORIES PER DEGREE, OF CHLORIDE ION IN 0.01 M SOLUTION AT 15°

Electrolyte	FdE/dT	AS*	ΔS_R	$\bar{S}_{Cl^-}$	Deviation from av.
HCl	−15.2	7.6	−22.8	28 2	0.2
LiCl	−23.1	0.0	−23.1	28.5	.5
NaCl	−21.9	.4	−22 3	27 7	.3
KCl	−21.7	.5	−22 2	27 6	.4
Average			−22 6	28 0	.4

A set of observations similar to those of Table II but with 0.1 M electrolytes gives 24.5 as the average entropy of chloride ion, at this concentration and 15°, the average deviation of individual results from the mean being 0.5. These values of $\bar{S}_{Cl^-}$ are in close agreement with those calculated by Chipman.[7]

In spite of the lack of correspondence of temperature, concentration and other experimental conditions in the various measurements on which these calculations are based, they appear to be of sufficient reliability to indicate the possibilities of this method of determination of partial molal entropies of ions. Absolute values for individual ions, as obtained here, are unnecessary in ordinary thermodynamic work, yet their use would agree with usual practice when pure substances are concerned. Comparison of these values with those calculated in other ways[8] is also of some interest. For these reasons this field seems worthy of further experimental development.

Summary

Thermodynamic equations are given connecting the entropy of transfer ions and entropy changes in single electrode reactions with the e.m.f.'s certain thermo-electric cells. Application of them is made to the calculation of the entropy of transfer of six of the common univalent cations, and chloride ion. As an illustration of the possibilities of the method in the field of ionic entropies, the partial molal entropy of chloride ion is calculated.

BERKELEY, CALIFORNIA

---

[7] Chipman, *Thesis*, University of California, 1926. Chipman made the assumption in his work that the potential gradient (corresponding to AS*) in solutions of lithium chloride and ammonium chloride is negligibly small. This was based in turn on an assumed connection between the potential gradient and the Soret effect, the measured values of the latter being very small in the solutions in question. These ideas are supported by the present calculations.

OBSERVATIONS ON THE RARE EARTHS. XXVI. THE PURIFICATION AND ATOMIC WEIGHT OF ERBIUM

BY ARTHUR EVAN BOSS WITH B. S. HOPKINS

RECEIVED JUNE 30, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

The object of the work described in this paper was to continue the purification of erbium material and to determine the atomic weight of erbium by using the chloride-to-silver ratio.

The accepted value for erbium is based on the work of Hofmann[1] on the oxide-to-sulfate ratio. The average of three determinations gave the value 167.68.

In 1917 Wichers, Hopkins and Balke[2] prepared erbium material of high purity and attempted to determine the oxide-to-chloride ratio. They found that the oxide, which they prepared by ignition of the oxalate, retained notable quantities of carbon dioxide, even after ignition at a temperature just below 900° for ten hours.

Sources of Material

The material used in the study of this element came from two different sources (1) Texas gadolinite and (2) Series M (bromates).

This material had been treated as described by Driggs and Hopkins[3] until fractions could be removed which showed only yttrium and erbium, and which were well removed from those fractions containing holmium on the one hand and thulium on the other. The material in the final fractionation series showed no indications of the presence of any rare earths other than yttrium and erbium. This yttrium-erbium material had been further purified by being run as a nitrate fusion series by F. H. Driggs.

Separation of Yttrium and Erbium

The nitrate fusions were continued, using the furnace built by Driggs and Hopkins for the purification of holmium.[3] After some fifty further fractionations, the four head fractions, on analysis by the permanganate method of Gibbs,[4] showed values which were alike within the limits of experimental error. This close agreement of equivalent weights must be taken as evidence of the removal of yttrium. The arc spectrum of erbium is not sufficiently well mapped to be useful in determining the purity. The observation of the magnetic susceptibilities, as used by Driggs and Hopkins to show the absence of dysprosium from their holmium, is much

[1] Hofmann, *Ber.*, 43, 2631 (1910).

[3] Driggs with Hopkins, *ibid.*, 47, 363 (1925).

[4] Gibbs, *Am. Chem. J.*, 15, 546 (1893).

less sensitive in the case of an erbium-yttrium mixture than is the determination of the equivalent weight.

Since Wichers, Hopkins and Balke found that the method of partial precipitation with sodium nitrite gave a rapid separation of yttrium and erbium, some of the yttrium-rich ends of the nitrate fusion series were taken, combined and subjected to fractionation with sodium nitrite. In this way practically pure yttrium material was separated at the one end of the series and erbium material at the other. The two head fractions, 8D and 8E, were taken for analysis.

Preparation of the Reagents for Atomic Weight Study

The purification of the reagents in this investigation was carried out in the same manner as described in earlier publications of this Laboratory.[5]

The erbium nitrate obtained from the fractions 18, 19, 17, 8D and 8E was purified by alternate precipitations as oxalate and hydroxide, the second hydroxide and the second oxalate precipitation being from conductivity water. The final oxalate from each fraction was dried and ignited to the oxide in a platinum crucible.

The anhydrous chloride was formed under the conditions described by Wichers, Hopkins and Balke.

Ratio of Erbium Chloride to Silver

The ratio of erbium chloride to silver was determined in essentially the same manner as described by Driggs and Hopkins on the atomic weight of holmium.

In the following tabulated data the number of the fraction from which the material was taken is shown, together with the weight of the anhydrous chloride, the weight of silver necessary and the atomic weight of erbium. The number in parenthesis shows the determination in which the material had been previously used.

The weighings were made by the method of substitution, the tare flask being of quartz and differing from the reaction flask by only a few milli-

TABLE I

RESULTS OF DETERMINATIONS

Determination	Fraction number	Weight of anhydrous chloride	Weight of silver	Ratio	Atomic weight of erbium
I	18	2.25485	2.66270	0.84683	167.69
II	19	0.30165	0.35630	,84663	167.63
III	17	1.02242	1.20761	.84665	167.64
IV	8D	0.38998	0.46068	.84654	167.60
V	8E	.38219	.45144	.84662	167.63
VI (IV)	8D	,17445	.20604	.84668	167.65
				Average	167.64

---

[5] Kremers, Hopkins and Engle, THIS JOURNAL, 40, 598 (1918).

grams. The weights were standardized to 0.01 mg. and all weighings were corrected to the vacuum standard.

The following densities were used: erbium chloride, 4.1; silver, 10.5; platinum weights, 21.5; platinum plated brass weights, 8.4. The atomic weight of silver was taken as 107.88 and that of chlorine as 35.457.

Summary

1. Fractionation of erbium-yttrium material from gadolinite by the nitrate fusion method yielded erbium material of constant atomic weight, as did also fractionation of similar material by the method of fractional precipitation with sodium nitrite.

2. The ratio of erbium chloride to silver was determined in six analyses. The value 167.64 was obtained for the atomic weight as the mean of the six determinations. This value agrees with the accepted value for this element, 167.7.

A COMPARISON OF TWO METHODS USED IN DETERMINATION OF PHOSPHORUS PENTOXIDE AS MAGNESIUM AMMONIUM PHOSPHATE

BY WALLACE MORGAN McNABB

RECEIVED AUGUST 6, 1927 PUBLISHED FEBRUARY 4, 1928

The object of this method was to check the value of the ammonium acetate method[1] in the determination of phosphorus pentoxide as magnesium ammonium phosphate with the earlier method in which ammonium acetate is not used.[2] The ammonium acetate method is designated A and the earlier method B.

In Method **A** weighed samples of monopotassium hydrogen phosphate were dissolved in 5–10 cc. of water. To this solution was added several drops of dilute 1:10 hydrochloric acid, then 25 cc. of a 20% solution of ammonium acetate and 30 cc. of magnesia mixture. (The magnesia mixture was prepared by dissolving 55 g. of crystallized magnesium chloride and 105 g. of ammonium chloride in water, adding four drops of 1:10 hydrochloric acid and diluting to a volume of 1 liter.) After heating the solution almost to boiling, several drops of phenolphthalein indicator were added drop by drop with constant stirring until a red color appeared. The solution was allowed to stand until cold ($1-1^1/_2$ hours), then about one-fifth

---

[1] Schmitz, *Z. anal. Chem.*, 65, 46 (1924).

[2] Treadwell and Hall, "Analytical Chemistry," John Wiley and Sons, Inc., New York, 1924, vol. 2, 6th ed., p. 380.

its volume of ammonium hydroxide (sp, gr. 0.95) was added; it was stirred vigorously, allowed to stand for ten minutes and then filtered. After the precipitate was transferred from the beaker the contents of the crucible was **well** washed with *2.5%* ammonium hydroxide. The last washing was made with 4–5 drops of an ammoniacal ammonium nitrate solution (saturated); it was then dried, ignited and weighed.

In Method B the solution containing the alkali phosphate (volume **5–10** cc.) was treated with several drops of 1:10 hydrochloric acid, **30** cc. of magnesia mixture and 20 cc. of a saturated solution of ammonium chloride. After heating the mixture almost to boiling, *2.5%* ammonium hydroxide was added slowly, while constantly stirring, until a precipitate began to form, and then the addition of ammonium hydroxide was regulated so that about four drops per minute were added. As the precipitate increased, addition of ammonium hydroxide was quickened until phenolphthalein gave a red color to the solution. After cooling (1–1$^1/_2$ hours), one-fifth of the volume of strong ammonium hydroxide (sp. gr. 0.95) was added, stirred for about one minute, allowed to stand for ten minutes and then filtered. The precipitate was transferred to the crucible, washed well with 2.5% ammonium hydroxide and finally with 4–5 drops of an ammoniacal solution of ammonium nitrate (saturated), dried, ignited and weighed.

The author has found that addition of ammonium nitrate before the ignition is carried out insures formation of a pure white magnesium pyrophosphate. It aids the oxidation of any organic material present which might tend to reduce pyrophosphate in the determination of various phosphates. This procedure is especially desirable in Method A as occasionally a trace of ammonium acetate clings to the precipitate and is easily oxidized by the ammonium nitrate.

All analyses were made from definite quantities of pure recrystallized monopotassium hydrogen phosphate Each filtrate was allowed to stand for not less than twenty-four hours. Any trace of phosphate could be recognized by rubbing the bottom of the beaker with a stirring rod. This test was found to be entirely satisfactory. All filtrates gave a negative test for phosphorus. The crucible with the precipitate was placed in a porcelain crucible containing a platinum foil in the bottom.[3] The outer crucible was at first heated very gently with a Bunsen burner, the temperature being gradually increased to full red heat. The ignitions were carried out to constant weight with a Méker burner.

Since excellent results were obtained using Gooch crucibles in the determination of arsenic pentoxide as magnesium ammonium arsenate,[4] the same crucibles were used in the determination of phosphorus. With Method A the results obtained from a series of analyses using the porce-

---

[3] McNabb, THIS JOURNAL, **49,891 (1927).**

[4] McNabb, *ibid.*, **49, 1451 (1927).**

lain Gooch crucible varied as much as 0.4 mg. with a 0.2000g. sample of phosphate, and there was as great a variation as 0.9 mg. for a 0.5000g. sample.

Due to these variations, the Monroe crucible was substituted. Results of the analyses are given in the table. Ignitions were carried out in the manner described above and gave a snow-white magnesium pyrophosphate. It is easier to carry out the precipitation in the presence of excess ammonium acetate. Acetate ions seem to prevent formation of secondary products and without the acetate it is tedious to produce pure magnesium ammonium phosphate. Sometimes *a* precipitate resembling aluminum hydroxide will form and is hard to filter, invariably giving high results.

Since phosphorus pentoxide is often determined as magnesium ammonium phosphate in the presence of molybdate, a check of Method A with B was made. According to Treadwell and Hall,[5] "if the solution contains more than 0.1 g. of phosphorus pentoxide, then aliquot parts for the analysis should be used." For this reason only 0.2000 g. of alkali phosphate was used for the determination of phosphorus pentoxide in the presence of molybdate ions. In analyses made by both methods and ignited to constant weight with a Méker burner, some of the ignited products retained a gray color and the results ranged from 0.1 to 0.3% high.

According to McCandless and Burton[6] "precipitates burned properly in *a* muffle do burn white and the molybdenum present is volatilized almost completely."

The table gives results of analyses using the two methods in the presence of 25 cc. of a 14% solution of ammonium molybdate, the volume of each solution being kept at 150–200 cc. Final ignitions were carried out in an electric muffle at 1000–1100° to constant weight. All ignited products on crushing were found to be white throughout. In the presence of molybdate ions a nice crystalline precipitate is easily formed using either method.

Conclusions

1. A comparison of the two methods of Schmitz in determination of phosphorus pentoxide as magnesium ammonium phosphate has been made. The ammonium acetate method is designated as Method A and the one in which ammonium acetate was not used designated as Method B. Four to five drops of an ammoniacal solution of ammonium nitrate was used in the last washing to insure complete oxidation of any organic material occasionally found in the analysis of phosphates.

2. All analyses were made from definite quantities of pure, recrystallized monopotassium hydrogen phosphate.

3. Using Method A, results obtained with porcelain Gooch crucibles and ignition carried out to constant weight with a Méker burner varied from 0.4 mg. in a 0.2000g. sample to 0.9 mg. in a 0.5000g. sample of phosphate.

4. Using Monroe crucibles and igniting to constant weight with a Méker burner, Method A gave an average percentage error of +0.02 calculated from weight of samples ranging from 0.2000 g. to 0.5000 g. Method B gave an average percentage error of —0.02.

5. In applying both methods in the presence of molybdate ions high results ranging from 0.1 to **0.3%** were obtained and some of the ignited products were of a gray color. Igniting in an electric muffle between

1000–1100° gave a white magnesium pyrophosphate. Both methods gave an average error of −0.05% (0.2000 g. sample of phosphate).

6. The advantage in Method A is that in the absence of molybdate ions it is easier to produce a crystalline precipitate.

THE ACTION OF ULTRAVIOLET LIGHT ON SOME COLLOIDAL DISPERSIONS OF GOLD[1,2]

BY JACOB J. BEAVER AND RALPH H. MULLER

RECEIVED AUGUST 6, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

The study of the effect of radiation upon colloidal dispersions of gold has been the object of numerous investigations. The earliest of these dealt with the reducing action of light upon gold salts, with the accompanying formation of a colloidal dispersion.[3] The accelerating effect of light during the reduction of gold salts by various reducing agents has also been known for some time.[4]

A comprehensive study of the significance of light in the formation and stability of colloidal gold has been made by Nordenson.[5] His paper contains a valuable survey and criticism of previous work on this problem. He investigated the effect of light upn the reduction of chlorauric acid by hydrogen peroxide. Reduction proceeds in the darkness or diffuse daylight with the formation of a coarse, bluish suspension. The exposure to the radiation of a quartz mercury-vapor lamp, during the reduction, leads to the formation of stable sols. The degree of dispersion and the color depend upon the length of the exposure. The sols prepared in this manner were examined spectrophotometrically as well as with the ultramicroscope and the dependence of the properties upon time of exposure was demonstrated. In addition he observed a coagulating effect of the

ultraviolet light which is similar to that induced by weak electrolytes. He was convinced that the coagulation is not due to a photo-electric effect, because the result was the same with positively as with negatively charged particles. Some exception, however, must be taken to his method of reversing the charge on the gold particles. The method was that proposed by Burton[6] and also used by Svedberg[7] and consists in the addition of aluminum sulfate until the direction of migration under an electrical field is reversed. Nordenson admits the possibility of interaction of the gold with the products of hydrolysis of the aluminum sulfate, but apparently considers the change in sign of the particle charge to be the only important result. He could detect no chemical change in the dispersion medium which would account for the coagulation by light. He offered two explanations for the phenomenon. (1) The light may cause a difference in potential between adjacent particles (Becquerel effect) leading to attraction and eventually to precipitation, (2) The light may disturb the adsorption equilibrium between particle and associated ions, leading to instability and later to coagulation.

In attempting to reproduce some of the many photochemical phenomena ascribed to gold sols, we were impressed by the strict dependence of these effects upon the previous history of the dispersion. Thus it was possible to prepare sols which were utterly indifferent to prolonged irradiation from the most powerful artificial source of ultraviolet light available. Other sols were prepared which: by the customary mode of designation, were "clear red and free from coarse particles" and yet were markedly sensitive to ultraviolet light.

The object of this investigation is to study the conditions under which sols can be prepared which will exhibit the photochemical properties ascribed to them and to ascertain why certain dispersions are not sensitive to light and others are decidedly sensitive. In addition, the photochemical changes themselves are investigated as far as the available sources of ultraviolet light permit.

Materials Used

All solutions were made up in water having a specific conductivity of 1 to 2×10^{-6} mhos. The potassium chloride employed was recrystallized three times from conductivity water and fused in a platinum dish. The gold wire and arcing apparatus were the same as described by Beans and Eastlack[8] with the addition of an electric stirrer. C. P. nitric and hydrochloric acids were used in the preparation of the chloroauric acid.

Redistilled ether was used to prepare the solutions of phosphorus.

Forty per cent. formalin was analyzed by the method of Blank and Finkenbeiner[9] and diluted to the desired concentration with conductivity water. Thirty per cent. hydrogen peroxide (superoxol, acetanilide free) was analyzed by means of a solution of potassium permanganate, standardized against Bureau of Standards sodium oxalate. A 50% solution of hydrazine hydrate was analyzed[10] with the same permanganate solution and both reagents were diluted to the desired concentration as needed. Fused C. P. potassium carbonate was made up to tenth normal concentration. Silver nitrate solution was checked gravimetrically and by the volumetric method of Mohr. The potassium carbonate solution was standardized against a solution of hydrochloric acid which had been accurately checked against the silver nitrate solution. Pure gallotannic acid was made up to 0.1% solutions as required. Eastman hydroquinone and pyrogallol and Eimer and Amend resublimed catechol and resorcinol were employed without further purification.

Preparation of the Gold Sols

Bredig Gold Sols.—One liter of 0.0001 M potassium chloride was arced for twenty-six minutes at 3.8 amps. The solution was surrounded by an ice-bath and the arcing interrupted occasionally to prevent an undue rise in temperature. The resulting sol was centrifuged for one hour with a force equal to 1200 times gravity and then siphoned into a well steamed nonsol bottle. A few sols that had been prepared for other purposes, in hydrochloric acid, potassium iodide and potassium bromide, were also studied.

Reduction Methods.—The technique employed in making these sols was uniform with one or two exceptions. It consisted in diluting chloroauric acid, prepared from pure gold wire, to a concentration equivalent to 0.05 g. of gold per liter. A liter of this solution was carefully neutralized with 0.1 N potassium carbonate using litmus as an indicator. The reduction was carried out at 85° in a well steamed Pyrex beaker heated by an electric hot-plate. The solution was stirred rapidly by an electric stirrer and the reducing agent added at a uniform rate from a microburet. Sols were prepared with the following reducing agents: phosphorus, formaldehyde, tannin, acetylene, hydrogen peroxide, hydrazine, pyrogallol, quinol, resorcinol and catechol.

The number of reducing agents that have been used for preparing gold sols is legion. No attempt was made to exhaust all the possibilities, but rather to make a sufficient variety of sols so that the conclusions drawn from their photochemical behavior would not be restricted to a special type of dispersion.

Behavior of the Dispersions toward Radiation

The gold sols, prepared as described above, were exposed to the direct radiation of a quartz mercury vapor lamp. For moderate irradiation, a 110-volt Copper-Hewitt quartz lamp was employed; while more intense light and the far ultraviolet were secured with the aid of a 220-volt Hanovia quartz lamp. Exposures were made in fused quartz flasks of about 250cc. capacity. These were thoroughly cleansed before use with aqua regia and well steamed. They were stoppered with clean new corks, care being taken that the solutions did not come in contact with the corks at any time during the experiment. The flasks were placed ten to twenty centimeters from the lamp and kept cool by a blast of air from an electric fan. This was the arrangement used for a qualitative survey of the properties of the various sols. More elaborate precautions were taken in the quantitative study of the light effects to be described later.

The preliminary experiments, made with the 220-volt lamp, showed that sols made with hydrogen peroxide, tannin, quinol, catechol, resorcinol and pyrogallol turned blue during the first two days' irradiation and then became clear red at the end of eight days' total exposure to the light. The hydrazine, phosphorus, formaldehyde, acetylene and Bredig gold sols were not affected by fourteen days' exposure to the quartz mercury arc.

These results, while only qualitative, bring out some very interesting facts, the most important being the behavior of those sols which did undergo a change in the light. They turned blue and resembled a sol to which an excess of electrolyte has been added. To use Nordenson's words, "The light has a slow coagulating effect which is very similar to that of a weak electrolyte." Unfortunately he did not observe that continued irradiation will peptize the unstable sol and produce a sol identical in appearance and behavior with the original. Since the color change evoked by electrolytes and by short exposures to light is the same, the inference, that light will completely precipitate sols, is not unnatural. However, the examination of more than a hundred gold sols prepared in a dozen different ways during the course of this investigation has shown that any colloidal dispersion of gold having associated with it the necessary stabilizing ions or possessing in general the attributes of a stable sol, though temporarily unstable for any reason, can be peptized to a stable red sol by prolonged exposure to the ultraviolet radiation from the mercury arc.[11]

In other words, any sol made blue by exposure to ultraviolet light can be restored to the original red color by prolonged exposure. Any

---

[11] By stability is meant the absence of coarse particles, as indicated by strong reflection of light by the sol, or by their ready removal by the natural or augmented gravitational field. To give our criterion of stability quantitative form we may adopt the one first used by D. J. Beaver (Beaver, *Diss.*, Columbia University, 1921) which is to centrifuge the sol for one hour with a force equivalent to 1200 times gravity.

sol which is blue and unstable at the time of formation, due, let us say, to too rapid reduction, but similar in all other respects to a stable sol, can be changed to a red sol by prolonged exposure.

The effect is not due to heating of the dispersion, because in all cases the sols were kept at room temperature or lower. The peptization is not a spontaneous reaction, for it was found that dispersions that had been made blue by exposure to the light did not regain their red color for months when stored in glass bottles in the sunlight, but required about two hundred hours' exposure to the ultraviolet light to effect peptization.

After peptization is effected the light seems to have no further effect. Reasons for this will be given later.

From the qualitative data given above, one cannot draw any definite conclusions as to the reasons for photochemical sensitivity or photochemical indifference. Why, for instance, should a sol prepared with hydrogen peroxide be sensitive to light, and one prepared with formaldehyde be insensitive? It will be seen later that with the exception of the Bredig sols the conditions under which the sol is formed determine its behavior toward ultraviolet light.

The function of radiation in the formation of gold sols was not investigated in detail here because Nordenson has shown the change in color caused by different periods of exposure. An attempt was made, however, to repeat some of his experiments. The rate of formation of hydrogen peroxide sols as a function of time of exposure to ultraviolet light was followed and agreed in general with his results although the results could not be checked with the precision implied by his data. His reaction mixtures, however, were made by adding a "few drops" of hydrogen peroxide to chloro-auric acid solutions. It soon became evident that the problem had not been sufficiently investigated from the chemical standpoint and, until the effect of amount of hydrogen peroxide and other factors were known, little importance could be attached to these values.

Some of these factors were investigated for the hydrogen peroxide sols and are described later.

Behavior of Photosensitive Sols

Among those sols which had exhibited sensitivity to light in the preliminary experiments, the sols prepared by the tannin method were investigated more closely. In attempting to reproduce one of these sols, which had proved very suitable for the purpose, a sol was produced, identical in appearance, but absolutely indifferent toward radiation. It was found that slight variations in the hydrogen-ion concentration of the chloro-auric acid accounted for the differences in these tannin sols.

Electrometric titrations of the chloro-auric acid with 0.1 *N* potassium carbonate were therefore made at room temperature (22–25°). A curve was then plotted of cc. of potassium carbonate against PH of the solution for the given gold content, and from this curve solutions of definite PH were made, heated to 65° and reduced with tannin. Stirring and rate of addition of the reducing agent were uniform. The temperature was maintained to within ± 1° throughout the reduction and the time required for the appearance of the first trace of color was noted. The time values were not as reproducible as might be desired but, since so many factors are involved in the rate of reduction, this is to be expected unless unusually great precautions are taken. The values are, however, accurate enough to indicate the significance of time of reduction and its apparent relationship to the hydrogen-ion concentration and the color and stability of the dispersion.

Table I gives the results of these experiments.

TABLE I

RESULTS OF EXPERIMENTS

No.	G. of Au/liter	PH	Temp., °C.	Time of red., seconds ± 10%	Color
1	0.025	3.16	65	312	Grayish suspension
2	.025	3.43	65	217	Bluish suspension
3	.025	3.76	65	17	Purple suspension
4	.025	4.16	65	16.5	Violet sol
5	.025	4.53	65	9.3	Red sol
6	.025	4.72	65	5	Red sol
7	.025	7.66	65	14	Red sol
8	.025	8.95	65	17	Red sol, trace of blue
9	.025	9.36	65	30	Bluish-red sol
10	.025	9.63	65	58	Violet sol

It will be seen from Table I that both the color and time of reduction depend upon the hydrogen-ion concentration of the solution. The more stable red sols are formed near the neutral point and are those which are most rapidly reduced. There is a greater toleration of alkali than of acid, as it requires very high concentrations of alkali to yield a suspension. All of the unstable dispersions with the exception of the coarse suspensions (Nos. 1–3) were peptized to stable red sols by prolonged exposure to the mercury vapor lamp. The red sols (Nos. 5–8) exhibited varying sensitivity toward the light, the minimum being found, by interpolation, to be in the vicinity of PH 7.0. This supports Ostwald's statement that the most stable sols by the tannin method are those in which the chloro-auric acid is made neutral to litmus. The rather wide range (*P*H 4.53–8.95) for the clear red sols was found to be restricted to tannin, and not typical of sols prepared by other methods, and is possibly due to a protective effect of the tannin.

The influence of alkali upon the stability of gold sols prepared by the reduction method is mentioned in the literature, the statement being made that gold sols are more stable in alkaline solutions than in neutral or acid solutions.[12] Pihlblad,[13] who studied the effect of size of particle on the light absorption of disperse systems, measured the shift of the absorption band in gold sols, due to the addition of alkali to the reaction mixture. He showed a drift toward the violet, that is, the tendency to form red sols upon the addition of alkali, but did not extend his measurements far enough to show that the color passes through a clear red and then becomes blue again.

It was decided to investigate this matter more accurately, choosing the hydrogen peroxide sols as they seemed to offer less complexity than the tannin sols. The color of each dispersion was determined spectrophotometrically. For this purpose a Brace spectrometer with a variable rotating sector which could be varied while running was employed. The spectrometer table was calibrated with the following spectral lines: Li, 6708 Å.; Na, 5896, 5890 Å.; Hg(arc) 5791, 5770, 5461, 4358, 4046 Å. A large calibration chart was made from these values from which values of the wave length could be read.

The sols were made under carefully controlled conditions and were all reduced at 85°. The percentage transmission was determined for the following wave lengths: 4331, 4847, 5102, 5263, 5461, 5925 and 6549 Å. Each transmission value given is the average of several determinations. In the extreme red and violet ends of the spectrum it was necessary to take the average of three or four matchings, since the visibility maximum lies in the green and comparison in the red and violet is very difficult and fatiguing to the eye.

Table II gives the absorption data for sols reduced at different hydrogen-ion concentrations with hydrogen peroxide. Fig. 1 shows percentage transmission plotted against wave length. The last column of Table II gives the wave length corresponding to the head of the absorption band and is obtained graphically from the absorption curves.

TABLE II

ABSORPTION DATA

Sol no.	PH	Per cent. transmission for wave length of							Head of abs. band, Å.
		4331	4847	5102	5263	5461	5925	6549	
6	4.35	70.5	53.8	55.4	53.0	51.0	55.2	59.6	5510
7	6.10	49.6	39.5	35.8	33.5	34.7	52.4	77.8	5315
9	7.45	40.6	33.6	29.3	30.2	38.5	66.0	90.0	5140
25	9.40	37.4	31.2	25.9	25.6	32.1	63.4	88.1	5180
39	10.00	41.0	38.0	37.5	34.9	35.3	61.1	84.3	5345
Colorstandard		27.3	8.3	5.9	10.0	24.3	78.7	87.5	5040

The Color Standard, the absorption spectrum of which is also included in Table II, is a convenient quantitative color reference and may be used

[13] Pihlblad, *Inaug. Diss.*, Univ. of Upsala, 1918.

qualitatively in judging the color of a dispersion. The standard is used by clinicians[14] and consists of 5 cc. of 20% by weight of cobaltous nitrate, $Co(NO_3)_2.6H_2O$, plus **0.30** cc. of **0.25%** of potassium dichromate solution plus 10 cc. of water.

Fig. 1 shows the progressive drift of the absorption band toward the violet end of the spectrum and then back toward the red end. Fig. **3B** shows the wave length corresponding to the maximum absorption plotted against the PH of the solution before reduction, and affords some information about the amount of colloid formed as well as its color.

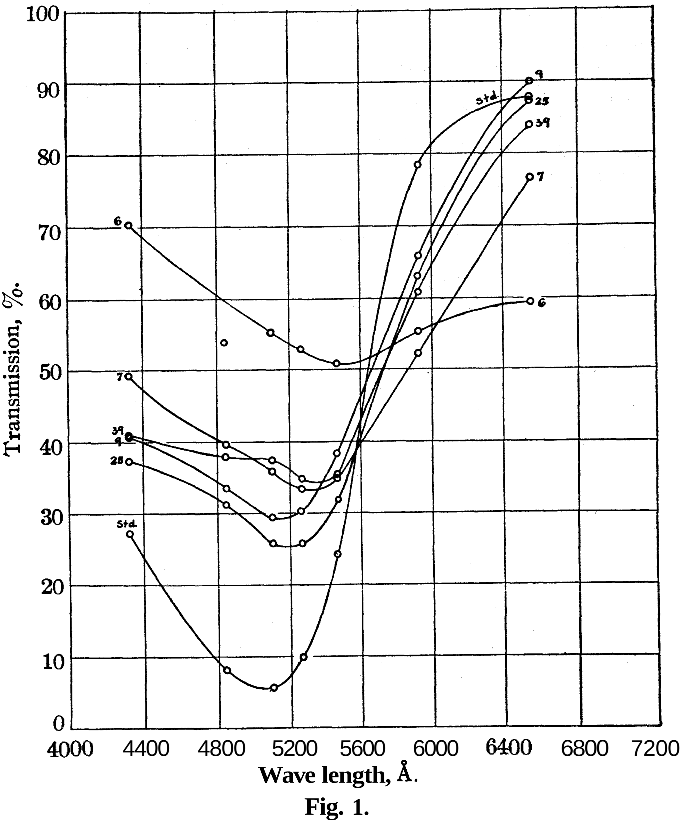

Fig. 1.

It can be seen that the transmissions at the head of the absorption bands of the bluish sols No. 6 and No. **39** are quite high, indicating little absorption of the light, while for the red sols No. 9 and No. *25* the transmissions of light at the heads of the bands are small, indicating great absorption. That this is really due to a difference in concentration of

the dispersed phase was shown by mapping the absorption of a very concentrated Bredig sol and then mapping the absorption of the same

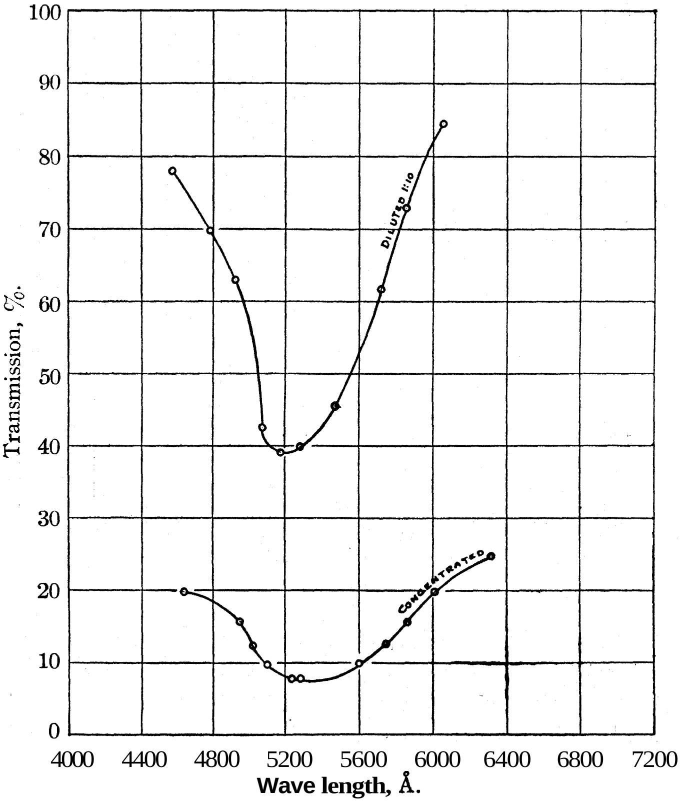

Fig. 2.

sol diluted 1:10. The maxima occur at the same wave length, but the transmissions at this wave length are 8.0 and 39.2%, respectively. The difference in shape of the curves is of little importance here, since that is influenced by reflection as well as by absorption; it is the percentage transmission at the maximum of absorption that we are concerned with. Table III and Fig. 2 illustrate this point.

Returning to the hydrogen peroxide sols, it will be seen that these experiments showed that both the color and the concentration of disperse phase are influenced by the hydrogen-ion concentration of the gold solution being reduced. This relationship is not as simple and general, however, as the above data might lead one to believe. While holding in general for the tannin sols, and quantitatively for the hydrogen peroxide sols, a similar study of dispersions made with phosphorus and hydrazine hydrate showed *a* continuous, but quite different, variation of color with hydrogen-ion concentration. Table IV gives the absorption determinations for sols prepared by the phosphorus method, and Table V the values for sols prepared by reduction with hydrazine hydrate. All reductions were carried out at 85°. The curves for these series are not plotted, as they are similar to the ones for hydrogen peroxide, but the dissimilarity is brought out by the plot of P_H against the wave length corresponding to the maximum of absorption, and is shown in Fig. **3A,** along with the one for hydrogen peroxide.

TABLE IV

PHOSPHORUS SOLS

Sol no.	P_H	Per cent. transmission for wave length of							Head of abs. band, Å.
		4331	**4847**	**5102**	**5263**	**5461**	**5925**	**6549**	
30	3.42	35.9	32.2	24.4	25.1	31.3	62.9	85.9	5110
33	4.35	44.2	33.1	24.5	23.8	26.7	59.5	84.5	5210
8	6.10	45.4	34.3	28.5	26.2	29.5	45.6	67.3	5245
3	7.45	37.2	34.5	29.5	27.1	30.0	48.1	68.4	5260
37	7.97	36.2	33.0	25.9	21.9	27.3	40.9	63.8	5270
Color standard		27.3	8.3	5.9	10.0	24.3	78.7	87.5	5040

TABLE V

HYDRAZINE HYDRATE SOLS

Sol no.	P_H	Per cent. transmission for wave length of							Head of abs. band, Å.
		4331	**4847**	**5102**	**6263**	**5461**	**5925**	**6549**	
20	3.42	41.1	43.9	41.6	35.4	37.7	38.9	44.0	5300
23	4.35	32.0	38.0	37.1	33.8	33.5	40.5	53.2	5380
26	6.10	34.0	37.1	28.8	24.1	22.3	35.1	63.7	5450
29	7.97	36.3	38.3	29.0	23.0	21.7	28.8	56.3	5440
32	9.40	34.0	38.0	27.1	23.4	22.0	40.3	66.5	5410
Color standard		27.3	8.3	5.9	10.0	24.3	78.7	87.5	5040

An examination of these curves (Fig. 3) shows immediately that the phosphorus and hydrazine hydrate sols are quite different from the hydrogen peroxide sols. In the case of phosphorus sols, the optimum conditions seem to be approached in acid solutions, below P_H 4.0, and above this value are relatively uninfluenced by the hydrogen-ion concentration. The same seems to be true of the hydrazine sols, though the optimum is approached at both ends of the *P*H range. It is obvious in both cases that other factors are concerned. Chief among these is the temperature.

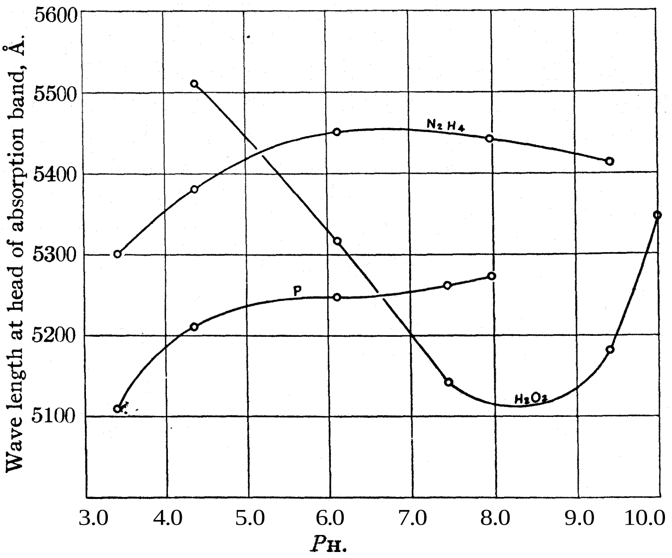

Fig. 3A.

Hydrazine sols are usually blue. At the particular temperature chosen, 85°, and over the PH range studied, they were red, with a tinge of violet. In the case of phosphorus, better sols are usually obtained by reduction

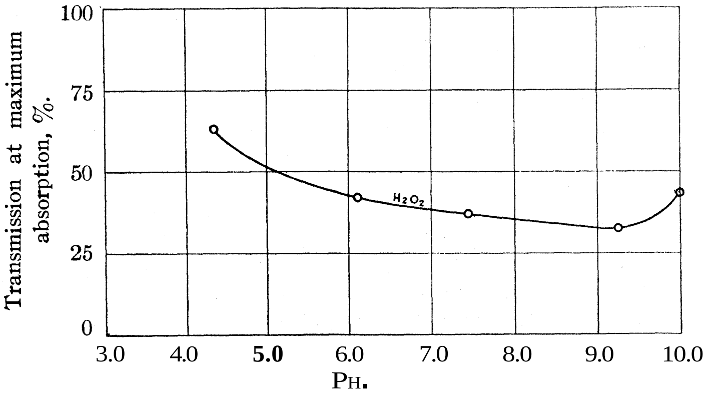

Fig. 3B.

in the cold, with subsequent heating to expel the ether. These curves show, then, that the given conditions are specific for the hydrogen peroxide sols. To establish all the criteria for stable sols of all types requires a detailed study of all the factors concerned with each specific case, and is beyond the scope of the present investigation.

Photochemically all these dispersions behaved as described above. All dispersions with a bluish or violet tinge could be peptized permanently to red sols. The sensitivity toward radiation was progressively less as neutrality was approached, and was a minimum at slight alkalinity (PH 7.5–9.0) for the peroxide sols. In this range (PH 7.5–9.0) the sensitivity, though very slight, varied, so that a number of the sols identical in appearance exhibited different behavior toward the light. All of the peroxide sols in this range would be designated as stable sols by the usual criteria of stability, so that it is evident that nothing can be predicted about the photochemical properties of a red sol from its appearance. It is only by a knowledge of the mode of preparation, such as the curve in Fig. 3 affords, that the possibility of photochemical reaction can be estimated.

The hydrogen peroxide sols were chosen for a detailed study of the photochemical properties since the general conditions for stability had been worked out and the dependence upon these conditions demonstrated. To employ red, stable sols for this purpose restricted the choice to the narrow range of hydrogen-ion concentration just mentioned, which is the range in which the light sensitivity is very small. However, it was imperative to use red sols in order to observe the various stages of the light change. The peptization of a blue sol represents only half of the phenomenon.

It soon became apparent that the most pronounced change in a sol upon illumination is the change in color. This change was followed by Nordenson in his experiments, but unfortunately it tells us little about the mechanism of the process. It is necessary to supplement such measurements with other tests in order to get an idea of the transformations taking place in the sol. With these sols the refractive index, conductivity and absorption were measured and in addition conductivity titrations were made. With the intensities of ultraviolet light at present available, these effects are very small and the utmost precision was necessary to measure them.

The reason for the small effects found was made evident by spectrograms taken in the ultraviolet with the quartz spectrograph. A fresh red sol showed complete absorption of wave lengths below 2150 Å. The same sol made blue by radiation absorbed everything below 2070 Å. and upon further exposure and peptization of this sol it absorbed all radiation below 2010 Å. If, therefore, the radiation between 2150 and 2010 Å. is responsible for the change from red to blue, it is evident that the peptized sol can undergo no further change, because it no longer absorbs the necessary wave lengths. From spectrograms taken for every sol investigated, it was found that the photosensitive sols absorbed the radiation below

2150 Å. This spectral region represents but a small fraction of the total radiant energy of the quartz mercury vapor lamp, and decreases very rapidly with the aging of the lamp. It is only with a new lamp that the far ultraviolet is available in appreciable intensity. It is for this reason that the observed effects required more than a week's exposure.

Refractive indices were determined with a Zeiss immersion refractometer, the cell containing the sol being immersed in a thermostat regulated at 25 ± 0.001°. The changes were at no time greater than five times the experimental error. A representative run was made with a somewhat more sensitive tannin sol to show the magnitude of the effect. The refractive index changed from 1.332658 in a red-violet colored sol to 1.332674 in a blue sol and then to 1.332631 in a clear red sol, which shows that there is a slight but definite increase of the refractive index as the sol becomes blue which decreases again as the sol is peptized by the radiation. Each reading of the refractive index represents the average of ten settings, and is subject to an error of eight parts in the sixth place. The hydrogen peroxide sols require about 180 hours for the same changes but the magnitude is even less. Wintgen[15] showed that in a colloidal dispersion the refractive index is a linear function of the concentration of the electrolyte and that no variation of the refractive index with degree of dispersion could be determined. Wiegner,[16] also pointed out that the linear relationship holds and could only be disturbed if varying degrees of dispersed phase affected the adsorption of ions present. In the above experiments the amount of dispersed phase is constant, so that the observed variations in refractive index would, according to these investigators, be ascribed to the substances adsorbed or otherwise associated with the colloid particle. The conductivity of the same sol under identical conditions changes in a similar manner to the extent of about 0.3%.

For an explanation of the effect of the radiation upon the sols it is necessary first of all to set forth our conception of the structure of a normal gold sol and then consider by what means radiation could modify this structure and produce the phenomena observed. Beans and Eastlack[8] have shown that anions capable of forming stable compounds with gold, in concentrations between 0.005 and 0.00005 M, are necessary for the stability of Bredig gold sols. Such ions are present in the chemically prepared sols and the two cases are probably quite similar; indeed, prolonged dialysis of any gold sol will eventually lead to precipitation.

Wilson[17] has extended the complex theory by applying the Donnan membrane equilibrium theory to it. According to him, the gold particle, combined in some manner, such as residual valence, with the stabilizing

---

[15] Wintgen, *Kolloidchem. Beihefte*, 7, 266 (1915).

[16] Wiegner, *Kolloid-Z.*, **20**, 7 (1917).

[17] Wilson, THIS JOURNAL, **38**, 1982 (1916).

anion, is surrounded with a liquid layer containing cations balancing the negative charges on the particle. The distribution of ions is different in this layer than in the bulk of the solution. Consequently the Donnan membrane equilibrium theory can be applied. Though the ion concentration product is equal in the surface layer and the bulk of the solution, the concentration of anion and cation is different in the surface layer, with the surface layer having a greater total concentration than the surrounding solution. This unequal distribution of ions will give rise to a difference of potential between the enveloping film and the surrounding solution. If the concentration of ions is increased in the bulk of the solution, this difference of potential decreases and with it the stability of the dispersion.

Since no other ions enter tht solution in these experiments, it can be assumed that the radiation itself disturbs the equilibrium, causing ions to move into the bulk of the solution, thus lowering the difference of potential and consequently the stability. The solution should now be blue and have a slightly greater conductivity and refractive index, due to the presence of more ions in the bulk of the solution. But, as we have seen, the change to a blue color is accompanied by a decrease of the absorption in the ultraviolet so that the destructive effect of the radiation cannot continue without limit. A return to true equilibrium conditions then takes place with a decrease in the refractive index and conductivity and a return to the red color. The latter postulate of course implies that there are two frequencies that are effective; one which turns the sol blue and the other which turns it red. At present there is no satisfactory method of isolating narrow spectral regions of sufficient intensity to prove this point although, as in many other photochemical reactions, this is a possible explanation.

To test this hypothesis as unequivocally as possible, the largest quartz flask available was filled with a freshly prepared peroxide sol and the following properties of the sol were determined: absorption curve, conductance, refractive index. The chloride-ion concentration was also measured by means of a conductance titration with silver nitrate. All measurements were made on portions of the same sol in order to have them strictly comparable. With the particular sol employed the blue color was attained after eighteen hours' exposure and the final peptization to red again after 183 hours. Table VI gives the values of the conductivity and refractive index. Table VII gives the data for the absorption spectra, and Table VIII the data for the conductance titrations, the plots of which are shown in Fig. 4.

The values given here are to show the relationship of the values to each other for one and the same sol. Individual determinations of each property were made in number upon various sols with similar results.

TABLE VI

VALUE OF CONDUCTIVITY AND REFRACTIVE INDEX

Peroxide sol, 0.025 g. of Au/liter. $P_H = 7.45$. Reduced at 85°.

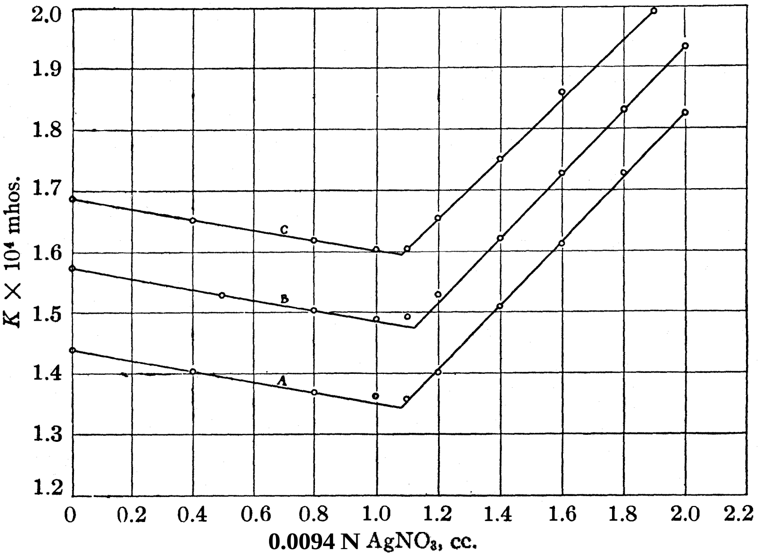
No.	Exposure, hours	Conductivity $\times 10^4$ mhos.	Refractive index, n_D	Color
2	0	1.458	1.332623	Red
2	18	1.462	1.332650	Blue
2	183	1.458	1.332623	Red

TABLE VII

ABSORPTION SPECTRA DATA

No.	Exposure. hours	Per cent. transmission for wave length of							Head of abs. band, Å.
		4331	4847	5102	5263	5461	5925	6549	
2	0	38.3	33.0	25.5	25.9	32.0	65.3	89.3	5175
2	18	49.0	43.0	35.5	31.5	33.9	52.0	69.4	5290
2	183	32.6	28.3	20.9	20.1	24.4	49.4	82.0	5210

Table VII brings out several important points. First, it will be seen that the absorption is at a maximum at 5175 Å., whereas in Table III the absorption for a sol of this P_H (7.45) is given as 5140. The difference of 35 Å., which is not a visible difference, represents the limit of reproducibility of the sols.



For curve B subtract 0.1 from value of K; for curve C, subtract 0.2.

Fig. 4.

It will also be seen that the absorption for the peptized sol (at 5210 Å.) did not quite return to the original value of 5175 Å. at the end of 183 hours, although the conductivity and refractive index had returned to the original values by that time. This emphasizes again the fact that the absorption spectrum of the dispersion is one of the most sensitive indicators of the changes taking place.

TABLE VIII

CONDUCTIVITY TITRATIONS

Sol No. 2. Titrated with 0.0094 N $AgNO_3$. Cell const. = 0.3820.

(A) Original sol		(B) After 18 hours' exposure		(C) After 183 hours' exposure	
$AgNO_3$, cc.	$K \times 10^4$ mhos.	$AgNO_3$, cc.	$K \times 10^4$ mhos.	$AgNO_3$, cc.	$K \times 10^4$ mhos.
0.00	1.439	0.00	1.474	0.00	1.487
.40	1.404	.50	1.430	.40	1.451
.80	1.370	.80	1.404	.80	1.419
1.00	1.363	1.00	1.390	1.00	1.404
1.10	1.358	1.10	1.393	1.10	1.405
1.20	1.402	1.20	1.430	1.20	1.455
1.40	1.510	1.40	1.522	1.40	1.552
1.60	1.613	1.60	1.628	1.60	1.662
1.80	1.729	1.80	1.733	1.90	1.794
2.00	1.828	2.00	1.836		

Neutral point = 1.080cc. Neutral point = 1.120 ± 0.002cc. Neutral point = 1.080cc.

These conductivity titrations indicate an increased concentration of chloride ion in the bulk of the solution in the blue sol, and a return to the original concentration in the peptized red sol. It will be observed that the initial conductivities in Table VIII do not check with those in Table VI, but are slightly higher. The samples for measurement were taken from the same solution. This discrepancy was observed on several occasions and is due to the absorption of carbon dioxide from the air. The error here is not serious for a test of the foregoing hypothesis, since it is the chloride ion with which we are concerned and its determination by the conductance titration with silver nitrate would not be influenced by the presence of dissolved carbon dioxide, due to the relatively higher solubility of silver carbonate.

The hypothesis outlined above required that the ionic concentration in the bulk of the solution should increase as the sol turns blue. The shift in color was shown and the increase in conductance as well as the greater value for the conductance titration were also demonstrated. Prolonged exposure reduced these values again and the absorption spectra showed the return to the original color.

Though the original and final red state seem to be identical, it is evident from the photochemical indifference of the latter that they are not the same. Spectrograms in the far ultraviolet bear this out, as the peptized sol no longer absorbs the effective radiation. It is possible that when peptization is effected, the ions are more firmly associated with the complex, which would account for the greater stability toward light as well as the lack of absorption bands in the effective region of the spectrum.

In addition to the above chemical sols, quantitative measurements were made on Bredig sols prepared according to the method of Beans and Eastlack.[8] Since these sols were uniformly stable to light, an attempt was made to see if their rate of precipitation by dilute solutions of electrolytes is affected by radiation.

Spear, Jones, Neave and Shlager[18] showed that the precipitation of colloidal platinum containing electrolytes is greatly accelerated by the action of ultraviolet light.

Gold sols prepared by the above method were exposed to the radiation from a quartz mercury lamp for various lengths of time and with different amounts of electrolyte (0.001 M $Th(NO_3)_4$), and the conductivity change measured very accurately. At the same time similar determinations were made on sols kept in the dark. In twenty-seven series of measurements the conductivity, which is a measure of the amount of sol precipitated, decreased at the same rate in the "illuminated" and in the "dark" sols. A plot of time divided by specific conductivity against time yielded straight lines the slopes of which depended on the amount of the electrolyte added but were independent of the kind of illumination or lack of it.

Using a photometric comparison method it was also shown that the rate of precipitation of the above Bredig gold sols was the same in the light and in the dark.

Nowhere is there a greater need for a powerful source of ultraviolet light, especially monochromatic light, than in the study of such effects as we are dealing with here. In view of the peptizing ability of the radiation as herein described, it should be possible, once such a source is available, to peptize sols during their formation or immediately after, and obtain dispersions with quite different properties.

Summary

1. The photochemical properties of gold sols depend upon the nature and method of preparation of the sols.

2. Of the sols studied, those which are sensitive to ultraviolet light are made blue and unstable by exposure, but by prolonged irradiation are peptized to stable red sols.

3. With other factors kept constant, the color, rate of formation and photochemical properties of chemically prepared gold sols were found to vary continuously with the hydrogen-ion concentration of the reduction mixture.

4. By assuming Wilson's theory of the structure of the colloidal gold particle and, further, that light can disturb the equilibria involved, it has been shown that the ion concentrations change in accordance with the requirements of the hypothesis.

[18] Spear, Jones, Neave and Shlager, THIS JOURNAL, 43, 1385 (1921).

5. The necessity for a more powerful light source for this type of investigation is emphasized.

6. The rate of precipitation of Bredig sols is not influenced by radiation.

THE PYROPHOSPHATE METHOD FOR THE DETERMINATION OF MAGNESIUM AND PHOSPHORIC ANHYDRIDE[1]

BY ALICE WHITSON EPPERSON

RECEIVED SEPTEMBER 2, 1927 PUBLISHED FEBRUARY 4, 1928

Probably no determination in analytical chemistry has been the subject of a greater number of conflicting statements than that involving the precipitation of magnesium ammonium phosphate. It is the purpose of this paper to give the results of extensive tests of such statements, and to urge the establishment of a standard procedure which defines, so far as they are known, the most favorable conditions for obtaining a normal precipitate of $MgNH_4PO_4$, and the subsequent ignition of that precipitate to pyrophosphate, $Mg_2P_2O_7$.

In investigating the conditions most favorable for the precipitation of magnesium ammonium phosphate, methods recommended for the determination of magnesium and of phosphoric anhydride were studied. Various procedures suggested in publications on the subject since 1873 were tested, and the effects of those impurities most likely to occur in the regular course of analysis were determined. In most cases short (four hours) single precipitations were made to determine the maximum effect of any variation, and overnight (sixteen hours) single precipitations were made to determine whether standing would cause the precipitate to regain normal composition. Reprecipitation under the conditions to be recommended was tried in many cases.

Since the final treatment of the magnesium ammonium phosphate should be the same whether the precipitate is obtained in the determination of magnesium or of phosphoric anhydride, some commonly recommended methods for obtaining pure pyrophosphate were first investigated and the following observations were made. (1) Solution of the magnesium ammonium phosphate in nitric acid, followed by evaporation to dryness and igniton, has no apparent effect on the final pyrophosphate. (2) Moistening the ignited pyrophosphate with one or two drops of nitric acid, followed by re-ignition, has no effect, either good or harmful. (3) Solution of the ignited pyrophosphate in nitric acid and evaporation of the solution was found to be literally impossible, confirming the experience of Lundell and

Hoffman.[2] Because of decrepitation and apparent breaking down of the compound accurate results cannot be obtained.[3] None of these expedients for obtaining a white residue is desirable or necessary if care is taken in the charring of the paper and ignition of the precipitate.

Tests were also carried out to determine the concentration of ammonia solution most desirable for use as wash water for the magnesium ammonium phosphate precipitate, that having been a matter of much dispute. Many authors have recommended solutions containing one-third ammonia water by volume. Such solutions are most inconvenient to use and were found to be unnecessary and undesirable. As shown in Table I, it was found that water containing from 2.5 to 10% of ammonia water (sp. gr. 0.90) by volume could be used for washing the precipitate with equally correct results, while no advantage was found in adding ammonium nitrate to the wash water.

correct results are largely dependent on the details of the operation, the procedure given has been followed as exactly as possible in all comparative tests, except for the variations stated.

Discussion of Procedures for the Determination of Magnesium

In the determination of magnesium, microcosmic salt ($NaNH_4HPO_4$) has been most often used as the precipitant. Since it has been stated that the presence of sodium in the reagent leads to precipitates of abnormal composition and high results, various reagents were tested. It was found that slightly higher results were obtained by the use of disodium phosphate or microcosmic salt as precipitants than by the use of diammonium phosphate, $(NH_4)_2HPO_4$. This is true only of single precipitations, however, because two precipitations give practically correct results in all cases, as shown in Table II. Apparently, any abnormality or occlusion in the precipitate is remedied by reprecipitation in the presence of a slight excess of the reagent.

[a] Largest residue in each series filtered after standing 24 hours, ignited and weighed.

In tests of procedures for the determination of magnesium, solutions of magnesium chloride made from Kahlbaum's c. p. salt were used. The solutions were slightly acidified with hydrochloric acid to prevent action of the alkaline solution on glass, and were kept in glass-stoppered bottles made of Jena glass. The solutions were first analyzed for magnesium content by a number of determinations as pyrophosphate. However, since this method was itself being tested, it seemed desirable to standardize the solutions by a different method. Accordingly, varying amounts of the solution, measured from a buret, were treated with precipitated mercuric oxide in water suspension. The solution was carefully dried and ignited and the process repeated until all of the magnesium chloride present was converted into oxide. It was then weighed as such. It is believed that a very accurate measure of the real magnesium content of the solution was thus obtained.[4] For the sake of convenient comparison, the weight of magnesium pyrophosphate calculated from the amount of magnesium oxide or phosphoric anhydride in the sample of solution taken is given in all tables.

Standard Procedure for the Determination of Magnesium

To the neutral or weakly acid solution of magnesium chloride, containing not more than 0.1 g. of MgO, add 5 cc. of concentrated hydrochloric acid, and methyl red indicator. Dilute the solution to 150 cc. and add 10 cc. or a 5- to 10-fold excess, of the precipitant, preferably a saturated solution of $(NH_4)_2HPO_4$. Then add ammonia water (sp. gr. 0.90) slowly, while stirring, to neutralization. Stir for about five minutes, or until the precipitate of $MgNH_4PO_4$ is well formed, then add 5 cc. excess of ammonia water and stir for ten minutes. Let stand for at least four hours, preferably overnight, filter and wash with water containing from 3 to 5% by volume of ammonia water (sp. gr. 0.90). Dissolve the precipitate by washing on the filter with warm 1:9 hydrochloric acid (sp. gr. 1.02). Add methyl red indicator and about 1 cc. of $(NH_4)_2HPO_4$ solution and finish the precipitation as before, but in a volume of 100 to 150 cc. In this precipitation digestion for four hours is sufficient. In igniting the final precipitate, the wet filter paper and precipitate should be placed in a weighed platinum crucible, charred without flaming, then ignited at a low temperature (approximately 500°) and with the lid open enough for circulation of air, until the residue is white, and finally at approximately 1000° to constant weight.

Discussion of the Results Obtained in the Determination of Magnesium

A summary of results obtained in the tests of procedures for the determination of magnesium is given in Table III. As shown in Table III-A,

---

[4] Fresenius-Cohn, "Quantitative Chemical Analysis," John Wiley and Sons, Inc., New York. 1904, Vol. 1, p. 276.

a large excess of ammonium chloride was found to produce high results for single precipitations but on reprecipitating under standard conditions the true values were obtained. Absence of ammonium chloride was found not to affect the precipitate materially.

[a] (1) Standard procedure followed throughout except for variation noted.
(2) Reprecipitated under standard conditions.
(3) First precipitation incomplete; second precipitation made from combined precipitates recovered from the filtrate, added to first precipitate.

A large excess of ammonia was found, Table III-B, to have about the same effect as ammonium chloride. Reprecipitation, in this case also, produced a normal precipitate, with correct results. A concentration of ammonia water higher than one-third by volume was found to give high results.

As shown in Table III-C, a very large excess of the precipitant, $(NH_4)_2HPO_4$, was found to give very low results in single precipitations. Apparently, the precipitate is partially soluble in a strong solution of $(NH_4)_2HPO_4$, for further precipitation occurred when the filtrate was diluted and allowed to stand. When the complete precipitate, obtained by repeated dilution, standing and filtration, was dissolved and reprecipitated under proper conditions, the results were very nearly correct. There should be no reason, however, in the ordinary course of analysis, for the addition of such a large excess of the precipitant.

The presence of sodium chloride in the solution was found, Table III-D, to produce high results with single precipitations, but on reprecipitating true values were obtained. Equal amounts of potassium chloride gave higher and less uniform results with single precipitations than the sodium chloride. Reprecipitation under standard conditions improved the result but did not bring it within the usual limits of experimental error.

The addition of the precipitant to an ammoniacal solution has long been practiced, and even recommended. Precipitations in hot ammoniacal solution gave decidedly high results, Table III-E, as did all single precipitations in ammoniacal solutions. Reprecipitation under standard conditions of precipitates from runs made in hot ammoniacal solutions gave results which were consistently lower than the true values. Apparently reprecipitation does not remedy the error. However, there should be no reason, in the ordinary course of analysis, for the addition of the precipitant to an ammoniacal solution, since it is necessary only to acidify the solution. The danger of error in precipitations if the solution is not acid when the reagent is added, is to be emphasized.

Precipitation in a neutral solution by the method of Jarvinen[6] gave average results, Table III-F, which were only slightly high, but separate results of a series were not sufficiently uniform to be within a reasonable limit of experimental error. Since this method requires that there be no excess of ammonium salts, it would necessitate in the usual course of silicate analysis an additional time-consuming operation for evaporation to dryness and driving off ammonium salts. In the case of the presence of sodium or potassium chloride, Table III-D, the method did not lessen the error in single precipitations.

Double precipitations in hot solution, according to the method of Gibbs,[7] gave closely agreeing, true results, Table III-G. It is therefore evident that cooling the solution before precipitation is unnecessary. However, it has been found that the crystalline precipitate is formed in a slightly coarser and more easily filterable condition, with less tendency to adhere to the sides of the beaker, when precipitation is made in a cool solution. Precipitations made in hot solution in the presence of sodium or potassium chloride, Table III-D, did not seem to obviate the necessity of reprecipitating to obtain true results.

---

[6] Jarvinen, Z. anal. Chem., 44, 333 (1905). In this method the solution, free from an excess of ammonium salts, is rendered neutral to lacmoid indicator and a normal solution of $(NH_4)_2HPO_4$ containing 40 cc. of 10% solution of ammonia per liter is added dropwise. When most of the precipitate has separated, a 1% solution of ammonia is added dropwise until the solution smells strongly of ammonia; then a 10% solution of ammonia to one-third the volume of the whole. The solution is filtered after two hours.

[7] Wolcott Gibbs, *Am. J. Sci.,* [3] 5, 114 (1873). Precipitation is effected with microcosmic salt from a concentrated, neutral boiling solution containing NH_4Cl. After cooling, $^1/_3$ of the volume of a 10% ammonia solution is added. No details are given as to excess of precipitant or time of standing, in which cases standard procedure was followed.

Single precipitations in the presence of ammonium oxalate gave slightly high results, Table III-H, but on reprecipitating under standard conditions correct values were obtained.

The presence of ammonium sulfate, arising from the use of sulfuric acid instead of hydrochloric in the course of analysis, showed no effect, Table III-K.

The presence of citric acid in amounts varying from 0.5 to 2.0 g. was found to have no effect on the precipitate, Table III-L.

In precipitating $MgNH_4PO_4$ from phosphate solutions containing an excess of $MgCl_2$, the results of similar variations in procedure are not always comparable to those obtained when precipitating from magnesium solutions containing an excess of phosphate.

Discussion of Procedures for the Determination of Phosphoric Anhydride

In the tests of procedures for the determination of phosphoric anhydride, solutions of diammonium phosphate, made from Kahlbaum's c. P. salt, were used. The solutions were kept in glass-stoppered Jena glass bottles and were slightly acidified with nitric acid to prevent action of the alkaline solution on the glass. The solutions were analyzed for P_2O_5 content by a number of determinations as magnesium pyrophosphate. In these determinations, a standard method, directly comparable with that used in the determination of magnesium, was used.

The only method for the determination of phosphoric anhydride which appeared practicable as a check on the magnesia method was an adaptation of the silver phosphate method. The method as used was developed for this investigation and was based on the possibility of obtaining quantitatively a uniformly normal precipitate of silver phosphate, Ag_3PO_4, the silver in which can then be obtained by the Volhard method. Various authors[8] have confirmed the value of such a method in different forms and it is believed that as given the method will be found accurate for the determination of phosphoric anhydride in solutions containing no interfering substances. The procedure developed is as follows.

To the cool phosphate solution, very slightly acid with nitric acid, and containing not more than 0.1 g. of P_2O_5, add 5 cc. of a saturated solution of sodium acetate. Add an excess of 10% silver nitrate solution until no more precipitate appears. Heat on the steam-bath for about ten minutes, then filter through a Gooch crucible and wash thoroughly with hot water. Dissolve the precipitate by washing through the crucible with dilute nitric acid (1:4, sp. gr. 1.10) and titrate with a standard solution of potassium thiocyanate, by the Volhard method, using ferric ammonium sulfate as

$(NH_4)_2HPO_4$	.00930	.00930
$(NH_4)_2HPO_4$	.00956	.00956

[a] Each result is the average of at least three closely agreeing determinations

Standard Procedure for the Determination of Phosphoric Anhydride

To the neutral or weakly acid solution of phosphate, containing not more than 0.1 g. of P_2O_5, add 5 cc. of concentrated hydrochloric acid, and methyl red indicator. Dilute the solution to 150 cc. and add 10 cc. or a 5- to 10-fold excess, of the precipitant, preferably magnesia mixture without ammonia (50 g. of $MgCl_2.6H_2O$, 100 g. of NH_4Cl and 5 cc. of concentrated HCl in 1 liter of H_2O). The solution should be acid after the addition of the precipitant. Then add ammonia water (sp. gr. 0.90) slowly, while stirring, to neutralization. Stir for about five minutes, or until the precipitate of magnesium ammonium phosphate is well formed, then add 5 cc. excess of ammonia water and stir for ten minutes. Let stand for at least four hours, preferably overnight, filter and wash with water containing from 3 to 5% by volume of ammonia water (sp. gr. 0.90). Dissolve the precipitate by washing on the filter with warm 1:9 hydrochloric acid (sp. gr. 1.02). Add methyl red indicator, 1 cc. of magnesia mixture and finish the precipitation as before but in a volume of 100 to 150 cc. In this precipitation digestion for four hours is sufficient. In igniting the precipitate, the wet filter paper with the precipitate should be placed in a weighed platinum crucible, charred without flaming, then ignited at a low temperature (approximately 500°) and with the lid open enough for circulation of air until the residue is white, and finally at approximately 1000° to constant weight.

Discussion of the Results Obtained in the Determination of Phosphoric Anhydride

As shown by figures given in Table V-A, an excess of ammonium chloride was found to give high results in single precipitations as in the case of magnesium. When the solutions were allowed to stand for sixteen hours the results, however, were better. On reprecipitating under "standard" conditions, the results were correct. Absence of added ammonium chloride did not affect the precipitate materially. It will be noted that in the case of large excess of ammonium chloride (25 g.) results were low, differing from the determination of magnesium. Apparently the same effect is noted later (Table V-C) where it is indicated that the presence of ammonium chloride has a tendency to compensate for high results due to large excess of magnesium chloride.

[a] (1) Standard procedure followed except for variation noted.
(2) Reprecipitated under standard conditions.

Excess ammonium hydroxide was found, Table V-B, to have substantially the same effect as in the determination of magnesium. A concentration higher than $^1/_4$ volume was found to give high results, as in the determination of magnesium, while reprecipitation gave correct results.

A large excess of the precipitant ($MgCl_2.NH_4Cl$) was found, Table V-C, to give high results on single precipitation, correct results being obtained by reprecipitating under standard conditions. Precipitations by the method of Schmitz[9] gave low results, probably owing to the extremely short time allowed before filtering. Tests of Mahon's assertion[10] that excess of ammonium chloride compensates for the error due to excess of magnesia mixture, showed his statements to be incorrect. However, results were very low when no ammonium chloride, or very small amounts, were present, indicating that the presence of this salt has the tendency claimed, but does not wholly remedy the condition.

Precipitations made in ammoniacal solutions were found, Table V-D,

---

[9] Schmitz, Z. anal. Chem., **45, 512 (1906);** *ibid.,* **65, 46 (1924).** A large excess (**150** cc.) of acidified magnesia mixture and **10–20** cc. of a saturated solution of NH_4Cl are added, the solution is heated to boiling and a **2.5%** solution of ammonia added, with constant stirring, until the solution is alkaline to phenolphthalein. The solution is then cooled and one-fifth of its volume of ammonia is added. The solution is filtered after standing for ten minutes.

[10] Mahon, THIS JOURNAL, 20, **445 (1898).** The method is not described in detail. It is stated that when $MgCl_2$ is in large excess the error is reduced by the presence of NH_4Cl, but the ratio necessary for accurate results is not indicated.

to give high results, contrary to statements of Neubauer.[11] Reprecipitation under standard conditions did not remedy the error.

Precipitations in exactly neutral solution, according to the method of Jarvinen,[12] gave results, Table V-E, that were not uniform and averaged slightly higher than the true figure, as was the case in the determination of magnesium.

Precipitations in hot solution gave slightly high results, Table V-P, differing from the determination of magnesium, which was not affected by the temperature of precipitation.

The presence of ammonium sulfate, owing to the use of sulfuric acid instead of hydrochloric, gave high results, Table V-G. In the determination of magnesium it had no effect.

Precipitations in the presence of citric acid, Table V-H, gave low results which were not uniform. This was not entirely remedied by reprecipitation under standard conditions.

Conclusions

The most significant fact brought out by these studies is that a double precipitation, the second under exactly defined conditions, is necessary, to insure the quantitative precipitation of $MgNH_4PO_4$. Consequently this procedure should be followed in all accurate work. It is also demonstrated that in the determination of magnesium the errors due to (1) a very large excess of precipitant, (2) the presence of potassium chloride and (3) the addition of the precipitant to an ammoniacal solution, were not entirely remedied by reprecipitation. These conditions may easily be avoided, however, except that due to excess of potassium chloride. In this case it was found that a third precipitation usually gave a precipitate of the desired composition and a correct result.

In the determination of phosphoric anhydride the only errors not remedied by reprecipitation are those due to (1) addition of the precipitant to the solution while ammoniacal, (2) precipitation in hot solution (slight

---

[11] Neubauer, *Z. anorg. Chem.*, 4, 251 (1893); *Z. angew. Chem.*, 9, 435 (1896). The phosphate is precipitated in 100 cc. of a cold solution containing 2.5% of ammonia by adding dropwise, with constant stirring, as many cc. of magnesia mixture as there are centigrams of P_2O_5 present. The solution is then stirred, allowed to stand for three hours, filtered, the precipitate washed with a 2.5% solution of ammonia and ignited to constant weight. A correction for loss on ignition is added by the author.

[12] Jarvinen, *Z. anal. Chem.*, 43, 279 (1904). The phosphate solution is mixed with NH_4OH until the odor of ammonia is noted. The solution is poured slowly, with constant stirring, into a neutral mixture of $MgCl_2$ and NH_4Cl. Free ammonia should be absorbed by the formation of the precipitate. If the mixture smells of ammonia, trimagnesium phosphate may be formed. After precipitation is complete, a 0.5% solution of ammonia is added until a strong odor of ammonia is detected; finally, one-third of the volume of a 10% solution of ammonia. The mixture is allowed to stand for two hours and filtered.

error only), (3) the presence of ammonium sulfate and (4) the presence of citric acid. The first two can be avoided; while the error caused by sulfate is negligible in any but the most accurate work.

The general impression of great difficulty and inaccuracy that has surrounded the determination of magnesium and phosphoric anhydride as magnesium pyrophosphate, is largely the effect of the mass of conflicting publications on the subject. The standard procedures here recommended have been found to give accurate results with reasonable care and the data presented should answer many questions as to the value of recommendations to be found in the literature on the subject.

THE EQUILIBRIUM PRESSURE OVER COEXISTING SALT HYDRATES AT TEMPERATURES BELOW 0°

BY J. B. AUSTIN

RECEIVED SEPTEMBER 6, 1927 PUBLISHED FEBRUARY 4, 1928

The phase relations for salt hydrates have been worked out fairly completely but there remain one or two minor points which appear not to have been specifically discussed. One of these is the question as to whether the vapor pressure curve of a system composed of two adjacent hydrates and vapor intersects the ice-vapor curve in the low temperature region.

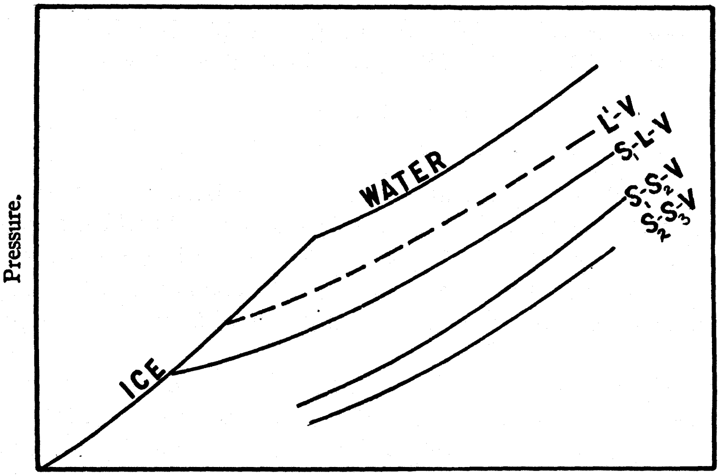
The principle involved will be evident from a consideration of the P-T diagram as given in Fig. I. The hydrates are denoted by S_1, S_2, S_3, etc.; the saturated solution by L, other solutions by L^{I}, L^{II}, etc.; ice by I and the vapor by V. The vapor pressure of all unsaturated solutions of the salt ranges between the water line and the line representing the vapor pressure of the system S_1-L-V; that of the system S_1-S_2-V is another line below the S_1-L-V line. Similarly, if other hydrates exist, there is a corresponding curve, for example, S_2-S_3-V for each pair of adjacent hydrates. Now the line for the unsaturated solution intersects the ice curve at the ordinary freezing temperature of the particular solution, the phases then present being I-L^{I}-V; that for the saturated solution S_1-L-V intersects the ice curve at the eutectic temperature, the four coëxisting phases being S_1-I-L-V. The question now arises as to whether the curve for systems composed of two hydrates and vapor will meet the ice-vapor curve if the temperature is sufficiently low; this point must, according to Blasdale, be considered.[1] Such an intersection would imply

---

[1] Blasdale, "Equilibria in Saturated Salt Solutions," Chemical Catalog Company, New York, 1927, p. 39.

a curious non-variant point at which I-S_1-S_2-V would be in equilibrium; or, in other words, that on cooling the system to a low enough temperature, solid water should split out from the higher hydrate provided the rate of reaction is appreciable. It is the purpose of this paper to consider such data as are available in order to ascertain the course of the vapor pressure curve for this type of system at low temperature.

From general theoretical considerations alone, the reality of such a point seems doubtful. In order that a hydrate may form, the tendency of the H_2O molecules to unite with the salt or salt hydrate molecule must be greater than the tendency to unite with one another. Hence, it seems likely that the escaping tendency of the H_2O molecules from a hydrate will always be less than from ice or, in other words, the vapor pressure curve of the hydrate pair system must always be below the ice-vapor curve.



Temperature.

Fig. 1.—The equilibrium pressure over coexisting salt hydrates below 0 °C.

Furthermore, Norton and Johnston[2] have shown that the equilibrium pressure over two adjacent hydrates may be determined by adding to a solution in equilibrium with both solid hydrates, a third soluble component, and then measuring the vapor pressure at the new transition temperature, which by regulation of the added solute can be made to have a range of values. Under such circumstances the vapor pressure of this system is equal to the equilibrium pressure of the two crystalline hydrates at the particular temperature, provided always that both hydrates are present as solid phases. Hence, if the hydrate curve is to cut the ice curve, the vapor pressure of the system S_1-S_2-L''-V (where L'' is the equilibrium solution containing also the third component) must at some

---

[2] Norton and Johnston, Am. *J. Sci.*, 12, 467 (1926).

temperature be equal to that of the system I-L''-V, a coincidence which would appear to be exceedingly improbable as a general rule.

The experimental data available are in accord with these conclusions. Vapor pressures plotted on a P-T diagram are not satisfactory for this purpose because data at low temperatures are not always available and extrapolation with any certainty is impossible. The plot of log p versus $1/T$ is no better because in some cases the lines are so nearly parallel to the ice-vapor curve that again uncertainty exists. But this log plot may be used in another way. The lines on this plot may be represented by the equation

$$\log p = \frac{Q}{2.3RT} + B$$

where p is the vapor pressure of the system, Q is the heat effect, T is the absolute temperature and B is a constant, so that their slope is proportional to the quantity Q. Now Q is the sum of several factors; for ice these are the heat of fusion of ice and the heat of vaporization per mole of water; for the hydrate, the heat of hydration plus the heat of vaporization per mole of water. The heat of vaporization of water appears in both so that any difference in Q is due to a difference between the heat of fusion of ice and the heat of hydration of the salt (or salt hydrate) per mole of water. It is obvious that if the heat of hydration of the salt per mole of water is greater than the molal heat of fusion of ice, the curves will not intersect and that they will intersect only if the converse holds.

The heats of hydration per mole of water have been calculated from the tables of Landolt-Börnstein[3] for some 200 salt hydrates and of this number only 10 showed a value of less than 1.437 cal., the molal heat of fusion of ice.[4] About 70% of such values were between 2.0 and 4.0, the average for all being **3.6.** These heat effects are not given for the temperatures under discussion but they are in general so much greater than 1.4 that it seems unlikely that their relative values will be altered very much by lowering the temperature.

The ten exceptions are: $KSH.{}^1/_4H_2O$, $K_2SO_3.H_2O$, $K_2S_2O_3.H_2O$, $KC_5H_7O_4.H20$ (pyrotartrate), $KC_4H_5O_5.H_2O$ (malate), $KC_4H_5O_4.H_2O$ (methyl malonate), $K(SbO)C_4H_4O_6.{}^1/_2H_2O$, $NaC_4H_7O_2.3H_2O$ (butyrate), $NaC_5H_9O_2.1{}^1/_2H_2O$ (valerate), $Sr(C_2H_3O_2)_2.{}^1/_2H_2O$.

A critical examination of the original sources shows that these ten values are open to criticism and suspicion. In the case of $KSH.{}^1/_4H_2O$, Sabatier's method[5] of preparation has since been shown to yield a product different from the above. The remaining values are due to Berthelot,[6]

[5] Sabatier, **Ann.** *chim. phys.*, [5] 22, **21 (1881).**

[6] Berthelot, "Thermochemie," Gautier Villars and Sons, Paris, 1897, Vol. II.

Massol[7] and Guntz.[8] The data of Berthelot were taken before he developed his bomb calorimeter and are obtained by difference from other measurements at different temperatures. Furthermore, his calculations are based on O = 8. Massol's work and the paper by Guntz come under these last objections; moreover, in no case are there data from which the degree of purity of the materials used may be estimated. In addition, the paper by Guntz contains a number of obvious typographical errors which tend to lessen confidence in his results.

In view of the striking agreement in all cases except those in which the data seem not to be reliable, it may be safely concluded that the two vapor pressure curves do not intersect and that this non-variant point does not in fact exist. From this it follows that under all conditions the vapor pressure of water above a pair of adjacent hydrates is less than that above ice or water. This means that the heat of hydration of salts per mole of water must always be less than the molal heat of fusion of ice, which furnishes a valuable criterion for the critical examination of experimental data on vapor pressures of salt hydrate pairs and on heats of hydration.

The author wishes to acknowledge his indebtedness to Dr. J. Johnston and Prof. H. W. Foote, whose criticism and advice have been most helpful.

Summary

It is shown that at any temperature the vapor pressure of water over a system composed of two solid hydrates and vapor must always be less than the vapor pressure of ice. This furnishes a criterion of the accuracy of data on the heats of hydration of salts.

OXIDATION OF HYDRAZINE
VIII. MONO-BELECTRONATORS AND DI-DELECTRONATORS[1]

BY R. E. KIRK AND A. W. BROWNE

RECEIVED OCTOBER 7, 1927 PUBLISHED FEBRUARY 4, 1928

Among the objectives of the current series of investigations have been (1) an elucidation of the mechanism involved in the oxidation of hydrazine and (2) a general classification of oxidizing agents,[2] possibly valid also in other reactions.

When the attempt is made to group oxidants together on the basis of their behavior toward hydrazine, it is found that substances of widely divergent oxidation potentials fall into the same category. It has been shown by extended experiments that the peroxide, permanganate and manganic ions, all of high potential, give distinctly different results when brought into contact, under similar conditions, with hydrazine ions in the presence of sulfuric acid. Hydrogen peroxide yields large amounts of both hydronitric acid and ammonia;[1a,1d,1f] potassium permanganate, small amounts of hydronitric acid and large amounts of ammonia;[1d] and manganic acetate no hydronitric acid but large amounts of ammonia.[3] On the other hand, the arsenate ion yields hydronitric acid and ammonia,'' while the cupric ion, of similar potential, gives ammonia but no hydronitric acid.[1e]

On the basis of these facts, hydrogen peroxide and arsenic acid would be grouped together, despite the marked disparity in their oxidizing power. Similarly, manganic and cupric salts would be placed in the same class. These instances are fairly typical of the large number that might be adduced.[4]

[4] Against the possible vague contention that this anomalous collocation of dissimilar oxidants might be attributed to specific catalytic effects may be cited the fact that both positive and negative ions are included in each of the groups concerned. It would be difficult to conceive of a catalytic process sufficiently broad in its scope to cover all of the cases under consideration.

Oxidation and Reduction as Delectronation and Electronation

It was stated in 1903 by J. J. Thomson[5] that: "A univalent electro-positive atom is one which under the circumstances prevailing when combination is taking place, has to lose one and only one corpuscle, before stability is attained; a univalent electro-negative atom is one which can receive one, but not more than one, corpuscle without driving off other corpuscles from the atom; a divalent electro-positive atom is one that loses two corpuscles and no more, and so on."

In the same year, Abegg[6] expressed more definitely the ideas first pre-adumbrated by Berzelius,[7] and later outlined by Ostwald,[8] concerning the relationship between chemical action and electric charges. The close correspondence now recognized between chemical and electrochemical actions is a logical outgrowth also of the epochal discoveries of Faraday.[9] According to Bancroft,[10] "The most striking characteristic of an electrolytic reaction is that it occurs in two places—at the anode and at the cathode. The peculiarity can be made less marked by bringing the electrodes nearer and nearer together. When the distance between them vanishes, we have a chemical reaction in the ordinary sense of the word, and not an electrochemical reaction."

The view that oxidation and reduction involve a transfer of electrons has been widely disseminated by Alexander Smith[11] and by Stieglitz,[12] who also extended the idea to the oxidation of organic substances. Similar concepts have been employed by Falk and Nelson,[13] by Fry,[14] and by L. W. Jones[15] and their associates to explain organic reactions.

The reasons for considering the fundamental mechanism in reactions of oxidation and reduction to involve a transfer of electrons have been carefully reviewed by Cady and Taft,[16] who believe that "in the absence of any proof to the contrary, the most convenient and the most generally

correct view is to regard the process as a direct transfer of charges. . ., a conception which is also in accord with the present electronic theory of valence. It must be understood that we are advancing no arguments against the formation of intermediate compounds in oxidation and reduction reactions, as there is experimental evidence on record in so large a number of cases that this is not a question for argument."

Direct evidence of reduction effected by electrons supplied either from a spark cathode or by the β-radiation from radium, and of oxidation effected by a-particles from radium has been presented by Pisarzhevskii and Rosenberg.[17] The restoration of electrostatic equilibrium through certain membranes that show ionic selectivity has been demonstrated by Girard and Platard[18] to occur as the result of a transfer of electrons rather than of ions.

On the basis of such experimental evidence as the foregoing, it seems reasonable to conclude that oxidation is to be regarded as essentially a process of *delectronation*,[19] and reduction as electronation.

Mono-Delectronators and Di-Delectronators

Oxidizing agents may be grouped in two classes: (1) those that accept one electron only per active unit (atom, ion or molecule) and *(2)* those able to accept more than one electron per active unit. Members of the first class, including such oxidants as ferric, manganic, ceric and cupric ions, may be termed mono-delectronators. The second class comprises *di-delectronators*[20] such as peroxide, chlorate and persulfate ions, as well as possible *tri-delectronators* and other *poly-delectronators*.[21]

Oxidation of Hydrazine by Mono-delectronators.—Hydrazine may be completely oxidized, under appropriate conditions, to nitrogen and water. Whenever its oxidation by mono-delectronators is incomplete, the sole by-product formed is ammonia. This may be most readily explained by assuming initial liberation of univalent N_2H_3 residues, or free radicals, each of which contains an atom of bivalent nitrogen, in accordance with the equation

$$N_2H_5^+ - \ominus = N_2H_3 + 2H^+ \qquad (1)$$

Subsequent condensation of two such residues would yield tetrazane, $NH_2.NH.NH.NH_2$, a compound of which organic derivatives have long

[19] "Delectronation" seems to the authors more euphonious than "de-electronation," which has been proposed by Cady and Taft [*Science*, 62,403 (1925)].

[20] "Mono-delectronator" and "di-delectronator" were first suggested in this Laboratory by E. W. Phelan in place of the rather cumbersome terms one-equivalent oxidizing agent and two-equivalent oxidizing agent.

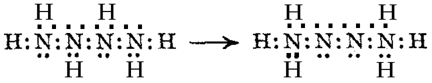
[21] A similar classification of reducing agents as *mon-electronators*, *di-electronators*, and *poly-electronators* is also possible.

been known.[22] Decomposition of this intermediate product would undoubtedly take place with formation of ammonia and nitrogen:

$$N_4H_6 = N_2 + 2NH_3 \qquad (2)$$

The first of these stages, that of delectronation, must be a reaction of the second order, as demonstrated by Bray and Cuy,[3,23] for the oxidation of hydrazine by the typical mono-delectronators, manganic ion and ferric ion. The second and third stages must proceed with greater velocity than the first, as otherwise further delectronation of the residues, either before or after condensation, would be evidenced.

Decomposition of the tetrazane may be conceived to involve a simple migration of two hydrogen nuclei, presumably very mobile, from the central to the external nitrogen atoms of the chain, in accordance with the conventional electronic diagram



$$H:\overset{H}{\underset{\cdot\cdot}{N}}:\underset{H}{N}:\overset{H}{\underset{\cdot\cdot}{N}}:\underset{H}{N}:H \longrightarrow H:\overset{H}{\underset{H}{N}}:\underset{\cdot\cdot}{N}:\underset{\cdot\cdot}{N}:\overset{H}{\underset{H}{N}}:H$$

with ultimate formation of a labile compound of molecular nitrogen and ammonia, $N_2.2NH_3$.

Among the mono-delectronators previously studied in this Laboratory'' are ferric, cupric, nickelic and cobaltic ions. Each of these oxidizes hydrazine under the specified conditions with formation of water, nitrogen and ammonia, but no hydronitric acid. The work of Benrath and Ruland[24] upon ceric ion, and that of Bray and Cuy[23] upon manganic and ferric ions show that these oxidants behave in an entirely similar fashion. Manganic ion was found under certain conditions to oxidize hydrazine quantitatively to water, nitrogen and ammonia in conformity with the typical reaction of mono-delectronation.

Prom the theory just outlined it is predictable that ceric ion, in common with all other mono-delectronators studied, would yield no hydronitric acid as a product of the oxidation of hydrazine. Repeated experiments conducted in this Laboratory, under conditions most favorable for the formation and isolation of the acid, yielded no trace of hydronitric acid, thus confirming the work of Benrath and Ruland. Since Sommer and Pincas[25] and Martin[26] have employed ceric ion for the quantitative oxidation of hydronitric acid, however, it might be urged that this action would account for the non-appearance of the acid as a product of the oxidation of hydrazine. Thiele[27] ascribed the relatively low yields of hydronitric

acid obtained in various reactions to the "easy oxidizability (leichten Oxydierbarkeit)" of the acid. This suggestion was effectually nullified by the work of Riegger.[28] Nevertheless, it has seemed desirable to obtain direct evidence for the case of the interaction of ceric and hydrazine ions, as to whether putative traces of hydronitric acid would escape oxidation by the ceric ion under the prevailing conditions.

Known amounts of hydronitric acid were introduced beneath the surface of a boiling mixture of ceric sulfate and sulfuric acid in various concentrations. Amounts as small as 0.0001 g. were found to pass through the solution without appreciable loss. This justifies the conclusion that the non-appearance of the acid must be attributed to the inherent character of the reaction, which is clearly one of mono-delectronation.

Oxidation of **Hydrazine** by **Di-delectronators.**—Hydrazine may be completely oxidized, under suitable conditions, by certain di-delectronators, at least, to nitrogen and water. In case the oxidation by di-delectronators is incomplete, hydronitric acid is also formed, under favorable conditions, and is invariably accompanied by ammonia. It is probable that bivalent N_2H_2 residues, which may be regarded as free radicals containing either two atoms of bivalent nitrogen or one atom of univalent nitrogen, are first formed in accordance with the equation

$$N_2H_5^+ - 2\ominus = N_2H_2 + 3H^+ \tag{3}$$

If this process involves the removal of one electron from each of the nitrogen atoms, the NH.NH radical would be formed; the removal of two electrons from one nitrogen, on the other hand, would yield the $N.NH_2$ radical.[29]

Various types of condensation, involving (a) two of these radicals of the same kind, (b) two of different kinds or (c) one of either kind with a molecule of hydrazine, may be considered to occur. Of the five possible bimolecular types only those will be discussed, however, that would yield compounds of which organic derivatives have been prepared.

Condensation of two $N.NH_2$ radicals would yield symmetrical tetrazene, $NH_2.N{:}N.NH_2$, of which numerous organic derivatives, formerly termed tetrazones, have been described.[30] This intermediate product would readily decompose, yielding molecular nitrogen and hydrazine, as follows

$$N_4H_4 = N_2 + N_2H_4 \tag{4}$$

The formation of nitrogen, primary and secondary amines and aldehydes as decomposition products of the tetra-alkyl tetrazenes, noted by Fischer[31]

---

[28] Riegger, This Journal, 33, 1569 (1911).

[29] It is possible that these initial products, instead of being free radicals, as here suggested, may be the much-sought di-imide, NH:NH, and its unsymmetrical isomer, $N{:}NH_2$, of which the azo compounds and the diazonium compounds are derivatives.

[30] For a comprehensive summary of these compounds see Wieland, "Die Hydrazine," Ferd. Enke, Stuttgart, **1913**, p. 38.

[31] Fischer, Ann., **199**, 324 (1879).

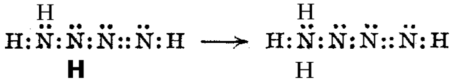
and by **Renouf**,[32] is explained by **Wieland**[33] as a result of the formation and subsequent decomposition of the tetra-alkyl hydrazines.

It is probable that all hydrazine molecules that undergo complete oxidation in acid solution to nitrogen and water pass through the stage represented by Equation 4. The relatively large amounts of nitrogen formed in many of the oxidation reactions studied indicate a preferential oxidation of the $N_2H_5^+$ ion to the unsymmetrical residue, $N.NH_2$, rather than to the symmetrical residue, NH.NH. In the case of mono-delectronators, the tetrazane first formed might yield symmetrical tetrazene on further **oxidation**.[34]

Condensation of two HN.NH radicals might conceivably yield **tetrimide**, $(NH)_4$, as an intermediate product. This seems unlikely, however, in view of the circumstance that no derivatives of this possible compound have yet been described. Condensation with subsequent rearrangement, possibly by way of **aminotri-imide**, as suggested by the work of Wohl and **Schiff**,[35] would result in the formation of unsymmetrical tetrazene, $HN{:}N.NH.NH_2$, of which numerous derivatives, formerly termed **buzylenes**[36] or **diazohydrazines**[35] have been prepared. These substances have long been known to yield derivatives of hydronitric acid and ammonia, and it seems inevitable that unsymmetrical tetrazene itself should decompose in corresponding fashion, in the sense of the equation

$$N_4H_4 = HN_3 + NH_3 \tag{5}$$

This decomposition may result from the migration of one hydrogen nucleus from a central to an external nitrogen atom, as indicated in the diagram[37]



$$H{:}\overset{H}{\ddot{N}}{:}\underset{H}{\ddot{N}}{:}\ddot{N}{::}\ddot{N}{:}H \longrightarrow H{:}\underset{H}{\overset{H}{\ddot{N}}}{:}\ddot{N}{:}\ddot{N}{::}\ddot{N}{:}H$$

[34] Minunni (ref. **22)** obtained evidence of the existence of a tetrazane of the type RR'N.NH.NH.NRR', which on oxidation yielded the symmetrical tetrazene, **RR'N.N:-N.NRR'.**

[35] Wohl and Schiff, Ber., **33,2741 (1900).**

[36] **Curtius,** Ber., 29,759 (1896).

[37] The use of the conventional electronic diagrams as a convenient device for picturing such molecular rearrangements is not to be construed as an acceptance by the authors of the possible implication that hydronitric acid is a non-polar compound, or that the valence of nitrogen, in any ordinary sense of the term, may be two and four in this compound [**Langmuir, THIS JOURNAL,** 41, **1543 (1919)].** On the basis of both experimental and theoretical considerations the acid may better be regarded as a polar compound, in which the central nitrogen atom tends to relinquish its five valence electrons, yielding three to the external nitrogen atom and two to the **imino** group. This finds expression in the formula $H\rightarrow N\leftleftarrows N\Rrightarrow N$. The N_3^- ion, either in solution or in the crystal lattice of the metallic **trinitrides,** should possess a symmetrical structure, and the nucleus of the central atom should be equidistant from the nuclei of the outer atoms, each

This would be tantamount to the formation of a labile molecular compound of ammonia and hydronitric acid, $HN_3.NH_3$, isomeric with ammonium trinitride.[38]

Condensation of one $N.NH_2$ with one HN.NH radical and subsequent rearrangement would again result in the formation of unsymmetrical tetrazene, which decomposes in the manner expressed by Equation 5.

Condensation of one $N.NH_2$ or of one HN.NH radical with a molecule of hydrazine should yield, after simple rearrangement, a molecule of tetrazane, which would decompose with formation of nitrogen and ammonia in accordance with Equation 2. This affords a satisfactory explanation of the fact that larger yields of ammonia than of hydronitric acid have been invariably obtained in the oxidation of hydrazine.

Among the di-delectronators previously studied in this Laboratory[1] are peroxide, persulfate, chlorate, bromate, iodate, arsenate, antimonate, selenate, tellurate and molybdate ions. Each of these has been found to oxidize hydrazine under suitable conditions[39] with formation of water, nitrogen, hydronitric acid and ammonia. The reaction of hydrogen peroxide upon hydrazine sulfate has been employed by Browne and Lundell[40] in this Laboratory, and by Martin[26] in the preparation of very pure hydronitric acid.

These experiments attest the validity of the classification, here proposed, for oxidizing agents that have already been investigated. The question now arises as to whether the theory will be of use as a means of predicting the behavior of hitherto unstudied di-delectronators.

Oxidation of Hydrazine by the Di-delectronator, Chlorauric Acid.—It was shown by Lenher[41] that chlorauric acid is reduced by hydrazine, with formation of metallic gold. Gutbier[42] employed hydrazine, and Gutbier and Resenscheck[43] phenylhydrazine in the preparation of gold hydrosols of different colors. No attempt seems to have been made by these investigators to ascertain whether or not hydronitric acid (or phenyl azide) was formed as a product of the reaction.

A solution of chlorauric acid was prepared by dissolving 0.8 g. of gold in aqua regia. Since the presence of oxides, oxy-acids, or oxychlorides

---

of which is furnished with eight electrons. This is in conformity with the recent work of Hendricks and Pauling [This Journal, 47, 2904 (1925)] upon the crystal structure of potassium and sodium trinitrides, but contradicts the statement of Carothers [This Journal, 45, 1734 (1923)] that "the structure $R-N=N\equiv N$ is, of course, impossible from the point of view of the octet theory."

[38] Ref. 1 h, p. 288, footnote 1.

[39] In the case of iodate ion no hydronitric acid is formed unless silver sulfate, which serves to prevent the liberation of iodine, is present.

[40] Browne and Lundell, This Journal, 31, 435 (1909).

[41] Lenher, *ibid.*, 35, 546 (1.913).

of nitrogen might result in the formation of hydronitric acid from hydrazine, thus masking the possible effect of the reagent, scrupulous care was taken to eliminate the last traces of these substances. The purified solution, diluted to 100 cc., was slowly introduced beneath the surface of a 200cc. portion of a boiling, 0.5% solution of hydrazine sulfate. In two experiments, in which a considerable excess of unoxidized hydrazine remained in the distilling flask, yields of 0.006 and 0.004 g. of hydronitric acid were obtained. The chlorauric acid was quantitatively reduced to metallic gold. The presence of ammonia in the residual solutions was established by qualitative tests.

The formation of hydronitric acid under the conditions just described, which were by no means the most favorable for its production, unequivocally fulfils the prediction concerning the behavior of chlorauric acid. The smallness of the yields is attributable to various factors, including (1) the relatively low concentration of sulfuric acid, (2) the momentary liberation of chlorine during the reaction and (3) the action of aurous ion as *a* mono-delectronator.

Complex Delectronators.—Oxidizing agents that undergo reduction in two or more stages may in certain cases manifest the characteristics of a mixture of mono- and di-delectronators. The course of the reduction would then be a resultant of the reactions of both types. In such cases it should theoretically be possible, by the use of suitable addition agents, wholly or in part to eliminate one type of reaction, or the other, thus rectifying the complex delectronator, by virtually converting it into a simple mono- or di-delectronator.

An indubitable instance of such rectification is afforded by the work done in this Laboratory[1"] upon the reaction between iodate ion and hydrazine ion in acid solution. This reaction yields iodide ion, readily oxidizable by iodate with liberation of iodine, which in monatomic form is a mono-delectronator. The reaction between iodine and hydrazine evidently takes precedence over that between iodate and hydrazine, with the result that no hydronitric acid is formed. The addition agent, silver sulfate, however, effects removal of the iodide, leaving the iodate ion free to act upon the hydrazine with formation of both hydronitric acid and ammonia.

In case each of the possible stages of a reaction involves simply an accession to the oxidant of the two electrons, the reaction would clearly be one of simple di-delectronation. If, on the other hand, any one of the stages consists in the transfer of a single electron, the reaction is one of complex delectronation.

Potassium permanganate, in its behavior toward hydrazine, affords another instance of complex delectronation. Browne and Shetterly[1d] found that small amounts of hydronitric acid and large amounts of ammonia were formed by the interaction of permanganate and hydrazine ions in acid solution. Since the yields of ammonia were considerably in excess of the values required by Equation 5, the conclusion may be drawn that the principal reaction, aside from that expressed in Equation 4, is one of mono-delectronation, as represented by Equations 1 and 2. This points toward manganic ion, readily formed by interaction of manganous and permanganate ions, as the principal agent. This conclusion is strongly confirmed by the work of Bray and Cuy.[3,23] Any addition agent that would reduce the concentration of manganic ion should increase the yield of hydronitric acid by rectifying the complex reaction to one of simple di-delectronation.[44]

Oxidation of Hydrazine by the Complex Delectronator, Ammonium Metavanadate.—From the work already done in this Laboratory[1b] upon the action of ammonium metavanadate in acid solution upon hydrazine, it is apparent that this reaction is not one of simple di-delectronation. Indeed, at first glance, it would appear, apart from the evidence of the formation of hydronitric acid, to be one of simple mono-delectronation involving reduction of trivalent vanadyl ion (quinquivalent vanadium) to bivalent vanadyl ion (quadrivalent vanadium), as follows

$$VO^{+++} + \ominus = VO^{++} \qquad (6)$$

It is probable, however, as suggested by Ditz and Bardach[45] for the reaction between vanadates and hydriodic acid, that a part of the quinquivalent vanadium is directly reduced to trivalent vanadium (univalent vanadyl ion), as follows

$$VO^{+++} + 2\ominus = VO^{+} \qquad (7)$$

In this reaction the trivalent vanadyl ion acts as a di-delectronator and is responsible for the formation of hydronitric acid.

It has been shown by the work of Gooch and Gilbert[46] that silver sulfate is reduced by vanadium with a valence of one, two or three, but is not reduced by vanadium with a valence higher than three. The presence of silver sulfate in a reacting mixture of hydrazine and ammonium metavanadate therefore serves to indicate whether or not the vanadium has been reduced below the quadrivalent stage. Metallic silver appears as a product of the reaction in every case where hydronitric acid is formed, and in no case where the acid is not formed. Unless the reduction proceeds beyond the stage represented by Equation 6, therefore, no hydronitric acid is obtained. In a second series of experiments it was found that diminution in the acidity of the solution favors mono-delectronation (Equation 6) and retards di-delectronation (Equation 7), until in a barely acid solution no hydronitric acid whatever is obtained.

---

[44] It is possible that addition of soluble sulfates or fluorides for example would produce this result.

[45] Ditz and Bardach, Z. *anorg. Chem.*, **93**, 97 (1915).

[46] Gooch and Gilbert, Am. J. *Sci.*, [4] 15,389 (1903).

Oxidation of Hydrazine by Chlorine, Bromine and Iodine.—In the nascent or monatomic condition the halogens are without doubt to be classified as mono-delectronators. Under such conditions that the diatomic molecules, the positive ions (Cl^+, Br^+, I^+), or the ions of the hypo-acids (OCl^-, OBr^-, OI^-) constitute the active units, however, the halogens should be capable of functioning as di-delectronators. Earlier observations" of the formation of small amounts of hydronitric acid from hydrazine by the action of chlorine and bromine confirm this supposition. The issue is complicated, however, by the possibility that halogenation may occur, with formation of halogenated residues as intermediate products, which may behave very differently from the radicals liberated by other oxidizing agents.

Chattaway[47] has investigated the action of chlorine and of bromine upon certain primary aromatic hydrazines, and has obtained various halogen substitution products of these substances. In so far as the decomposition of these compounds has been studied it would appear strictly analogous to the decomposition of the corresponding derivatives of free hydrazine to form nitrogen gas and hydrogen chloride.

Despite the probable predominance of halogenation in the oxidation of hydrazine by the free halogens, small amounts of hydronitric acid and ammonia may nevertheless be obtained under suitable conditions, indicating that di-delectronation must occur to some extent during the process.

Experiments in which freshly prepared chlorine water was introduced beneath the surface of a boiling 1% solution of hydrazine sulfate containing one-half of its volume of concentrated sulfuric acid, yielded appreciable amounts of hydronitric acid and ammonia, both in the absence and in the presence of silver sulfate. With bromine smaller yields, found to vary directly with the concentration of the sulfuric acid and to increase in the presence of silver sulfate, were obtained.

With iodine detectable amounts of hydronitric acid were formed only in the presence of silver sulfate. The probable effect of the addition of silver sulfate is to reduce the concentration of iodide ion and thus to favor the formation of iodous ions (I^+). Increase in the acidity of the solution would undoubtedly produce the same effect. The iodous ion, obviously a di-delectronator, is capable of yielding hydronitric acid under favorable conditions, but the necessarily low concentration of the ion precludes the formation of more than small amounts of this product.

Summary

A classification of oxidizing agents (and reducing agents) has been suggested on the basis of the number of electrons transferred per active unit.

---

[47] Chattaway, *J. Chem. Soc.*, 93, 852 (1908); 95, 1065 (1909).

The hitherto unaccountable similarity in the behavior of various oxidants of widely divergent potentials toward hydrazine is now explained on the ground that they are either *mono-delectronators,* yielding ammonia as the only by-product of the reaction, or *di-delectronators,* yielding both ammonia and hydronitric acid.

Further applications of this idea are projected, particularly for the case of other oxidation-reduction reactions in the fields of inorganic and organic chemistry in which intermediate products are formed.

MICELLES AND THE ACTIVITY COEFFICIENT IN ALKALI SILICATE SOLUTIONS

BY MERLE RANDALL AND JESSIE Y. CANN

RECEIVED OCTOBER 24, 1927 PUBLISHED FEBRUARY 4, 1928

The theory of colloidal electrolytes as used by McBain[1] postulates the replacement of a simple ion formed by the dissociation of an electrolyte, by a heavily hydrated polyvalent micelle or ion "which carries the equivalent sum-total of electrical charges" of the ions which it replaces. This theory was carefully considered by McBain and Salmon,[2] and by McBain, Laing and Titley,[3] who determined the dew point lowering and freezing point lowering of soap solutions. And from their data, Randall, McBain and White[4] calculated the activity coefficients.

McBain and Salmon[2] predicted that solutions of sodium silicate and certain other salts of the heavy metals, as well as the soaps, would be found to contain varying quantities of micelles. Recently, Harman[5] has postulated on the basis of his freezing point measurements, the existence of micelles in concentrated sodium silicate solutions containing a large excess of silica.

Before considering the constitution of the alkali silicate solutions as determined by their colligative properties, we will examine the significance of the activity coefficient of a solution in which micelles may be formed.

The Activity Coefficient in Solutions Containing Micelles

The activity of a solute is the ratio of the escaping tendency, or fugacity, of that constituent of a solution divided by the escaping tendency of the constituent in some standard state which is arbitrarily chosen.[6] The escaping tendency is, of course, independent of any assumed constitution

of the solute. For convenience, when dealing with electrolytes, the chosen standard state is defined with reference to the infinitely dilute solution, and the activity is taken equal to the product of the activities of the ions into which the electrolyte is assumed to dissociate.[7] The activity coefficient of an ion is the number by which the stoichiometrical molality of the ion is multiplied to obtain the activity, and the activity coefficient of the solute is the geometrical mean of the activity coefficients of the ions.

We shall consider a solute in which the negative ions of a uni-univalent strong electrolyte are replaced by ionic micelles. Let us call m the molality of the solute AB, and n the number of univalent negative ions which unite to form an ionic micelle. The molality of the positive ion constituent is also m. If the negative ion constituent is present only in the form $(B_n)^{n-}$, then the molality of the solute and also the molality of the micelle ion is $m' = m/n$. Neglecting the hydration,[6] we may write

$$A_nB_n = nA^+ + (B_n)^{n-};\ a_2 = a_+{}^n a_- \qquad (1)$$

where a_2 is the activity of the solute, and a_+ and a_- are the activities of the positive ion and negative micelle, respectively. For the mean molality, we find

$$m_\pm = (m_\pm{}^n m')^{1/(n+1)} = m_+/n^{1/(n+1)} \qquad (2)$$

From Equation 2, we see that as n becomes a very large number, the mean molality of the ions becomes nearly equal to the molality of the positive ion constituent. Or, if n is infinite, we should say that the whole of the solute was a single particle, possessing the entire negative charge of the solution, surrounded by the univalent positive ions. If all the ions obeyed the law of the perfect solution, then the freezing point lowering of such a solute would be the same as that of a non-electrolyte having the same molality as that of the positive ion constituent. Consequently, in the limit, when n becomes very large, ν, the number of ions produced by the dissociation of each molecule of AB, approaches unity. Following the treatment by Bjerrum,[8] we should expect a micelle as formulated in Equation 1 to be a progressively weaker electrolyte as the value of n is increased. In the limit, when n becomes very large, perhaps the micelle would no longer behave as an electrolyte. We shall show in a later section that the micelles of sodium acid silicate behave as slightly weak electrolytes. The un-ionized micelles postulated by McBain and Salmon[2] can possibly be explained in this way.

In the ordinary manner, we have the ionic strength of the solution

$$\mu = (m_+ + m'n^2)/2 = m_+(n + 1)/2 \qquad (3)$$

As n increases, the ionic strength rapidly increases and becomes infinity in the limit when n becomes infinite.

[8] Bjerrum, *Kgl. Danske Videnskab. Selskab Math.-fys. Medd.*, 7, No. 9 (1926).

The activity coefficient of a solute is proportional to the square root of the ionic strength. If the solution is completely dissociated, the activity coefficient for a given ionic strength will be less, the greater[9] the value of n. The "association" in the Bjerrum[8] sense would still further reduce the expected activity coefficient of the micelles.

In the discussion of the activity coefficient of soaps by Randall, McBain and White,[4] the activity of the solute was set equal to the square of the product of the stoichiometrical molality and the activity coefficient, and we shall adopt the same convention in discussing the sodium acid silicates. Although, if for purposes of formulating a mechanism which will explain the divergence of the activity coefficients of these substances from those of typical uni-univalent electrolytes, we assume the existence of micelles, this device is in no way essential to the thermodynamic treatment. We selected as the solutes[6] the sodium ion and hydrosilicate ion, or sodium ion and univalent soap ion, because they were simple, and because in the dilute solution the behavior of the electrolytes was the same as that of typical electrolytes. The actual molality of the various ionic micelles, or of the various hydrates, or of the neutral micelles, or of undissociated substances is unknown; but their fugacity is the same as that of the solutes arbitrarily chosen, for they are in equilibrium with these substances. As long as no solute molecule is present whose composition cannot be expressed in terms of the ions chosen as solutes, and as long as these substances are in equilibrium, it is immaterial which of the species is chosen as the solute. Accordingly, the species with the simplest formula is used.

In the case of the hydrolysis of one of the ions, as that of SiO_3^{--}, the case is different, for the composition of the products of hydrolysis cannot be expressed in terms of the ions formed from the chosen solute. But, by drawing the curve as we shall do in Fig. 1, we assume that the curve as drawn is the curve which would be given by a substance of this nature if no hydrolysis occurred. Therefore, in taking the area under the curve, we obtain, with no great error, the activity coefficient of the normal silicate, without hydrolysis.

We shall now consider the various experimental determinations of the freezing point lowering,[10] vapor pressure lowering,[10a] dew point lowering[11] and boiling point raising[12] of the various sodium silicate solutions.

Activity Coefficient of Sodium Silicate Solutions

Harman,[10a] Bennett[11] and Cann and Gilmore,[12b] took the molality of their silicate solutions equal to twice the molality of the sodium ion constituent. Numerous investigators[13] have shown that hydrolysis of the solutions is increased with dilution and with increase of temperature. For this reason, Harman,[10a] Bennett[11] and Cann and Gilmore,[12b] took the value of ν in the freezing point equation of Lewis and Randall[7] equal to 4, for solutions of all ratios of Na_2O to SiO_2. They then calculated the activity coefficients of the various solutions by the methods of Lewis and Randall.? Their calculations tacitly assume for the reaction

$$Na_2SiO_3\,(aq) + H_2O\,(l) = 2Na^+ + OH^- + HSiO_3^- \qquad (4)$$

$K = 1$, in accordance with the conventions adopted by Lewis and Randall in developing the basic equations used. In other words the activity of the sodium silicate is made equal to the geometric product of the activities of the ions on the right of Equation 4.

In a later paper, Harman[14] calculated the two dissociation constants of metasilicic acid from electrometric titration curves. His curves show definitely two "breaks" such as are found when sodium carbonate is titrated with hydrochloric acid.

We have recalculated the values of the activity functions[15] $h/m^{1/2}$ and $j/m^{1/2}$ for all the above measurements. We have used $\nu = 3$ for ratios of 1:1 of Na_2O to SiO_2 and $\nu = 2$ for ratios of 1:2 to 1:5. In the latter case, the molality was taken equal to the number of gram atoms of sodium ion constituent. These assumptions correspond to $K = 1$ for the reactions

$$Na_2SiO_3\,(aq) = 2Na^+ + SiO_3^{--} \qquad (5)$$
$$NaHSiO_3\,(aq) = Na^+ + HSiO_3^- \qquad (6)$$

It has been impossible to eliminate the effect of hydrolysis, but in the concentrated solutions this effect cannot be large,[13] and the method of extrapolation here used eliminates to a great extent the effect in the more dilute solutions.

Sodium Metasilicate.—The values of $j/m^{1/2}$ and $h/m^{1/2}$ for the various silicates containing $1Na_2O{:}1SiO_2$ are shown plotted against the square root of the molality in Fig. 1. The average values of $j/m^{1/2}$ for barium

nitrate[16] are shown as the dotted curve. Fig. 1 also shows for comparison the values of $j/m^{1/2}$ for the ratio Na_2O:1.4SiO_2, if we assume the molality equal to the moles of Na_2O and $v = 3$.

The effect of hydrolysis is seen in the negative values of $j/m^{1/2}$ and $h/m^{1/2}$ which, for a hydrolyzed substance will approach $-\infty$ at infinite dilution. In molal solution the hydrolysis is not large and we gain an idea of the activity coefficient of sodium silicate, when defined in accordance with Equation 5, by drawing the solid curve, to follow the general direction of the curve for barium nitrate. The activity coefficient of the normal sodium silicate as calculated by the equation

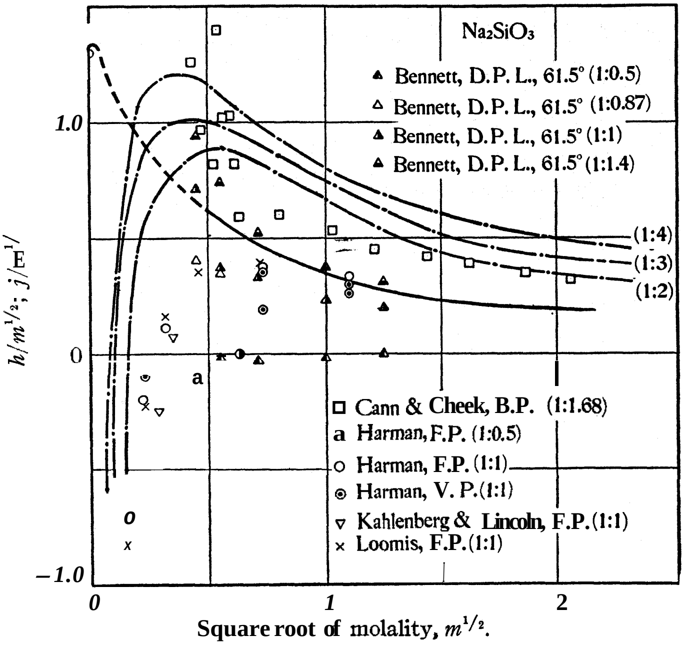

Fig. 1.—Activity function of sodium metasilicate.

$$\log \gamma = -j/2.303 - (2/2.303) \int_0^m (j/m^{1/2}) dm^{1/2} \qquad (7)$$

for round molalities is shown in the second row of Table I. The temperature coefficient of the activity coefficient has been neglected and the values are approximate for any temperature between 0 and 100".

[16] Randall and Scott, THIS JOURNAL, 49, 647 (1927).

The neutral sodium silicate is about as weak, that is, has the same activity coefficient, as barium nitrate, which was shown by Randall and Scott[16] to be weaker than typical strong electrolytes of the same valence type. We should, therefore, expect a slight "association" in the Bjerrum[8] sense, but such an effect is not apparent in the values of $j/m^{1/2}$, because of the large hydrolysis.

Our activity coefficient represents approximately the mean activity coefficient of the Na^+ and unhydrolyzed SiO_3^{--} ions present in any solution of an ionic strength three times the molality given in Row 1, when we assume the principle of the ionic strength.

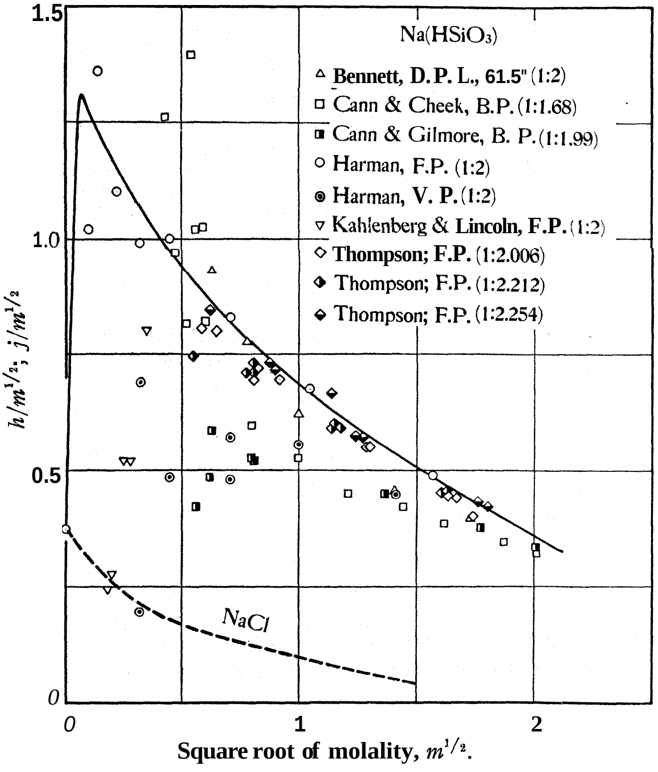

Fig. 2.—Activity function of sodium acid silicate.

Sodium Acid Silicates.—The values of $j/m^{1/2}$ and $h/m^{1/2}$ for the various silicates with ratios $1Na_2O{:}1.68SiO_2$ to $1Na_2O{:}2SiO_2$ are shown in **Fig.** 2; those for ratios $1Na_2O{:}2.55SiO_2$ to $1Na_2O{:}3SiO_2$ are shown in Fig. 3; those for ratios $1Na_2O{:}3.154SiO_2$ to $1Na_2O{:}5SiO_2$ are given in Fig. 4. The molality is that of sodium ion constituent and the acid silicates have been assumed to dissociate in accordance with Equation 6. The silica in excess of 2 moles of SiO_2 per Na_2O has been assumed to be combined in the univalent negative ion. Fig. 2 also shows as a dotted curve the average values of $j/m^{1/2}$ for sodium chloride.

The curves of Figs. 2 to 4 are similar to those obtained for moderately strong acids, such as dichloro-acetic. No typical uni-univalent salts, such as the uni-bivalent cadmium chloride or mercuric chloride, with low activity coefficients, have been noted, although one of us has plotted the values of $j/m^{1/2}$ and $h/m^{1/2}$ for all published measurements.

Randall, McBain and White[4] plotted the values of $j/m^{1/2}$ and $h/m^{1/2}$ for the various sodium and potassium soap solutions. In the dilute solutions the values appear to be about the same as those for potassium chloride. At a concentration of about 0.05 M for a soap with a large number of carbon atoms to about 0.3 M for a soap with a small number, the values of $j/m^{1/2}$ begin to increase (log γ to decrease), the increase becoming larger, the greater the molecular weight of the soap. This rise is at the concentration in which micelles were assumed to begin to form as determined by conductance, viscosity and other data. The curves of Figs. 2 to 4 resemble the portions of the plots[4] of the data for the soaps in the higher concentrations. If the data are to be considered reliable, there is no evidence of behavior like that of sodium chloride in dilute solutions, and if the silicates give a rapid rise in the $j/m^{1/2}$ curve, as in the soap solutions, then this rise occurs in much more dilute solutions.

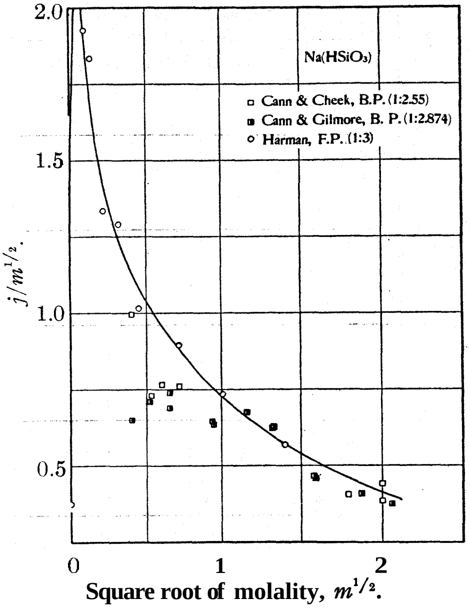

Fig. 3.—Activity function of sodium acid silicate.

Micelles can be assumed to form according to the equation

$$n(\mathrm{HSiO_3}\cdot y\mathrm{SiO_2}\cdot z\mathrm{H_2O^-}) = [r\mathrm{HSiO_3}\cdot s\mathrm{SiO_2}\cdot w\mathrm{H_2O}]^{n-} + x\mathrm{H_2O} \quad (8)$$

in which molecules of monovalent hydrosilicate ion with an indefinite amount of added water and silica unite to form the micelle with n negative charges and a new indefinite amount of water and silica of solvation. All of the silica will presumably remain in the micelle. The value of n may be a fairly large constant number, or it may vary with the concentration. We can confidently expect that in the infinitely dilute solution, the micelles will be completely dissociated or hydrolyzed, in which case $j/m^{1/2}$ will approach the same limit as typical uni-univalent electrolytes, just as

Bjerrum[8] has assumed for the behavior of partly associated substances. If the micelles persist to a sufficiently low concentration, then there will appear no such minimum in the $j/m^{1/2}$ curves as was found in the case of the soaps, and we may draw our average curve, somewhat as shown in Figs. 2 to 4. The approximate activity coefficients as calculated from these curves for the various ratios are shown in Table II.

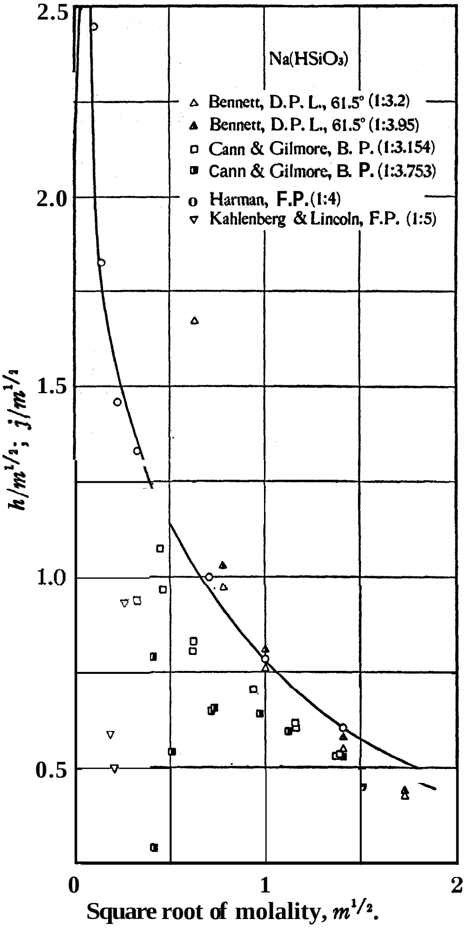

Fig. 4.—Activity function of sodium acid silicate.

The existence[17] of crystalline salts of the type $Na_2Si_2O_5$ is cited as an argument for the existence of $Si_2O_5^{--}$ in solution. The acid salt, $KHSi_2O_5$,[17b] has been prepared. However, the existence or non-existence of a crystalline salt does not necessarily indicate the presence of a considerable amount of the corresponding ions in solution, for they may react with the water, or may be in rapid equilibrium with an ion such as $HSiO_3^-$. Silicate solutions are known to change their thermodynamic properties with time, and some of these reactions may be slow. In the case of the measurements used in Figs. 1 to 4, a sufficient time to reach a stable state elapsed.

The broken curves of Fig. 1 show the average curves which correspond to the final mean curves taken from Figs. 2 to 4, when the molality of the acid silicates is taken as equal to one-half that of the sodium ion constituent and the divalent hydrated $Si_2O_5^{--}$ is assumed to be the principal negative constituent of the solutions. The excess silica is assumed to be combined in this negative ion in a way similar to that used in the former consideration of univalent $HSiO_3^-$. The values of $j/m^{1/2}$ for the acid sili-

cates, calculated on the basis of $\nu = 3$, ($Na_2Si_2O_5$), show a larger number of negative values in the dilute solutions than those calculated on the basis of $v = 2$, and this may be taken as an argument for the use of our convention.

Since the curves of Figs. 2 to 4 can be explained by assuming the existence of micelles, we will study the solutions of the highest silica-sodium oxide ratios on the basis of the limiting case, that the number of charges upon the micelles is very large. But before proceeding, we will digress to consider the freezing point function in a mixture of electrolytes.

The Freezing Point Function in Mixtures

If, for any particular type of electrolyte, the values of $j/m^{1/2}$, or $h/m^{1/2}$, are divided by the value of the limit[15a] (at the temperature considered) at zero molality ($j^{\circ}/m^{\circ 1/2}$), and these numbers are plotted against the square root of the molality, as in Fig. 5, the curves for all strong electrolytes of the various valence types will coincide if the effect of the size of the ions, hydration, etc., is the same.[18]

The function j is a property of the solvent. We may imagine the lowering of the freezing point to be the sum of the partial lowerings caused by each of the several constituents of a mixed electrolyte, such that $j = j_2 + j_3 + \ldots$. The value of $j_2/m_2^{1/2}$ or of $j_3/m_3^{1/2}$ will approach the same limit at infinite dilution as that approached by $j/m^{1/2}$ for a pure substance of the same valence type, but will depend upon the value of the ionic strength of the solution, rather than upon the molality of the particular constituent. If there is a common ion we must consider the function $j_2/m_{2\pm}^{1/2}$; but it is obvious from the definition[15] of j that if $m_{\pm}$ is substituted for m, then the sum of the various partial values of j will be greater than the total j. If the principle of the ionic strength is obeyed, then we should expect the curve of $(j_2/m_{2\pm}^{1/2})/(j_2^{\circ}/m_{2\pm}^{\circ 1/2})$ to be identical with the curve of Fig. 5.

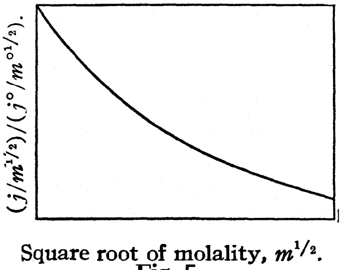

Fig. 5.

The assumptions of the previous paragraph do not enable us to determine

---

[18] Unpublished summary of colligative properties.

the activity coefficient of the several constituents of a mixture, nor the individual activity coefficients of the ions, for the division of the effect of the ions can only be made if we know the individual activities of the solutes. The idea, however, with the assumption of the principle of the ionic strength, enables us to examine qualitatively such curves as those of Fig. 6.

Micelles and Activity Coefficient of Sodium Ion

If a considerable portion of the hydrosilicate is in the form of large micelles, then in fact only one ion is formed per molecule of $NaHSiO_3$ dissociated, namely, a sodium ion; and the value of ν in the freezing point equation is one. We show the values of $j/m^{1/2}$ and $h/m^{1/2}$ calculated on this basis in Fig. 6. The limit at zero molality of $j/m^{1/2}$ for the freezing point measurements will be the same as that for uni-univalent substances, namely, 0.375, and if the usual assumptions[7] in estimating an individual ion activity are made, then the values should vary with the square root of the molality in about the same way as those for sodium chloride.

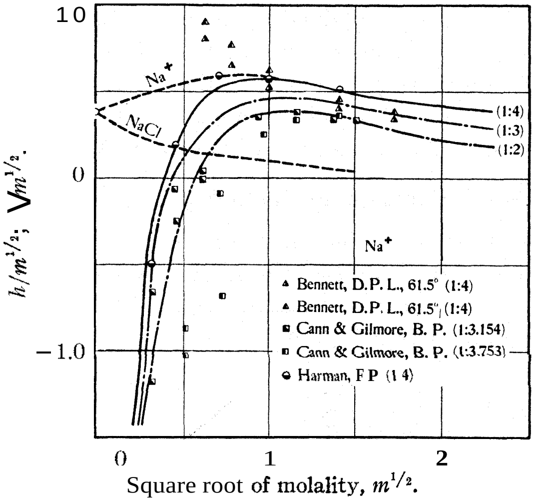

Fig. 6.—Activity function of sodium acid silicate.

Because of the very large charge upon the micelles, and the contribution to the ionic strength of a solution of these large ions, the scale of abscissas should be stretched to the right, and the values of $j_+/m_+^{1/2}$ should appear to decrease much less rapidly than those of sodium chloride. On the other hand, the presence of the large negative ions will cause an association in the Bjerrum[8] sense, because of the much larger distance of minimum approach of the centers of the charges, for complete dissociation, the effect of which would be shown in large values of $j/m^{1/2}$.

Below about 0.3 M the values of $j/m^{1/2}$ on the basis of $\nu = 1$ are in most cases negative, which is to be expected if the micelles dissociate to such an extent that the average number of ions formed per molecule is much greater than one.

We also show in Fig. 6 the values of $j/m^{1/2}$ calculated from the values of the freezing point lowering corresponding to the smoothed curves of Figs. 2 to 4. The values from the curves become negative at higher concentrations, the lower the silica-sodium oxide ratio in the silicates. This may be interpreted as indicating, as is also evident from the curves of Figs. 2 to 4, that the size and number of the micelles is less in the solutions of lower ratios.

The charge of the micelle, if we arc to explain the effects in this way, is greater, the greater the silica content of the negative constituent. The activity coefficient of the sodium ion, basis $v = 1$, is smaller $(j/m^{1/2}$ is larger) in accordance with the idea that the Bjerrum "minimum approach" is larger and "association" therefore greater. Further, we should expect the size of the micelle containing a given number of charges to be greater the greater the relative silica content; therefore the micelle which would have a certain charge density upon its surface (surface/charge) would have a greater number of charges.

In a very real sense the assumption that the ions existing in acid silica solutions are $Si_2O_5^{--}$ or some hydrated multiple thereof may be considered as the first stage in the formation of a micelle, for undoubtedly the negative constituent consists of many different sorts of micelles all in equilibrium (more or less rapid) with each other. But, as we do not have a method of picking out the concentrations of the individual species of micelles, we may as well take $HSiO_3^-$ just as we do in the case of water when we choose H_2O as the species to represent this substance.

Unfortunately, we are unable to fully interpret Harman's[13f] measurements with the sodium amalgam electrode, as the original data are not given and the correction for liquid potential used by him is uncertain. The values in the dilute solutions are the least valuable but the data in concentrated solutions indicate qualitatively that the activity of the sodium ion is smaller, at a given concentration, the higher the silica-sodium oxide ratio. This is in accord with the observations given in a previous paragraph.

All the micelles referred to have been considered to be ionic micelles. McBain and Salmon[2] postulate both ionic and neutral micelles. It is possible that the distinction between the two forms is the same as that between the "associated" (Bjerrum) barium nitrate[16] and the dissociated barium nitrate. There has been no suggestion of the separate existence of neutral (McBain and Salmon) micelles in the silicate solutions.

The results of conductivity measurements and other data do not contradict our explanations.[19]

Summary

1. The theoretical consequences of the choice of the standard state for solutes is considered in relation to the activity coefficient and ionic strength of solutions containing micelles.

---

[19] The Editor has kindly called our attention to an article by Linderstrøm-Lang, *Compt. rend. trav. lab. Carlsberg,* **16,** No. 6 (1926), in which is given a different explanation of the low activity coefficient of such solutions as are here considered.

2. The activity coefficient has been calculated for sodium silicate solutions with various ratios of sodium oxide to silica.

3. Sodium metasilicate solutions behave as typical uni-bivalent electrolytes. The value of ν in the freezing point equation is taken equal to 3 instead of 4 as taken by previous authors. Although sodium metasilicate solutions are largely hydrolyzed, the choice of $\nu = 4$ is not consistent with our conventions regarding the definition of activity coefficients.

4. Sodium acid silicates are not largely hydrolyzed, The formula is taken as $NaHSiO_3$ rather than $Na_2Si_2O_5$, and $\nu = 2$ rather than $\nu = 4$. The acid silicates show extremely low activity coefficients.

5. The low activity coefficients of the acid silicates are explained by the assumption of the existence of ionic micelles which are not entirely dissociated into simple ions except in very dilute solutions.

6. The percentage of substance existing as micelles in the silicates increases with the ratio of silica to sodium oxide.

7. The number of aggregated acid silicate ions forming a micelle increases as the percentage of silica increases.

8. The effect of the ionic micelle upon the individual ion activity of sodium ion is discussed.

PRIMARY SALT EFFECT IN A ZERO TYPE REACTION

BY MARTIN KILPATRICK, JR.[1]

RECEIVED OCTOBER 27.1927 PUBLISHED FEBRUARY 4, 1928

The present work is a further attempt to distinguish experimentally between the "activity rate theory" and the Brönsted formula for reaction rate in dilute solution.

According to the activity rate theory, the velocity of a reaction between A and B can be expressed by the equation

$$v = ka_Aa_B$$

where a_A and a_B are the activities of A and B, respectively.

Brönsted's[2] general formula may be written

$$v = kc_Ac_B.f_Af_B/f_X$$

where k depends on the temperature and the solvent and f_A, f_B and f_x are the activity coefficients of A, B and the "critical complex," respectively. For a solution so dilute that the activity coefficients of molecules and ions depend only on the charge, the general formula is

$$v = kc_Ac_B.f_{z_A}f_{z_B}/f_{z_A + z_B}$$

---

[1] National Research Fellow.

[2] Bronsted, Z. *physik. Chem.*, 102, 169 (1922).

where f_z represents the activity coefficient of an ion of valence z. The effect of salt upon the rate of reaction due to change in the value of the kinetic activity factor, $f_{z_A}f_{z_B}/f_{z_A+z_B}$, is called "primary salt effect." For the case of a reaction between a non-electrolyte and an ion

$$A^0 + B^z \longrightarrow (A,B)^z \longrightarrow \text{products}$$

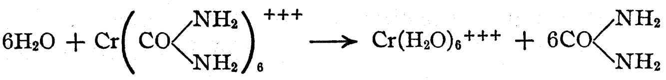
the kinetic activity coefficient becomes f_0f_z/f_z and in dilute solution should have a limiting value of one. The deviation from unity is linear with the concentration and consequently a linear salt effect is expected. According to the activity rate theory an exponential salt effect is predicted, since the rate is considered proportional to the product of the activities of the reactants.

The results of kinetic studies of reactions of this type (chiefly hydrogen and hydroxyl ion catalysis) have been used in an attempt to establish an experimental basis for the activity rate theory.[3] However, as already pointed out,[4] these experiments were carried out in solutions of high electrolyte concentration and are unsuitable for the purpose. In the first place, an investigation of the specific effect of the catalyst's activity cannot be carried out in concentrated salt solutions where numerous other factors influence the reaction rate and veil the effect sought. In the second place, one is prevented from taking advantage of the pronounced and uniform variations shown by ionic activity coefficients in dilute solution with change of salt concentration. For reactions studied in dilute solution the effect is linear and contradictory to the activity rate theory. A more critical test would be furnished by the study of a reaction involving a polyvalent ion, as in this case an exponential salt effect would be of much greater magnitude.

For these reasons a further experimental study of a reaction of the type

$$A^0 + B^z \longrightarrow \text{products}$$

where $z > 1$ in dilute solution seemed desirable. The reaction finally chosen was that between water and the hexa-urea chromium ion



$$6H_2O + Cr\left(CO\Big\langle\begin{matrix}NH_2\\NH_2\end{matrix}\right)_6^{+++} \longrightarrow Cr(H_2O)_6^{+++} + 6CO\Big\langle\begin{matrix}NH_2\\NH_2\end{matrix}$$

It is probable that the reaction takes place in steps and that the equation above does not represent the mechanism of the reaction. This, however, does not affect the kinetic equation

$$A^0 + B^{+++} \longrightarrow (A,B)^{+++} \longrightarrow \text{products}$$

---

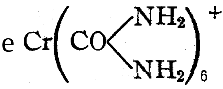
The reaction can be followed by determining the rate of disappearance of the



$Cr\left(CO\begin{smallmatrix}NH_2\\NH_2\end{smallmatrix}\right)_6^{+++}$

ion.

Experimental Part

The chromium urea chloride was prepared according to the method of **Pfeiffer**,[5] and converted to the nitrate by precipitation with nitric acid. Preliminary experiments showed that the reaction was very sensitive to diffused light. The rate of disappearance of the $Cr(NH_2CONH_2)_6^{+++}$ ion was determined by withdrawing samples of the reacting solution and precipitating with $K_3Co(CN)_6$ as $Cr(NH_2CONH_2)_6Co(CN)_6$. To test the quantitative accuracy of the method, known quantities of chromium urea nitrate were weighed out and the chromium urea cobalticyanide precipitated using varying excesses of potassium cobalticyanide and in the presence of different concentrations of potassium nitrate. The solubility of the precipitate increased in the presence of salt. Using a four-fold excess of potassium cobalticyanide (the filtrate being less than 0.01 molar in cobalticyanide) the method yielded results within 1% of the calculated weight in the presence of potassium nitrate up to 0.2 molar. Since the reaction is somewhat faster in pure water than in slightly acid solution, probably due to a slight effect of the OH ion, all experiments were carried out in solutions 0.001 *M* in nitric acid. The reaction is not catalyzed by hydrogen ion. The experiments were performed at 22.50° in a thermostat from which all light was excluded. A typical experiment ran as follows: 1.496 g. of chromium urea nitrate (0.002500 mole) was weighed out, dissolved in water, enough nitric acid was added to make the solution 0.001 M in nitric acid, and the whole was diluted to one liter and placed in the thermostat. At suitable intervals 100cc. portions were pipetted out and run into 15 cc. of solutions containing 0.001 mole of potassium cobalticyanide and enough potassium nitrate to make the final concentration of potassium nitrate 0.2 M. After cooling the solutions in ice, with frequent shaking, the precipitates were filtered onto weighed porous plate crucibles, washed with 5 cc. of water containing potassium cobalticyanide and finally with alcohol. The precipitates were dried at 90°.

The results are shown in Table I. The velocity constants are calculated by the formula

$$h = \frac{2.30}{t}\log_{10}\frac{c_0}{c_t}$$

where t is expressed in hours, c_0 represents the initial concentration and c^t that at time *t*.

---

[5] Pfeiffer, *Ber.*, 38, 1926 (1903).

TABLE I

A TYPICAL EXPERIMENT

Time, hours	Wt. ppt., g. of $Cr(NH_2CONH_2)_6Co(CN)_6$		$k \times 10^5$
0	0.1575		...
46.3	.1154		672
71.9	.0961		687
120.1	.0691		681
144.1	.0602		668
168.2	.0509		669
102.1	.0434		671
		Average	674
		Av. dev.	0.9%

Table I shows that the disappearance of the chromium urea ion follows a unimolecular law. Table II gives a summary of the results of similar experiments carried out in the presence of potassium nitrate.

TABLE II

VELOCITY AT DIFFERENT SALT CONCENTRATIONS

$Cr(NH_2CONH_2)_6^{+++}$ 0.0025 M in all experiments; HNO_3 0.001 M

KNO_3, moles per liter	$k \times 10^5$	KNO_3, moles per liter	$k \times 10^5$
0	669	0 100	667
0.025	662	.150	G67
.050	674	.200	G58

From Table II it is evident that if there is any salt effect it is within the experimental error of the measurements (less than 2%). If the reaction rate were correctly expressed by the formula

$$V = k\, a_A a_B$$

the velocity constant would have decreased to approximately one-fourth its original value as the equivalent salt concentration increased from 0.0075 to 0.2075.[5a] My results are in direct contradiction to the activity rate theory and furnish substantial support to the Bronsted formula.

It is interesting to note that while the magnitude of the primary salt effect in this case is within the experimental error of the measurements, there are instances where the salt effect for this type of reaction is of considerable magnitude even in dilute solution. In the decomposition of nitrosotriacetonamine by hydroxyl ion the effect is about 7% in 0.1 N salt solution.[6,7] For the diazo-acetic ester reaction catalyzed by hydrogen ion the effect is 14% in 0.1 N salt solution.[8] For the mutarotation of glucose'the salt effect is again within the experimental error

---

[5a] This estimate is based upon the change in the activity coefficient of a trivalent ion calculated from the solubility measurements of luteo hexacyano cobaltiate in potassium chloride solutions [Brönsted and Petersen, THIS JOURNAL, 43, 2265 (1921)].

[6] Bronsted and King, THIS JOURNAL, 47, 2523 (1925).

[7] Kilpatrick, *ibid.*, 48, 2091 (1926).

[8] Bronsted and Duus, *Z. physik. Chem.*, 117, 299 (1925).

of the measurements.[9] Other examples are given by Brönsted.[10] For hydrogen-ion catalysis the salt effect is positive and for hydroxyl-ion catalysis negative. In all cases the effect is linear in dilute solution and consequently cannot depend on the activity of the reacting ion.

The author wishes to thank Professor J. N. Bronsted for many valuable suggestions.

Summary

1. A kinetic study has been made of a zero type reaction in which the reacting ion is trivalent.

2. The reaction serves as a critical test of the activity rate theory and the Bronsted formula. The results are in agreement with the Brönsted formula.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. VI THE ELECTRIC MOMENTS OF CERTAIN NITRO DERIVATIVES OF BENZENE AND TOLUENE

BY JOHN WARREN WILLIAMS AND CHRISTIAN H. SCHWINGEL

RECEIVED NOVEMBER 4, 1927 PUBLISHED FEBRUARY 4, 1928

Measurements of the dielectric constants of binary mixtures in which the first component, the solvent, is known to have no electric moment permit a calculation of the molar polarization, and therefore of the electric moment, of the second component. This calculation has been detailed in a number of places.[1,2,3] The purpose of this paper is to present dielectric constant and density data for solutions of a number of nitro derivatives of benzene and toluene in the non-polar solvent benzene, with the results of the calculations for the electric moments of the solute molecules.

The method used for the determination of the dielectric constants of the binary mixtures was given in the first paper of the series.[4] Their densities were determined by means of an Ostwald-Sprengel pycnometer. Both dielectric constant and density determinations were made at 25°; in every case the usual precautions for precision work were taken.

Purification of Materials

All substances used for the measurements reported were purified by the usual methods of crystallization or distillation or both. With the exception of the solvent, benzene, an outline of the method of purification for each particular substance used will not be given. These substances are tabulated with their melting points as determined by means of thermometers calibrated by the U. S. Bureau of Standards, and the method of purification used is indicated.

Benzene.—The benzene, obtained in a thiophene-free condition from the Eastman Kodak Company, was frozen out twice. After drying with phosphorus pentoxide it was fractionally distilled; boiling point (760 mm.) 80.10-80.20°.

Substituted Benzene Compounds

TABLE OF MELTING POINTS OF MATERIALS

Compound	Melting point, °C.	Compound	Melting point, °C.
Mononitrobenzene[a]	5.1– 5.4	*sym.*-Trinitrobenzene[b]	121.1–122.3
o-Dinitrobenzene[b]	116.0–116.5	o-Nitrotoluene[c]	–10.6––10.9
m-Dinitrobenzene[b]	89.0– 89.5	*m*-Nitrotoluene[c]	15.5– 16.0
p-Dinitrobenzene[b]	171.5–172.0	*p*-Nitrotoluene[b]	52.2– 52.9

[a] Purified by fractional crystallization and distillation.

[b] Purified by recrystallization from benzene.

[c] Purified by distillation.

Results

The results of the experimental determinations are given in Table I. The columns of this table give, from left to right, the mole fraction of the benzene which was used as the solvent, M. F. C_6H_6; the density of the solution, d_4^{25}; the observed dielectric constant, ϵ; the molar polarization of the solution, $P_{1,2} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{f_1M_1 + f_2M_2}{d} = f_1P_1 + f_2P_2$; and the molar polarization of the second component, $P_2 = \frac{P_{1,2} - f_1P_1}{f_2}$.

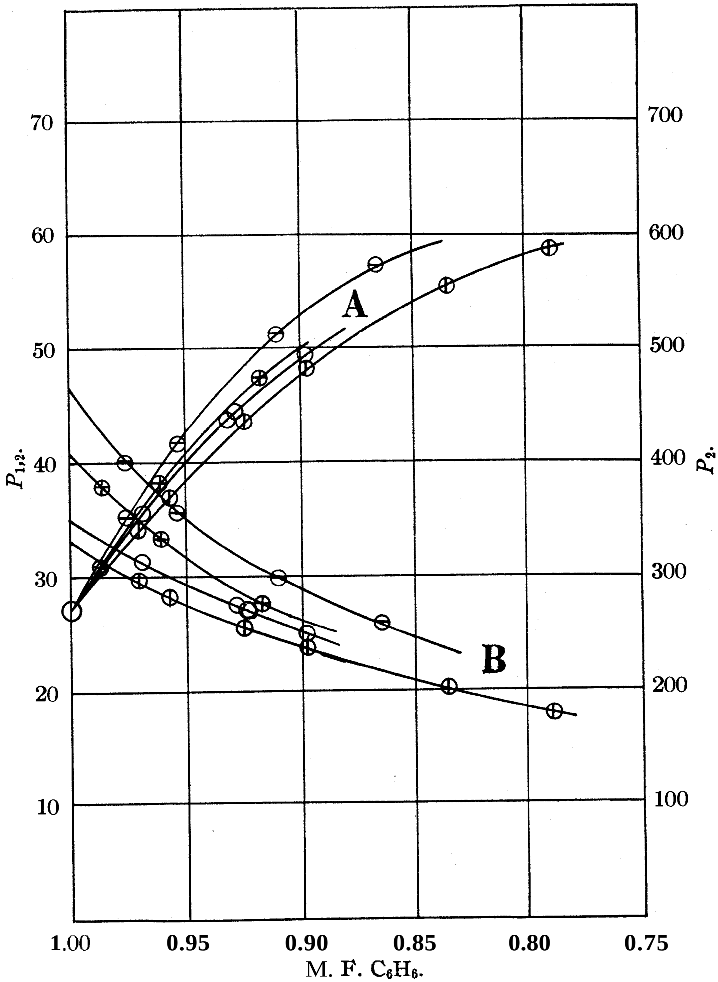
[b] Correct to ±0.004.

In Fig. 1 are presented curves showing, first, the molar polarization of the solution plotted against the mole fraction of the solvent and, second, the molar polarization of the solute molecule plotted against the mole fraction of the solvent for mononitrobenzene and the nitrotoluenes. The latter curves are important in that they show exactly the manner in which the molar polarization of the second component, P_2, in infinitely dilute solution in the non-polar solvent is obtained. The molar polarization values of the second component for dilute solutions of finite concentration, obtained from the expression, $P_2 = (P_{1,2} - f_1P_1)/f_2$, are extrapolated to infinite dilution in the manner indicated. The curves for the other solute molecules are similar in all respects and have not been included.



⦶—*o*-Nitrotoluene, ⊕—*m*-nitrotoluene, ⊖—*p*-nitrotoluene, 0—mononitrobenzene; A—$P_{1,2}$ curves. B—P_2 curves.

Fig. 1.

Calculation of the Electric Moments of the Solute Molecules

The calculations of the electric moments of the various solute molecules were made in the manner described in a previous article,[3] and making like assumptions. The results of these calculations are given in Table II. The symbols used in the earlier article have been retained throughout.

TABLE II

ELECTRIC MOMENTS OF SOLUTE MOLECULES AT 25°

Molecule	P_a	P_2''	P_2'	$a \times 10^{18}$
Mononitrobenzene	348	33	315	3.90

m-Nitrotoluene	407	38	369	4.20
p-Nitrotoluene	463	38	425	4.50

Discussion

The solute molecules were so chosen that the effect of the introduction of similar and dissimilar groups on the electric moment of the compound could be studied. Within the last two years data have accumulated so that the effect produced may be compared with the results of others. For example, Errera[5] has determined the electric moments of the various dichloro-, dibromo- and di-iodobenzenes, that is, benzene derivatives containing like atoms in various positions in the molecule. Smyth and Morgan[6] have also presented the results of experimental work and calculations for the dichlorobenzenes. Of the molecules studied in this article the dinitrobenzenes should show changes similar to those of the dichloro-, dibromo- or di-iodobenzenes. It is also possible to compare the results obtained for the nitrotoluenes, derivatives of benzene containing one positive and one negative group, with the calculations of Smyth and Morgan for the cresols.

For purposes of comparison Table III has been prepared. It is at once apparent that the changes produced in the electric moments of the molecules reported in this article parallel very closely the effects found by Smyth and Morgan,[6] not only in the case where similar atoms or groups of atoms are substituted in the benzene ring, but also in the case where dissimilar ones are substituted. And in the same manner that the moments of the various disubstituted compounds were calculated from vectorial considerations by these authors, it is possible to calculate the moments of the various dinitrobenzenes and nitrotoluenes, making use of the values $\mu = 3.90 \times 10^{-18}$ e.s.u. for nitrobenzene, and $\mu = 0.40 \times 10^{-18}$ e.s.u. for toluene.[7] The results of such calculations show an agreement with the experimentally determined values of the same order of magnitude

[6] Smyth and Morgan, THIS JOURNAL, 49, 1030 (1927).

[7] Krchma and Williams, *ibid.*, 49, 2408 (1927).

as that shown by Smyth and Morgan. In this connection an article by J. J. Thomson[8] is also of interest.

TABLE III

COMPARISON OF ELECTRIC MOMENT DATA

Smyth and Morgan		Williams and Schwingel	
Substance	$\mu \times 10^{18}$	Substance	$\mu \times 10^{18}$
C_6H_5Cl	1.61	$C_6H_5NO_2$	3.90
o-$C_6H_4Cl_2$	2.30	o-$C_6H_4(NO_2)_2$	6.05
m-$C_6H_4Cl_2$	1.55	m-$C_6H_4(NO_2)_2$	3.81
p-$C_6H_4Cl_2$	0	p-$C_6H_4(NO_2)_2$	0.32
C_6H_5OH[a]	1.73	$C_6H_5NO_2$	3.90
o-$CH_3C_6H_4OH$[a]	1.54	o-$CH_3C_6H_4NO_2$	3.75
m-$CH_3C_6H_4OH$[a]	1.76	m-$CH_3C_6H_4NO_2$	4.20
p-$CH_3C_6H_4OH$[a]	1.81	p-$CH_3C_6H_4NO_2$	4.50

[a] Calculated by Smith and Morgan from data of Philip and Haynes, *J. Chem. Soc.*, 87, 998 (1905).

The value of the moment found for symmetrical trinitrobenzene, $\mu = 1.08 \times 10^{-18}$ e.s.u., is, without doubt, too high. The same thing may be said of the value found for *p*-dinitrobenzene. From theoretical considerations zero values should have resulted. Owing to the limited solubility of these substances in benzene, the method of calculation becomes less accurate, so that the values obtained must be considered as being indistinguishable from zero.

Höjendahl, in a brief note to *Nature*,[9] has published the results of an experimental study in which the electric moments of a number of substituted benzene molecules are tabulated. In several cases a direct comparison between the results of Höjendahl and those of this article may be made. This comparison is given in Table IV.

TABLE IV

COMPARISON OF ELECTRIC MOMENT DATA

Molecule	$\mu \times 10^{18}$ (Williams and Schwingel)	$\mu \times 10^{18}$ (Höjendahl)
o-Dinitrobenzene	6.05	5.95
m-Dinitrobenzene	3.81	4.02
p-Dinitrobenzene	0.32	0.80
o-Nitrotoluene	3.75	3.62
p-Nitrotoluene	4.50	4.30

Since Hojendahl has taken the value $\mu = 3.75 \times 10^{-18}$ e.s.u. for the nitrobenzene molecule from the results of earlier work[1] and since the dielectric constant data were obtained with apparatus standardized using the data from which this value was calculated,[10] it would be expected that his results would be consistently lower than the ones reported in this

---

[8] Thomson, *Phil.* Mag., 46, 513 (1923).

[9] Hojendahl, *Nature*, 117, 892 (1926).

[10] Conversation with Dr. Höjendahl

article, all of which are based on absolute measurements,[4] and which give a value, $\mu = 3.90 \times 10^{-18}$ e.s.u., for nitrobenzene in benzene solution. On this basis the results for o-dinitrobenzene and the nitrotoluenes must be virtually in agreement. In the case of the *p*-dinitrobenzene inaccuracies in the method of calculation which has to be employed will probably account for the high electric moment, $\mu = 0.80 \times 10^{-18}$ e.s.u., obtained by Höjendahl. Its value should approach zero.

The value obtained for m-dinitrobenzene, on the basis of the reasoning given above, is not in agreement with that reported in this article.

Höjendahl[10] has more recently repeated the measurements on the system benzene-m-dinitrobenzene, giving a value $\mu = 3.70 \times 10^{-18}$ for *m*-dinitrobenzene, one which is substantially in agreement with that presented in this article.

Summary

1. Dielectric constant and density data at 25° have been obtained for benzene solutions of nitrobenzene, o-, m- and p-dinitrobenzene, symmetrical trinitrobenzene and o-, m- and *p*-nitrotoluene.
2. The data have been applied to the calculations of the electric moments of the various solute molecules.
3. The results of these calculations have been critically discussed. In a number of cases they have been compared with the results of other investigators. They are in agreement with the physical basis provided by Errera, Smyth and Morgan, Thomson, and others, for the determination of the positive or negative character of the benzene substituents.

A NEW METHOD FOR SEPARATING ARSENIC FROM ANTIMONY

BY LEROY W. MCCAY

RECEIVED NOVEMBER 8, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

The conversion of arsenic into arsenic acid according to Reich and Richter,[1] its precipitation as silver arsenate and the calculation of the arsenic from the weight of the salt, or the amount of silver in it, have been studied by Pearce and Low,[2] McCay[3] and, comparatively recently, by Eschweiler and Rohrs.[4]

---

[1] Post, "Chemisch-Technische Analyse," Vieweg and Son, Braunschweig, 1881, p. 396; see also Dingler's *Polyt. Journ.*, 50, 475 (1883).

[2] Pearce and Low, *Chem. News*, 48, 85 (1883).

[3] McCay, *ibid.*, 48, 7 (1883); *Am. Chem. J.*, 8, 77 (1886).

[4] Eschweiler and Rohrs, *Z. angew. Chem.*, 36, 464 (1923).

When a *hydrofluoric* **acid** solution of arsenic acid is neutralized with ammonium or potassium hydroxide, and silver nitrate added to it, all of the arsenic is immediately precipitated as silver arsenate.

Antimonic acid and its alkali salts dissolve readily and completely in warm, moderately dilute hydrofluoric acid, and the solutions can be diluted indefinitely with water without becoming turbid. Such solutions yield no precipitates when neutralized or made alkaline with ammonium or potassium hydroxide. A neutral solution of an alkali antimoniate gives with silver nitrate a white, curdy precipitate of silver antimoniate. If, however, the solution be made strongly acid with hydrofluoric acid and then neutralized, the addition to it of silver nitrate forms no precipitate, if the materials and reagents are free from chlorides. The resulting solution is perfectly clear, and remains so permanently. Antimony pentafluoride is an extremely stable compound, so stable, indeed, that its aqueous solution, providing a little free hydrofluoric acid be present, undergoes no change, or a very sluggish one, when treated with hydrogen sulfide,[5] a fact used in testing antimonic acid for trivalent antimony. On the difference in the behavior of neutralized hydrofluoric acid solutions of arsenic and antimonic acids toward silver nitrate I have based a very satisfactory method for separating arsenic from antimony.

Experimental Part

A solution of dihydrogen potassium arsenate was made up by dissolving 12 g. of the salt in two liters of water, and the arsenic in 25 cc. was determined (1) by the pentasulfide[6] and (2) by the Reich-Richter method (Pearce-Low modification); found according to (1) 0.0631 and 0.0632 g. As, and according to (2) 0.0628 and 0.0630 g. The average of the four results is 0.0630 g. In a sample of crystalline potassium acid pyroantimonate tetrahydrate quite free from arsenic, the antimony was determined by dissolving a convenient amount in a small platinum dish in about 25 cc. of hot dilute nitric acid to which 2–3 cc. of 48% hydrofluoric acid had been added.[7] The solution was transferred to a 400cc. quartz dish, diluted somewhat, 10–15 cc. of concd. sulfuric acid was added to it, the liquid was evaporated as far as possible on the water-bath and then heated carefully[8] for a few minutes to strong fuming over a free flame. To reduce the antimony to the trivalent state, a piece of sulfur weighing

[5] McCay, THIS JOURNAL, 31, 374 (1909); Furman, *Ind. Eng. Chem.*, 15, 1073 (1923), footnote.

[6] McCay, ***Am. Chem. J.*, *9*, *174*** (1887).

[7] Nitro-hydrofluoric acid is the best of solvents for tin and antimony and their alloys [McCay, THIS JOURNAL, 36, 2375 (1914)].

[8] Just before the acid begins to fume there is a slight effervescence, due probably to the decomposition of the fluorides. Owing to the size of the dish, however, there is little danger of loss.

about 2 g. was now dropped into the dish, it was covered and the acid heated to gentle boiling for twenty minutes. In the main

$$\mathrm{Sb_2O_5 + 2SO_2 = Sb_2O_3 + 2SO_3}$$

When cold, 100 cc. of dilute hydrochloric acid (20 cc. concd. HCl to 80 cc. of H_2O) was poured into the dish, the sulfur was filtered off, the volume of the filtrate brought to 200 cc. and the antimony determined with a 0.1 N $KMnO_4$ solution (Kessler),[9] or a 0.1 N $KBrO_3$ solution (Gyory).[10] Both solutions were standardized against purest antimony. The average of four closely agreeing results obtained by the former method was 47.95%, the average of two by the latter 47.96%. Of the two methods that of Gyory is the more reliable.

Weighed amounts of the pyro salt were dissolved as above directed in a platinum dish holding comfortably 250 cc., known volumes of the standard solution of the potassium arsenate run in, the volume in each case was brought to 100 cc. and the solution neutralized as follows: a drop of methyl orange was added and strong ammonia dropped in until every trace of pink had disappeared; the liquid was of a pure gold color and faintly but distinctly alkaline to sensitive litmus paper. The solution was then heated to boiling and the arsenic precipitated as silver arsenate with silver nitrate in slight excess. After long and vigorous stirring with a platinum spatula, tied to the end of a short stick, so as to coagulate the precipitate and cause it to settle completely, the clear supernatant liquid was tested with a piece of sensitive litmus paper. When not distinctly alkaline, a few drops of dilute ammonia (1 vol. concd. NH_4OH solution to 4 vols. H_2O) were added until the paper became decidedly blue and a single drop produced in the clear supernatant liquid no trace of turbidity. No precipitation of silver oxide is possible.[11] This method of neutralizing the solution is more reliable than that of Bennett.[12] His solutions contained no antimony and, of course, no hydrofluoric acid.

Silver arsenate is slightly soluble in water. According to G. S. Whitby,[13] 100 g. of water at 20° dissolves 0.00085 g. of the salt. According to my experiments, 100 g. of water at laboratory temperature dissolves 0.0013 g. (average of four well agreeing determinations). In water containing *silver nitrate*, even when ammonium nitrate or sulfate is present and the solution is decidedly ammoniacal, the solubility of the salt is practically negligible.

When cold, the silver arsenate was transferred to a filter paper, or Neubauer crucible, and washed with water containing ammonium nitrate

and a little silver nitrate (5. g. of NH_4NO_3 and 0.25 g. of $AgNO_3$ per liter). The amount of silver nitrate adhering to the well-drained precipitate is so small that it may be disregarded. For safety's sake, however, it may be removed with a little alcohol, the washings being rejected, as they contain no antimony. The precipitate was finally dissolved in nitric acid and the silver determined according to Volhard. The filtrate was caught in a Pyrex flask or beaker and, after the removal of the silver with a minimum amount of hydrochloric acid, poured into the large quartz dish, 10–15 cc. of concd. sulfuric acid was added and the evaporation, reduction and titration were carried out as already directed. Both arsenic and antimony being determined volumetrically, no errors can be caused by the entrance into the solutions of materials dissolved from the glass funnels, flasks, etc.

TABLE I

SEPARATION OF ARSENIC AND ANTIMONY

As taken (as H_2KAsO_4), g.	As found, g.	Antimony taken (as $H_2K_2Sb_2O_7 + 4H_2O$), g.	Antimony found, g.
0.0630	0.0630	0.1932	0.1933
.0630	.0629	.1514	.1516
.0630	.0628	.1201	.1205
.0630	.0630	.1105	.1104
.0630	.0631	.1404	.1405
.0252	.0251	.0960	.0958
.0252	.0252	.0965	.0973

The antimony was determined by titration with potassium permanganate.

While arsenic is converted into its higher state of oxidation with ease, the complete oxidation of antimony to its quinquivalent condition takes place with difficulty.[14] The product left on treating antimony with hot fuming nitric acid in large excess always contains some of the element in the trivalent condition. Concentrated hydrochloric acid and potassium chlorate, permanganic and chromic acids cannot for obvious reasons be employed here. My experience has been that potassium persulfate is the best reagent for effecting a complete oxidation. This fact having been established by a large number of qualitative experiments, 1.983 g. of pure antimony was dissolved in a platinum dish in 50 cc. of hot nitro-hydrofluoric acid, prepared by mixing 40 cc. of dilute nitric acid (1:4) with 5 cc. of 48% hydrofluoric acid. The resulting solution was diluted to about 100 cc., most of the free acid neutralized with ammonia, the liquid heated to gentle boiling and 6 g. of potassium persulfate added in small portions at a time. During the boiling the dish was kept covered with a quartz clock glass. When cold, the solution was neutralized with ammonia and diluted to 500 cc.; found, in 25 cc., 0.0994 g. of

---

[14] Bošek, *Trans. Chem. Soc.*, 1895, p. 515; Hoffman, *Inaug. Dissert.*, Berlin, 1911.

Sb. By Rose's test[15] not a trace of trivalent antimony could be detected in it. With this standard solution[16] and that of the dihydrogen potassium arsenate used in the first series of separations the results given in Table II were obtained. To the mixture of convenient amounts of the two solutions a few drops of nitric acid and 2–3 cc. of hydrofluoric acid were added and the separations and determinations carried out as above directed.

TABLE II

SEPARATION OF ARSENIC AND ANTIMONY

As taken, g.	As found, g.	Sb taken, g.	Sb found, g.
0.0504	0.0507	0.0994	0.0993
.0504	.0508	.0994	.0993
.0252	.0253	.0994	.0996
.0126	.0124	.0994	.0994
.0126	.0126	.0994	.0997

The antimony was determined by titration with potassium bromate. Since dilute solutions of ammonium fluoride made slightly alkaline seem to have but slight action on Pyrex glass a number of separations were made in Pyrex beakers. The filtrates from the silver arsenate after removing the silver were evaporated in the large quartz dish. Although this dish has been used in a large number of determinations the inner surface still retains its highly pearly luster.

TABLE III

SEPARATION OF ARSENIC AND ANTIMONY IN PYREX GLASS

As taken, g.	As found, g.	Sb taken, g.	Sb found, g.
0.0630	0.0635	0.0994	0.0997
.0504	.0503	.0994	.0997
.0252	.0254	.0994	.0998

A mixture of 0.1026 g. of arsenious oxide and 0.1203 g. of potassium acid pyroantimonate tetrahydrate was dissolved and the arsenic and antimony were precipitated with hydrogen sulfide. The sulfides were treated in a platinum dish with fuming nitric acid, most of the acid was evaporated off, 2 cc. of hydrofluoric acid and a little water were added, the solution was warmed until clear and diluted to 100 cc. After oxidizing the antimony completely to the quinquivalent state with potassium persulfate, the separation of the two elements was made as directed: As taken (as As_2O_3) 0.0777 g.; As found, 0.0780 g.; Sb taken (as $H_2K_2Sb_2O_7 + 4H_2O$), 0.0577 g.; Sb found, 0.0579 g.

---

[15] Fresenius, "Qualitative Chemical Analysis," John Wiley and Sons, Inc., New York, 1921.

[16] It was kept in a Pyrex flask. At the end of a month the liquid left was perfectly clear and the antimony concentration had not changed. A small, transparent, gelatinous deposit proved to be potassium silicofluoride.

If a mixture of the sulfides of arsenic, antimony and tin is to be examined, it is best dissolved in a small platinum or quartz dish in boiling concd. sulfuric acid, a piece of pure sulfur being dropped into the dish to yield sulfur dioxide which reduces the arsenic and antimony to the trivalent condition. After diluting the solution, adding hydrofluoric acid and filtering into a large platinum dish, the arsenic and antimony are reprecipitated with hydrogen sulfide and separated as above directed. The tin remains in solution and may be determined by any one of the methods proposed by McCay[17] and by Furman.[18] A mixture of the sulfides of arsenic, antimony and tin of known composition was analyzed: As taken, 0.0768 g.; As found, 0.0771 g.; Sb taken, 0.1208 g.; Sb found, 0.1215 g.; Sn taken, 0.2014 g.; Sn found, 0.2013 g.

Summary

1. From a hydrofluoric acid solution of arsenic and antimonic acids, made weakly but distinctly alkaline with ammonia, silver nitrate in excess precipitates completely the arsenic as silver arsenate, quite free from antimony.
2. The amount of arsenic is found by dissolving the precipitate in nitric acid and determining the silver in it by the method of Volhard.
3. The filtrate from the silver arsenate, after removing the silver with a minimum amount of hydrochloric acid, is mixed with concentrated sulfuric acid and evaporated, the acid heated to strong fuming, boiled gently in the presence of a piece of sulfur and the antimonous acid titrated with potassium permanganate or potassium bromate according to the details given.

THE OXIDATION STATES OF RUTHENIUM IN ITS HALIDE COMPOUNDS

BY WILLIAM R. CROWELL AND DON M. YOST

RECEIVED NOVEMBER 10,1927 PUBLISHED FEBRUARY 4, 1928

Introduction

In order to interpret the results of an investigation on the catalytic reduction of perchloric acid by hydrobromic acid,[1] and to make more complete the tables of reactions given in "Qualitative Analysis for the Rare Elements" by A. A. Noyes and W. C. Bray,[2] accurate information was needed as to the chemistry of ruthenium in its lower states of oxidation; for the literature on the nature and properties of the quadri-, tri- and bivalent compounds is not consistent. The experiments described in this paper were therefore carried out with the view of helping to remove the uncertainty as to the states of oxidation of ruthenium in its halide compounds.

We wish to express here our appreciation of the helpful suggestions made by Professor A. A. Noyes. Financial assistance was received through a grant made to him by the Carnegie Institution of Washington.

A review of the previous work has recently been published by J. L. Howe.[3] It will suffice therefore to mention here only those researches directly related to our investigation.

A series of experiments carried out by Ruff and Vidic[4] shows that ruthenium tetroxide is reduced completely by potassium iodide in normal acid to the trivalent state and no further; and that, when 2 N hydrobromic acid is used as the reducing agent, the reduction products consist of ruthenium in both the tri- and quadrivalent states, the proportions of each depending on the experimental conditions. Their results show, however, that even with hot concentrated hydrochloric acid trivalent ruthenium is produced only very slowly.

Under the belief that solutions of trivalent ruthenium chloride resulted from the action of hydrochloric acid, Remy and Wagner[5] obtained with sodium amalgam results which they interpreted as indicating that the deep blue compounds of ruthenium contain the metal in the univalent state, contrary to the prevailing idea that they are bivalent. Zintl and Zaimis[6] arrived at the same conclusion when they found that a small

excess over one equivalent of titanous sulfate or chromous sulfate produced a deep blue color in solutions which they believed to contain the ruthenium as a trivalent chloride. By reducing a ruthenium chloride and bromide dissolved in absolute alcohol with hydrogen in contact with platinum black, Gall and Lehmann[7] obtained deep blue solutions, from which on evaporation solid compounds resulted whose composition was found to correspond to the formulas $RuCl_2$ and $RuBr_2$. Zintl and Zaimis accounted for these compounds by assuming them to be $HRuCl_2$ and $HRuBr_2$; but the fact[8] that such compounds of other univalent metals are very unstable makes this assumption improbable.

Another source of confusion has arisen from the fact that until recently two distinct types of pentachlorosalts of trivalent ruthenium were believed to exist and were given the formulas $M_2RuCl_5.H_2O$ and $M_2Ru(H_2O)Cl_5$. Howe, however, as a result of the work of Charonnat[9] and recent experiments of his own, now considers that the formulas of these salts are $M_2RuCl_5.H_2O$ and M_2RuCl_5OH; that is to say, that the ruthenium in those compounds exists in the trivalent and quadrivalent states, respectively. It should be mentioned that S. G. C. Briggs[10] is not in aggreement with these conclusions.

Plan of the Investigation

The general plan of the investigation was as follows:

(1) To confirm the results of Ruff and Vidic that ruthenium is reduced by iodide in an acid solution to the trivalent state. This was done by determining the number of equivalents of iodine liberated in an acid solution of potassium iodide by the ruthenium tetroxide obtained by distilling with potassium permanganate a known volume of a stock solution of ruthenium chloride which had been evaporated with sulfuric acid to dense white fumes.

(2) To study the states of oxidation of ruthenium in the solution of its chloride obtained by dissolving in hydrochloric acid an hydroxide prepared by the reduction of potassium ruthenate with ethyl alcohol by the method of Krauss and Kiikenthal. This was done by determining the number of equivalents of iodine liberated in a hydrochloric acid solution of potassium iodide by known volumes of the ruthenium chloride solution before and after chlorination.

(3) To determine the states of oxidation of ruthenium produced by reduction of unchlorinated and chlorinated chloride solutions with titanous sulfate, especially its state in the yellow and deep blue solutions obtained successively with this reagent. This was done by making a potentiometric

titration of a known volume of the chloride solution with titanous sulfate, noting the number of equivalents of titanium required to produce a marked inflection in the titration curve and also the number of equivalents required to produce the yellow and blue colors in the solution.

(4) To study in ways similar to those described in (2) and (3) a salt of ruthenium bromide prepared by digesting the chloride with bromine and hydrobromic acid and evaporating the solution with potassium bromide.

Preparation of Standard Ruthenium Solutions

Stock solutions of ruthenium chloride were made by heating for five minutes just below the boiling point with concentrated hydrochloric acid an hydroxide which had been prepared by the reduction of potassium ruthenate with ethyl alcohol as described by Krauss and Kükenthal.[11] It was found that the hydroxide would not dissolve completely even on continued heating, but left a small black residue, which was filtered off. The concentration of the ruthenium was determined by evaporating definite volumes of the stock solution to dryness and igniting the residue in a stream of hydrogen, whereby the ruthenium is converted to the metallic state.

Reduction of Ruthenium Tetroxide by Iodide to the Trivalent State

Since the conclusion that ruthenium is reduced by iodide to the trivalent state is the basis of the following work, it seemed desirable to confirm the results of Ruff and Vidic to this effect. For this purpose a definite volume (5.00 cc.) of the stock solution of ruthenium chloride was evaporated with sulfuric acid till dense white fumes appeared; 10 cc. of water was added, followed by 20 cc. of a solution containing 1 g. of potassium permanganate, and the resulting mixtures were distilled in a current of carbon dioxide.[12] The distillate containing the ruthenium as tetroxide was absorbed in a 2 N hydrochloric acid solution containing potassium iodide. The liberated iodine was determined with standard thiosulfate. The results are given in Table I.

TABLE I

RESULTS OF THE DISTILLATION EXPERIMENTS

Cc. of Ru solution (0.01475 atomic)	Cc. of 0.0509 *N* thiosulfate Required	Cc. of 0.0509 *N* thiosulfate Calcd. for five equivalents	Atoms of iodine liberated per atom of Ru
5.00	7.10	7.25	4.90
5.00	7.24	7.25	4.99
5.00	7.17	7.25	4.95

---

[11] Krauss and Kükenthal, *Z. anorg. allgem. Chem.*, 132, 316 (1924).

[12] This distillation process may also be used for the preparation of ruthenium tetroxide and is far more satisfactory for this purpose than any of the other known methods (see Ruff and Vidic, Ref. 4).

Reduction of Ruthenium by Iodide in Solutions of its Chloride

A definite volume (5.00 cc.) of a stock solution of ruthenium chloride 0.0295 atomic in ruthenium was diluted with enough water and hydrochloric acid to make the final acid concentration 2 N and the volume 100 cc.; 1 g. of potassium iodide was added and the liberated iodine was titrated with 0.0487 *N* thiosulfate, using starch as the indicator. Of the thiosulfate 0.76 cc. was used, while 3.03 cc. would have been required if the ruthenium had all been in the quadrivalent state. This shows that the ruthenium hydroxide prepared according to Krauss and Kükenthal contains a considerable proportion of quadrivalent ruthenium.

Chlorine was bubbled slowly for five minutes through two other 5.00-cc. portions of the stock solution in 100 cc. of 2 N hydrochloric acid, the excess of chlorine was expelled by boiling, 1 g of potassium iodide was added and the liberated iodine was determined as before.[13] Typical results are given in Table II.

TABLE II

IODIMETRIC TITRATION OF. RUTHENIUM CHLORIDE SOLUTIONS

Expt.	Cc. of Ru soln. (0.0295 atomic)	Cc. 0.0487 *N* $Na_2S_2O_3$ Unchlorinated soln.	Chlorinated soln.	Calcd. for one equivalent
1	5.00	0.76	..	3.03
2	5.00	..	3.02	3.03
3	5.00	..	3.10	3.03

The color of the unchlorinated solutions was light orange-red; that of the chlorinated solutions, dark orange-red.

These results show that in the chlorinated solution the ruthenium is all in the quadrivalent state, and that the acid solution of the hydroxide contains both trivalent and quadrivalent ruthenium.

Titration of Ruthenium Solutions with Titanous Sulfate

Measured volumes (5.00 cc.) of a stock solution 0.0148 atomic in ruthenium were diluted with enough water and hydrochloric acid to make the volume 50 cc. and the acid concentration 2 *N;* these solutions were titrated electrometrically in an atmosphere of carbon dioxide with a 0.0222 N titanous sulfate solution. The points where a rapid change in potential occurred are shown in Table III.

TABLE III

ELECTROMETRIC TITRATIONS OF RUTHENIUM SOLUTIONS WITH TITANOUS SULFATE

Expt.	Temp., C.	Cc. of Ru soln., 0.0148 atomic	Cc. of Ti^{III} soln., 0.0222 atomic Unchlorinated soln.	Chlorinated soln.	Calcd. for one equivalent
1	25	5.00	1.10	..	3.33
2	25	5.00	..	3.30	3.33
3	80	5.00	..	3.22	3.33

---

[13] The possibility that RuO_4 might be present in the chlorinated mixtures is precluded by the concentration of the hydrochloric acid and the treatment by heating.

The electrometric titration curves corresponding to the experiments given in the table are shown in Fig. 1. A sharp break in the curves occurs when one equivalent of titanous salt is added to the chlorinated solution. In the case of the unchlorinated solution the break occurs when about one-third of an equivalent is added. No further breaks of a reproducible nature were observed in the curves, although several equivalents of titanous sulfate were always added.

The curves resulting from the titration of the cold mixtures are similar to that shown by Zintl and Zaimis. The color changes observed during the titration with titanous sulfate were practically the same as those described by them. At first the solutions are dark orange-red (if previously chlorinated). When nearly one equivalent of the reducing agent has been added the color becomes bright yellow. After passing the end-point the color changes rapidly through olive green to dark blue; and this blue color persists even after several equivalents have been added. In the solutions heated to 80° a small dark precipitate formed.

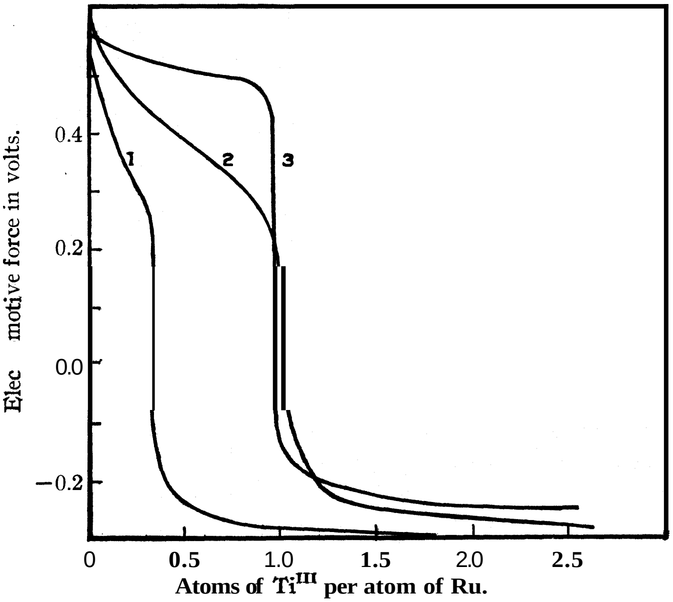

Fig. 1.—Electrometric titrations. Curve 1, unchlorinated solution at 25°; Curve 2, chlorinated solution at 25°; Curve 3, chlorinated solution at 80°.

These results clearly show that the sudden change in potential occurs when all of the quadrivalent ruthenium has been reduced, that is, at the transition from the trivalent to the bivalent state, and not at the transition from bivalent to univalent as concluded by Zintl and Zaimis, and that, therefore, in all probability, the blue color is characteristic of bivalent, not univalent, ruthenium as had been considered to be the case previous to the work of these investigators. In the case of the unchlorinated solution, the break in the curve confirms our conclusion, drawn from the iodimetric titrations, that quadrivalent ruthenium is present.

Preparation and Behavior of a Bromide Salt of Quadrivalent Ruthenium

It was found that when ruthenium chloride solutions containing moderate amounts of hydrobromic acid are heated with bromine a crimson solution results after the excess of bromine has been expelled. On treating these solutions with a small excess of potassium bromide and evaporating in a vacuum desiccator containing sulfuric acid and solid sodium hydroxide a black crystalline residue results. This residue was washed with water and alcohol and dried in the desiccator again. The product thus obtained was analyzed for bromine, potassium bromide and ruthenium as follows. A weighed amount was ignited in a stream of hydrogen, the hydrobromic acid liberated was absorbed in acidified silver nitrate solution and the resulting silver bromide dried and weighed. The potassium bromide remaining in the residue after ignition was extracted with water and the bromide in the extract was determined as silver bromide. Finally, the residue of ruthenium remaining after the extraction was ignited in a stream of hydrogen and then weighed as the metal. The salt was found to have the following percentage composition.

	Ru	KBr	Br (liberated as HBr)
Found, %	17.03	38 29	40 25
Calcd. for K_2RuBr_5OH, %	17 05	39 91	40 20

This is probably the same salt that Howe described originally[14] as $K_2RuBr_5.H_2O$, but which he now considers[3] to be K_2RuBr_5OH. The results given here are in accord with this conclusion but care must be exercised in drawing conclusions from the results of the analysis alone, for the calculated composition of the salt $K_2RuBr_5H_2O$ would also be in good agreement with the analytical results.

To determine to which of these formulas the behavior of the salt corresponds, its power of oxidizing iodide was studied. A solution of the salt was made up by dissolving a weighed amount in 2 N hydrochloric acid and diluting to a definite volume with more acid of the same concentration. Measured volumes of this solution were diluted to 100 cc. with 2 N hydrochloric acid, potassium iodide was added and the liberated iodine was titrated with standard thiosulfate. The results are presented in Table IV. They clearly show that in the bromide the ruthenium is in the quadrivalent state, thus eliminating the possibility that the salt is $K_2RuBr_5.H_2O$.

[14] Howe, THIS JOURNAL, 26, 944 (1904).

TABLE IV

IODIMETRIC TITRATIONS OF THE BROMIDE SALT

Expt.	Cc. of Ru soln., 0.00742 atomic	Cc. of 0.0500 *N* thiosulfate Used	Calcd. for one equivalent
1	10.00	1.40	1.48
2	20.00	2.95	2.96
3	25.00	3.65	3.70

Known volumes of the same stock solution were also titrated electrometrically with standard titanous sulfate solution, both before and after treating with chlorine. The excess of chlorine and liberated bromine was expelled by boiling. The color changes were the same as those observed in the experiments with the ruthenium chloride solutions. The results are recorded in Table V. They again show that in the bromide salt the ruthenium is quadrivalent.

TABLE V

ELECTROMETRIC TITRATIONS OF THE BROMIDE SALT

1	10.00	2.65	..	2.65
2	10.00	2.62	..	2.65
3	10.00	..	2.70	2.65
4	10.00	..	2.70	2.65

Summary

The conclusion of Ruff and Vidic that ruthenium compounds in hydrochloric acid solution are reduced by iodide to the trivalent state and no further was confirmed by titrating with thiosulfate the iodine liberated in a solution of the tetroxide obtained by distilling with sulfuric acid and permanganate a known volume of a stock solution of ruthenium chloride which had been evaporated with sulfuric acid to dense white fumes (see Table I).

A hydrochloric acid solution of the ruthenium hydroxide prepared by reducing potassium ruthenate with ethyl alcohol by the method of Krauss and Kiikenthal was found to liberate about one-fourth of an atom of iodine per atom of ruthenium, showing that the hydroxide is a mixture of trivalent and quadrivalent compounds. When this solution was saturated with chlorine and the excess expelled by boiling, one atom of iodine was liberated for each atom of ruthenium (see Table II).

Electrometric titrations with titanous sulfate were made with the hydrochloric acid solution of ruthenium hydroxide and with the solution of it that had been treated with chlorine. In both cases an end-point was reached when all of the quadrivalent ruthenium had been reduced to the trivalent form, not as concluded by Zintl and Zaimis when the ruthenium was reduced to the bivalent state (see Table III and Fig. 1). It may therefore be concluded that the dark blue compounds which form after a small excess of titanous sulfate has been added are compounds of bivalent ruthenium, not of univalent ruthenium as supposed by these authors and by Remy and Wagner.

A bromide salt of ruthenium was prepared by digesting the chloride with bromine and hydrobromic acid and evaporating the solution with potassium bromide. An analysis of this salt showed that it conforms to the formula $K_2RuBr_5(H_2O)$ or K_2RuBr_5OH. Titrations of hydrochloric acid solutions of this salt with thiosulfate after treating it with potassium iodide, and with titanous sulfate by the electrometric method, showed that the ruthenium in the salt was in the quadrivalent state (see Tables IV and V). These results indicate that the true formula of the salt is K_2RuBr_5OH, thus confirming the recent views of Howe.

THE CRYSTAL STRUCTURE OF THE SYSTEM CADMIUM-MERCURY

BY ROBERT FRANKLIN MEHL[1]

RECEIVED NOVEMBER 14, 1927 PUBLISHED FEBRUARY 4, 1928

The system cadmium-mercury is interesting for a number of reasons. Its composition-temperature diagram (Fig. 1) is the only known example of Roozeboom's Type IV.[2] Various compositions among the mercury-rich alloys have been used in the construction of standard cells. Numerous measurements on electrode potential, and on vapor pressure, of the liquid and partly liquid alloys have led a number of investigators to postulate the existence of intermetallic compounds.[3] These, however, do not appear on the constitution diagram proposed by Bijl[4] (Pig. 1) and repeatedly confirmed.[5] Recently T. W. Richards and C. E. Teeter, Jr.,[6] measured the heats of dilution of these alloys in mercury at room temperature and found no critical points suggestive of a compound.

A few measurements of the crystal structure of the system have been

[6] Unpublished research.

reported by Cl. v. Simson,[7] but apparently the study was only qualitative, for no analysis of structure was made.[8]

Although the structure of cadmium is well known,[9] the data for mercury are conflicting. L. W. McKeehan and P. P. Cioffi[10] studied its structure at the temperature of boiling liquid air and obtained diffraction spectra indicative of a simple rhombohedral structure, whereas N. Alsen and G. Aminoff[11] obtained diffraction data for mercury imbedded in solid carbon dioxide quite different, and concluded that at this temperature mercury is hexagonal. R. W. G. Wyckoff has briefly discussed these differences[12] and has suggested that the complete disagreement might be explained by the occurrence of a transition point.

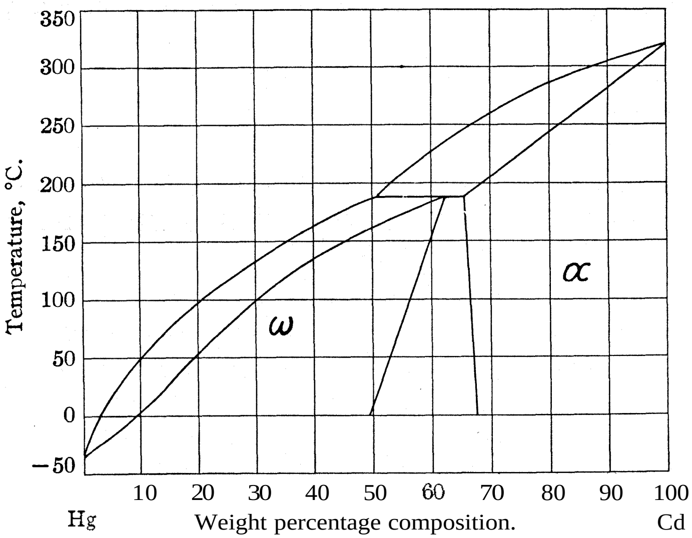

Fig. 1.

If we assume that the diagram of Bijl (Pig. 1) actually represents the mercury-cadmium equilibrium, the problem of the crystal structure af mercury can be attacked in an indirect way. Cadmium is the only metal, so far as known, which forms extensive solid solutions with mercury. Both the w- and the a-solid solution are terminal solid solutions, formed

presumably by simple substitution and exhibiting the space lattice of the solvent metal alone, possibly somewhat altered in dimension.[13] A determination of the structure of the ω-solid solution should, therefore, give the lattice type for mercury.

In order, therefore, to present additional evidence on the constitution of the cadmium-mercury system with especial reference to intermetallic compounds, and indirectly to determine the crystal structure of mercury (*with the assumption of the validity of the constitution diagram proposed by Bijl,*) the present study was undertaken.

Materials and Method

The alloys were made up determinately and not analyzed.[14] The cadmium bore a manufacturer's analysis of 99.961% cadmium, 0.015% zinc, 0.023% lead and 0.001% iron. The mercury was "Redistilled Mercury," which was passed through a nitric acid tower a dozen times and twice distilled in partial vacuum with a stream of dry air. The alloys were melted in Pyrex tubes under paraffin and quenched from the liquid state, the ω-solid solutions in liquid air and the α-solid solutions in ice water. No loss of mercury or cadmium was observed during the preparation and the synthetic compositions given in Table I are, therefore, to be taken as representative of the final compositions.

It became apparent soon after the beginning of the work that drastic deformation followed by prolonged annealing was necessary, especially for the ω-solid solution, to develop a structure crystalline enough to give sufficient diffraction lines for an analysis of structure. Each alloy bar (0.75cm. square) was therefore hammered on an anvil into a nail shaped piece, 0.30 cm. in diameter at the top, tapering to a point at the bottom. These pieces were annealed in a high temperature thermostat[15] and were subsequently treated as noted in Table I.

The powder method of analysis was used, with the "X-Ray Diffraction Apparatus" supplied by the General Electric Company. Early attempts to obtain spectra from wires were unsuccessful because of the high opacity of the alloys. Later experiments on alloy foil were abandoned when it was found an easy matter to obtain filings of the alloys sufficiently fine to pass a 200-mesh sieve. The powdered alloy mixed with finely ground

---

[13] This is generally true of terminal solid solutions, with the exception of iron-carbon and manganese-carbon; see G. L. Clark, "Applied X-Rays," McGraw-Hill Book Company, New York, 1927, p. 204.

[14] Most of the alloys were stock alloys from another investigation (T. W. Richards and C. E. Teeter, Jr., unpublished research). The author wishes to thank Dr. C. E. Teeter, Jr., for his kindness in making them available for this work.

[15] Similar to that designed by J. H. Haughton and D. Hanson, *J. Inst. Metals,* No. *2,* 18, **173** (1917), except that the low temperature bulb was eliminated entirely. A constancy in temperature of 2 or 3 degrees up to 650 degrees was attainable.

flour as a diluent,[16] and packed into thin-walled glass (Pyrex) tubes of inside diameter 0.5 mm. (approximately), gave the most satisfactory films. Half the length of each tube was devoted to the alloy powder, and the other half to a 1:1.7 mixture of twice recrystallized sodium chloride and flour.

Each film thus had the standard sodium chloride spectrum alongside the alloy spectrum. A film calibration was calculated from the measured positions of the sodium chloride lines[17] and applied to the lines measured for the alloy. All of the measurements given in Table II are so corrected. The time of exposure was usually twenty-four; hours, with 17–18 milliamperes passing through the X-ray tube.

Experimental Results

The measurements obtained from the films are given in Table II. The spectra obtained for the w-solid solution were much less sharp than those for the a-solid solution, and also less complete, as shown by Table II. Film 35 was probably the best in the ω-field. Film 36 was very poor, showing only scattered spots, with no fully developed lines. Film 40 was poor, with all lines diffused and striated except the one at 0.941° Å., which was sharp. Film 45 was poor.

It is clear from the data in Table II that the spectra for all compositions in the w-field are identical, not only in type but, within the error of measurement, in dimension also. Although the corresponding lines on the different films often appear to differ slightly in position, there is no progressive variation in position with alloy composition. In order to arrive at a series of values for the spectral lines best representative of the alloys

---

[16] The table of dilutions proposed by W. P. Davey, *Gen. Elec. Rev.*, *28*, 589 (1925), was used in calculating the proportions of alloy powder and flour.

...	121	934	1	8
(.844)	113		trace	4

The interplanar spacings observed correspond very closely to those required by either the face-centered tetragonal lattice of axial ratio 0.520 or the body-centered tetragonal lattice of axial ratio 0.740. These two lattices are equivalent and alternative.[18] Table III also gives the theoretical spacings as measured from the graph of Hull and Davey[19] for the face-centered tetragonal lattice of axial ratio 0.520. The intensities are averages taken from estimations on films numbers 42, 47, 44, **34,** 30 and **35.** The dimensions for the unit face-centered tetragonal prism are $a_0 = 5.570$ Å., $c_0 = 2.896$ Å., or for the unit body-centered tetragonal prism are $a_0 = 3.932$ Å., $c_0 = 2.910$ Å. The two values for c_0 should be equal. The difference originates in the error in the establishment of the correct axial ratios and in the absolute values of the lines chosen to give a_0.

The assumption of simple substitution in the ω-solid solution may be tested by a comparison of the calculated and the observed densities. Table IV gives the densities for a series of compositions calculated on the basis of a face-centered tetragonal lattice of axial ratio 0.520, which has four atoms in the unit cell. These densities are compared with densities obtained from the density-composition curve determined by Maey,[20]

---

[18] An inspection of tetragonal symmetry shows that any face-centered tetragonal lattice is equivalent to a body-centered tetragonal lattice of axial ratio $\sqrt{2}$ times the axial ratio of the former.

[19] Hull and Davey, Phys. *Rev.,* 17, 569 (1921).

[20] Maey, *Z. physik. Chem.,* 50, 200 (1905).

and the agreement is found to be very good, indicating that the assumption of simple substitution is valid.

TABLE IV

DENSITY OF CADMIUM-MERCURY ALLOYS

Composition by weight, % cadmium	Calcd. density	Observed density (Maey)
0.0	14.72	(14.6–14.7)
23.0	12.48	12.43
30.0	11.93	11.96
40.0	11.21	11.25
50.0	10.58	10.72

The density for pure mercury calculated on the assumption of a face-centered tetragonal lattice of axial ratio **0.520** is **14.72.** It is interesting that an extrapolation on Maey's curve to the mercury axis indicates a density of solid mercury at room temperature between 14.6 and **14.7.** The atomic volume calculated from a density of **14.72** is **13.63,** as compared with **13.01** for pure cadmium. These atomic volumes are close, in conformity with the extensive solid solution formation observed. The density calculated from the data of McKeehan and Cioffi[21] for a temperature of —115° is **13.97,** and the corresponding atomic volume is **14.36.** If no solid-solid transitions are assumed, the effect of rising temperature should be to decrease the density and to increase the atomic volume. At room temperature, therefore, the density calculated from the data of McKeehan and Cioffi is much lower than that obtained by an extrapolation of Maey's density curve, and the atomic volume is much further from the atomic volume of cadmium than that calculated from the structure data on the ω-solid solution, a condition not favorable to the formation of extensive solid solution.

It seems possible, therefore, that the crystal structure of pure mercury at its melting point is the same as that observed for the mercury-rich cadmium-mercury solid solutions. If an actual determination of the crystal structure of mercury at its melting point should show a different lattice, the composition-temperature diagram of the system as proposed by Bijl would have to be modified. At present the weight of evidence seems to be against such a modification.

The 60.1% cadmium alloy comes in the heterogeneous field, $\alpha + \omega$, but shows only the lattice of the a-solid solution. The 73% cadmium alloy is in the a-field near the limit of solid solubility. No change in the lattice type or in the lattice dimensions are evident from the spectral lines given in Table I. A change in dimension would be manifested by a progressive change in the positions of the spectral lines with change in composition. No such displacement may be found in the measurements

---

[21] Ref. **10, p. 445.**

given in Table II. The average positions of the various spectral lines calculated from films 19, 38, 42, 22 and 46 give a spectrum which agrees very closely with that obtained from film 48 for pure cadmium, both of which fit closely to Hull and Davey's graph for the triangular, close-packed lattice of axial ratio 1.89. The side of the unit triangle is 2.980 Å., as found by Hull.[9a] The density calculated for the 73% cadmium alloy is 9.72 as compared with the value 9.70 derived from Maey's data, indicating simple substitution in the a-solid solution.

There is no indication in the present work of the existence of any intermetallic compounds at room temperature. The composition range from 0 to 23% cadmium, however, has not been investigated, though if the structure of mercury at its melting point should prove to be similar to that observed for the ω-solid solution, the possibility for compound formation in this composition range would be very small. Nor does the present work afford any basis for the frequent postulation of intermetallic compounds in the liquid alloys, which if present in the liquid state should also be manifested in the solid state, since temperature rise usually has the effect of dissociation. So far as the author is aware there is no evidence of any intermetallic compound existent in the liquid state which is not also existent in the solid state.[22]

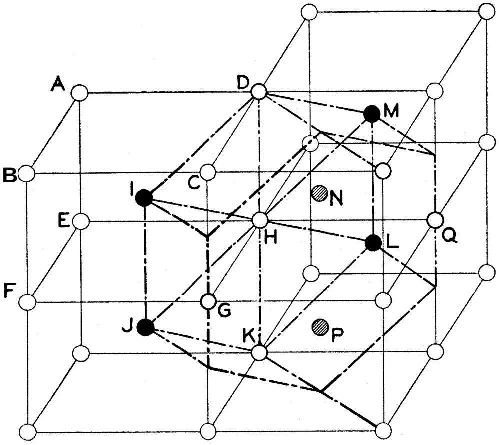

Fig. 2.

Although the similar atomic volumes of mercury and cadmium doubtless favor the extensive solid solution formation observed, it is difficult to see why two lattices so different as the face-centered tetragonal and the close-packed triangular should show such an extensive isomorphism. The tetragonal lattices pictured in the usual way, with lines drawn parallel to the tetragonal coordinates, do not suggest the presence of any hexagonal arrangement of atoms. It should be distinctly emphasized, however, that these lines are purely artificial, and that important orientations exist in many lattices which they are insufficient to depict and in fact frequently mask.

It may be shown, however, that in the w-solid solution there is actually an hexagonal arrangement closely approximating the unit hexagonal

---

[22] **Cf. the work of Bornemann, et al., on the electrical conductivity of liquid alloys,** *Metallurgie,* **7,396,655,730,755 (1910); 9,473 (1912);** *Ferrum,* **11,276,289,330 (1913)**

prism in the a-solid solution. Fig. 2 represents six unit cells of the body-centered tetragonal lattice exhibited by the o-solid solution. Cell ABCD-EFGH is such a unit cell. Let us consider, however, atoms DIJKLM, which lie in a plane and form a hexagon. Geometrically it may be shown that for the lattice of the ω-solid solution DI = DM = JK = KI, = 3.139 Å., and that IJ = MI, = 2.910 Å.; angle IDM = angle JKI, = 125°46′, and angle DMI, = angle MLK = angle KJI = angle JID = 117'7'. This hexagon is therefore nearly equilateral. It may also be shown that it is the basal hexagon of an hexagonal prism, half of which is indicated in Fig. 2 by dotted lines. Fig. 3 represents the fully developed prism. The similarity between this and the ordinary close-packed hexagonal prism is striking, and would be complete if DIJKLM were a perfect hexagon and if atoms G, N, Q and P were displaced to the left in their plane so that atom P were brought into the center of the triangular prism of which JKH is a basal plane. The same is true of the other atoms in the GNQP plane. This deformed hexagonal prism is repeated throughout the lattice and serves completely to define it, that is, it is a unit cell. The density for the 40% cadmium alloy calculated from it agrees with that given in Table IV. The basal hexagon will be equilateral when the axial ratio for the body-centered tetragonal lattice is 0.816.

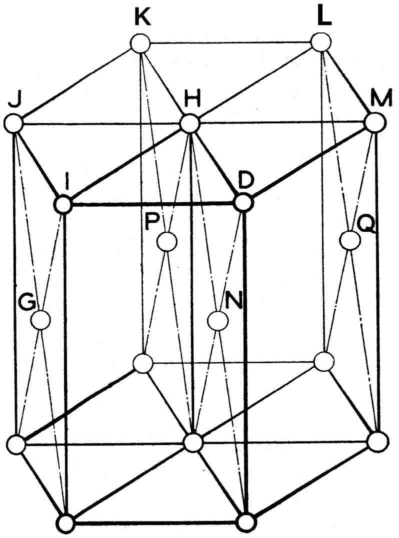

Fig. 3.

The dimensions of the unit cell are $a_0 = 3.139$ Å., $a_0' = 2.910$ Å., $c_0 = 5.561$ Å., whereas the dimensions of the unit hexagonal cadmium prism are $a_0 = 2.980$ Å. and $c_0 = 5.632$ Å. The a- and the ω-solid solutions are therefore very similar both in lattice dimensions and in atomic volume, thus satisfying two of the conditions necessary for solid solutions formation.

The author wishes to acknowledge his indebtedness to Professor Albert Sauveur, whose kindness made available the apparatus used in this work.

Summary

The crystal structure of the system cadmium-mercury has been investigated by a study of the diffraction of X-rays. It has been shown that there are at least two, and probably only two, types of lattice in the system, a face-centered tetragonal lattice of axial ratio 0.520 (or a body-centered lattice of axial ratio 0.740) found in alloys of from 23 to 50%

cadmium by weight, and a triangular close-packed lattice of axial ratio 1.89, found in alloys of from 60 to 100% cadmium by weight.

The conflicting data on the crystal structure of mercury are discussed and it is suggested that the present work indirectly indicates a face-centered (or body-centered) tetragonal structure. It is pointed out that the frequent assumption of intermetallic compounds in this system receives no support from the present crystal structure data.

The isomorphism of cadmium and the face-centered tetragonal component (which may be mercury) is favored by similar atomic volumes and also by the presence in the face-centered tetragonal lattice of an atom arrangement closely approximating the unit hexagonal prism of cadmium both in lattice type and in the unit cell dimensions.

A NEW METHOD FOR THE STUDY OF CATAPHORETIC PROTEIN MOBILITY[1]

BY HAROLD A. ABRAMSON

RECEIVED NOVEMBER 19, 1927 PUBLISHED FEBRUARY 4, 1928

It has previously been shown[2] that the cataphoretic migration of inert particles suspended in gelatin gels represents the movements of the micellae of the gelatin. That is, there seemed to be a rapid formation of a sheath of the gel about the particle which changed its sign at the iso-electric point of the protein. The study of the migration of the particle, therefore, afforded a simple means of studying the cataphoresis of the gelatin micellae themselves. This has led to the study of the influence of proteins on the migration of quartz particles in sols of low concentration. A concentration of 1 X 10^{-7} already lowers ζ, the electrokinetic potential, appreciably. Between concentrations of about 1.10^{-5} and 1.10^{-4} g. per liter the maximum effect of the protein is reached and the particles behave like gelatin. Egg albumin shows a similar influence.

A suspension of quartz particles in a dilute solution of the proteins mentioned (within limits of dilution) gives the absolute electrophoretic migration of the protein micellae. The complete data and theory of these phenomena will be presented elsewhere.[3] Svedberg and Tiselius[4] have used a rather elaborate method to determine the mobility of egg albumin. It seemed that a comparison of their method with ours was of interest.

---

[1] The researches here reported were made in part during a tenure of a Medical Fellowship of the National Research Council.

[2] Freundlich and Abramson, Z. *physik. Chern.*, 128, 25 (1927).

[3] Z. *physik. Chern.*, in press.

[4] Svedberg and Tiselius, THIS JOURNAL, 48, 2272 (1926).

Method

The migration of the quartz particles was studied in a type of micro-electrophoresis cell described elsewhere.[2] Fairly pure powdered egg albumin (Merck) is made up in $M/50$ acetate buffer solutions.[5] Concentrations of 1×10^3 g. per liter of egg albumin are preferred because at this concentration the correction for dielectric constant is probably negligible and the solutions are sufficiently concentrated to give maximum values of {. The quartz particles should be between 0.5 to 5.0μ, and 1.0 mm.^{3} of the final solution should have between 10,000 to 100,000 particles. No attention need be paid to the shape or state of aggregation of the quartz particles as, contrary to the theoretical considerations of Debye and Hückel,[6,2] cataphoretic migration of quartz particles in water and aqueous solutions is independent of the form of the particle and of the state of aggregation. Consequently, measurements may be made from any particle. (An occasional particle shows a wide deviation from the mean which is unexplainable on the basis of its shape. Such values are discarded.) Although equilibrium seems to set in more quickly, fifteen minutes are allowed to elapse between the making of the suspension and the measurements.

Experimental

The data for egg albumin are presented here in order to compare our values with those of Svedberg and Tiselius for the same protein.[4] These authors used a 1.0% albumin solution. As the dielectric constant of a solution of this protein at this concentration is 72,[7] it follows from the Helmholtz-Lamb equation, $V = \zeta HD/4\pi\eta$, in which V = velocity of particle, ζ = electrokinetic potential, H = potential drop per cm., η = viscosity of the medium, all in C. G. S. electrostatic units, that the values observed by Svedberg and Tiselius in the more concentrated solution should be lower than those observed here. Further, the presence of a 1% protein solution may alter the {-potential itself (see Table II). This is actually the case. The data given in Table I, a typical experiment, have been

TABLE I

4.5	+ .16	+ 2	5.75	−1.0	−13
4.81	− .09	− 1.5			

In Pig. 1, Svedberg and Tiselius' data have been corrected for D, and have been also recalculated for 21°. The dots represent our data from three different experiments. The open circles are the recalculated figures

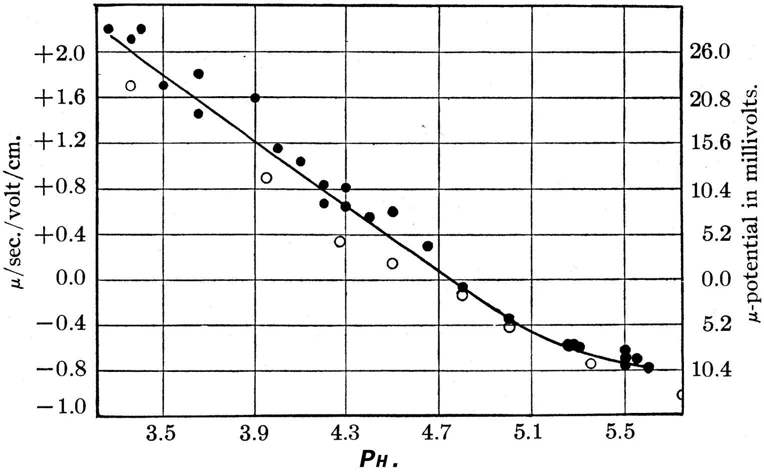

Fig. 1.—The dots indicate protein mobility found in the experiments described in this communication. The open circles are the recalculated data from Svedberg and Tiselius. The signs on the ordinate refer to the charge.

of Svedberg and Tiselius. This correction is 15% for the difference in temperatures and 11% for D. It is evident that the method presented here compares favorably with that of Svedberg and Tiselius. It is further obvious that it affords a most sensitive means of detecting proteins in extremely small quantities and presents a new means of studying their behavior. It also admits of a macroscopic variation.

It is a pleasure to thank Professor H. Freundlich for his continued guidance.

Summary

1. Quartz particles suspended in dilute protein solutions under certain

conditions move cataphoretically as if the migration were due to a surface consisting of the pure protein.

2. Based upon this adsorption of protein by quartz, a method for studying the mobility of protein is presented.

3. The results for egg albumin for a variable hydrogen-ion concentration agree satisfactorily with the values given by Svedberg and Tiselius.

THE DETECTION OF TRACES OF BERYLLIUM AND THE COLORIMETRIC DETERMINATION OF THIS ELEMENT

BY I. M. KOLTHOFF

RECEIVED NOVEMBER 21, 1927 PUBLISHED FEBRUARY 4, 1928

Recently[1] it has been shown that adsorption indicators can be used advantageously for the detection and colorimetric determination of some elements. In a solution weakly acid with acetic acid and acetate (PH about 5.5) aluminum, for example, gives a very nice and sensitive color reaction with 1,2,5,8-oxyanthraquinone. For magnesium, we found titan yellow to be an excellent reagent.[2]

In investigations on the solubility of the slightly soluble metal hydroxides it is of great practical advantage to have color reactions at our disposal with which we can determine traces of dissolved oxides. For the determination of the solubility of beryllium hydroxide (which is extremely small at the isoelectric point) at different hydrogen-ion concentrations we wanted such a method. As is well known, there are only a very few characteristic reactions for beryllium, and only two color reactions have been described in the literature.[3] For this reason we tried to detect and determine it by means of adsorption indicators. The beryllium hydroxide is precipitated at the proper PH in the presence of some useful indicator and the color of the solution or the lake formed is observed.

1,2,5,8-Oxyanthraquinone as Indicator[4] (0.1% solution in alcohol).—To 10 cc. of the solution, 0.1cc. indicator and 6 to 8 drops of 4 *N* ammonia

[2] Kolthoff, *ibid.,* 24, 254 (1927).

[3] The aluminon (aurintricarboxylic acid), which forms a red lake with aluminum [Hammett and Sottery, THIS JOURNAL, 47, 142 (1925); Lundell and Knowles, *Ind. Eng. Chem.,* 18, 60 (1926)], is also suitable for the detection of beryllium [A. R. Middleton, THIS JOURNAL, 48, 2125 (1926)]. According to the statements of Middleton, this reaction is not as sensitive as those described below in this paper.

[4] After writing this paper the author found that the reagent has been already applied by Hellmut Fischer, *Wissenschaftl. Veröffentl. Siemens Konzern,* 5, 99 (1926); *Chem. Zent.,* 1927, *I,* 495, who determined the dyestuff in the lake in a colorimetric way. As no details are given in the abstract referred to, the practical statements made above may be of some value.

are added, the mixture is boiled and the color observed after five minutes' standing.

A solution containing 500 mg. of beryllium in a liter gives a flock with dark blue color; the supernatant liquid is colorless. With 50 mg. of beryllium per liter, the lake is violet blue; with 5 mg. of beryllium per liter no lake is formed; the solution has a blue-violet color.

A blank without beryllium gives a violet color; if the color of the unknown is compared with that of the blank, 0.5 mg. of beryllium per liter may be detected by the blue-violet color.

In the presence of ammonium chloride, the sensitivity is not changed, the lake formed settling out much sooner. Ten cc. of solution with 0.1 cc. of indicator, 1 cc. of 4 N ammonium chloride and 6 to 8 drops of 4 N ammonia are boiled and observed after five minutes. Five mg. of beryllium per liter gives a flock with a blue-violet color. More dilute solutions only give a blue-violet color (as without ammonium chloride); after standing overnight the lake flocculates with the same shade. In this way even 0.5 mg. of beryllium per liter can be detected. Aluminum, which very often occurs in the presence of beryllium, interferes. It forms a violet lake with the dyestuff and in the presence of excess aluminum the blue-violet color of the beryllium lake can no longer be seen. The aluminum has to be removed (see below)

Unfortunately, the blank without beryllium gives a solution with a violet color, and for this reason it is hard to apply the reaction described for a colorimetric determination of the element. Therefore a search was made for some other reagent more suitable for this purpose.

Curcumin as Reagent (0.1% solution in alcohol).—In weakly alkaline solution, this indicator is adsorbed by the beryllium hydroxide with the formation of an orange-red color.

To 10 cc. of solution are added 1 drop of indicator (no more), 0.5 cc. of 4 N ammonium chloride and 6 to 8 drops of 4 N ammonia.

A solution containing 50 mg. of beryllium per liter gives a flocculent precipitate with a red color; with 1 mg. of beryllium per liter the color is orange-red. If the color is compared with that of a blank, the sensitivity may be increased to 0.05 mg. of beryllium per liter. The color of the blank is yellow-brown.

The appearance of the solution changes on standing, as the lake flocculates. After standing overnight, the adsorption compound sinks to the bottom of the test-tube and may be detected by its color (orange-red).

The reaction is very suitable for the quantitative colorimetric determination of beryllium in concentrations between 1 and 0.05 mg. per liter. If the color is compared with solutions of known beryllium content after the same time of standing, the method gives good results. Not more than

0.5 to 1 cc. of 4 N ammonium chloride should be added to 10 cc. of solutions; otherwise the sensitivity is decreased.

Potassium, sodium, lithium, calcium and barium do not interfere. Magnesium decreases the sensitivity somewhat, but 1 mg. of beryllium per liter in the presence of 1 g. of magnesium per liter can be detected in the way described.

Aluminum has a disturbing effect as it also forms a colored lake. For the detection of aluminum this reaction, however, is not very suitable. If beryllium is to be detected in the presence of aluminum, the slightly acid solution is treated with an excess of sodium fluoride. The main part of aluminum precipitates in the form of Na_3AlF_6, and the rest in solution does not interfere. After standing for one hour, the liquid is filtered and the filtrate treated in the way described above. One mg. of beryllium per liter could be detected in the presence of 1 g. of aluminum per liter. We may remark here that sodium fluoride decreases the sensitivity of the reaction for beryllium somewhat.

Ferric iron interferes and can be made harmless in the same way as described for aluminum. Or, more easily still, the iron may be precipitated at room temperature with an excess of sodium hydroxide, and 1 drop of curcumin and an excess of ammonium chloride added to the filtrate. Two mg. of beryllium per liter in the presence of 1 g. of iron per liter could be easily seen.

It may be mentioned here that in strong alkaline solutions beryllium does not react with the curcumin (the beryllium hydroxide dissolves again). Under these conditions magnesium gives a distinct color reaction, however, not as sensitive as with titan yellow.

Ten cc. of solution with 1 drop of reagent and 1 cc. of 4 N sodium hydroxide gives an orange color with 10 mg. of magnesium per liter, an orange-yellow color with 5 mg. per liter and an orange-brown color (distinctly different from a blank) with 1 mg. per liter. Perhaps the curcumin is useful for determining amounts of magnesium between 1 and 10 mg. of magnesium per liter.

The tap water of Minneapolis, containing 16.5 mg. of magnesium per liter, gave a very distinct reaction.

Summary

1. Curcumin is a very useful reagent for the detection and colorimetric determination of traces of beryllium.

2. The sensitivity extends to 0.05 mg. of beryllium per liter.

3. A method is described for the detection of beryllium in the presence of aluminum and ferric iron.

STUDIES ON THE SYSTEM CALCIUM OXIDE-ALUMINA-FERRIC OXIDE[1]

BY W. C. HANSEN, L. T. BROWNMILLER AND R. H. BOGUE

RECEIVED NOVEMBER 25, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

This investigation of the system calcium oxide-alumina-ferric oxide has been undertaken as one step in a program to determine the constitution of portland cement and the role played by each component in the manufacture and utilization of cement. The system has been found to be complex and only that part has been explored which appears to be of significance in the above-mentioned problem. This part, however, includes a large portion of the system.

Very little pertaining to the system CaO-Al_2O_3-Fe_2O_3 is found in the literature. Three contributions have been made, however, which are of interest.

Le Chatelier[2] believed that a compound existed of the composition $3CaO.Al_2O_3.Fe_2O_3$.

Shepherd, Rankin and Wright[3] observed that $2CaO.Fe_2O_3$ and $5CaO.3Al_2O_3$ reacted, but the reaction products were not determined.

Campbell[4] found that alumina and ferric oxide were capable of replacing each other in certain combinations with calcium oxide.

The Binary Systems

Two of the binary systems making up the ternary system under consideration have been studied. These are the systems CaO-Al_2O_3[5] and CaO-Fe_2O_3.[6] The system Al_2O_3-Fe_2O_3 has not been reported but a knowledge of it is not necessary for the investigation given here.

The data from these systems are plotted[7] on the sides of the triangular diagram, Fig. 1. Dotted lines have been drawn out from the quadruple points to indicate the origin of the boundary curves. With this preliminary information we are in a position to determine the ternary combinations and temperature relations existing in a part of the ternary system

The Ternary System

Experimental Procedure

The raw materials employed in this study consisted of precipitated calcium carbonate, alumina and ferric oxide.

Analyses of these materials are given in Table I.

[8] By H. C. Stecker.

The general principles involved in phase equilibria studies and the methods of experimentation have been very fully discussed by Rankin and Wright.[5]

The samples for study were prepared by mixing the finely powdered raw materials in a beaker with distilled water. These mixtures were placed on a hot-plate and stirred several times as evaporation proceeded to prevent segregation. When dry the mixtures were melted in platinum in an electric resistance furnace.[9] These melts of about 20 g. each were crushed in a steel mortar and ground in an agate mortar for use in the experiments described later.

Sosman and Hostetter[10] have shown that the dissociation of ferric oxide to ferro-ferric oxide increases with rise in temperature and time of heating. To minimize this dissociation as far as possible these preliminary samples were melted in an interval of about twenty minutes and at as low a temperature as possible. After a few samples had been studied the temperatures at which the others would melt could be estimated.

Crystallization was found to be very rapid in melts in this system, as it is in the $CaO-Fe_2O_3$[6] and $CaO-Fe_2O_3-SiO_2$[11] systems. Many of the melts obtained as described above crystallized completely so that their crystalline phases could be studied without additional treatment. Small charges of those that were not entirely crystallized were remelted in the quenching furnace[11] and cooled slowly to allow complete crystallization.

The crystalline phases were studied microscopically and their indices of refraction determined by the immersion method. The necessary high index media were prepared by the methods described by Larsen and Merwin[12] and by Brownmiller.[13]

Undercooled glasses could not be obtained by quenching melts in this system. It was necessary, therefore, to determine the melting relations by means of heating curves and to deduce the phase relations from the microscopic and heating curve data with the aid of the phase rule. This method is not so accurate nor so satisfactory as the quenching method, but it is believed that the phase relations reported herein are correct. Further work will be necessary to establish some of the boundary curves more exactly and to clear up other minor points in this part of the system.

Experimental Results

One ternary compound was found in the system $CaO-Al_2O_3-Fe_2O_3$. It has the oxide formula $4CaO.Al_2O_3.Fe_2O_3$ and the composition[14] CaO,

[13] Brownmiller, *Am. Mineralogist*, 12, *43* (1927).

[14] All compositions are given in percentage by weight.

46.1%; Al_2O_3, 21.0%; Fe_2O_3, 32.9%. It melts[15] congruently at 1415 ± 5°. This compound forms easily from the finely powdered components at temperatures well below its melting point. Its density[16] was found to be 3.77.

The optical properties of $4CaO.Al_2O_3.Fe_2O_3$ are as follows: biaxial, negative, with a medium optic axial angle. $\alpha_{Li} = 1.96 \pm .01$, $\beta_{Li} = 2.01 \pm .01$, $\gamma_{Li} = 2.04 \pm .01$. The indices for the yellow mercury line ($\lambda = 578$) are $a = 1.98 \pm .01$, $\beta = 2.05 \pm .01$, $\gamma = 2.08 \pm .01$. Occasional polysynthetic twinning was observed. The compound often occurs as prismatic grains with extinction angle against the prismatic faces very small. Pleochroism γ = brown and a = yellow-brown.

$4CaO.Al_2O_3.Fe_2O_3$ and CaO form a eutectic mixture of the composition CaO, 56%; Al_2O_3, 17%; Fe_2O_3, 27%; which melts at 1395 ± 5°. A partial temperature-concentration diagram of this system is given in Fig. 2.

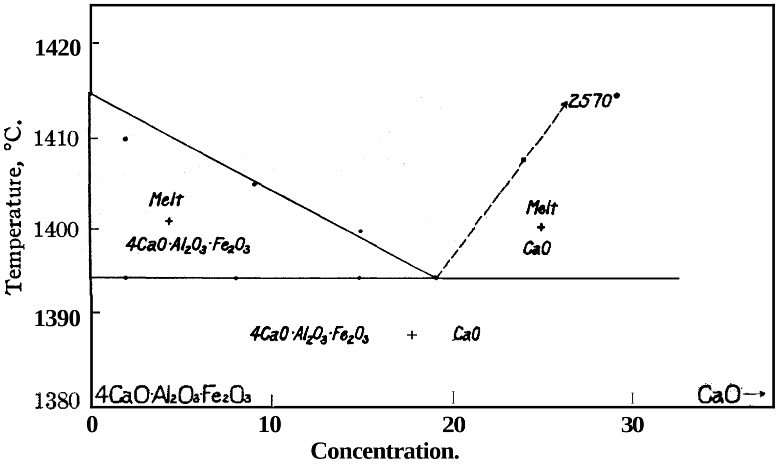

Fig. 2.—Partial temperature-concentration diagram of the system $4CaO.Al_2O_3.Fe_2O_3$-CaO.

$4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$ form a complete series of solid solutions. The melting range of these solid solutions could not be determined from the heating curves. Only one distinct break was obtained on each of the heating curves. It appears, therefore, that the melting range of these solid solutions is very narrow, probably less than ten degrees. The temperatures of the observed thermal breaks are plotted against composition in Fig. 3. $2CaO.Fe_2O_3$ dissociates at 1435° into CaO and liquid. A thermal change was observed at this temperature in the heating curve obtained from the composition CaO, 41.5%; Al_2O_3, 1.5%; Fe_2O_3, 57.0% or $2CaO.Fe_2O_3$, 93% and $4CaO.Al_2O_3.Fe_2O_3$, 7%. This observation, in con-

[15] All temperatures are given in centigrade degrees.

[16] Determined by Wm. Lerch using Le Chatelier's method, described in U. S. Bureau of Standards, Circular 33, 1917.

junction with the curve obtained in Fig. 3, indicates that CaO and solid solution are in equilibrium with liquid and vapor at 1435' in the above composition. That is, therefore, a quadruple invariant point. Charges of this composition were quenched from 1435' and examined microscopically for CaO. It was not possible, however, positively to identify CaO in those quenched charges.

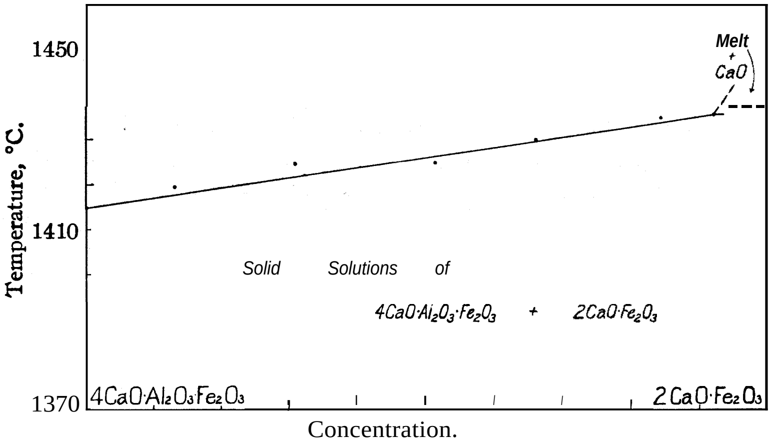

Fig. 3.—Temperature-concentration diagram showing the melting relations in the solid solution of $4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$.

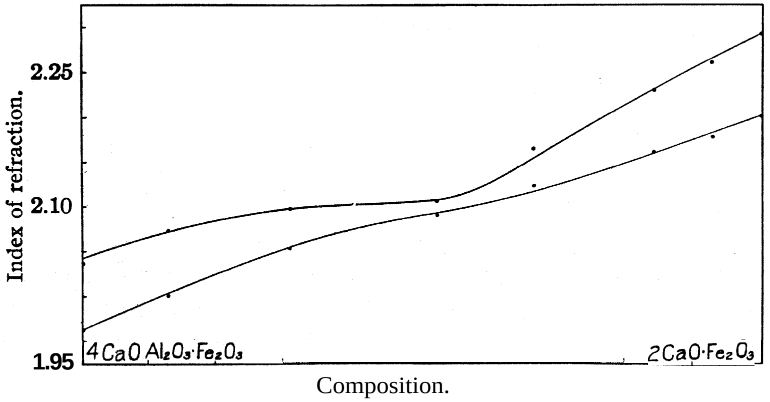

Fig. 4.—Indices of refraction of the solid solutions of $4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$ plotted against composition.

The α and γ indices of refraction of this series of solid solutions are shown graphically in Fig. 4. $2CaO.Fe_2O_3$ is biaxial, positive and $4CaO.Al_2O_3.$-Fe_2O_3 is biaxial, negative. The solid solutions rich in $2CaO.Fe_2O_3$ are positive while those rich in $4CaO.Al_2O_3.Fe_2O_3$ are negative. The exact composition at which the character changes has not been determined.

In Fig. 5 there are shown the fields below the line $CaO.Al_2O_3$-$CaO.Fe_2O_3$ which were studied in this investigation. The region above that line has not been explored. The five fields below this line show the regions in which the various compounds and solid solutions occur as the final products of crystallization of melts of these compositions.

In Fig. 6 the fields are shown in which CaO, $3CaO.Al_2O_3$, $5CaO.3Al_2O_3$, $4CaO.Al_2O_3.Fe_2O_3$ and solid solutions occur as primary phases. The dots in that figure represent the compositions studied during the investigation.

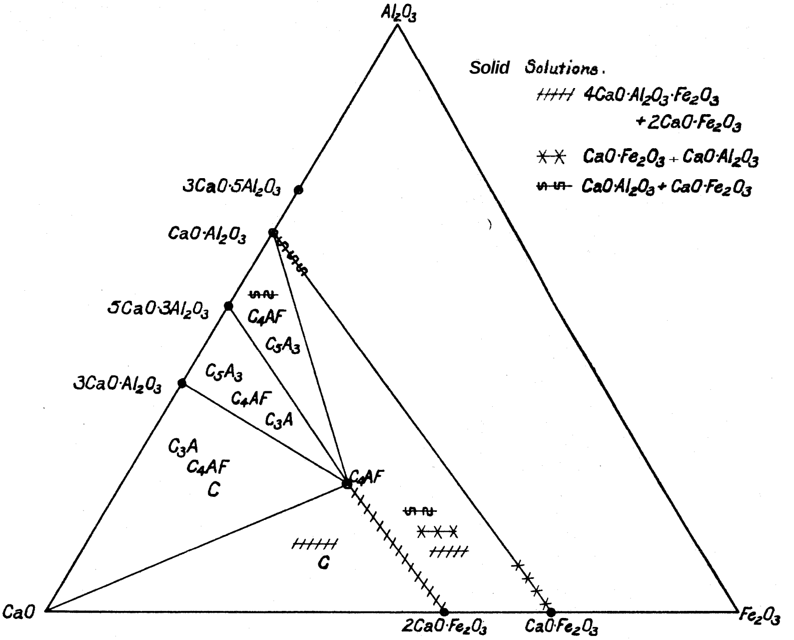

Fig. 5.—Diagram showing the final products of crystallization of melts in a portion of the ternary system CaO-Al_2O_3-Fe_2O_3.

The final melting temperatures of some of the compositions are given in that figure. These temperatures with those in the other figures are sufficient for the construction of a solid model of the liquidus surface of this portion of the system.

The two dashed lines (Pig. 6) radiating from the composition $4CaO.Al_2O_3.Fe_2O_3$ are not true boundary curves. A boundary curve is a line representing the compositions and temperatures at which two solid phases are in equilibrium with liquid and vapor. Since the compound $4CaO.Al_2O_3.Fe_2O_3$ forms a continuous series of solid solutions with $2CaO.Fe_2O_3$ there can be no boundary curve separating the fields in which $4CaO.Al_2O_3.Fe_2O_3$ and the solid solutions with $2CaO.Fe_2O_3$ separate as primary phases. It seems desirable, however, to indicate, in some manner, the compositions at which the primary phase changes from $4CaO.Al_2O_3.Fe_2O_3$ to a solid solution of $4CaO.Al_2O_3.Fe_2O_3$ with $2CaO.Fe_2O_3$.

The quintuple invariant point (Fig. 6) at which CaO, $3CaO.Al_2O_3$, $4CaO.Al_2O_3.Fe_2O_3$, liquid and vapor are at equilibrium was found to have the composition CaO, 54%; Al_2O_3, 37%; Fe_2O_3, 9%; and to melt at 1345 ± 5°. If a line is drawn from $3CaO.Al_2O_3$ to $4CaO.Al_2O_3.Fe_2O_3$ in Fig. 6, as it is in Fig. 5, and the two figures are compared, it will be observed that CaO occurs as a primary phase in a part of the triangle $3CaO.Al_2O_3$—$4CaO.Al_2O_3.Fe_2O_3$—$5CaO.3Al_2O_3$. When crystallization is allowed to take place slowly in melts whose compositions fall within that triangle, the CaO combines with the liquid and disappears so that CaO is not a final product of crystallization in that field. It was found possible to quench the charges in which CaO occurs as the primary phase in this field and prevent its recombination. That made it possible to establish the quintuple point, referred to above, by both heating curves and quenches.

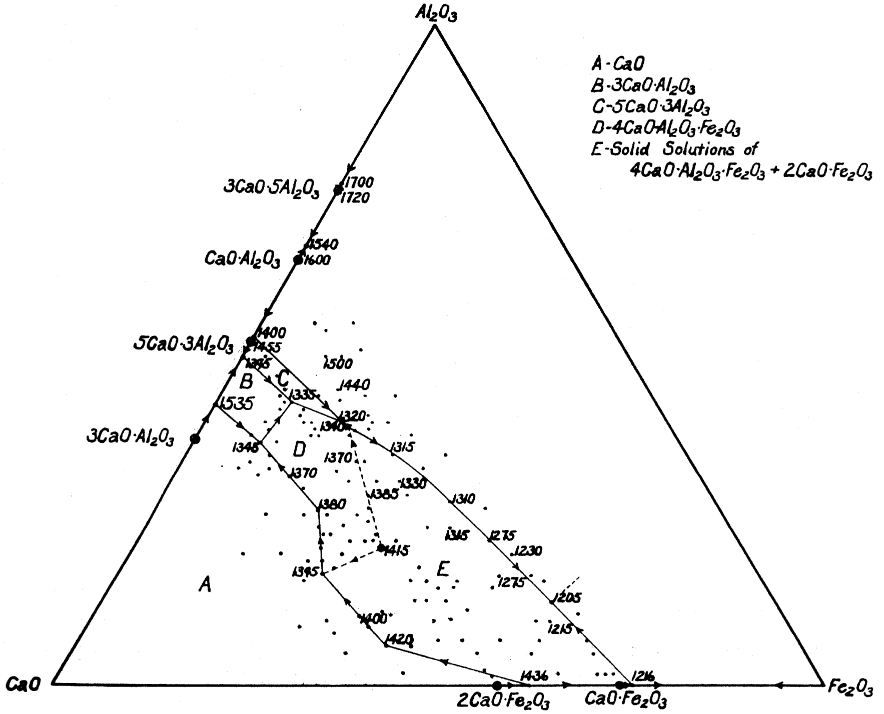

Fig. 6.—Diagram showing the fields in which CaO, $4CaO.Al_2O_3.Fe_2O_3$, $3CaO.Al_2O_3$, $5CaO.3Al_2O_3$ and solid solutions of $4CaO.Al_2O_3.Fe_2O_3$ + $2CaO.Fe_2O_3$ separate as primary phases. The dots represent the compositions studied.

$4CaO.Al_2O_3.Fe_2O_3$ and $5CaO.3Al_2O_3$ form a eutectic mixture of the composition CaO, 47%; Al_2O_3, 43%; Fe_2O_3, 10%; which melts at 1335 ± 5°. The temperature-concentration diagram of this system is given in Fig. 7.

The quintuple invariant point at which $3CaO.Al_2O_3$, $5CaO.3Al_2O_3$, $4CaO.Al_2O_3.Fe_2O_3$, liquid and vapor are at equilibrium appears to have very nearly the same composition and melting temperature as the binary eutectic of $5CaO.3Al_2O_3$ and $4CaO.Al_2O_3.Fe_2O_3$. Perhaps these two points can be differentiated when a greater number of samples are studied in the region of that point. This quintuple point, therefore, is given tentatively as CaO, 47%; Al_2O_3, 43%; Fe_2O_3, 10%; and 1355 ± 5°.

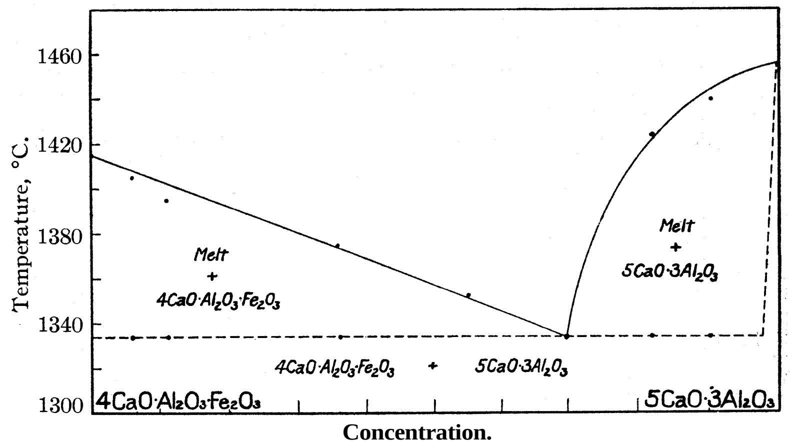

Fig. 7.—Temperature-concentration diagram of the system $4CaO.Al_2O_3.Fe_2O_3$-$5CaO.3Al_2O_3$.

$CaO.Al_2O_3$ takes up about 15% of $CaO.Fe_2O_3$ in solid solution and $CaO.Fe_2O_3$ appears to take up about 10% of $CaO.Al_2O_3$. The indices of refraction of $CaO.Al_2O_3$ increase from $\alpha_{Na} = 1.643$ and $\gamma_{Na} = 1.663$ to about 1.70 for α and 1.72 for γ. Those of $CaO.Fe_2O_3$ decrease from $\omega_{Li} = 2.465$ and ϵ_{Li} 2.345 to about 2.25 for ω and 2.13 for ϵ.

The melting relations existing between $CaO.Al_2O_3$ and $CaO.Fe_2O_3$ are shown in Fig. 8. It may be seen there that a eutectic mixture of the composition CaO, 28%; Al_2O_3, 13%; Fe_2O_3, 59% is formed. This mixture melts at 1205 ± 5°. This melting was observed in all of the samples within the four-sided figure (Fig. 5) $CaO.Al_2O_3$-$CaO.Fe_2O_3$-$2CaO.Fe_2O_3$.-$4CaO.Al_2O_3.Fe_2O_3$. In that region, when crystallization of the melts is completed, three crystalline phases are found. They are solid solutions of $CaO.Al_2O_3$ in $CaO.Fe_2O_3$, $CaO.Fe_2O_3$ in $CaO.Al_2O_3$ and $4CaO.Al_2O_3$.-Fe_2O_3 in $2CaO.Fe_2O_3$.

This point is, therefore, the quintuple invariant point at which the three solid solutions are in equilibrium with liquid and vapor. It would seem, therefore, that $CaO.Fe_2O_3$, which melts incongruently at 1216° into $2CaO.Fe_2O_3$ and liquid, in taking up $CaO.Al_2O_3$ in solid solution, has its incongruent melting point lowered to 1205 ± 5°. At this temperature this solid solution of $CaO.Al_2O_3$ in $CaO.Fe_2O_3$ dissociates into liquid and solid solutions of $2CaO.Fe_2O_3$ + $4CaO.Al_2O_3.Fe_2O_3$.

Samples having compositions falling on the line $CaO.Al_2O_3$-$4CaO.Al_2O_2.Fe_2O_3$ (Fig. 5) do not consist of those two compounds at equilibrium. The $CaO.Al_2O_3$ takes up some $CaO.Fe_2O_3$ which raises its indices of refraction. In some of the samples, small amounts of $5CaO.3Al_2O_3$ were found. The phase that should correspond to $4CaO.Al_2O_3.Fe_2O_3$ had somewhat lower indices of refraction. This phase was found to have α about 1.95 and γ 2.04 for the mercury yellow light.

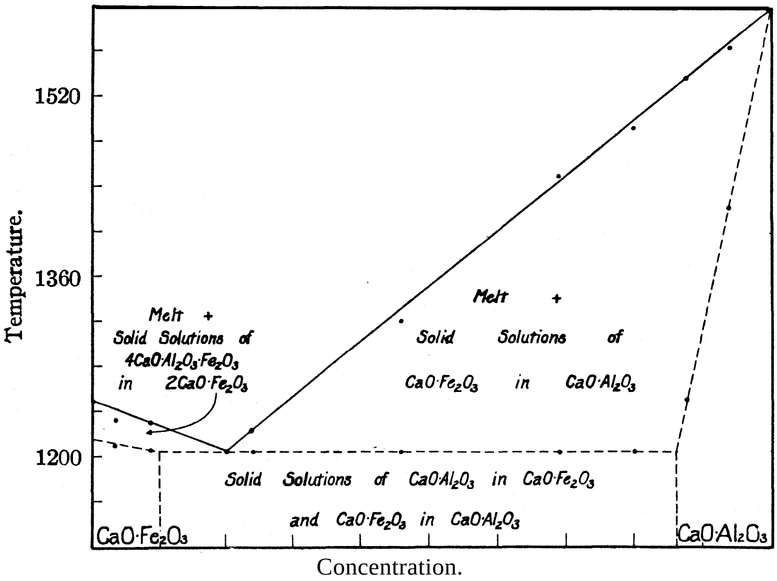

Fig. 8.—Diagram showing melting relations existing between $CaO.Fe_2O_3$ and $CaO.Al_2O_3$.

These results may be explained as follows. If $CaO.Al_2O_3$ takes up a certain amount of $CaO.Fe_2O_3$, the ratio of the remaining Al_2O_3 and CaO to the Fe_2O_3 is too great to form $4CaO.Al_2O_3.Fe_2O_3$ or its solid solutions with $2CaO.Fe_2O_3$. Therefore, some of the Al_2O_3 and CaO is combined as $5CaO.3Al_2O_3$. The other phase then is $4CaO.Al_2O_3.Fe_2O_3$ with a little $2CaO.Fe_2O_3$ in solution. From the lowered indices of refraction it would seem that $4CaO.Al_2O_3.Fe_2O_3$ and its solid solutions with $2CaO.Fe_2O_3$ are capable of taking up very small amounts of $CaO.Al_2O_3$ in solid solution. Therefore, in Fig. 5, the line $CaO.Al_2O_3$-$4CaO.Al_2O_3.Fe_2O_3$ should be drawn from $CaO.Al_2O_2$ to some point on the solid solution line of 4CaO.-

$Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$. The exact course of this line has not been established and is therefore shown as ending at $4CaO.Al_2O_3.Fe_2O_3$.

The indices of refraction of $3CaO.Al_2O_3$ and $5CaO.3Al_2O_3$ are raised slightly in this system. Values as high as 1.735 were found for $3CaO.Al_2O_3$ and 1.720 for $5CaO.3Al_2O_3$.

None of the binary compounds of CaO with Al_2O_3 and Fe_2O_3 are found as the pure compounds within the ternary system as shown by their optical properties. The exact amount and nature of all of the solid solutions formed within this system have not been fully determined.

The compositions and melting temperatures of the quadruple and quintuple points found in this ternary system are given in Table II.

TABLE II

QUADRUPLE AND QUINTUPLE POINTS IN THE SYSTEM $CaO\text{-}Al_2O_3\text{-}Fe_2O_3$

Crystalline phases	Composition, weight percentage CaO	Al_2O_3	Fe_2O_3	Temp., °C.
Quadruple Points				
CaO, $4CaO.Al_2O_3.Fe_2O_3$	56	17	26	1395 * 5
CaO, solid solutions of $4CaO.Al_2O_3.Fe_2O_3$ + $2CaO.Fe_2O_3$	41.5	1.5	57.0	1435 ± 5
Quintuple Points				
CaO, $3CaO.Al_2O_3$, $4CaO.Al_2O_3.Fe_2O_3$	54	37	9	1345 ± 5
$3CaO.Al_2O_3$, $4CaO.Al_2O_3.Fe_2O_3$, $5CaO.3Al_2O_3$	47	43	10	1335 ± 5
$4CaO.Al_2O_3.Fe_2O_3$, $5CaO.3Al_2O_3$, solid solutions of $CaO.Al_2O_3$ + $CaO.Fe_2O_3$	42	40	18	1320 ± 5
Solid solutions of $4CaO.Al_2O_3.Fe_2O_3$ + $2CaO.Fe_2O_3$, $CaO.Al_2O_3$ + $CaO.Fe_2O_3$, $CaO.Fe_2O_3$ + $CaO.Al_2O_3$	28	13	59	1205 ± 5

In this paper the experimental results obtained in the system $CaO\text{-}Al_2O_3\text{-}Fe_2O_3$ have been presented. The application of these findings to the problem of the constitution of portland cement will be presented in another paper.

The authors take pleasure in expressing their appreciation to Dr. Herbert Insley of the Bureau of Standards for advice and assistance in the microscopical studies.

Summary

A part of the $CaO\text{-}Al_2O_3\text{-}Fe_2O_3$ system has been studied. One ternary compound of the composition $4CaO.Al_2O_3.Fe_2O_3$ was found in this part of the system. Its melting point and optical properties have been determined.

$2CaO.Fe_2O_3$ and $4CaO.Al_2O_3.Fe_2O_3$ form a complete series of solid solutions. The melting relations and optical properties of these solutions are given.

$CaO.Al_2O_3$ and $CaO.Fe_2O_3$ form limited solid solutions with each other.

$3CaO.Al_2O_3$ and $5CaO.3Al_2O_3$ have higher indices of refraction than they have in the binary system.

The fields in which CaO, $3CaO.Al_2O_3$, $5CaO.3Al_2O_3$, $4CaO.Al_2O_3.Fe_2O_3$ and solid solutions of $4CaO.Al_2O_3.Fe_2O_3$ and $2CaO.Fe_2O_3$ separate as primary phases from these ternary melts are shown diagrammatically.

Resistance coils which must have a perfectly constant resistance are always made of constantan (identical with ideal) or of manganin, as the resistances of both alloys are nearly independent of the temperature. These wires corrode easily. Nevertheless, the bad surface quality due to this corrosion causes no inconvenience since the whole coil is protected by paraffin. The very low thermoelectric force of manganin against copper renders its use almost imperative whenever direct current is involved. The somewhat better surface qualities of constantan are more than offset by its exceptionally high thermoelectric force against copper.

If, however, a measuring wire with slide contact is needed, as in the Wheatstone Bridge, then one faces an entirely different problem. One does not need in this case the very low temperature coefficient of the resistance because the different parts of the wire have nearly the same temperature, but one needs a wire with a bright surface which is not attacked either by the air or by the acid fumes of the laboratory. For this reason many authors favor the use of platinum wire. Its surface remains always perfectly clean, but its electric resistance has too high a temperature coefficient. It increases by 30 to 40% if the temperature rises from 0 to 100°, so that even the small changes of temperature which one produces when moving the contact slide with the hand have a noticeable effect on the position of the zero point.

The best resistance wire for Wheatstone Bridges, which, on request, was offered by Hereus for the use in the chemical laboratory, is platin-iridium. Apart from its very high price, however, it still has too high a temperature coefficient. An American company which manufactures resistance wires as a specialty was also unable to make us any satisfactory offer.

The question arose as to whether one could not replace the copper in constantan (60% Cu + 40% Ni) by the more noble metals of the same group, silver or gold. Since the jewelers recently began to use nickel-gold alloys called white gold, our first experiments were made with four of these alloys found on the market. One of them, a 14 K. white gold, was found to replace most favorably the constantan or the platinum measuring wire of the Wheatstone Bridge. Its electrical, chemical and mechanical properties make it a nearly ideal alloy for our purpose, especially if one is working with alternating current, as one generally is in the chemical laboratory. Its thermoelectric force against copper, although only half as large as that of constantan, is still too large to allow the substitution of manganin by the new alloy if very accurate measurements have to be made with direct current.

Prom a mechanical point of view, too, the new gold alloy has remarkably fine qualities. It is easy to pull thin wires of it; the alloy is hard enough to eliminate all abrasion at the contact point and it has an exceptionally high tensile strength, about 125 kg./sq. mm. This is four times more than constantan, even more than ordinary steel wire. One has, of course, a great advantage in being able to pull a measuring wire quite tightly without fear of breaking it.

The following table contains some of our results.

TABLE I

EFFECT OF CHEMICALS

	Ammonia	Concd. HCl	Concd. HNO_3
Constantan	Corrodes quickly	Dissolves slowly	Dissolves rapidly
14 K. white gold	No action	No action	Extracts Ni and Cu
18 K. white gold	No action	No action	No action

ELECTRIC QUALITIES

	Resistance, $10^4 \rho$	Temp. coefficient, $10^{-4} \cdot \frac{1}{\rho} \cdot \frac{d\rho}{dt}$	Thermoelectric force against copper, M. V./100°
Platinum, c. p.	0.126	38.0	−0.75
Constantan	.49	0.2	+4.5
14 K. white gold	.42	2.2	+2.6
18 K. white gold	.38	4.2	+3.82

The question further arose whether or not this temperature coefficient of 2.2 of the 14 K. white gold would still be too high to allow the use of the alloy for our purpose. This question was solved in the following way. A Wheatstone Bridge was constructed with a 100cm. long measuring wire of ordinary platinum, the temperature coefficient of which was 25, that is, more than 10 times that of the 14 K. white gold. When the zero point was about in the middle of the measuring wire, one side of the wire was touched with the hand and the displacement of the zero point observed. Then a radiator was turned on, on one side of the bridge or, the outside temperature being at freezing, a window was opened so that the draft came sideways onto the measuring wire. The zero point was of course displaced but even under these extreme conditions the displacement was never more than 1 mm. Hence with the 14 K. white gold wire used under these conditions the faults would always have been less than 0.1 mm. That means that under ordinary conditions or even under bad conditions the temperature coefficient of the 14 K. white gold measuring wire will never be the cause of any noticeable error.

Summary

White gold,[1] which has already partially replaced platinum in jewelry, replaces it advantageously in the alternating current Wheatstone Bridge when the latter is used in a chemical laboratory where constantan corrodes too rapidly. Constantan, exposed to the air of the laboratory, had to be cleaned after a few weeks, while white gold still gave perfectly good contacts after ten months.

Good surface qualities of the measuring wire are of the greatest importance, especially in modern laboratory technique where amplifiers are used in connection with very weak currents.

A REVISION OF THE ATOMIC WEIGHT OF TITANIUM. III
THE ANALYSIS OF TITANIUM TETRABROMIDE

BY GREGORY PAUL BAXTER AND ALBERT QUIGG BUTLER

RECEIVED DECEMBER 19, 1927 PUBLISHED FEBRUARY 4, 1928

In two recent papers[1] the purification and analysis of titanium tetrachloride are described. The atomic weight of titanium computed from the experimental results is 47.90, a value considerably lower than that obtained by Thorpe, 48.1, which has been in use for some time. As a check on our recent work we have prepared and analyzed pure titanium tetrabromide and have obtained the same value as that found by analysis of the tetrachloride. Although in outline the two methods are similar, yet the differences in the physical and chemical properties of the compounds involved make it improbable that both results are affected by constant errors to the same extent.

Purification of Materials

Water, nitric acid, silver and bromine were purified by the methods usual when extreme refinement is necessary.[2]

Carbon was prepared from rock candy crystals, by charring, followed

---

[1] 14 K. white gold wire similar to the one described above can now be obtained from Baker & Co., Inc., Newark, N. J.

by ignition first in a covered porcelain crucible, then in an exhausted quartz tube.

Arsenic trioxide was several times recrystallized, once from very dilute hydrochloric acid, then from water. The product was chloride free.

Helium was very kindly provided by the U. S. Navy Department. It was purified and dried by being passed over concentrated sulfuric acid, hot calcium, hot copper oxide, hot copper, silver nitrate solution, solid potassium hydroxide, concentrated sulfuric acid and phosphorus pentoxide, in an all-glass apparatus. This gas may have contained a trace of hydrogen formed by decomposition of traces of water by the copper, but since this impurity could only result in the production of a small amount of hydrogen bromide in the synthesis of the titanium tetrabromide, it was allowed to remain.

Titanium tetrabromide was prepared by the action of bromine at a high temperature on (a) metallic titanium, or (b) a mixture of carbon and titanium dioxide. Because of the action of nitrogen on titanium at high temperatures, helium was used as the carrier of the bromine. The products of several experiments were combined for the final purification by fractional distillation.

Titanium dioxide kindly furnished by the Valentine Valspar Co. served as the starting point in every case. To prepare metallic titanium the powdered dioxide was mixed with a 50% excess of magnesium powder by grinding and the reaction was started by igniting the mixture in a muffle. The product was extracted with an excess of hydrobromic acid and the residue digested with two successive portions of fresh acid at nearly boiling temperature Washing by decantation followed, with centrifugal settling of the rather finely divided titanium in order to promote efficiency. The clean metal was dried on an electric hot-plate and after powdering was ignited in a high vacuum.

In the preparation of the tetrabromide from titanium, the metal was contained in a hard glass tube connected at one end by a ground joint with the apparatus for purifying helium and charging it with bromine, at the other by means of a ground joint of large diameter with a glass bulb which served as condenser. The reaction tube sloped toward the receiver at all points. Because of the high boiling point of the tetrabromide, 238°, especial cooling of the condenser was unnecessary. The helium could be passed either directly into the reaction tube or through bromine in a bubbling flask and then over the titanium. In a run the apparatus was first swept out with helium. Then the current of helium was directed through the bromine, and the titanium was heated electrically to redness. At the same time the bromine was warmed to increase its vapor pressure. The product, judging from the color, was at first nearly free from bromine, but before long uncombined bromine began to accompany the tetrabromide to a marked extent. Two experiments of this sort were both interrupted by accidents to the apparatus so that the total resulting quantity of tetrabromide was not more than 60–70 g.

In a third experiment, instead of titanium, a mixture of ground, ignited titanium dioxide with a considerable excess of carbon was employed. The result of this experiment was satisfactory so far as yield is concerned although the former method gave every indication of being equally good under favorable conditions. About 200 g. was obtained from this experiment.

The material produced by the two methods was next separately freed from a large part of the excess of bromine by exhausting the containers with an efficient water pump while at the same time the container was warmed in a paraffin bath and the liquid boiled vigorously to flush out as much of the residual air as possible. The containers were then closed by fusing a capillary connection. Both containers were then connected through special fused-in joints (a, Fig. 1)[3] to a large bulb which was also connected with a Hempel fractionating column terminating in a special joint. By means of a Gaede mercury pump this bulb together with the fractionating column was thoroughly exhausted and sealed off. In succession the special joint of each container was opened and the contents distilled into the receiving bulb. Then the container was sealed off by fusing a capillary. The combined sample, of about 100 ml. in volume, was a reddish-brown mass, partly liquid owing to the excess of bromine.

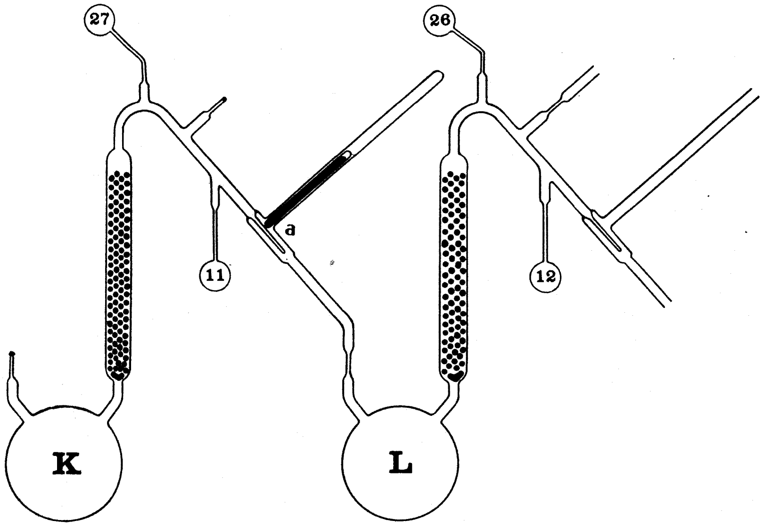

Fig. 1.

Fractional distillation in exhausted apparatus followed. The apparatus was modified slightly from one distillation to another but in general a distillation was carried out as follows. The material was contained in the exhausted bulb K (Fig. 1) attached through the Hempel column and the special joint to the receiving bulb L, which in turn was attached to a similar system also thoroughly exhausted. The special joint was then opened by means of the hammer weighted with mercury. The still K was warmed to about 150" in a paraffin-bath and the most volatile fraction of the tetrabromide was collected in the bulb 11 which was disconnected by sealing the capillary. The greater part of the tetrabromide was distilled into L, and the capillary was sealed. The residue in K was then collected in 27 and sealed off. After the receiver L had been connected to a similar exhausted system, the distillation process was repeated. During the distillation the fractionating column was jacketed with asbestos paper. Although

refluxing was very efficient, choking of the column was negligible. In all, 18 such fractional distillations were carried out. After the third, sixth and ninth distillation cracks in the apparatus necessitated transference by pouring to another bulb, which was exhausted while hot by means of a water pump and sealed off. The last nine distillations were, however, free from any such accident.

The complete course of the fractional distillation is shown in Fig. 2. The large lettered circles represent separate distillations, the small circles the fractions removed. The fractions to the right are the more volatile ones, while the fractions to the left are the less volatile ones. The fractions analyzed, as well as the atomic weights found in the analyses, are given in the figure.

Probable impurities in the crude tetrabromide included, besides bromine, hydrogen bromide from hydrolysis of the titanium tetrabromide when exposed to moisture in the air, carbon tetrabromide from action of bromine on charcoal and silicon tetrabromide from silicon contained in the titanium dioxide or from the glass. The boiling points and the effect on the atomic weight of titanium of one-tenth of one per cent. impurity of each are given in Table I.

The removal of the bromine was very rapid, for no evidence of its presence was obtained after the first three distillations. Presumably the still more volatile hydrogen bromide was removed at the same time. No tests for the other impurities were made, since all past experience with the distillation of inorganic halides has indicated that, when boiling points are as widely separated as in this case, separation is very rapid. Furthermore, the constancy in

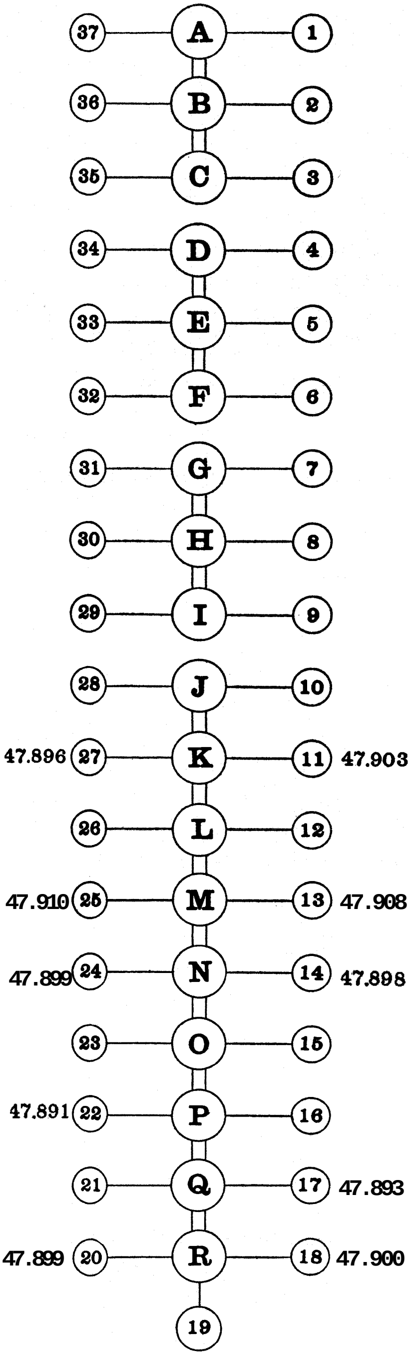

Fig. 2.

TABLE I

	B. p., °C.	Effect of 0.1% of impurity
$TiBr_4$	230	....
HBr	−69	−0.050

CBr_4	190	− .040
$SiBr_4$	153	− .021

composition of the fractions of the tetrabromide after the initial stages in the fractional distillation is evidence in the same direction. At any rate it is clear that purification by this method had reached a limit.

The final product was a lemon-yellow solid at ordinary temperatures and melted to a somewhat darker liquid.

Method of Analysis

The titanium tetrabromide was analyzed as in the case of the tetrachloride by solution in dilute nitric acid and comparison of the solution with silver. Since nitric acid slowly acts on the tetrabromide to liberate bromine, a small amount of arsenious acid was added to the nitric acid beforehand. Under these conditions no odor or color of bromine was ever detected.

A still more rigorous test for possible loss of bromine was made by dissolving one fraction of the tetrabromide in nitric acid containing arsenious acid, and drawing air slowly for two hours over or through the solution and then through a solution of ammonia. The latter was finally evaporated to small volume and tested for bromide by comparison with known quantities in a nephelometer. Various concentrations of bromide and nitric acid were used.

TABLE II

Concn. of $TiBr_4$, %	Concn. of HNO_3, normality	Bromide found, mg.	Concn. of $TiBr_4$, %	Concn. of HNO_3, normality	Bromide found, mg.
1.0	0.5	0.15	1.0	0.25	0.10
0.5	.5	.005	0.5	.20	.04
.5	.5	.3	.75	.18	.10
.5	.4	.05	.5	.12	.01
.5	.4	.15	.5	.12	.005
.5	.3	.10	.5	.12	.02
.5	.25	.005	.5	.12	.000
.5	.25	.005	.5	.10	.05

Since the loss of bromide from the solution seemed to be negligible at concentrations of nitric acid around 0.1 N, this concentration of nitric acid was used for the solution of the titanium tetrabromide.

The more important details of the method of analysis were as follows. In order to find the density of the glass bulb containing the tetrabromide, it was weighed first submerged in water of known temperature, and then, after being cleaned and dried, by substitution in air of known density.[4]

The weighed bulb was next broken under one liter of 0.1 N nitric acid containing 0.1 g. of dissolved arsenious oxide in a heavy-walled, glass-stoppered flask, and the solution was allowed to stand for several hours. No turbidity ever appeared and the hydrobromic acid fumes formed at first were quickly absorbed by the solution. The solution was then filtered into the glass-stoppered precipitating flask or bottle, through a weighed platinum-sponge Gooch crucible, on which the fragments of the glass bulb were collected after they had been washed with pure water. In order to prevent the retention of titanic acid, the crucible and the glass were further washed with hot 6 N nitric acid, and after being washed with water and dried at 250° were weighed. A second treatment with nitric acid ordinarily did not produce a change in weight of more than 0.02 mg., but in four experiments a third treatment was necessary before constant weight was secured. This method of collecting and weighing the glass was found satisfactory in the analysis of titanium tetrachloride.

The weight of titanium tetrabromide was obtained as the difference between the weight of the bulb and the weight of the glass, both corrected to vacuum. Very nearly the exact weight of pure silver necessary to combine with the tetrabromide was dissolved in nitric acid with especial precautions to avoid loss by spattering and, after dilution until approximately 0.1 N, the solution was slowly added to the bromide solution, which at this stage also was as dilute as 0.1 N and in many cases no more than 0.05 N. Thorough shaking and standing for several days followed. With the aid of a nephelometer the bromide and silver in the solution were adjusted to equivalence by the addition of hundredth normal solutions. Several weeks always elapsed between the precipitation and the final adjustment of the end-point, so that occluded material had abundant opportunity for being extracted from the precipitate of silver bromide.

No attempt was made to estimate the silver bromide quantitatively, since in the analysis of the tetrachloride the silver chloride was found to be badly contaminated with titanium compounds.

Weights were standardized by the substitution method of Richards.[5] Vacuum corrections were applied as follows.

	Density	Vacuum correction per gram
Weights	8.3	
Silver	10.49	−0.000031
Glass	2.5	+ .000335
Air	0.001293 (0° and 760 mm.)

					Average	.851788	47.900

Discussion

The extreme deviation of the calculated values for the atomic weight of titanium is 0.019 unit, but six of the results fall within a range of 0.007 unit. The "probable error" of the mean is 0.0013 unit, but it is far from certain that the accuracy of the final average is as great as this, owing to constant errors which it is impossible entirely to eliminate.

If the results are arranged in the order of decreasing volatility of the fractions of tetrabromide no trend is apparent, for the average of the first five results is 47.900, and the average of the last five 47.899.

Fraction of $TiBr_4$	Atomic weight of titanium	Fraction of $TiBr_4$	Atomic weight of titanium
11	47.903	20	47.899
13	47.908	22	47.891
14	47.898	24	47.899
17	47.893	25	47.910
18	47.900	27	47.896

In his initial examination of titanium in the mass spectrograph, Aston[6] found doubtful indications of an isotope of mass 50 besides the main isotope of mass 48, but apparently this indication has not been confirmed. The atomic weight 47.90 is in accord with the general rule that the masses of individual isotopes fall short of integral values when the mass number is between 20 and 200, but leads to a "packing fraction" nearly three times as large as that corresponding to Aston's curve connecting packing fraction with mass number.[7] This discrepancy may be due to an undiscovered isotope of mass number less than 48.

---

[6] Aston, *Phil. Mag.*, **47,** 397 (1924).

[7] Aston, *Proc. Roy. Soc. (London)*, **115A,** 510 (1927).

Under the conditions of the distillation no separation of the bromine isotopes is to be feared, as the constancy in composition of the fractionated material also indicates.

The analyses of titanium tetrachloride and titanium tetrabromide thus agree in yielding the value 47.90 for the atomic weight of titanium.

This research has been assisted by a grant from the Bache Fund of the National Academy of Sciences.

NOTES

Alkali Earth Metals in Saccharate Solutions and their Use in Alkalimetry.—Theoretically it would be most desirable to find some substance the equivalent weight of which could be directly weighed out, put into solution and diluted to a given volume to yield a standard of predetermined normality that would not require standardization or adjustment. The writer has been carrying on some work in an attempt to realize, partially at least, this ideal.

To this end different materials that would yield calcium oxide have been converted to that substance or to calcium hydroxide and have been dissolved to form a standard solution in a 30% cane sugar. These attempts were successful in so far as the attainment of the final results were concerned, but so much time was consumed that the method was not considered practical. In the course of further investigations, it was found that samples of metallic calcium in the form of 0.05 inch wire and about 96% pure went into solution at the rate of 1 g. in about eight minutes, on the average. In the ten cases tried a solution of predetermined normality was obtained, employing, of course, a correction factor to allow for the impurities. The calcium was obtained from the General Electric Company and, though impure, was so uniform that samples from different parts of the lots were found to yield identical solutions. The chief impurity is metallic magnesium which, together with its oxide, is almost insoluble in 30% sucrose, a fact that might be employed in separating small amounts of magnesium from large percentages of calcium especially in the analysis of metallic calcium. It would seem easy to eliminate this impurity by employing pure calcium chloride as an electrolyte instead of that obtained as a by-product from magnesian bitterns.

Another source of impurity is the rapid tarnishing of clean surfaces of metallic calcium when exposed to moist air, as reported in the literature. The film so formed is slow to appear in ordinary air and since it is very thin and consists of a high calcium compound, the error from this source seems negligible; however, it can easily be sandpapered off from the warm metal much as rust is removed from standard iron wire. The warm calcium which does not tarnish readily can then be enclosed in a suitable weighing bottle, cooled and weighed. The metal used in the above experiments was weighed in the open air with excellent results.

Some doubts seem to exist as to whether it would be feasible to produce C. P. metallic calcium. The very recent notable success of Syracuse University in producing 99.9+% metallic barium, a more reactive metal than calcium, should satisfactorily answer this question. In addition, The American Magnesium Corporation in a letter to the writer stated that that company has produced metallic calcium analyzing 99.98% metal. Moreover, it is common knowledge that very pure metallic sodium, still more reactive than the alkali-earth metals, has been produced commercially for years in enormous quantities at a reasonable price.

The size of wire is an important factor in the production of metal suitable for analytical work. Half-inch sticks are too large, as solubility is too slow; 0.05 inch wire is rather small, as the length of a tenth-equivalent is too great for convenience. One-eighth inch sticks would probably be most suitable so that the length of a tenth-equivalent weight would be convenient.

To ascertain whether or not the solution of calcium saccharate so prepared was suitable for general analytical work, titrations of carbonic acid, acid potassium phthalate and succinic acid were carried out with satisfactory results, employing the common indicators. To further test out the solution in actual practice, samples were distributed to m'embers of the chemical faculty for general use. These reported that the solutions were as satisfactory as the bases commonly employed.

The purpose of these notes is to interest, if possible, some producer of metallic calcium to furnish this element in sufficient purity to satisfy the requirements as outlined and at a non-prohibitive price. The successful accomplishment of this object seems attainable by attention to the exclusion of magnesium from the electrolyte employed in the method now used. The financial rewards of such a course seem to be assured because it would enable the chemist to prepare, with a single weighing, a standard alkali of predetermined normality, carbonate free and ready for use without previous standardization by an auxiliary substance.

A Pipet for **Micro-Analyses.**—The accurate delivery of small amounts of fluid is essential for micro-analyses. Folin[1] has stated that the Ostwald pipet is accurate to the order of 0.1%. Van Slyke and Neill[2] have improved this. They calibrate between marks and place a stopcock under the bottom mark. Their pipet is excellent for introducing fluids into the Van Slyke gas apparatus but is not equally practicable for other uses. Unless the end is washed a variable and unknown amount of fluid clings to the tip.

The pipet which we use is a modification of Van Slyke's, with a glass Luer adapter sealed to the bottom end. This ground end fits snugly into a hypodermic needle B of small gage, 18–23, which is cut off horizontally and ground on a stone. Trevan and Bainbridge[3] have shown that drops of the order of 0.00015 cc. can be removed from such a needle tip. For corrosive liquids a platinum needle may be used.

A test of the amount delivered indicated a surprising degree of accuracy. One worker obtained for a given pipet the following weights of water: 0.9982, 0.9981 and 0.9980 g. A second investigator weighed the water delivered from the same pipet as 0.9982 and 0.9983 g.

Apparatus for **Micro-Filtration.**—The centrifuge tube technique for the separation and washing of precipitates has been very useful for micro-analyses. In the course of development of a method for potassium, however, a small amount of material was lost when the supernatant fluid was poured off. To overcome this difficulty the following form of apparatus was devised (Fig. 1).

The principle is that of a Caldwell crucible. The filter is made by mounting a one inch funnel in a Witt filtering apparatus (this is essentially a suction flask with a ground glass removable top so that the filtrate may be recovered in a small inner container. If the precipitate only is to be saved, an ordinary suction flask is satisfactory). Into the

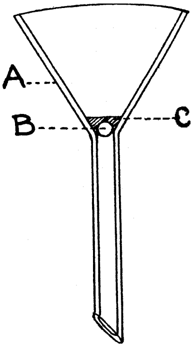
funnel, A, a glass pearl, B, is dropped and over the bead is poured a suspension of finely shredded asbestos, C, to form a layer about 1/32 of an inch thick. The mat is allowed to drain and suction is applied (see Fig. 1).



A—one inch glass funnel; B—small glass pearl or bead; C—mat of fine grained asbestos. Drawing is 3/4 actual size.

Fig 1

The precipitate and mother liquor are transferred to the micro-filter and the filtrate is removed by gentle suction. One drop of fluid is sufficient to wash the precipitate on the mat. With intermittent suction a precipitate can easily be washed five to ten times with one cc. of solution.

To remove the precipitate the funnel is inverted and a glass rod is inserted into the stem. Precipitates such as calcium, sodium, potassium, phosphorus, etc., that are to be dissolved before determination may be dissolved either on the mat, or in a separate container after removal together with the mat. In the latter case, a second filtration through the same apparatus gives a solution free of asbestos.

The materials for this micro-filter are at hand in every laboratory. They are inexpensive. During a year of use not a single determination has been lost.

CORRECTION

Through the work of Paul S. Roller[1] it has come to my attention that the signs of two terms in Equation 10 of my paper on titration[2] are incorrectly recorded. The term $3K_WK_A^{-2}$ in the coefficient of $(H^+)^3$ should be negative, as should also the last term of the equation. I wish also to confirm the result obtained by Roller by an independent method concerning the limiting strength of acid necessary for appearance of an inflection in titration with a strong base, the values of the ionization constants given in my paper for this case being too large, due to a numerical error, by one power of ten.

Note on the Changes in Composition of Compressed Air after Long Storage in a Steel Cylinder.—In connection with a study of the composition of outdoor air,[1] a steel cylinder of compressed air was secured from the compressed air plant at the Laboratory of Technical Engineering of the Massachusetts Institute of Technology and brought to the Nutrition Laboratory of the Carnegie Institution in the fall of 1910 as a control on gas analyses made with outdoor air. Disregarding the earlier series of analyses in which the technique was developing, in the chemical composition of this gas the percentage of carbon dioxide was 0.032 and of oxygen was 20.870.[2]

The analyses were made with the exceedingly exact Sondén gas analysis apparatus, which is described in the cited monograph. The cylinder has remained in the Laboratory unused since that time. Recently the composition of the air has again been determined using the new form of the Carpenter gas analysis apparatus.[3] On the day on which these analyses were made, the composition of the outdoor air was reported as 0.030% for carbon dioxide and 20.940% for oxygen, the usual figures found with this apparatus Two analyses of the air in the cylinder gave identical figures, both for carbon dioxide and oxygen, as 0.024% for carbon dioxide and 20.321% for oxygen. In the compressing of gas in these cylinders naturally the larger amount of water is removed, and yet there is enough moisture in the cylinder to facilitate oxidation.

The decrease in oxygen percentage incidental to seventeen years' storage is explained by the oxidation. The decrease in carbon dioxide content can be explained only by the presence of alkaline material in the cylinder.

Summary.—Analyses of compressed air after seventeen years' storage in a steel cylinder gave evidence of a slight drop in carbon dioxide percentage and a drop of approximately 0.6% in oxygen percentage.

INSULIN AND AMINO ACID CATALYSIS

BY JOHN M. ORT

RECEIVED JUNE 20, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

In a former paper[1] it was shown that in the presence of certain amino acids, the action of very dilute hydrogen peroxide on dextrose is hastened. Under the conditions of the experiments, other amino acids are without effect within six hours. This paper is a report of further studies on this action by the use of the oxidation-potential method. This time both dextrose and levulose were investigated. The effect of insulin on each was also determined, both in the presence and in the absence of the amino acids.

With the same technique as before, a study was made first on the influence of the rate of bubbles of the nitrogen gas which passed through the solutions, stirring them and freeing them from dissolved oxygen. In the former experiments the nitrogen passed through at a rate of approximately *25* bubbles a minute from the fire-polished end of a 6 mm. Pyrex capillary tube of 1 mm. bore, about 4 cm. below the surface of the liquid. In the experiments reported at this time, the rate of bubbles was approximately 2 a second. Doubling this rate did not have a significant effect on the shapes of the time-potential curves, in which form the data are presented.

The slower rate in the former experiments was considered safe since at that rate it was felt the nitrogen would completely carry out any oxygen that might diffuse into the chambers at the top, either through or around the rubber stoppers. On the other hand, substances reacting in the blood streams of animals are subjected to much more violent shaking and mixing than would be given by the twenty-five a minute rate. Therefore, it seems desirable to have present in the experiments the effect of the more rapid stirring, since it is hoped that the results may have some significance in connection with the mechanism of sugar oxidation in *vivo*.

In all experiments the solutions were first freed from most of the dissolved air by the very rapid passage of nitrogen (about 20 bubbles a second) for approximately one hour late in the afternoon. After this the rate was reduced to about 25 bubbles a minute in'the former experiments and to about 2 a second in this series, and the nitrogen allowed to bubble through the solutions at the slower rate overnight. The next morning the potentials were found to be changing but very slowly, and the dissolved air was assumed to be completely removed. Hydrogen peroxide was then added and the drifts of the oxidation potentials with time were followed. Longer periods of standing, before the addition of the hydrogen peroxide,

---

[1] Ort and Bollman, THIS JOURNAL, 49,805–810 (1927).

did not change the results significantly. Neither did shorter periods, provided the removal of dissolved oxygen had proceeded far enough to develop within the solution a moderate reducing intensity of approximately −0.15 volt. When hydrogen peroxide was added much before this, the resultant oxidation potentials often rose to 0.3 volt and over. The latent reducing power of the sugars under these conditions seemed to be temporarily paralyzed, for recovery to the previous negative potentials was delayed. The same was true if too much hydrogen peroxide was added at one time.

It is again pointed out that the results of these experiments can have only a qualitative significance. In the absence of a single, definite, reversible, oxidation-reduction equilibrium no exactly reproducible potentials can be expected. It is only assumed that the differences in the general shapes of the curves correspond to actual differences in the courses of oxidation of dextrose and levulose by hydrogen peroxide under the various conditions studied.

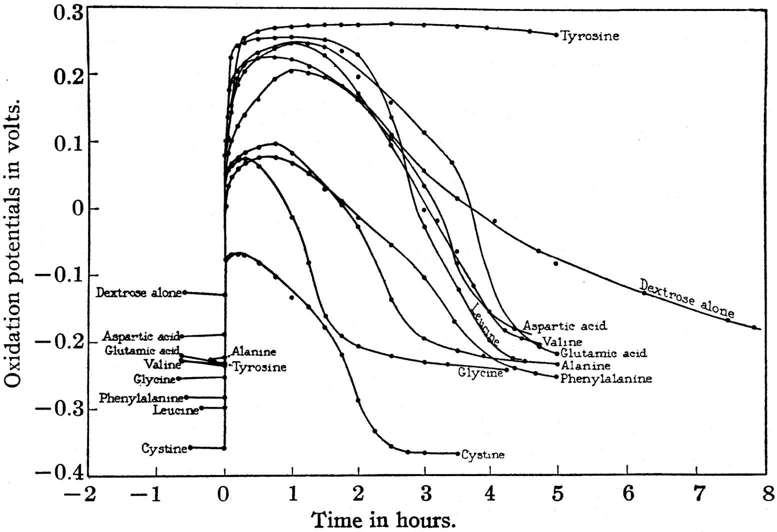

Fig. 1.—Dextrose and the amino acids.

Results of Experiments

Figure 1 shows the effect of several of the amino acids on the action of 0.5 cc. of 0.03% hydrogen peroxide added at time zero to a solution of 200 mg. of dextrose in a buffer at PH 10 and a temperature of 30°. The amount of amino acid present was 0.001 mole. With the exception of tyrosine, all had at least some accelerating action. This is somewhat different from the results published before. Glutamic acid and aspartic acid had little effect at the slower rate of bubbling, which is the only difference between the two sets of experiments. In Fig. 1, glycine, alanine and phenylalanine stand together as a group apart from valine, leucine, glutamic acid and aspartic acid. This grouping seems to parallel even closer the grouping, as shown by the latest work, according to specific dynamic action. Tyrosine alone, which has been found to have marked specific dynamic action, seems out of place. But with tyrosine in the experiments as performed in vitro, the solutions became more oxidizing than the others, under which conditions, as already mentioned, the reducing power of dextrose becomes temporarily paralyzed. In *vivo* the blood has a posing action, which would prevent such an oxidizing intensity. At least tyrosine seems to have an effect on the oxidation of dextrose somewhat different from that of the other amino acids studied.

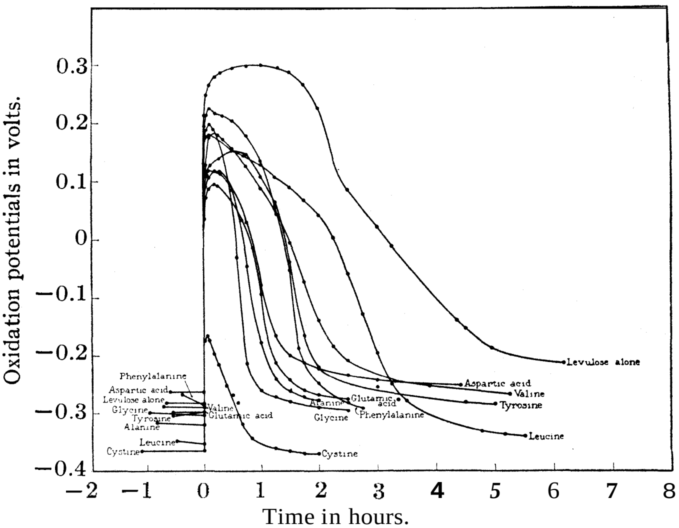

Fig. 2.—levulose and the amino acids.

Figure 2 shows the results of similar experiments on levulose. As would be expected, recovery occurs sooner and more rapidly than with dextrose. With the exception of cystine, which exists in solution in a reversible system, glycine, alanine, glutamic acid and aspartic acid are the most effective catalyzers. This division seems to have no relation whatever to specific dynamic action In comparing these curves to those in Fig. 1, it is interesting to note that for levulose as well as dextrose the rate of recovery is greatest in almost all cases in a region of oxidation potentials bordered very roughly by 0.05 and —0.15 volt. It can also be seen that in both cases the rate of fall in potentials drops off sharply in the neighborhood of —0.2 volt.

In Fig. 3 is shown the action of hydrogen peroxide on solutions of insulin and the amino acids, without any sugar. One cc. of Lilly's U 20 Illetin was added in each case at the start of the run, the other details being as before. With the exception of cystine no action was indicated. These

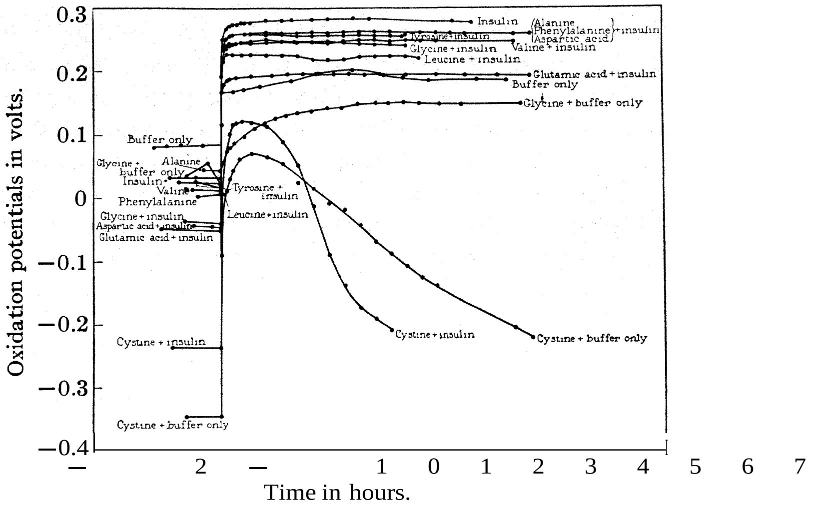

Fig. 3.—Insulin and the amino acids.

experiments were performed as controls for the studies with insulin on dextrose and levulose.

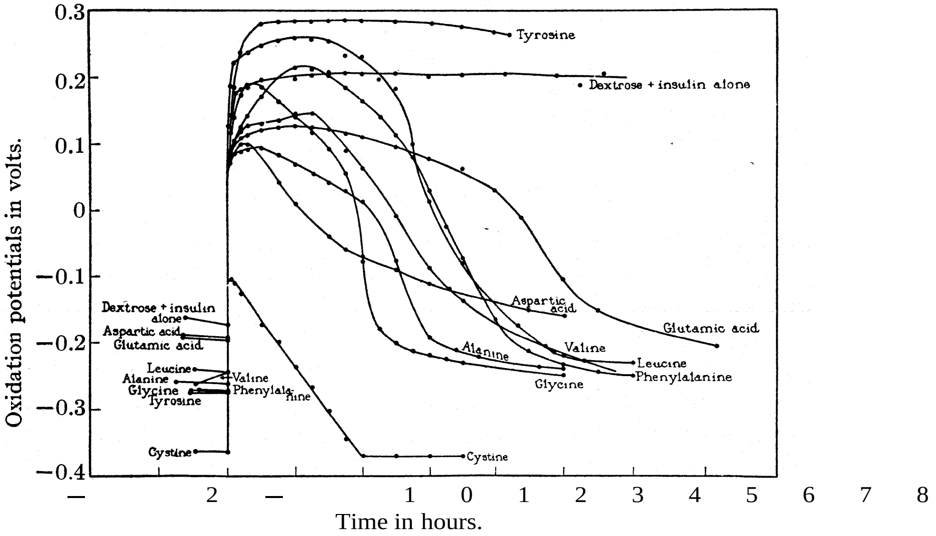

Fig. 4.—Dextrose, insulin and the amino acids.

The effect of insulin on the amino acid catalysis with dextrose is shown in Fig. 4. The action of hydrogen peroxide on dextrose alone seems to be retarded by insulin. This is true to a less extent also in the presence of glutamic acid, glycine and phenylalanine. The catalysis in the presence of cystine and of aspartic acid was somewhat increased. Little change was found for tyrosine, alanine, valine and leucine. The grouping of the amino acids closely according to specific dynamic action seems somewhat lost in the presence of insulin, although complete recovery to reducing conditions, after addition of hydrogen peroxide, is reached again first in the presence of glycine, alanine and phenylalanine, cystine as usual being excepted.

Finally, Fig. 5 shows the results of similar experiments on levulose with insulin and the amino acids. Again the action of hydrogen peroxide on the sugar alone is retarded by the insulin. There is little suggestion of a grouping of the amino acids according to specific dynamic action. The presence of insulin seems to be without much effect on the amino acid catalysis, although most of the curves in Fig. 5 are a little closer together than those in Fig. 2. Again, even when insulin is present, as shown in Figs. 4 and 5, attention is called to the fact that the maximal rate of recovery in all cases is in a region of oxidation intensity approximately between 0.05 and −0.15 volt and that the drop in potentials is abruptly slowed down below −0.2 volt.

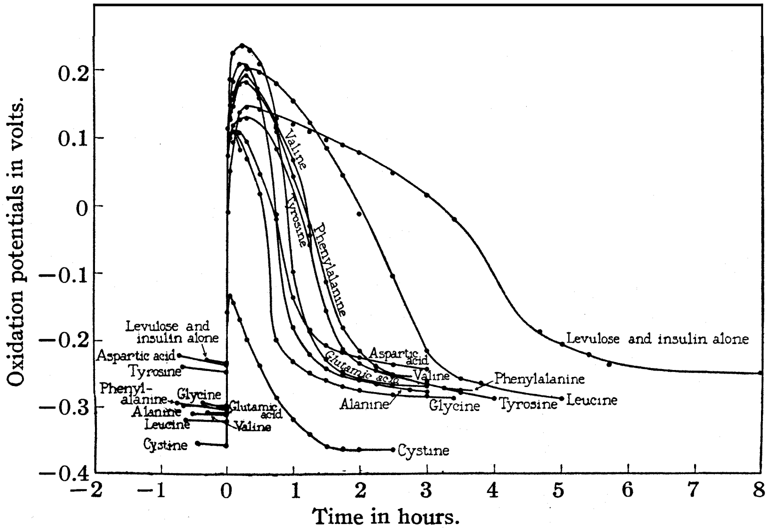

Fig. 5.—**Levulose, insulin and the amino acids.**

Summary

A further study was made on amino acid catalysis of the action of hydrogen peroxide on dextrose and this was continued to include the action on levulose. The sole diierence between the experiments on dextrose alone and those already published is in the faster bubbling of nitrogen gas in these reported at this time. The parallelism between the grouping of the amino acids as catalyzers with dextrose and their grouping according to specific dynamic action is even closer than in the former experiments. Tyrosine alone, which yields slightly higher oxidation potentials than the others, is an exception. At these higher potentials whenever they were obtained in any manner with dextrose alone or with other amino acids it was noticed that the reducing power of the sugar was temporarily paralyzed and the return to more negative potentials much delayed. The connection between amino acid catalysis with levulose and specific dynamic action is much less close than with dextrose.

When insulin was added it was found that the action of hydrogen peroxide on both dextrose alone and levulose alone was retarded. For both sugars insulin had no marked effect on the amino acid catalysis. Some effect, however, was noticed in a smoothing out of the differences between the various amino acids.

Attention is called to the fact that in all cases the maximal voltage change towards a return to reducing conditions takes place in a region approximately between 0.5 and —0.15 volt and that below —0.20 volt the drop is rather quickly stopped. It is hoped in a future paper to discuss the significance of these facts in relation to the mechanism of sugar oxidation in alkaline solutions.

A STUDY OF THE OPTIMAL CONDITIONS FOR THE PREPARATION OF TERTIARY BUTYLMAGNESIUM CHLORIDE

BY HENRY GILMAN AND E. A. ZOELLNER

RECEIVED JULY 18. 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

It was previously shown by Gilman and McCracken[1] that the yields of the four butylmagnesium bromides decrease in striking fashion with the increasing complexity of branching of alkyl groups, and to such an extent that *tert.*-butylmagnesium bromide gave a yield less than one-fourth of that obtained with n-butylmagnesium bromide. *Tert.*-butyl alcohol is now available at a low cost and the chloride is readily prepared from it in very good yield. Because alkyl chlorides give better yields of RMgCl compounds than the corresponding alkyl bromides[1] a study has been made of several factors affecting the optimal conditions for the preparation of *tert.*-butylmagnesium chloride. As a result of such studies, this tertiary Grignard reagent can now be prepared in quite satisfactory yields.

---

[1] Gilman and McCracken, THIS JOURNAL, 45, 2462 **(1923).** Also, Gilman and Kirby, *ibid.*, 48, 1733 (1926) for better yields obtained from chlorides over bromides.

Experimental Part

The apparatus and technique used was essentially that of Gilman and McCracken.[1] The yields were determined quantitatively by the acid titration method of Gilman, Wilkinson, Fishel and Meyers.[2] As an additional check on the yields, several large-sized preparations of trimethylacetic acid were made from *tert.*-butylmagnesium chloride and carbon dioxide. The complex secondary reactions, involving among other things the evolution of considerable isobutylene and isobutane, will be reported later.

Temperature.—Bouveault,[3] who used *tert.*-butylmagnesium chloride in a number of reactions, recommended that the temperature be kept at from 5 to 15° in order to diminish the extent of decomposition evidenced by the evolution of isobutane and isobutylene. We found, on the contrary, that better yields are obtained when the reaction mixture is allowed to reflux as a result of the heat of reaction or is refluxed gently (by use of a water-bath) during the addition of chloride. Solvents other than diethyl ether were not used. In one preparation, the mixture was refluxed after removing aliquots for analysis, and there was practically no change in the concentration of RMgCl compound from that originally present.

Number of Moles of Ether.—Gilman and McCracken[4] have very recently shown that the number of moles of ether required for an optimal yield of Grignard reagent varies with the RX compound. For example, they showed that n-butylmagnesium bromide could be prepared in highest yield with but one mole of ether per mole of halide. With benzylmagnesium chloride 6–7 moles of ether was recommended and with phenylmagnesium bromide 4–5 moles of ether.

With gentle refluxing of the ether solution and a given rate of addition (about 90 drops or 1.4 cc. per minute), the best yield was obtained with about 7–8 moles of ether per mole of chloride.

Rate of Addition of RX Compound.—Gilman and Meyers[5] showed that ethylmagnesium iodide is formed with best yields when the halide in ether is added slowly to the magnesium and ether. This is particularly true in the preparation of *tert.*-butylmagnesium chloride. When the rate of addition is very slow (less than 0.7 cc. per minute) then the yield does not increase but actually decreases to a slight extent. This may be due to the evolved gases (and particularly the circulating hydrogen atmosphere[4,5]) carrying off more of the chloride before it had a chance to reach the magnesium.

---

[2] Gilman, Wilkinson, Fishel and Meyers, THIS JOURNAL, 45, 150 (1923). For further data on the reliability of this method and a criticism of another method of analysis see Gilman and Meyers, *Rer. trav. chim.*, 45, 314 (1926).

[4] Gilman and McCracken, *Kec. trav. chim.*, 46,463 (1927).

[5] Gilman and Meyers, THIS JOURNAL, **45,** 159 (1923).

The rate of addition in a moderate-sized run is of more significance for ordinary laboratory work than that in the small-sized runs made in the special apparatus. The best yield of trimethylacetic acid, prepared from *tert.*-butylmagnesium chloride and carbon dioxide, was realized when one-half mole of the chloride in 7 moles of ether was added to the magnesium during three hours. This slow addition was at the rate of 2 cc. of halide solution per minute Unquestionably this time can be decreased, for in the small 0.1 mole runs a maximum yield was obtained when the solution was added over a period of two hours.

A possible reason for the better yields when the rate of addition is low is the diminution of a secondary reaction between *tert.*-butylmagnesium chloride and *tert.*-butyl chloride. This finds support in an experiment where the addition of *tert.*-butyl chloride to a solution of *tert.*-butylmagnesium chloride (free from unused magnesium) produced a significant decrease in the quantity of Grignard reagent from that originally present.

Stirring.—In view of the decidedly helpful effect of stirring noted in earlier work, no study was made of this factor and stirring was used throughout all the preparations.[5,6]

Kind of Magnesium.—Gilman and Meyers[5] in their study of the optimal conditions for the preparation of ethylmagnesium iodide used magnesium turnings of three arbitrary grades, coarse, medium and fine. They showed that under a given set of conditions the finer the grade of turnings the higher the yield, but that the factor most affected was the rate of reaction, inasmuch as coarse turnings used over a longer period of reaction gave the same yield as the fine turnings.

No study was made of any reaction rates with *tert.*-butylmagnesium chloride, but there is no question concerning the decided improvement in yield that comes with the use of very fine turnings approximating a powder. This fine material of about 150 mesh was freshly turned and kept in a tightly rubber-stoppered bottle when not in use. A coarser metal of about 30 mesh is also quite satisfactory. Some of the ordinary coarse turnings commercially available for Grignard reactions should not be used for the preparation of *tert.*-butylmagnesium chloride if a finer metal can be had. Fine turnings that give good yields are commercially available in this country.

The finer turnings are recommended largely on the basis of the better yields of trimethylacetic acid from fair-sized preparations of *tert.*-butylmagnesium chloride. The finer turnings, however, would be recommended on the basis of the much smaller runs carried out in the special flasks for estimating quantitatively the yield of RMgX compound. The improvement in yield with the use of finer turnings was more marked in the larger runs.

---

[6] Grignard used a shaking device very early in his studies of organomagnesium halides.

The yield of *tert.*-butylmagnesium bromide in one of the smaller-sized runs was 33.1%. Under corresponding conditions the yield of *tert.*-butylmagnesium chloride was 49.71%. Earlier results by Gilman and McCracken under different conditions showed *tert.*-butylmagnesium bromide to be formed in a 20.6% yield.

The maximum yield of *tert.*-butylmagnesium chloride obtained in the several experiments was 58%. In large-sized runs the yield is improved as is evidenced by a 62% yield of trimethylacetic acid from a two and one half mole run of *tert.*-butyl magnesium chloride and carbon dioxide in which fine commercial turnings were used, and by a 69–70% yield when 200 mesh magnesium powder was used.

The authors gratefully acknowledge a liberal supply of *tert.*-butyl alcohol from the Petroleum Chemical Corporation of New York.

Summary

As a result of a study of several factors in the preparation of *tert.*-butylmagnesium chloride it is now possible to 'obtain this Grignard reagent in quite satisfactory yields,

A FURTHER STUDY OF THE INTERACTION OF SULFUR AND PARA-TOLUIDINE IN THE PRESENCE OF LITHARGE: THIO-PARA-TOLUIDINE AND RELATED COMPOUNDS[1]

BY MARSTON TAYLOR BOGERT AND LEONARD SMIDTH[2]

RECEIVED AUGUST 2, 1927 PUBLISHED FEBRUARY 4, 1928

Introductory

Sulfur dissolves freely in molten p-toluidine to a perfectly clear, transparent, pale yellow solution, which can be heated to about 180° before there is evidence of any reaction, when a slow evolution of hydrogen sulfide begins, gradually increasing as the temperature rises and accompanied by a darkening of the solution, with the ultimate production of dehydrothio-p-toluidine (V), primulines (VI), and other substances.

In the presence of litharge, or other hydrogen sulfide absorbents, however, the reaction begins at much lower temperature (130–145"), as shown first by Merz and Weith,[3] with thio-p-toluidine (III) as the chief product.

This Merz and Weith process has been investigated by Bogert and Mandelbaum,[4] who found that the melt contained both thio- and dithio-

---

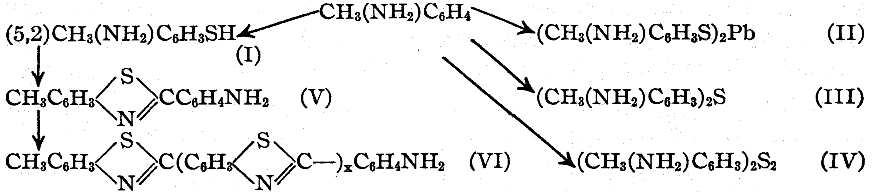
[4] Bogert and Mandelbaum, THIS JOURNAL, 45, 3045 (1923).

p-toluidine (IV) and who proved that the sulfur in these products was *ortho* to the amino and *meta* to the methyl groups.

In examining this Merz and Weith fusion further in the experiments which follow, we used one equivalent of sulfur per mole of p-toluidine and, in addition to thio- and dithio-*p*-toluidine, succeeded in isolating from the melt small quantities (less than 1%) of dehydrothio-p-toluidine.

It is our belief that the first product of the action of sulfur upon *p*-toluidine in these fusions is the mercaptan(I), and that this is the progenitor of most of the other products formed, as shown in the following diagram



Ziegler[5] argued many years ago, in discussing the production of dehydrothio-p-toluidine from p-toluidine and sulfur, that since sulfur possesses many properties which recall those of the halogens, it might be expected to substitute either nuclear or side-chain hydrogen depending upon conditions, that high temperature favored side-chain substitution and that the first phase of the reaction, therefore, probably consisted in the formation of p-aminobenzylmercaptan, which condensed with a second mole of p-toluidine to *p*-aminobenzyl-*p*-toluidine, $H_2NC_6H_4CH_2$-$NHC_6H_4CH_3$, and this latter was then transformed into dehydrothio-p-toluidine by the further action of the molten sulfur. The Farbwerke Hoechst[6] subsequently patented the manufacture of dehydrothio-p-toluidine from paminobenzyl-p-toluidine, but no one has yet reported the finding of any p-aminobenzyl-p-toluidine in the dehydrothio-p-toluidine melt, and the experiments of Bogert and Snell[7] demonstrated quite conclusively that the dehydrothio-p-toluidine obtained in following out these patent specifications owed its origin to unchanged p-toluidine remaining in the initial material used. In fact, when toluene itself is heated with sulfur for some time, stilbene is formed in very small amount,[4,8] but no benzyl mercaptan.

Bogert and Mandelbaum[4] separated the products of these Merz and Weith fusions by taking advantage of their different basicities and extracting them successively from a benzene solution of the melt with a series of acids each stronger than its predecessor, p-toluidine thus being removed first, then thio-p-toluidine and finally dithio-*p*-toluidine.

[5] Ziegler, *Ber.*, 23, 2475 (1890).

[6] Farbwerke Hoechst, Ger. pat. 104,230 (May 8, 1899); *Friedlander,* **5,** 83 (1901).

[7] Bogert and Snell, *Color Trade J., 14,* 109 (1924).

[8] Aronstein and van Nierop, *Rec.* trav. *chim.,* 21,450 (1902).

We have now found that the opposite procedure is preferable, namely, the extraction of the melt with excess of mineral acid and the fractional precipitation of the bases by gradual neutralization of this acid solution with ammonia, whereby they are separated in the reverse order, dithio-p-toluidine being thrown down first and *p*-toluidine last.

A perusal of the experimental details of the two processes will make it manifest that the former (fractional extraction with acids) was better adapted to the recovery of the thio-p-toluidine than of the dithio compound, because of the accumulation of tars in the final extracts. For similar reasons, the ammonia precipitation method favored the recovery of the dithio derivative, and incidentally disclosed the fact that the amount of dithio formed was much greater than previously suspected. The two methods thus supplement each other in a very helpful manner and indicate that, based upon the amount of p-toluidine actually consumed in the reaction, the yield of thio-*p*-toluidine is about 25–30%, and of dithio 15–20%.

In the presence of hydrochloric acid, p-toluidine and sulfur interacted to give mainly tar, with but very small amounts of impure dithio-*p*-toluidine, although it has been stated by Hodgson[9] that the latter can be obtained in this way.

Efforts to convert thio-p-toluidine into the 3,9-dimethylphenothiazine,[10] by the action of soda lime, zinc chloride or concd. hydrochloric acid all failed.

Although, as is well known, thio-p-toluidine can be easily diazotized and combined with suitable couplers to form azo dyes, our experiments show that it does not itself function as a coupler for diazotized aromatic bases.

Like Truhlar,[11] we, too, experienced considerable difficulty in getting pure compounds by the application of the diazo reaction to thio-p-toluidine, the products being mostly tars from which we were unable to isolate any crystalline material; but when these tars were oxidized with a mixture of nitric and sulfuric acids, crystalline sulfones were isolated in approximate purity.

In the experiments to obtain a chlorine derivative, the action of concd. hydrochloric acid upon the diazonium chloride gave rise to what appeared to be a mixed ether, whose percentage composition corresponded to the formula $(CH_3C_6H_3ClSC_6H_3CH_3)_2O$, and which may be identical with a product obtained by Truhlar in a similar reaction, described by him as an easily frozen oil containing chlorine and which he was unable to identify.

Attempts to substitute the amino groups by bromine resulted in the

replacement of one amino by bromine and the other by hydrogen, as proved by the formation of a monobromo sulfone on oxidation. The di-iodo sulfone, however, was obtained from thio-*p*-toluidine in good yield. All efforts to get a dicyano derivative through the diazo reaction were unavailing.

Experimental Part

Fusion of *p*-Toluidine, Sulfur and Litharge.—These fusions were carried out as described by Bogert and Mandelbaum,[4] except that we found that a slightly lower temperature (130–140°, instead of 140–145°) gave rather better results.

To determine what effect, if any, the litharge had upon p-toluidine in the presence of steam, litharge and the toluidine were added to boiling water and the mixture boiled for some time under a reflux condenser. No change whatever occurred and the p-toluidine crystallized from the colorless aqueous solution as the latter cooled.

A suspension of litharge and sulfur (excess) in boiling water rapidly blackened with formation of lead sulfide and evolution of traces of sulfur dioxide. .

The fusion conditions were varied as follows:

(1) When an intimate mixture of sulfur (1, 1.5 and 3 equivalents) with excess of litharge was added slowly *to* molten p-toluidine (one mole), there was some improvement in the yield of thio-p-toluidine, but more p-toluidine remained unchanged and was recovered.

(2) A mixture of *p*-toluidine (one mole) and excess of litharge was added to molten sulfur (1.5 or 5 equivalents), but the yields of thio-*p*-toluidine were not thereby improved and more tar was formed.

Working up of the Melt.—The cold pulverized melt obtained from *535* g. (5 moles) of p-toluidine, 160 g. (5 equivalents) of sulfur and 800 g. (2.8 moles) of litharge, was extracted repeatedly with 800 cc. portions of 10% hydrochloric acid (or sulfuric) with which it was boiled vigorously for five minutes and the extract filtered hot. The use of stronger acid caused such a copious effervescence of hydrogen sulfide that it was difficult to keep the solution from boiling over.

Each hot filtered 800 cc. acid extract was poured into 1000 cc. of cold water, which precipitated weakly basic resins. The filtrate from these resins was then warmed and treated carefully with ammonium hydroxide solution until the odor of p-toluidine was detected. This precipitated the mono- and dithiotoluidines. Neutralization (with ammonia) of the filtrate from these thiotoluidines caused the separation of practically pure *p*-toluidine.

To recover as much as possible of the mono- and dithiotoluidines present, the thiotoluidine precipitates from the four acid extracts were combined, redissolved in 1800 *g.* of 10% hydrochloric acid and ammonium hydroxide solution added cautiously to this solution, whose temperature was maintained sufficiently high (30–50°) to cause the precipitated dithio compound to separate in a viscous and not a solid form. The color of this viscous precipitate changed as the addition of ammonia proceeded, being yellow at first, then pink and finally red. It was removed mechanically as it accumulated. When all of the crude dithio compound had been precipitated, further addition of ammonia caused the separation of the solid monothio-*p*-toluidine and the precipitate became crystalline. The first portions of this crystalline precipitate were contaminated with some of the dithio derivative and were removed and worked up separately. Further addition of ammonium hydroxide to the filtrate precipitated thio-p-toluidine as a pale yellow solid. The neutralization with ammonia was continued until the odor of p-toluidine was noted or, in the absence of unchanged p-toluidine, until neutrality was reached.

The crude products were purified by a repetition of the process described. In the case of the crude disulfide, its hot dilute acid solution was first poured into sufficient cold water to separate small amounts of basic resins. The filtrate was then precipitated carefully by ammonia as before, any thio-p-toluidine obtained being worked up with the crude thio-p-toluidine fraction. With a little experience the end-points in this separation are easily and quickly noted.

The yields of crude products from one of these fusions were as follows: weakly basic resins (precipitated from acid solution by dilution), 70 g.; dithio-p-toluidine, 80 g., or 17%; monothio, 121 g. or 26%; p-toluidine recovered, 167 g. The yields of mono- and dithiotoluidine are calculated on the basis of the net amount of p-toluidine consumed in the operation.

From one of these fusions, conducted at 140–145°, 20 g. of the resinous products precipitated by dilution of the acid solution was extracted repeatedly with large volumes of boiling water and yielded a total of 0.96 g. of impure dehydrothio-*p*-toluidine (m. p. 186°), or less than 1% of that calculated from the initial materials. When the fusion temperatures were below 140°, only traces of this compound could be found in the melts. No trithio-p-toluidine was isolated from the melt, nor any compounds other than those already mentioned.

The Interaction of *p*-Toluidine and Sulfur in the Presence of Concentrated Hydrochloric Acid.—Hodgson[12] reports a nearly theoretical yield of trithio-o-toluidine when he heated together o-toluidine, hydrochloric acid and sulfur for two to three hours at 185–190°, and similar results in the case of aniline.[13] We repeated this work with o-toluidine and obtained excellent yields of the trithio-o-toluidine, melting at 225° (uncorr.). Hodgson gives the melting-point of the pure product as 226–227° (uncorr.).

In his original patent,[9] Hodgson states that p-toluidine, under similar conditions, gives a dithio derivative, and hence we carried out various experiments with p-toluidine, hydrochloric acid and sulfur, following the Hodgson process, but succeeded in obtaining only very small amounts of impure dithio-p-toluidine, together with some unchanged p-toluidine and a large amount of tar. The difference in the behavior of the two toluidines when treated in exactly the same way was striking.

Thio-*p*-toluidine, as prepared by the process described, was usually colorless and melted above 100°. Its further purification was accomplished by crystallization from diluted alcohol; or the solution in hot 10% hydrochloric acid, after precipitation of any disulfide (unless the disulfide is precipitated first by ammonia, the addition of concd. hydrochloric acid tends to throw down its hydrochloride as well as that of the monosufide), was treated with concd. hydrochloric acid until precipitation began, when the solution was allowed to cool and the hydrochloride separated in colorless, feathery

needles, which were dissolved in boiling water and the free base precipitated by neutralization with ammonia. A single crystallization from diluted alcohol than gave colorless leaves, m. p. 103–104°, in agreement with the literature.

Heated above its melting-point, it was unchanged at 150°; at 180–190°, small amounts of ammonia were given off; at 200°, ammonia and hydrogen sulfide; at 205–210°, ammonia, hydrogen sulfide and p-toluidine (identified by its odor, its melting point and the melting point of its aceto derivative). The residue was brown and amorphous, and its benzene solution was strongly fluorescent.

No change was detected when thio-p-toluidine and concd. hydrochloric (or 25% sulfuric) acid were heated together for six hours at 200°, except the formation of some p-toluidine. When fused for several hours with sulfur, thio-p-toluidine was not decomposed, nor could any dehydrothio-p-toluidine be isolated from the melt.

A mixture of 71 g. of thio-p-toluidine (m. p. 103–104°) and 19 g. of sulfur was heated at 140–150° and 65 g. of litharge added gradually during eight hours. By extracting the cooled and pulverized melt with hydrochloric acid, 60 g. of crude thio-*p*-toluidine (that is, 84.5% of the original amount) was recovered, together with a small quantity of acid-soluble tars. The thio-p-toluidine formed in the p-toluidine-sulfur fusion, therefore, is not very rapidly or extensively decomposed by the litharge and sulfur added.

In acid solution, thio-p-toluidine refused to couple with diazotized sulfanilic acid. On the other hand, azo dyes are readily produced by uniting diazotized thiotoluidine with suitable couplers, and were patented long ago by Dahl & Co.[14] We verified this by coupling the diazotized thiotoluidine with H-acid in sodium carbonate solution and obtained an azo dye which gave deep purple shades on wool, fast to light, acids, alkali or soap.

Diaceto Derivative.—This was prepared as recorded by Bogert and Mandelbaum[4] and corresponded in appearance and melting point with their description. It was subjected to some further tests, with the following results.

To attempted bromination, nitration or sulfonation, it proved very resistant, decomposition generally occurring before the desired substitution could be realized. At laboratory temperature, a mixture of concd. nitric and sulfuric acids (75:30) oxidized it to the corresponding diaceto sulfone; this proved to be a convenient way of preparing the latter compound, instead of the permanganate method employed by Bogert and Mandelbaum.

Bis(2-Acetamino-5-methylphenyl) Sulfoxide, $(CH_3CONHC_6H_3(CH_3))_2SO$.—Attempts to oxidize thio-p-toluidine in acetone solution with hydrogen dioxide, by the method of Gazdar and Smiles,[15] resulted in tar and unchanged initial material, but no appreciable yield of sulfoxide. Hinsberg,[16] however, has found that aceto derivatives often can be used advantageously for such oxidations and we followed this lead successfully.

To a well cooled solution of 5 g. of thio-*p*-toluidine in 6 cc. of acetic anhydride, there were added 20 cc. of glacial acetic acid and 2 cc. of 30% hydrogen dioxide ("Superoxole"). After standing for twelve hours at room temperature, the solution was poured into a large' volume of water and the acid neutralized with ammonia. The precipitate crystallized from alcohol in colorless hexagonal plates, m. p. 212° (corr.); yield, 2 g. or 28%.

Anal. Calcd. for $C_{18}H_{20}O_3N_2S$: C, 62.75; H, 5.87. Found: C, 62.79; H, 5.89.

Bis(2-Chloro-5-methylphenyl) Sulfone.—A solution of 5 g. of thio-p-toluidine in 80 cc. of water and 12 cc. of concd. hydrochloric acid was diazotized at 0° with an aqueous solution of 3.3 g. of sodium nitrite and 6 g. of copper powder was added. After standing for an hour, the mixture was heated at 100° until the evolution of gas ceased. The tarry precipitate was oxidized as described beyond for the analogous iodo derivative. The product was a pale brown, amorphous solid which decomposed slowly above 95°; yield, 2.1 g., or 33%. It was readily soluble in chloroform or acetone, less readily in benzene and practically insoluble in alcohol.

Anal. Calcd. for $C_{14}H_{12}O_2Cl_2S$: C, 53.32; H, 3.84. Found: C, 53.91; H, 3.46.

Bis(2-Chloro-5,5′-dimethylphenylsulfide)-2,2′-Oxide, $(CH_3C_6H_3ClSC_6H_3CH_3)_2O$.—A solution of 24.5 g. of thio-p-toluidine in 100 cc. of concd. hydrochloric acid and 150 cc. of water was diazotized at 0° (some of the thiotoluidine hydrochloride tends to separate as the temperature of the solution falls) by a solution of 15 g. of sodium nitrite in 75 cc. of water. After standing for thirty minutes at 0°, the solution was poured into 450 cc. of concd. hydrochloric acid and the mixture left overnight at room temperature. Gas was evolved slowly. The solution was heated gradually to boiling. A black oil soon separated and the reaction appeared to be at an end. The oil was removed, washed with strong aqueous caustic alkali, then with water, after which it was distilled at 80 mm. pressure and a fraction collected at 265° which formed a colorless oil that darkened gradually on standing; yield, 15 g. or 59%.

Anal. Calcd. for $C_{28}H_{24}OCl_2S_2$: C, 65.75; H, 4.69; S, 12 52; Cl, 13.90. Found: C, 65.66; H, 5.07; S, 12.81; Cl, 14.42.

This compound was insoluble in strong caustic alkali solutions. A distinctive and striking property was the deep blue color it gave when treated with concd. sulfuric acid. Oxidation with acid permanganate failed to yield a crystalline sulfone, while strong oxidation with nitric acid broke down the molecule to unidentified products soluble in the diluted acid.

2-Bromo-5,5′-dimethylphenyl Sulfone, $CH_3BrC_6H_3SO_2C_6H_4CH_3$.—Ice was added to 17 g. of concd. sulfuric acid until the temperature was reduced to 0°, when 5 g. of thio-p-toluidine was stirred in and the solution diazotized with an aqueous solution of 3 g. of sodium nitrite. To this diazo solution, there were added 30 g. of potassium bromide and 10 g. of copper powder, and the rest of the process followed that described for the analogous chloro and iodo derivatives. The product was a brownish, amorphous solid which decomposed slowly at about 69–72°; yield, 1.6 g. or 24%. It dissolved easily in chloroform, acetone or benzene, less freely in ether, only slightly in carbon tetrachloride and was practically insoluble in alcohol.

Anal. Calcd. for $C_{14}H_{13}O_2BrS$: C, 51.69; H, 4.00. Found: C, 52.16; H, 3.64.

These figures indicate that one only of the two original amino groups of thio-*p*-toluidine was replaced by bromine, while the other was substituted by hydrogen, but not enough pure material was left to check this by determining also the percentage of bromine present.

Bis(2-Iodo-5-methylphenyl) Sulfone.—To a diazo solution prepared from 5 g. of thio-p-toluidine and the requisite amounts of hydrochloric acid and sodium nitrite, there was run in slowly a cold saturated aqueous solution of 12 g. of potassium iodide. When the first rapid evolution of nitrogen subsided, the mixture was warmed at 100" until no more gas was given off. The black, viscous precipitate was collected, washed with water, dissolved in glacial acetic acid and sufficient potassium acid sulfite added to convert any free iodine into potassium iodide. When this solution was poured into water, a yellow, gummy precipitate separated. This was added in small quantities to a mixture of concd. nitric (15 cc.) and sulfuric (6 cc.) acids and the mixture warmed until a copious evolution of nitrogen oxides occurred. The oxidation was completed very quickly. The acid liquid was poured into water, the precipitate removed, warmed with strong caustic soda solution, the undissolved material dissolved in boiling glacial acetic acid, the solution decolorized and poured into water. The precipitate was collected, washed with hot alcohol and subjected to further purification by re-solution in glacial acetic acid, decolorization and reprecipitation by dilution. This precipitate, when washed with water and alcohol and dried, appeared as a pale brownish, amorphous solid which began to decompose in the neighborhood of 82°; yield, **4.3** g. or 42%. **It** dissolved freely in chloroform, acetone or carbon disulfide, less readily in benzene, but slightly in ether and was practically insoluble in alcohol or carbon tetrachloride.

Anal. Calcd. for $C_{14}H_{12}O_2I_2S$: C, **33.73; H, 2.43;** S, **6 44;** I, **50.96.** Found: C, **33.14; H, 2.25;** S, **6.30;** I, **50.25.**

Dithio-*p*-toluidine.—The crude product obtained in the process described was purified further by dissolving it in hot alcohol, adding water or, better, ammonium hydroxide solution, to incipient clouding and allowing the solution to cool. The yellow, lustrous leaflets obtained, melted at **88–89",** in accord with the literature.

Hodgson[17] reports that when dithio-aniline (10 g.) is boiled for eight hours with dry aniline (20.4 g.), the yield of monothio-aniline is practically equal to that calculated, but that the presence of water retards this reaction and may inhibit it entirely. From this latter statement, it would seem unlikely that much thio-aniline could be formed from the dithio during an aniline-sulfur-litharge fusion, for steam is given off continuously during this reaction due to the gradual addition of the litharge. Yet, K. A. Hofmann[18] states that he obtained thio-aniline by heating an aniline solution of dithio-aniline for one and one-half hours at 170–180°, with the gradual addition of somewhat more than one mole of litharge, and Hodgson,[19] who repeated Hofmann's experiments, isolated both o,o - and o,p -monothio-anilines from the melt.

It seemed desirable, therefore, to ascertain the behavior of dithio-p-toluidine under similar conditions, and the following experiments record the results.

A mixture of 6 g. of dithio-*p*-toluidine (carefully purified and free from the monothiotoluidine) and **20** g. of p-toluidine was heated for eight hours at 140–150**'**, while **10** g. of litharge was added gradually to the melt. From this melt there were recovered **5.1** g. of the original disulfide and **18** g. of p-toluidine, but no thio-*p*-toluidine. Increase in the fusion temperature to 165° did not alter this result materially, except that at the higher temperature some tar was formed.

To determine the effect of sulfur and litharge upon the disulfide, 9 g. of the latter was heated with **4** g. of sulfur for eight hours at 160–165°, while **10** g. of litharge was added gradually. Most of the initial disulfide was recovered from the melt unchanged, together with about **0.7** g. of acid-soluble resins.

Like the monosulfide, this disulfide may be used for the preparation of azo dyes.[9,20]

[17] Hodgson, **J.** *Chem. Soc.*, *125,* **1856** (1924).

[18] **K. A.** Hofmann, *Ber.,* **27,2810 (1894).**

[19] Hodgson, **J.** *Soc. Dyers Colourists, 40,* **333 (1924).**

[20] British Dyestuffs Corp. Ltd. and H. H. Hodgson, Brit. pat. **235,334** of April **1, 1924.**

Diazotized and coupled with H-acid in sodium carbonate solution, it gave a dye which produced purplish shades on wool, lighter in tone than the corresponding dye from the monosulfide, but resembling it in its fastness to light, acids, alkali and soap.

PICRATE.—Equal moles of the disulfide and picric acid were mixed in hot benzene solution and the picrate was crystallized as the solution cooled. Recrystallized from benzene it formed long, silky, yellow needles

The DIACETO DERIVATIVE has been described by Bogert and Mandelbaum.[4] When it was oxidized either with nitric acid or with acid permanganate, the product appeared to be a sulfonic acid. We failed to obtain either a sulfoxide or a sulfone.

2-Amino-5-methylphenyl Mercaptan, $CH_3(NH_2)C_6H_3SH$.—Reduction of dithio-p-toluidine by zinc dust and acetic acid, or by tin and hydrochloric acid, gave the zinc or tin salts of the mercaptan, from which the mercaptan itself was liberated by the action of hydrogen sulfide.

In a typical experiment, **10** g. of the crude disulfide was dissolved in **200** cc. of boiling glacial acetic acid, 20 g. of zinc dust added gradually and the mixture refluxed for an hour. Longer boiling of the acetic acid solution proved detrimental to both yield and purity of the product. It was then filtered hot, the filtrate diluted with **2.5** volumes of water and allowed to stand for ten to fifteen minutes. On longer standing, impurities present in a crude initial disulfide are also likely to separate. The white, flocculent precipitate of zinc salt was collected, washed with water, then with a little ether and dried at **110°**; yield, 5.6 g. or 45%.

Anal. **0.9824** g. ignited gave **0.2319** g. of ZnO, or **23.60%**: calcd., **23.82%**.

Liberated from its zinc or tin salts by hydrogen sulfide, the mercaptan gradually oxidized in the air to the disulfide.

Summary

1. A further study has been made of the Merz and Weith reaction for the production of thio-p-toluidine from *p*-toluidine, sulfur and litharge, and a new method of separating the products worked out which depends upon their fractional precipitation from acid solution by ammonia.

2. Various experiments are recorded which throw light upon the probable mechanism of the reaction, and indicate that the action of sulfur upon *p*-toluidine follows a somewhat different course from that of sulfur upon either aniline or o-toluidine.

3. Additional properties and reactions of both thio- and dithio-p-toluidine are described, including their conversion into various derivatives.

AROMATIC PROPERTIES OF SOME ALIPHATIC COMPOUNDS LOCAL ANESTHETICS DERIVED FROM ALIPHATIC CARBOXYLIC ACIDS

BY HENRY GILMAN, L. C. HECKERT AND R. MCCRACKEN

RECEIVED AUGUST 17, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

The differences between aromatic and corresponding aliphatic compounds are largely of degree and not of kind. There are probably no rigidly exclusive aromatic characteristics. Functional groups that have the so-called aromatic properties are almost invariably attached to a tertiary carbon atom that has some degree or other of unsaturation. A fair basis of comparison would restrict correlation to aliphatic compounds that have functional groups of a related type. When this condition is met, in part or in whole, one observes that practically all the so-called distinctive aromatic properties are shown by varied aliphatic compounds.[1]

The present work extends such correlation to include the comparative physiological action of some aromatic compounds with related aliphatic types. Previously, Gilman and Pickens[2] showed a correlation, based on physiological action, between some aromatic heterocyclic types (furan, thiophene and pyrrole) and benzene. For comparative purposes the same physiological action, namely, local anesthetic action, has been studied. It has been found that the diethylamino-ethyl esters of carboxylic acids (where the carboxyl group is attached to an ***unsaturated*** carbon atom, $RCH{=}CHCO_2CH_2CH_2N(C_2H_5)_2$) show a distinct, although small, local anesthetic action. Where the same grouping is attached to a saturated carbon atom there is no local anesthetic action.

For comparative purposes it is interesting to observe that when the unsaturated acid contains also a phenyl radical, as in cinnamic acid, the anesthetic action is increased. Also, the cinnamic acid ester of diethylaminopropyl alcohol ("Apothesin") is distinctly active. Its high potency is no doubt partly due to the introduction of the phenyl radical into the acrylic acid and partly to the fact that the amino-alcohol part of the molecule contains an additional carbon atom.

Experimental Part

The hydrochlorides of the diethylamino-ethyl esters were prepared by a standard technique involving the interaction of the acid chloride

---

[1] Space does not permit of reference to the many works in this field. A general and leading account of some such correlations is to be found in Johnson and Hahn's translation of Henrich's "Theories of Organic Chemistry," John Wiley and Sons, Inc., New York, 1922, in particular see pages 182–183, 232 and 234–235

with diethylamino-ethanol in an inert medium, generally benzene or ether.

Diethylamino-ethyl **Acrylate** Hydrochloride, $CH_2{=}CHCO_2CH_2CH_2N(C_2H_5)_2.HCl$.—Eight g. or **0.088** mole of acrylic acid chloride[3] in **50** cc. of dry benzene was added dropwise to **11** g. or **0.094** mole of β-diethylamino-ethanol in **50** cc. of benzene. The hygroscopic hydrochloride of diethylamino-ethyl acrylate melted at 93° when crystallized from benzene.

Anal. Calcd. for $C_9H_{18}O_2NCl$: Cl, **17.07;** N, **6.70.** Found: Cl, **16.89, 16.53;** N, **6.30.**

Preliminary to the above synthesis, β-chloro-ethyl α,β-dibromopropionate, $CH_2BrCHBrCO_2CH_2CH_2Cl$, was prepared by passing hydrogen chloride into a mixture of α,β-dibromopropionic acid and ethylene chlorohydrin. The yield of ester boiling at 153° **(20** mm.) was **92.9%;** n^{30} = **1.9080;** d_4^{20} = **1.5241.**

Anal. Calcd. for $C_5H_7O_2Br_2Cl$: Br, 54.31; Cl, **12.03.** Found: Br, **54.20;** Cl, **12.02.**

Diethylamino-ethyl **β,β-Dimethylacrylate** Hydrochloride, $(CH_3)_2C{=}CHCO_2CH_2CH_2N(C_2H_5)_2.HCl$.—This compound was prepared from dimethylacrylic acid chloride and diethylamino-ethanol in ether. When crystallized from acetone it melted at 128.5–130°.

Anal. Calcd. for $C_{11}H_{22}O_2NCl$: Cl, **15.07.** Found: Cl, **15.2.**

Diethylamino-ethyl Trichloro-acetate Hydrochloride, $CCl_3CO_2CH_2CH_2N(C_2H_5)_2.HCl$.—The same general conditions were followed here as in the preparation of the β,β-dimethylacrylate ester hydrochloride. The compound melted at 144–145°.

Anal. Calcd. for $C_8H_{15}O_2NCl_4$: N, **4.68.** Found: N, **4.76.**

Diethylamino-ethyl Acetate, $CH_3CO_2CH_2CH_2N(C_2H_5)_2.HCl$, melted at 116–117°.

Anal. Calcd. for $C_8H_{18}O_2NCl$: Cl, **18.12.** Found: Cl, **18.09, 18.14.**

Some preliminary reactions were carried out between diethylamino-ethanol and the acid chlorides of fumaric and monochloro-acetic acids. From these the hydrochloride of 8-diethylamino-ethanol was obtained.

Pharmacological Tests

The authors are indebted to Dr. Oliver Kamm of Parke, Davis and Company of Detroit for the results of the pharmacological tests. The method of testing was that described earlier.[2] Cocaine was selected arbitrarily as a standard and given a weight of 10. On a scale of this kind, the relative and rather approximate ratings of the hydrochlorides are as follows: diethylamino-ethyl dimethylacrylate is 1; diethylamino-ethyl acrylate is also 1; diethylamino-ethyl trichloro-acetate is slightly less than 1; and diethylamino-ethyl acetate is zero. "Apothesin," diethylaminopropyl cinnamate, has a rating of approximately 8 on this basis.

Diethylamino-ethyl trichloro-acetate was selected in this study because trichloro-acetic acid has, among other properties, a conductivity that places it nearer to aromatic compounds than acetic acid.

It is interesting to note that the comparative effectiveness of the diethylamino-ethyl esters of acrylic and dimethylacrylic acids places them

---

[3] Prepared according to direction.; of Moureu, *Ann. chim. phys.*, *[7]*2, 161 (1894).

not far from two of the aromatic types previously reported,[2] namely, diethylamino-ethyl 2-thiophenecarboxylate (with a rating of 1) and diethylamino-ethyl 2-furancarboxylate (with a rating of less than 1).

Summary

A study of the local anesthetic action of some diethylamino-ethyl esters of aliphatic carboxylic acids shows that the chemical correlation of aromatic compounds with some related aliphatic compounds can be extended to include physiological action.

THE TAUTOMERISM OF HYDROXY QUINONES

BY LOUIS F. FIESER

RECEIVED SEPTEMBER 16, 1927 PUBLISHED FEBRUARY 4, 1928

It is the purpose of this paper to apply to the problem named in the title certain of the principles governing chemical equilibria, and to present the results of experiments which were carried out with the view of testing and applying this theoretical treatment of the subject.

1. The General Theory

Hydroxynaphthoquinone is typical of the compounds under consideration. While only one form of the substance is known in the solid state,[1] it is necessary to recognize the presence of two tautomeric forms in its solutions in order to account for the course of the hydrolysis of 2-alkoxy-1,4-naphthoquinones and 4-alkoxy-1,2-naphthoquinones, for a single solid substance results in each case.[2] Among the reactions which demonstrate the presence of hydroxy-a-naphthoquinone in the equilibrium mixture is that with diazomethane,[2] while the ready, reversible reaction of hydroxynaphthoquinone with sodium bisulfite must involve a β-naphthoquinone derivative. Thus these tautomers, which may be referred to as the α and β forms of hydroxynaphthoquinone, must be present in all solutions of the substance and the constant of the tautomeric equilibrium may be defined by the following equation

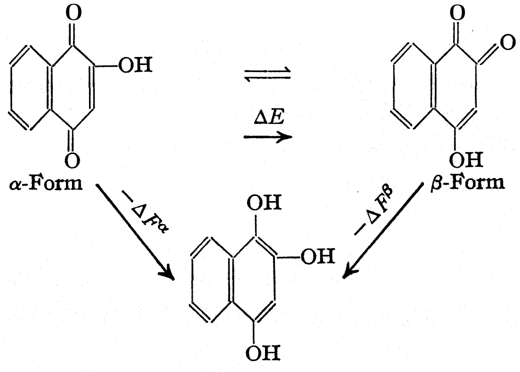
$$K = [\alpha\text{-Form}]/[\beta\text{-Form}] \qquad (1)$$

---

[1] Miller's statement to the contrary, *J. Russ. Phys.-Chem. Soc.*, **43**, 440 (1911), must be discounted. It is possible that the change in his sample on storage and the variation of the point of decomposition of this substance are both due in part to a reaction of the material with glass. Some of the samples which Miller prepared by different methods undoubtedly contained impurities. Dr. Samuel C. Hooker has informed me that, by following with the microscope the crystallization of a red sample of this quinone, he found the red color to be due to the presence of impurities removed only after numerous crystallizations.

[2] Fieser, THIS JOURNAL, 48, 2922 (1926).

In order to obtain a method of estimating the magnitude of K, use may be made of the fact that the tautomers have a common reduction product.



For the purpose of the following theoretical treatment it is convenient to postulate the free energy changes involved in the conversion of one tautomeric quinone into the other and in the conversion of each quinone into the common hydroquinone. It should be clearly realized that it is not possible at the present time to determine directly any of these quantities. There remains, however, the possibility of developing a method of reasoning by analogy which will serve to give an approximate evaluation of the tautomeric equilibrium constant, and it is with this end in view that a thermodynamic analysis of the problem will be presented. The free energy change in the conversion of the a-form at unit concentration in a given solvent into the β-form at the same concentration, AF. is equal to the free energy of reduction of the a-form $(-AF^{a})$ minus the free energy of oxidation of the reductant to the β-form $(-\Delta F^{\beta})$

$$\begin{array}{llll} & \text{a-Form} + 2\text{H} & = \text{Reductant} & -\Delta F^{\alpha} \\ & \text{Reductant} & = \beta\text{-Form} + 2\text{H} & + \Delta F^{\beta} \\ \hline \text{(Adding)} & \text{a-Form} & = \beta\text{-Form} & -\Delta F^{\alpha} + \Delta F^{\beta} \\ \textbf{(Or)} & & \Delta F = -\Delta F^{\alpha} + \Delta F^{\beta} & \end{array} \qquad (2)$$

The free energy changes in the reduction of the two quinones are conveniently expressed in terms of the normal reduction potentials of the tautomers in the solvent in question, E_0^{α} and E_0^{β}, since $-$ A F = nFE_0. Making these changes, and substituting for A F the expression RT ln K, Equation 2 becomes, for 25°

$$\log K = (E_0^{\beta} - E_0^{\alpha})/0.0296 \qquad (3)$$

There is thus a simple relationship between the equilibrium constant of the tautomerization and the difference in the normal reduction potentials of the two tautomers. That form which has the lower reduction potential will predominate; thus, if E_0^{α} is less than E_0^{β}, K will be greater than one and [α-Form] > [β-Form]. This principle is novel to the organic chemist only in its quantitative aspects. Dimroth for example in assigning structures to certain hydroxynaphthoquinone derivatives arbitrarily wrote the α-naphthoquinone formulas because, as he says, "in general, para quinones are more stable than ortho quinones," ("im allgemein Parachinone stabiler sind als Orthochinone.")[3] The first statement of the idea was probably that of Kehrmann,[4] who applied it to a study of the structure of the azines. Beschke[5] presented evidence in support of his conception that, if a given substance can give rise to two different quinones on oxidation, the quinone of lower oxidizing power will result. The presence of a common reduction product is not, however, essential for the interconversion of the tautomers. To be sure, Equation **3** was derived with the use of normal potentials, that is, electrode potentials of mixtures containing equivalent quantities of the oxidant and reductant, but it applies equally well to the "pure solutions" of the quinones.

Before considering extensions of Equation **3,** it will be well to demonstrate how this equation can be applied to the solution of practical problems. The isolation of the tautomeric forms of an hydroxy quinone has not yet been accomplished, and it is not likely that potential measurements could be carried out with such substances without the occurrence of a tautomeric change. However, although the terms E_0^β and E_0^α cannot be determined directly, it is possible in many instances to estimate these potentials, or the difference between them, from the known values of compounds of related structure. The soundness of this process of reasoning depends upon the nature of the analogy of which use is made in any particular case. In the following pages, in which an attempt has been made to determine the approximate composition of the equilibrium mixtures of certain hypothetical tautomer pairs, various methods of predicting the potentials of the tautomers have been employed, and each case should be judged on its own merits.

2. Hydroxynaphthoquinone

It will be seen from Equation **3** that all that is required for an evaluation of the equilibrium constant, K, is a knowledge of the difference between the potentials of the tautomers. Although there is at present no way of predicting the potentials of the two possible forms of hydroxynaphthoquinone, it is possible to decide which form would have the higher potential and to estimate the magnitude of the difference between the two values from a knowledge of the potentials of the ethers, I and II. While the potentials of these ethers may not be the same as those of the corresponding hydroxy compounds, it is highly probable that the difference

---

[3] Dimroth and Kerkovius, Ann., 399, 36 (1913).

[4] Kehrmann, *Ber.*, 31, 977 (1898).

[5] Beschke and Diehm, Ann., 384, 173 (1911).

between the two values is approximately the same as the difference between the potentials of the two tautomers.

Data which will permit a prediction of the magnitude of this difference are furnished by the results of e. m. f. measurements with a series of ethers of the type of I and II (Table I). In order to prevent the hydrolysis of the o-quinone ethers it was necessary to employ a neutral solution, while the insolubility of some of the ethers in water necessitated the use of an alcoholic solution. The solvent which was consequently employed (see table) did not permit the use of the ordinary reducing agents and so the quinones were reduced with hydrogen and a catalyst and the hydroquinones titrated electrometrically with potassium ferricyanide dissolved in the same solvent. The normal reduction potential (E_0) is equal to the e. m. f. of the cell: Pt | Solvent A, Quinone, Hydroquinone | Solvent A | H_2 | Pt, at the point of half-reduction. Under ΔE_1 and ΔE_2 are given the average differences between E_0 and the potential at 20% and at 80% oxidation. The theoretical value is 17.8 mv.

9	**n-Butyl**	.422	.423	.421		21.2	18.9	.422

Table I indicates that there is a slight decrease in reduction potential with increasing size of the alkoxyl group. Since of these groups the methoxyl is the most similar in structure to the hydroxyl group, the difference in the potentials of the two methyl ethers may be taken as a measure of the difference in potential of the two tautomerie hydroxy compounds, though the result is much the same if any other pair of ethers is selected. Substituting the value $E_0^\beta - E_0^\alpha = 0.080$ v. in Equation **3,** it is found that for hydroxynaphthoquinone K = 502. This means that in the solvent in question only 0.2% of the β-form is present in the equilibrium mixture. From the facts known concerning the variation of quinone reduction potentials with changes in temperature and in solvent (at constant P_H),[6] it can be said that the composition of the equilibrium mixture will be changed to an inappreciable extent by such changes in the conditions. These conclusions are in agreement with all of the known properties of the substance in question and this theoretical treatment finds particular support in the course of the hydrolysis of ethers of the β-form.[2]

3. Naphthopurpurin

There are two structures, IIIa and IIIb, which represent the possible tautomeric forms of naphthopurpurin.[7] It is not difficult to predict what the reduction potential of a pure substance possessing the structure of IIIa would be, for this differs from naphthazarin, IV, only in having an extra hydroxyl group, and the effect of such a group on the potential of a quinone is easily determined. By the use of certain analogies, a prediction can also be made concerning the potential of IIIb. Thus an idea can be gained of the relative values of E_0 for the two tautomers and, consequently, of the equilibrium constant.

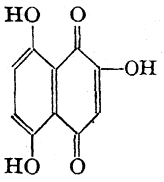
The potential of naphthopurpurin itself can be determined by direct measurement; but this measurement furnishes no indication of the possible existence of two tautomers in the solution. The value found will depend upon the potentials and the concentrations of the tautomers, but there is no way of deducing from this value, taken by itself, the composition of the mixture or the potential of either tautomer. However, if on reasoning by analogy it can be shown, for example, that IIIa would have a much lower potential than IIIb, there is reason to believe that in a solution of naphthopurpurin IIIa predominates to the practical exclusion of IIIb. In this event, the experimentally determined potential of naphthopurpurin would represent the potential of tautomer IIIa in practically pure form, and a comparison of the experimental value with the value predicted for IIIa would furnish a check on the validity of conclusions drawn solely from a consideration of the potentials predicted for the tautomers.

The potential of naphthopurpurin, together with data required for the predictions indicated, is given in Table II. While compound No.

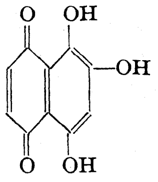
---

[6] Conant and Fieser, THIS JOURNAL, 44, 2480 (1922).

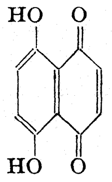
[7] In view of the definite chemical and electrochemical evidence pointing to the P-quinonoid structure for hydroxynaphthoquinone, it is not necessary to consider an o-quinone formula for naphthopurpurin or for the dihydroxyquinone, V, below.



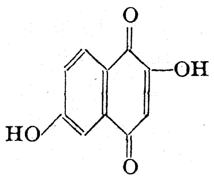
IIIa



IIIb



IV[8]



V

TABLE II

REDUCTION POTENTIALS AT 25°

Solvent: 50% alcohol, 0.1 N in HCl and 0.2 N in LiCl.

No.		E_0, v.				ΔE_1, mv.	ΔE_2, mv.	E_0 (av.), v.
10	Naphthopurpurin (III)	0 243	0 243	0 244	0 243	21.8	20.7	0.243
11	Naphthazarin (IV)	.362	361	359	362	20.2	20 9	361
12	2,6-Dihydroxy-1,4-naphthoquinone (V)	.303	.304	.302		18.1	18.6	303

12 was titrated electrometrically with titanous chloride, this reagent could not be employed with the other quinones because highly colored precipitates were formed. In these cases the hydroquinone solutions were prepared by catalytic hydrogenation and titrated with a solution of benzoquinone.

In order to estimate the potential of IIIa, the potentials of 2-hydroxy-1,4-naphthoquinone (E_0 = 0.356 v.),[9] of naphthazarin (IV), and of a-naphthoquinone (E_0 = 0.483 v.)[9] under comparable conditions are re-required. Thus E_0 (IIIa) = 0.356 − (0.483 − 0.361) = 0.234 v. For a prediction concerning IIIb, it is necessary to know the potential of naphthazarin (IV) and the effect of a hydroxyl group in the β position in the benzoid ring. The latter information is furnished by a comparison of hydroxynaphthoquinone with its 6-hydroxy derivative, V. Then E_0 (IIIb) = 0.361 − (0.356 − 0.303) = 0.308 v. Since the potential predicted for IIIa is 0.074 v. lower than the value estimated for IIIb, it is reasonable to suppose that IIIa is the predominant tautomer. Assuming the accuracy of these predictions, the equilibrium constant for naphthopurpurin calculated from Equation 3 is 157, whence about 0.4% of the less stable tautomer, IIIb, is present at equilibrium.

If this reasoning is correct, the experimentally determined value for naphthopurpurin must be very close to the actual potential of IIIa. The value predicted for IIIa, 0.234 v., agrees just as closely with the value found, 0.243 v., as could be expected. It is not yet possible to calculate potentials with greater accuracy than this. Thus, from the potentials of 4-ethoxy- and 4-(n-propoxy)-1,2-naphthoquinone (Table I), one would expect the n-butyl derivative to have a potential of 0.430 v.; but the actual value is 0.422 v. The above discrepancy of 0.009 v. is thus of little sig-

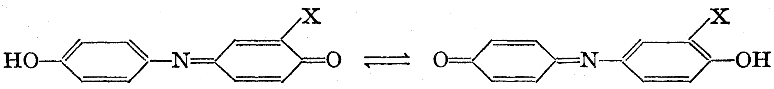
[9] Conant and Fieser, THIS JOURNAL, 46, 1858 (1924).

nificance. It is significant, on the other hand, that the predicted potential for the other tautomer, IIIb, is 0.065 v. higher than the potential found for naphthopurpurin. It is inconceivable that naphthopurpurin has the structure of IIIb and that the discrepancy in the values is due to the inaccuracy of the calculations.

4. Indophenols

An extensive field for the application of the ideas here presented is that of the indophenols, for in the case of any unsymmetrical indophenol two tautomeric forms such as VIa and VIb are possible. Clark and his collaborators, who have carried out a comprehensive study of the electrode potentials of a wide variety of these substances,[10] have recognized throughout the necessity of taking account of the tautomerism of these substances and they have frequently adduced evidence to show that a tautomeric change has taken place during or after the prepaxation of certain of their compounds. On the other hand, they do not appear to have fully appreciated the fact that the tautomers will have different reduction potentials and that the position of the tautomeric equilibrium depends upon the difference between the two values. While it is not now possible with the aid of this principle to interpret much of the data of these authors in terms of the problem of the effect of substituent groups, a few theoretical considerations may serve to clarify the problem. From the facts known about quinones, it may be said that a substituent group always has a greater effect on the potential when it is attached to the quinonoid nucleus than when situated in an adjacent benzene ring, but that the direction of the effect is the same in each instance. If the substituent, X, is an alkyl or an hydroxyl group, both VIa and VIb will be lower in potential than the parent compound, VIa will be lower in potential than the tautomer and will predominate in the equilibrium mixture. Just the reverse is true when the substituent is a halogen or an acidic group and in this case VIb will predominate; but even if more precise predictions were possible, it would be difficult to tell how they correspond with experimental results because the e.m.f. measurements represent equilibrium values. The relationship between such a value and the potential of a single pure tautomer may be defined in the following way. The equation for the electrode potential of one tautomer (α-Oxid), whether alone or in an equilibrium mixture, at such a PH that no dissociation takes place, is



VIa VIb

---

[10] (a) Clark and Cohen, *Pub. Health* Repts., 38, 933 (1923); (b) Cohen, Gibbs and Clark, *ibid.*, 39, 381 (1924); (c) *ibid.*, 39, 804 (1924); Gibbs, Cohen and Cannan, *ibid.*, 40, 649 (1925).

$$E^a = E_0^\alpha + 0.059 \log [H^+] + 0.0296 \log [\alpha\text{-Oxid}]/[\text{Red}] \qquad (4)$$

If no tautomer is present, [a-Oxid] is equal to the total concentration of the oxidant $[\text{Oxid}]_T$, and the equation applies in the usual way; otherwise the only determinable concentration, the total concentration of the oxidant, is equal to the sum of [a-Oxid] and [β-Oxid]. Expressing the latter quantity in terms of the former and of the equilibrium constant, K, it is seen that

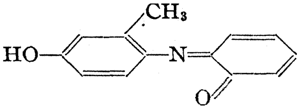
$$[\text{Oxid}]_T = [a\text{-Oxid}] + [\beta\text{-Oxid}]/K$$

whence,

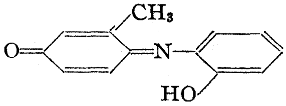
$$E^a = E_0^\alpha + 0.059 \log [H^+] + 0.0296 \log [\text{Oxid}]_T/[\text{Red}] + 0.0296 \log K/(K+1) \qquad (5)$$

If the potential of such a mixture is determined under the usual "normal" conditions ($[H^+ = 1$; $[\text{Oxid}]_T = [\text{Red}]$), the value found, E^a, will differ from the normal potential of the α-oxidant by the amount $0.0296 \log K/(K + 1)$. Thus if two different tautomers had the same potential ($K = 1$), the apparent normal potential of the mixture would be 8.9 mv. lower than the normal potential of either tautomer. This factor obviously complicates the interpretation of data on the effect of simple substitution where the tautomers may be very close to each other in potential.

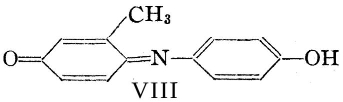
When the two tautomers represent widely different structural types, their potentials may be so far apart that one form will predominate almost exclusively and it should be possible to determine its structure. For example, Cohen, Gibbs and Clark[10c] report measurements with *m*-cresol-o-indophenol, to which, simply on the basis of the mode of preparation, they assign Formula VIIa. There are, however, two reasons for preferring Formula VIIb, the first being that the methyl group will have a greater effect in lowering the potential of the parent compound when it is attached to the quinonoid nucleus than when situated as in VIIa. But a more fundamental difference in the two structures is that one is o-quinonoid, the other p-quinonoid. Not only are o-quinones always much higher in potential than isomeric *p*-quinones by about 0.07 to 0.10 v., but this also applies to the quinonimines,[11] which are closely related to the indophenols in structure. Thus, both because of its *p*-quinonoid structure and because of the location of the methyl group, VIIb most certainly has the lower potential, and the value of this potential would not be expected to differ greatly from that for *m*-cresol-*p*-indophenol, VIII, while the other tautomer



VIIa



VIIb



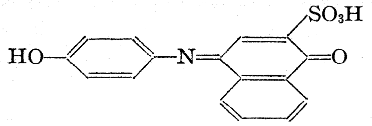
VIII

---

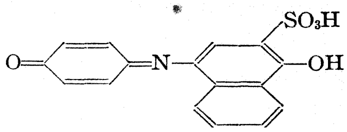
[11] Conant and Pratt, This Journal, 48, 3178 (1926).

must have a potential in the neighborhood of 0.1 v. higher. The experimental results confirm this prediction. The normal potential reported for the "ortho"-indophenol, VII, is 0.647 v.,[10c] while that for the *p*-indophenol, VIII, is 0.632 v.[10b]

Another case to which the same reasoning may be applied is that of 1-naphthol-2-sulfonic acid indophenol,[10a] IX. On considering IXa to be a



IXa

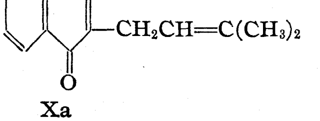


IXb

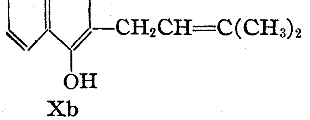
derivative of phenol-indophenol, for which $E_0 = 0.649$ v.,[10b] adding to this value the known effect of attaching a sulfonic acid group to α-naphthoquinone (0.066 v., av.)[9] and subtracting the difference in the potentials of *p*-benzo- and *p*-naphthoquinonimines (0.175 v.,), a value of 0.540 v. for the potential of IXa is obtained. This, of course, is only a rough estimate, and the same is true of any prediction about IXb. However, it is difficult to see how IXb can differ greatly in potential from phenol-indophenol, $E_0 = 0.649$ v., and this is such a decidedly higher figure that there can be little doubt that the substance corresponds essentially to IXa. The experimentally determined value of 0.544 v., since it agrees well with the above estimate for IXa, clearly demonstrates that this is the case.

5. Lapachol and Related Compounds

There is ample evidence in the foregoing facts not only that the factors governing the tautomeric equilibrium have been correctly defined but also that tautomeric quinones in general exist in solution in a condition of equilibrium. While it seems likely that the latter proposition is an entirely general rule, it is of considerable importance to submit the problem to extensive experimental inquiry. A promising series of compounds for this purpose is that of the type of lapachol, X. With highly substituted quinones of this character, addition to the quinone nucleus is retarded,[2] reduction proceeds slowly (see Experimental Part) and it is conceivable that there might be a condition of delayed equilibrium preventing the less stable tautomer, Xb, from rearranging into Xa. Indeed, according to statements in the literature, one such case is known.



Xa



Xb

For the opportunity to study potentiometrically a number of compounds of the lapachol group, I am greatly indebted to Dr. Samuel C. Hooker, who kindly placed at my disposal pure samples of these materials, some of which had been prepared[12] 34 years ago and had been preserved unchanged. Several similar compounds which have recently been prepared synthetically[13] were included in this study, the results of which are summarized in Table III. In every case the quinone was titrated electrometrically with titanous chloride solution, though two of the determinations with Compound No. 23 were made by titration of the hydroquinone.

Since a number of these substances are very reactive in the sense, for example, that lapachol may be converted by various acidic reagents into α- or β-lapachone or chlorohydrolapachol, some fear was entertained that some such changes might occur on dissolving the compound in the alcoholic hydrochloric acid solution or during the course of the measurements. The results of the measurements themselves lead me to believe that this is not the case. Thus, for example, if hydroxyhydrolapachol suffers any reaction, β-lapachone will surely be among the products formed. This quinone has a potential so much higher than that of the original substance or of any other compound likely to be formed (a-lapachone) that its presence would be unmistakably revealed in the titration curve. However, at the suggestion of Dr. Hooker, whose interest has greatly encouraged me in this work, I attempted to prove that some of these very sensitive compounds remain unaltered. At the completion of a titration, in which, as a rule, 0.05 g. of material was dissolved in 200 cc. of solvent, the solution was exposed to the air until oxidation was complete. Water was then added, the solution was extracted thoroughly with ether, the ethereal solution was washed well with water, dried and the ether evaporated. In many cases the original material was obtained directly in crystalline, and very nearly pure, form; but in every instance it was possible to test the residue with such reagents as ammonia or bisulfite solution for the presence of appreciable quantities of by-products and then to obtain the main product in pure form by crystallization. Compounds No. 13, 18, 19, 20, 22, 28, 31, 32, 36 and 37 were so investigated and in every case the material recovered was found by melting point and mixed melting point determinations to be identical with the original material. Since representatives of all of the types of compound most easily affected are included in this list, it is believed that none of the figures in Table III are in error as a result of any change in the quinones, though they do vary in probable accuracy for reasons discussed in the Experimental Part.

[14] Monti, *Gazz. chim. ital.*, **45**, II, 51 (1915), prepared this substance by hydrogenating the acetyl derivative, or the hydroquinone triacetate, of lapachol and hydrolyzing and oxidizing the products, but she was unable to effect the hydrogenation of lapachol itself with hydrogen and palladium catalyst. It has been found (experiment of Miss Evalyn W. Brodie) that this hydrogenation is easily accomplished with the aid of the platinum-oxide platinum black catalyst of Roger Adams, the reaction being conducted in alcoholic solution at about 40 lbs. pressure. Oxidation of the hydrolapacholhydroquinone formed takes place on exposing the solution to the air; the product, crystallized from petroleum ether, melted at 88–89' (M. 87–89").

[15] Rennie, *J. Chem. Soc.*, *68, 784* (1895).

[16] Through an oversight, this compound was incorrectly called 1-methyl-3,4-benzo-5,6-coumaranquinone in the paper in which it is described.

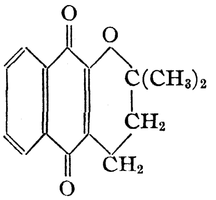
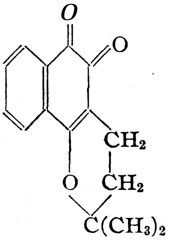
The bearing of these results on the problem of tautomerism may be stated in the following way. In order to determine, in light of the present theory, whether lapachol has the structure of Xa or Xb or is an equilibrium mixture of the two, it is necessary to have some information regarding the relative potentials of the two forms. Of course, judging from the facts known about the simple naphthoquinones, it is probable that the p-quinone form has the lower potential of the two, but this conclusion



XI



XII

---

[17] Paternb, *Gazz. chim. ital.*, 19, 622 (1889).

is placed upon a more secure basis by the observation that of the isomers of lapachol, a and β-lapachone (XI and XII), the p-quinone is lower in potential than the isomer by 0.099 v. Lapachol, then, should correspond to Xa. The potential of lapachol has been determined, but there is no altogether sound basis for deciding whether or not the value is consistent with Xa. However, it will be recalled that the potential of hydroxynaphthoquinone is very close to that of a series of its *p*-quinone ethers and, if the *p*-quinonoid structure for the hydroxy compound is granted, it is safe to say that lapachol should correspond with some degree of approximation to a-lapachone, since the latter is similar, in structure and properties, to an alkyl-alkoxy-naphthoquinone. It may be objected that the two substances differ in their degree of saturation and are therefore not comparable, but the figures for lapachol and its hydrogenation product (No. 14) are so close together as to indicate that a double bond situated as it is in lapachol has no appreciable influence upon the potential. At least there is ample justification for stating that lapachol, if it has the structure of Xa, should have a potential closer to that of a-lapachone than to that of β-lapachone. This is in fact the case: the value is 0.017 v. lower than that of a-lapachone and 0.116 v. lower than that of the 8-isomer. Thus both the electrochemical theory and the electrochemical results favor Formula Xa. Hooker[12a] was led to regard lapachol as a *p*-quinone because of its resemblance to hydroxynaphthoquinone, because of its yellow color (a-lapachone is yellow, β-lapachone is red) and because it volatilizes with steam. A further fact which affords strong support of this view is that lapachol reacts only to a very slight extent with sodium bisulfite,[13b] thus differing from almost all o-quinones.

What has been said of lapachol is true of almost all of the hydroxy compounds in the table (Group A). In those cases where the heterocyclic ortho and para quinone isomers are listed under B and C, it is seen that the o-isomer always has the higher potential and that the hydroxy quinone always corresponds much more closely in potential to the p-quinone heterocyclic derivative. This statement is true even though a surprising value appears for one of the heterocyclic compounds, namely, No. **32.** The potential of this p-coumaranquinone is much higher than those of the p-chromanequinones, Nos. **33** and 34, while the isomeric o-coumaranquinone, No. 24, as well as the coumaran, No. 25, are close in potential to the *o*-chromanequinones, Nos. **26** and 28. That No. **32** has the same heterocyclic ring as No. 24 is clearly demonstrated by a series of interconversions described in the Experimental Part; but an interpretation of the potential of the substance is still to be sought.

The potential of *iso*propylfuran-β-naphthoquinone (No. **31)** is higher in relation to the o-coumaran and *o*-chromanequinones than is the isomer, No. **36,** in relation to the corresponding *p*-quinones but, when it is observed that the furan derivatives alone possess unsaturated heterocyclic rings, this is not altogether surprising. A similar situation is found in the relationship between anthraquinone and phenanthrenequinone and with other unsaturated heterocyclic analogs of these compounds.[18]

But even though we are still far from a complete understanding of the relationship between reduction potentials and structure, the peculiarities here noted do not affect the question at issue. The two furan derivatives, Nos. 31 and 36, surely differ very decidedly in potential and the hydroxylic substance, *iso*-β-lapachol (No. 22), agrees closely with the α-isomer in potential and not at all with the @-isomer. Therefore, it is believed that this compound has the structure of XIIIa. This conclusion is supported by the fact that the potential of the compound is just about what would be expected from a consideration of the values for the unsaturated alcohols, Nos. 19 and 20, and from the fact that an alcoholic hydroxyl group produces a slight increase in the potential (compare Nos. 14 and 18), provided that the substance in question is regarded as a *p*-quinone. On the other hand, this conclusion is contrary to the views of Hooker,[12b] who discovered the compound and assigned to it Formula XIIIb. Hooker's reason for adopting the o-quinone formula was largely because the substance is red in color, and to anyone who has had occasion to observe the sharp distinction between the red or orange o-quinones of Group B and the yellow *p*-quinones of Group C, the argument does not lack plausibility. Indeed, in an earlier paper[13b] I made use of this property, in the absence of other evidence, in assigning a tentative structure to the phenyl chromanequinone, No. 27, and the results of the present experiments indicate the correctness of the choice of the o-quinonoid formula in this case, But I do not consider the color of a quinone, even in a group of fairly closely related substances, to be an infallible guide to its structure. There are, in fact, cases in which the rule that *p*-quinones are yellow in color does not hold. Among p-naphthoquinones which are decidedly red in color, mention may be made of naphthazarin, whose structure is not equivocal, and of naphthopurpurin; while a wide variety of halogen substituted 2,5- and 2,6-dialkoxy-*p*-benzoquinones is described in the literature as being red.[19] On the other hand, there is no exception to the

[18] Fieser and Ames, THIS JOURNAL, 49, 2604 (1927).

[19] (a) Kehrmann, J. *prakt. Chem.*, [2] 40, 365 (1889); (b) Jackson and Bolton, THIS JOURNAL, 36, 1473 (1914); (c) Levine, *ibid.*, 48, 797 (1926); (d) Hunter and

rule that the stable form of a quinone is the form possessing the lowest oxidizing power, unless the present case constitutes an exception and the reduction potential of a quinone, in contrast to the color, is a well defined and well understood physico-chemical constant.

A further fact which supports the contention that *iso*-β-lapachol is a *p*-quinone is that the substance does not react with sodium bisulfite. The bisulfite reaction, like color, is not an absolutely safe criterion of structure, for a few o-quinones, such as Compound No. 27 and 4-phenylmethoxy-1,2-naphthoquinone,[13a] react only to a slight extent with sodium bisulfite; but, considered together with other properties, it is not without value.

The results given in Table III permit of several interesting observations concerning the relationship between reduction potential and structure, the more important of which will be briefly mentioned. While an hydroxyl group attached to a quinonoid nucleus lowers the potential by about 120 mv.,[9] an hydroxyl group in a saturated or unsaturated side chain or in a saturated heterocyclic ring raises the potential by from 8 mv. to 28 mv., the effect being greater the closer the group is to the quinonoid ring. The quinonoid substitution of chlorine or bromine causes an average increase in potential of 18 mv.,[9] and side chain substitution of these elements produces about the same effect. An increase in the size of an alkyl group, or an increase in the number and character of the alkyl or aryl groups attached to a saturated heterocyclic ring, produces no appreciable alteration in the potential. The presence of a double bond in a side chain has little influence on the potential, regardless of its position.

6. Certain Alkoxy Naphthoquinones

Reference has been made to the fact that hydroxynaphthoquinone and its *p*-quinone ethers have about the same reduction potentials and that this fact, granting the assumption of the *p*-quinonoid structure of the hydroxy compound, indicates that the hydroxyl and alkoxyl groups have approximately the same potential-lowering effect. In an attempt to establish the correctness of this conclusion by independent evidence and thus further establish the correctness of the reasoning of Section 2, several 2-methoxy-3-alkyl-1,4-naphthoquinones, such as the methyl ether of lapachol, were prepared and examined potentiometrically, the idea being that, since lapachol exhibits little tendency to exist in an o-quinonoid form,[20] a comparison of it with its ether is of somewhat greater significance than

---

Levine, *ibid.*, 48, 1608 (1926). It is of significance that certain diaryl-*p*-benzoquinones [(e) Pummerer and Prell, Ber.. 55, 3111 (1922); (f) Pummerer and Fiedler, *Ber.*, 60, 1439 (1927)], as well as 2,5-dihydroxy-*p*-benzoquinone [(g) Scholl and Dahll, *Ber.*, 57, 81 (1924)], have been obtained in both a yellow form and an orange or red form.

[20] The failure of lapachol to react readily with sodium bisulfite is evidence of this point.

in the case of hydroxynaphthoquinone. But no satisfactory potential measurements could be obtained with any of these compounds, the difficulty apparently being that equilibrium between the quinone and its reduction product was never attained, or was reached extremely slowly.

Isonaphthazarin and its mono- and dimethyl ethers were next examined (see Table IV), but the results are inconclusive. A consideration of the reduction potentials of a-naphthoquinone (E_0 = 0.483 v.) and of hydroxynaphthoquinone (E_0 = 0.356 v.) shows that one quinonoid hydroxyl group produces a potential lowering of 0.127 v. If isonaphthazarin is regarded as a p-quinone (XIV), it appears that a second hydroxyl group has an effect of only 0.074 v., or that the effect of each of the two groups is only 0.100 v. While such a result is not without parallel,[9] it is equally permissible to consider isonaphthazarin to be a β-naphthoquinone derivative, when the effect of each of the two hydroxyl groups is represented by a quantity, 0.147 v., which is somewhat more comparable with the value for one such group.

TABLE IV

REDUCTION POTENTIALS AT 25°[21]

Solvent: 50% alcohol, 0.1 *N* in HCl and 0.2 N in LiCl.

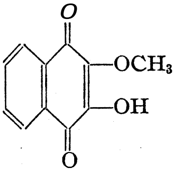
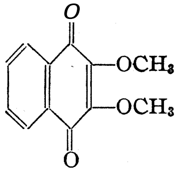
XIV



XV



XVI

The red color of isonaphthazarin is hardly indicative of an o-quinonoid structure in view of the fact that naphthazarin is likewise red. Negative evidence in favor of the p-quinone formula is furnished by the fact that sodium bisulfite is without action on the substance, while the conversion of the compound into XVI (yellow, insoluble in bisulfite solution) by the action of diazomethane affords some support of this view. However, the evidence is not sufficiently conclusive to warrant a final decision, and consequently the relationship of isonaphthazarin to its ethers, XV and XVI, which are probably *p*-quinones, cannot be adequately defined, though the fairly regular increase in potential from XIV to XV to XVI is suggestive. I am inclined to consider that isonaphthazarin is a p-quinone, that in the dihydroxy series an ether has a considerably higher potential than

---

[21] Determined by titration of the hydroquinones with benzoquinone solution

the corresponding hydroxy compound, that in the series of the alkylhydroxy-naphthoquinones an ether is only slightly higher in potential than the hydroxy compound (compare a-lapachone and hydrolapachol), and that there is no difference between the two in the case of hydroxynaphthoquinone. But these conclusions, even if they were adequately established, would not serve to answer the question stated at the beginning of this section.

7. The Influence of the Hydrogen-Ion Concentration on the Position of the Tautomeric Equilibrium

The equations given above apply only to solutions which are of such acidity or of such a character that no ionization of either the oxidant or the reductant takes place. In view of the striking color changes which frequently accompany the dissolution of hydroxy quinones in alkali, and particularly because it has often been assumed that such a color change is the result of a process of tautomerization, it is of considerable interest to extend the simple equations to include solutions of any hydrogen-ion concentration.

The case of a quinone containing a single dissociable hydroxyl group, whose hydroquinone has three hydroxyl groups, will be considered (e. g., hydroxynaphthoquinone). A general expression for the electrode potential of a solution of one pure tautomer (a-Oxid) of any acidity is as follows[22]

$$E^{\alpha} = E_0^{\alpha} + 0.0296 \log [\alpha\text{-Oxid}]_T + \underbrace{0.0296 \log (k_1k_2k_3 + k_1k_2[\mathrm{H}^+] + k_1[\mathrm{H}^+]^2 + [\mathrm{H}^+]^3)/[\mathrm{Red}]_T}_{\textbf{Term } (a)} - 0.0296 \log (k_{\alpha} + [\mathrm{H}^+]) \qquad (6)$$

in which $[\alpha\text{-Oxid}]_T$ and $[\mathrm{Red}]_T$ are the total concentrations of the oxidant and reductant and thus account for both the dissociated and undissociated material, k_1, k_2 and k_3 are the three dissociation constants of the reductant, and k, is the dissociation constant of the quinone, or oxidant. This equation applies equally well to the potential of the tautomer in an equilibrium mixture, provided that a means can be found for evaluating $[\alpha\text{-Oxid}]_T$. A similar equation applies to the second tautomer (β-Oxid) and, since the two tautomers have a common reduction product, Term (a) is identical in each case and we may write

$$E^{\beta} = E_0^{\beta} + 0.0296 \log [\beta\text{-Oxid}]_T + \textbf{Term } (a) - 0.0296 \log (k_{\beta} + [\mathrm{H}^+]) \qquad (7)$$

It is obvious that in an equilibrium mixture the potentials of the two systems must be identical ($E^{\alpha} = E^{\beta}$). On equating (6) and (7) the following expression results:

$$0.0296 \log [\alpha\text{-Oxid}]_T/[\beta\text{-Oxid}]_T = (E_0^{\beta} - E_0^{\alpha}) + 0.0296 \log (k_{\alpha} + [\mathrm{H}^+])/(k_{\beta} + [\mathrm{H}^+]) \qquad (8)$$

Defining a general tautomeric equilibrium constant, or the ratio of the

---

[22] *Compare Clark and Cohen, Pub. Health Repts.*, **38,** 666 (1923).

concentrations of the two reactants in any solution, thus: $K' = [\alpha\text{-Oxid}]_T/[\beta\text{-Oxid}]_T$, Equation 8 becomes

$$\log K' = (E_0^\beta - E_0^\alpha)/0.0296 + \log (k_\alpha + [H^+])/(k_\beta + [H^+]) \qquad (9)$$

Equation 9 shows that in acid solutions where $[H^+]$ is considerably greater than k_α or k_β, the equilibrium constant is a function only of the difference in the normal potentials of the tautomers, that is, the equation reduces to Equation 4, which was derived in a different way. In alkaline solutions where $[H^+]$ is inappreciable with respect to k_α and k_β, the equilibrium constant is again independent of $[H^+]$ but its logarithm differs from that of the value in acid solution by the term $\log (k_\alpha/k_\beta)$. These relationships for the extremes of acidity and alkalinity where the quinones exist as undissociated molecules or as ions, respectively, may be expressed as follows

$$\log K(\text{un-ionized}) = (E_0^\beta - E_0^\alpha)/0.0296 \qquad (10)$$

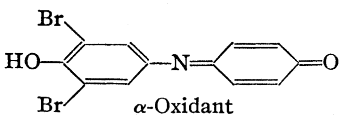
$$\log K(\text{ionized}) = (E_0^\beta - E_0^\alpha)/0.0296 + \log (k_\alpha/k_\beta) \qquad (11)$$

On combining these expressions

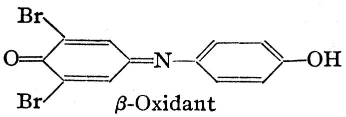
$$K\ (\text{ionized}) = K\ (\text{un-ionized})\ (k_\alpha/k_\beta) \qquad (12)$$

The extent of the change in the equilibrium constant on passing from an acid to an alkaline solution is thus dependent upon the ratio of the dissociation constants of the two tautomers. If these constants are the same, as is probably approximately true in the case of hydroxynaphthoquinone, no change in the equilibrium constant will result.

The above equations apply equally well to the indophenols. In a number of the substances of this type which were examined by Clark and his collaborators,[10] the hydroxyl group of one tautomer is surrounded by halogen atoms and will consequently have a dissociation constant greater than that of the second tautomer in which this group is situated in a benzene ring. As a result, the composition of the equilibrium mixture will vary with the PH of the solution in a manner defined by Equation 9. Clark, observing that the apparent dissociation constant of 2,6-dibromophenol-indophenol is considerably greater than the dissociation constant of phenol-indophenol, concluded, with reason, that the predominant tautomer was that in which the hydroxyl group is in the halogen substituted ring[10b,c] (XVIIa) but it must be noted that such statements apply only in the PH range at and beyond which dissociation of the oxidant becomes appreciable. It is reasonable to suppose that the ratio of the dissociation constants of the two tautomeric forms of XVII is approximately



α-Oxidant
XVIIa

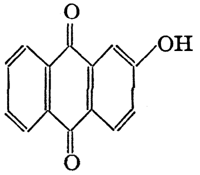


β-Oxidant
XVIIb

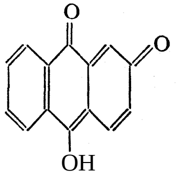
equal to the ratio of the apparent dissociation constant of this substance to the dissociation constant of phenol-indophenol, whence: $k_\alpha/k_\beta = 250$. Then, by Equation 12, the tautomeric equilibrium constant of the ionized quinones is two hundred and fifty times as great as that of the quinones in the un-ionized condition. The process of dissociation greatly increases the proportion of the a-oxidant in the equilibrium mixture. Obviously the fact that this tautomer predominates when the quinones are dissociated furnishes no basis for considering that this is true under any other conditions.

The case of naphthopurpurin, III, is also illustrative. The fact that this substance, like hydroxynaphthoquinone, is a stronger acid than naphthoquinones with hydroxyl groups only in the benzenoid nucleus (see Experimental Part) might be taken as evidence that the one hydroxyl group of doubtful position is attached to the quinone nucleus as in IIIa, which may be termed the a-form. But the argument only applies to the ionized substance. The product of the three dissociation constants of this a-form will surely be greater than the corresponding product for the β-form, IIIb, which means that K(ionized) is greater than K(un-ionized), and again ionization favors the a-form.

Finally, it is of interest to consider the possibility of tautomeric change in the hydroxyanthraquinone series. The properties of the β-derivative, XVIII, for example, leave little doubt that under all ordinary conditions the substance corresponds to XVIIIa (a-form), and yet, largely in order to account for certain color phenomena, the assumption has often been made that a rearrangement to XVIIIb (β-form) takes place on the formation of salts of this substance.[23] Now the normal reduction potential of XVIIIb, which has an extended quinonoid structure similar to that of amphi-naphthoquinone, would surely be much the higher of the two; consequently the constant for the un-ionized quinones must be a large number, indicating that XVIIIa predominates. A change to XVIIIb on ionization can only take place if the dissociation constant of this substance is considerably less than that of XVIIIa. But from what is known regarding the acidic strength of hydroxy quinones, it appears highly probable that the



XVIIIa



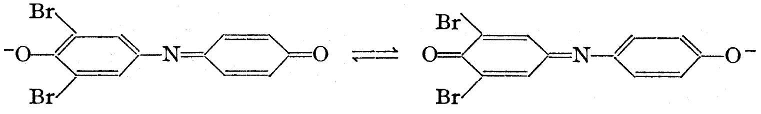
XVIIIb

---

[23] Scholl and Zincke, Ber., 51, 1419 (1918); this paper contains references to the earlier literature; Barnett, "Anthracene and Anthraquinone," D. Van Nostrand Co., New York, 1921, p. 252; Goodall and Perkin, *J. Chem. Soc.*, 125, 470 (1924); Moir, *ibid.*, 1927, 1809.

dissociation constant of XVIIIb is not less, but greater, than that of the more stable tautomer, and this reasoning leads to the conclusion that under no conditions can a tautomeric change in the manner indicated occur.

Before concluding this discussion it seems advisable to call attention to the question of the validity of postulating the existence of a tautomeric equilibrium between ions. While it is hardly appropriate to consider in any detail the subject of the mechanism of reactions in connection with a problem which is concerned solely with equilibria, some statement of the possibilities in this direction is necessary. A conception which has been of service in developing the present theory is that each tautomer preserves its structure on ionization but that a rearrangement of its linkages and a shift of the charge from one center to another is possible. Thus the ions of XVIIa and XVIIb would have the following structures and they would be in equilibrium with each other



IXa IXb

An alternate view is that the change from one ion to the other takes place only by the combination of the ion with a hydrogen ion, tautomeric change, and dissociation. The resultant equilibrium would be the same in either event.

On the other hand, one may question the existence of tautomers in the ionic state and prefer to consider that the dissociation of the two tautomers produces a single ion, an ion to which it is impossible to assign a formula such as IXa or IXb. It then would be necessary to suppose that one oxygen atom of this ion has a different tendency than the other oxygen to combine with a hydrogen ion, for the two un-ionized molecules have, or can have, different dissociation constants. Thus the conception of a single ion with two tendencies to combine with hydrogen ion is contrasted with the view that there are two ions, each of which has a definite affinity for hydrogen ion. If the former view were adopted it would be necessary to consider the whole question of tautomerism from a point of view different from that given above and with the use of a new terminology. In this paper preference has been given to the latter idea, which permits the use of ordinary organic formulas and which introduces no novel conceptions, but I do not wish to indicate that this view is considered to be the only one by means of which it is possible to arrive at the conclusions here presented.

I expect to consider the problem of the tautomerism of the amino quinones in a future communication.

Experimental Bart

Alkoxy-naphthoquinones.—The quinones listed in Table I have been described previously,[2] with the exception of the two *n*-propoxy derivatives. The latter substances were prepared in the usual manner by the action of n-propyl iodide on the silver salt of hydroxynaphthoquinone in benzene suspension, 10% of the salt being converted into hydroxynaphthoquinone, while of the remainder 74% was converted into the o-quinone ether and 13% into the p-quinone ether. The p-quinone ether was also prepared by esterification of the hydroxy compound with n-propyl alcohol and hydrogen chloride.

4-(*n*-Propoxy)-1,2-naphthoquinone crystallizes from ligroin-benzene in the form of very long, thick, orange-yellow needles, m. p. 116°.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.19; H, 5.60. Found: C, 71.97; H, 5.66.

2-(*n*-Propoxy)-1,4-naphthoquinone crystallizes from ligroin or from water, forming long, pale yellow needles melting at 91°.

Anal. Calcd. for $C_{13}H_{12}O_3$: C, 72.19; H, 5.60. Found: C, 72.17; H, 5.74.

The remarkable ease with which hydrolysis of the o-quinone ethers of this series takes place has been noted.[2] On examining samples which had been prepared one year previously and stored in cork-stoppered specimen tubes, it was observed that specimens of the ethyl and allyl[13a] ethers had lost their luster; they were yellow and not orange-yellow; they were partially soluble in cold ammonia solution and a marked odor of allyl alcohol was apparent in the tube containing the allyl derivative. Analysis of the latter (dried) material, which was originally an analyzed sample of alloxy-β-naphthoquinone, indicated that it was a mixture of 46.5% of the ether and 53.5% of hydroxynaphthoquinone (calcd.: C, 70.34; H, 4.03. Found: C, 70.34; H, 4.04).

Alkyl Methoxynaphthoquinones.—Since compounds of the type of lapacbol are strongly acidic substances, it was to be expected that diazomethane would attack the hydroxyl group before adding to the double bond. This was the case, for compounds were obtained which, from the results of analysis and of hydrolysis experiments, were found to be ethers; their melting points and analyses are listed in the accompanying table.

TABLE V

2-ALKYL-3-METHOXY-1,4-NAPHTHOQUINONES

Alkyl group	M. p., °C.	Calcd., % *C*	Calcd., % H	Found, % *C*	Found, % H
—$CH_2CH{=}C(CH_3)_2$	53	74.97	6.30	74.99	6.28
—$CH_2CH{=}CHC_6H_5$	90.5	78.92	5.30	78.92	5.36
—$CH_2C_6H_5$	83.5	77.67	5.07	77.56	5.10
—$CH(C_6H_5)_2$	112.5	81.33	5.12	81.26	5.12

In each case the compound was obtained, on evaporating the ethereal solution, in the form of an oil which solidified on rubbing. Crystallized from ligroin or petroleum ether, the substances, with exception of the last one, formed short, well-formed, yellow needles. The diphenylmethyl derivative formed hard lumps of crystal aggregates. The substances are all very readily soluble in the usual organic solvents and very sparingly soluble in water. Unlike the alkoxy-α-naphthoquinones, they are hydrolyzed with considerable difficulty by sodium hydroxide or alcoholic alkali. Triphenylmethplhydroxynaphthoquinone did not react with diazomethane under conditions suitable for the preparation of the above compounds.

Polyhydroxynaphthoquinones.—The most convenient method of preparing naphthazarin is that patented by Baeyer and Co.[24] and more fully described by Charrier and

---

[24] Ger. Pat. 71,386.

Tocco.[25] Fuming sulfuric acid of the concentration called for not being available, it was found that satisfactory results were obtained by adding a solution of 25 g. of sulfur in 375 cc. of 18% fuming sulfuric acid to a well-stirred suspension of 50 g. of 1,5-dinitronaphthalene in 230 cc. of concd. sulfuric acid. The temperature was not allowed to rise above 60°, though it is sometimes necessary to maintain this temperature by external heating for a short time in order to complete the reaction. The product was worked up in the usual way; average yield, 26 g. A sample for the potential measurements was pursed by sublimation.

The preparation of naphthopurpurin at first presented some difficulties because neither this substance nor naphthazarin is easily identified. Alkaline solutions of mixtures of the two quinones can be prepared which are indistinguishable in color from an alkaline solution of naphthopurpurin. Finally, recourse was had to potentiometric analysis. Since the two quinones differ decidedly in reduction potential (Table II) a titration curve (of the catalytically prepared hydroquinone solution) serves to reveal the presence of one of these substances in a mixture consisting largely of the other, and it furnishes a fairly accurate idea of the relative concentrations. The titration curve consists of two distinct logarithmic curves and it is easily interpreted. Only traces of naphthopurpurin were detected in samples prepared according to Jaubert[26] by grinding together 4 g. of naphthazarin, 8 g. of finely powdered manganese dioxide and 8 cc. of concd. sulfuric acid. On dissolving the same quantity of the quinone in 30 cc. of concd. sulfuric acid, slowly sprinkling in 8 g. of manganese dioxide, with very vigorous stirring, and heating the mixture for twenty minutes at 125°, a product containing equal parts of naphthazarin and naphthopurpurin resulted. At 160° the material was largely destroyed.

The manganese dioxide method was soon abandoned for a modification of a method described in the patent literature,[27] in which the oxidation of naphthazarin is accomplished by the action of air in an alkaline'solution. In order to separate the product from traces of unchanged material, advantage was taken of the fact that naphthopurpurin is much the stronger acid of the two It is also of advantage to purify the monosodium salt, for naphthopurpurin itself does not crystallize at all well from any of the available solvents.

A solution of 5 g. of naphthazarin in 1.2 liters of water containing 35 cc. of 6 N sodium hydroxide solution was heated on the water-bath, with a rather rapid stream of air passing through the solution, for four and one-half hours. The solution was rendered just acid with acetic acid, when the color changed from fuchsin-red to a dull red, cooled and a slight amount of precipitated material was removed by filtration. In order to obtain the sodium salt, the solution is best concentrated to a volume of about 500 cc. and treated with an equal volume of saturated sodium chloride solution. The dark red salt then separates in the form of a fine powder. It dissolves rather readily in water but does not crystallize without the use of sodium chloride and it was not obtained in a form entirely free from this reagent. The barium salt, obtained by adding barium chloride solution to a hot solution of the sodium salt, is only moderately soluble in water and it can thus be washed free of inorganic material.

Anal. Calcd. for $(C_{10}H_5O_5)_2Ba$: Ba, 25.08. Found: 24.90.

Naphthopurpurin prepared from the reprecipitated sodium salt corresponded in properties with Jaubert's material. In its strongly acidic character, this quinone closely

[27] Ger. pat. 167,641.

resembles 2-hydroxy- and 2,6-dihydroxy-1,4-naphthoquinone. All of these substances dissolve readily in sodium acetate solution and are precipitated from an alkaline solution only by a large excess of acetic acid. This property is not shared by naphthoquinones containing hydroxyl groups only in the benzenoid ring, such as juglone or naphthazarin, while the presence of a second hydroxyl group or of an alkyl group in the quinonoid nucleus somewhat decreases the acidic strength of hydroxynaphthoquinone.

2,6-Dihydroxy-1,4-naphthoquinone was obtained from 6-hydroxy-1,2-naphthoquinone[28] in the manner described by Dimroth and Kerkovius.[29] Some improvement was effected in the preparation of the starting material, 2.6-dihydroxynaphthafene. Schaeffer's salt (150 g.) was fused with potassium hydroxide according to the directions of Willstätter and Parnas[30] but, since it appears that 2,6-dihydroxynaphthalene readily undergoes decomposition in alkaline solution, the product was not cooled and dissolved in water, but the melt, while still hot, was ladled out into a mixture of 700 cc. of concd. hydrochloric acid and enough ice to give a final volume of about 5 liters. The crude product was crystallized with the use of animal charcoal from 2 liters of water, when it was observed that some decomposition occurs during the process of dissolution unless the suspension is vigorously stirred. The yield of light brown material melting at 209° (uncorr.) was 50 g., and the substance dissolved in alkali with the color and the fluorescence of the product obtained by the above-named authors after a lengthy process of purification.

Isonaphthazarin-dimethyl Ether.—Isonaphthazarin[31] was crystallized from glacial acetic acid and the sample melted at 282°. On adding 1.1 g. of this substance to an ethereal solution of diazomethane prepared from 5 cc. of nitrosomethylurethan, a rapid evolution of nitrogen took place, the red crystals soon dissolved and long, yellow needles were deposited. Recrystallized from ether, the substance melted at 115°. It is readily soluble in alcohol or ligroin, very readily soluble in ether or benzene and insoluble in water or in bisulfite solution.

Anal. Calcd. for $C_{12}H_{10}O_4$: C, 66.04; H, 4.62. Found: C, 65.86; H, 4.65.

Isonaphthazarin Monomethyl Ether.—The action of alkali on the above substance is very interesting because a single ether group is attacked and the resulting substance is resistant to hydrolysis to a marked degree. In this behavior, 2,3-dimethoxy-1,4-naphthoquinone closely resembles 2,3-dichloro-1,4-naphthoquinone, only one of whose chlorine atoms is replaced by the action of alkali or of amines. The latter reactions have been enumerated and discussed by Fries and Ochwat,[32] who regard the substitution reactions as involving either a "mobile" atom or 1,4-addition. While I am inclined to consider the hypothesis of 1,4-addition as the more attractive, particularly as applied to the hydrolysis of alkoxy naphthoquinones,[2] it seems odd that the 1,4-addition of alkali to the system,  $-\underset{|\atop \mathrm{OR}}{\mathrm{C}}=\underset{|\atop \mathrm{OR}}{\mathrm{C}}-\underset{|}{\mathrm{C}}=\mathrm{O}$, takes place readily, while a similar addition to the systems  $-\underset{|\atop \mathrm{OR}}{\mathrm{C}}=\underset{|\atop \mathrm{O^-}}{\mathrm{C}}-\mathrm{C}=\mathrm{O}$ and  $-\underset{|\atop \mathrm{OR}}{\mathrm{C}}=\underset{|\atop \mathrm{R}}{\mathrm{C}}-\overset{|}{\mathrm{C}}=\mathrm{O}$ (lapachol methyl ether) occurs only very slowly.

The dimethyl ether was warmed on the water-bath for a short time with 1% sodium hydroxide solution. It soon dissolved with the production of a deep red solution from

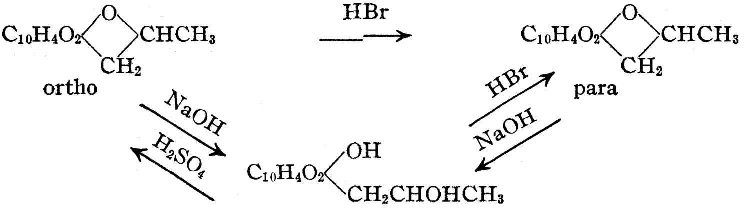
which, on acidification, a yellow product separated in quantitative yield. The compound crystallized from water, in which it dissolves readily at the boiling point, in the form of fluffy clusters of small needles; from ligroin-benzene solution stout yellow needles were deposited, m. p. 152°. Like hydroxynaphthoquinone, the substance forms a soluble bisulfite addition product. Prolonged boiling of the alkaline solution of the ether failed to bring about further hydrolysis.

Anal. Calcd. for $C_{11}H_8O_4$: C, 64.70; H, 3.95. Found: C, 64.43; H, 4.14.

1-Methyl-4,5-benzo-3,6-coumaranquinone (No. 32).—The peculiar position of the potential of this compound suggested the possibility that the structure ascribed to it[13a] might be incorrect. The compound had been previously obtained only as a by-product in the conversion of 2-allyl-3-hydroxy-1,4-naphthoquinone into its hydrochloride and, in very small yield, directly from the latter substance, and it had not been adequately studied. It has now been found that a better yield can be obtained as follows. Two g. of allyl-hydroxy-naphthoquinone was dissolved in 20 cc. of glacial acetic acid, 10 cc. of constant-boiling hydrobromic acid was added and the solution was heated on the water-bath for one and one-fourth hours. On pouring the solution into a large volume of water, a brown oil separated and soon solidified. The collected material was treated with ammonia solution until the extract was no longer red and it was then dissolved in glacial acetic acid, a small quantity of chromic acid was added to destroy oily impurities, the solution was diluted and allowed to cool. A further crystallization from ligroin gave a pure product, m. p. 166–167°; yield, 0.5 g.

On boiling this substance with diluted sodium hydroxide solution, a deep red solution results and on acidification there is precipitated a compound which has the appearance of 2-(β-hydroxypropyl)-3-hydroxy-1,4-naphthoquinone. The latter substance was previously obtained from the isomeric o-coumaranquinone and the relationship of the two isomers to each other would be adequately established by proving the identity of the two samples of the alcohol. Such a comparison, however, was not convincing because the melting point of the material depends to some extent upon the rate of heating, the state of subdivision and probably upon the condition of the glass surface of the capillary. On the other hand, each specimen was converted into the *p*-coumaranquinone (No. 32), a substance easily identified, by following the above directions for the allyl derivative. The o-coumaranquinone, No. 24, was likewise transformed into its isomer by a similar treatment, and it could be obtained from the hydroxypropyl derivative by the action of concd. sulfuric acid. This series of conversions, summarized as follows



proves that the heterocyclic ring is the same in the two isomers.

E.m.f. Measurements.—The procedure for carrying out a titration with a hydroquinone solution was as follows. Sufficient of the quinone for two determinations was dissolved in a suitable solvent and the solution was placed, together with some 5% platinized asbestos, in a 500cc. bottle. The rubber stopper of this bottle carried tubes for the admission and outlet of hydrogen and a tube extending to the bottom and ending in a wide, flared tube fitted with a filter plate covered with filter paper and secured in position with gauze and thread. To the upper end of this tube was attached a short section of pressure tubing into which a glass tube could later be fitted for the purpose of removing the hydroquinone solution. This filter tube was freed of solution and of air with a stream of hydrogen and then closed. The air in the bottle was displaced by hydrogen, the bottle was closed to the atmosphere and the whole was shaken mechanically, the bottle being connected to a hydrogen reservoir under a slight pressure At the same time the oxidation-reduction half-cell vessel was freed of oxygen with a stream of nitrogen and, when reduction of the quinone was complete, connection between this vessel and the bottle was made through a nitrogen-filled tube and half of the solution was transferred under hydrogen pressure. The solution was then swept with nitrogen while acquiring the temperature of the thermostat and a titration with a solution of a suitable oxidizing agent was carried out. The remainder of the solution in the bottle was shaken for an additional period of time before the second titration; consequently, if reduction were incomplete in the first instance, this fact would be revealed by a lack of agreement in the two determinations. While the shape of the titration curve usually affords sufficient evidence of incomplete reduction or of air leakage, it is of value to have this additional check on the method, particularly because in a few instances the quinone solution does not lose its color on hydrogenation. This was generally true in the case of certain anthraquinones to be described in a future paper. In some instances hydrogenation was so slow in the presence of platinized asbestos that the platinum-oxide platinum black catalyst of Adams[33] was employed.

The alcoholic phosphate buffer solution mentioned in Table I was prepared by diluting **1.9** liters of **a** solution 0.087 M in potassium dihydrogen phosphate and 0.087 M in disodium hydrogen phosphate to a volume of 3.5 liters with **95%** alcohol. It was estimated that the resulting solution contains approximately 37% of alcohol.

Reference has been made to the failure to obtain satisfactory measurements with any of the compounds listed in Table V. To this list may be added 2-cinnamyl-, 2-diphenylmethyl- and 2-triphenylmethyl-3-hydroxy-1,4-naphthoquinone. With all of these compounds the potentials were not constant, the end-point was uncertain and the approximately determined normal potentials differed in duplicate titrations by as much as 20 mv. It will be noted that all of these substances are *p*-quinones completely substituted with large groups.

In the lapachol series (Table III) considerable difference in the behavior of the various compounds was noted. Since the determinations were all carried out in very nearly the same manner, the time required for the actual titration is of some significance in indicating, it is believed, the relative velocities of reduction. With the hydroxy-*p*-quinones of Group A, from one and one-half to three hours was required; with the heterocyclic *p*-quinones (Group C), the titrations occupied from one to two hours, while with the heterocyclic o-quinones (Group B), a titration was completed in about twenty minutes, even in the case of the phenylated derivative, No. 27. In Groups A and C, reduction was the slowest with the most highly substituted compounds such as dibromohydrolapachol and hydroxy-a-lapachone. These facts may be interpreted in the following manner. Regardless of their character, substituents attached to an *o*-naphthaquinone cannot hinder the 1,4-addition of hydrogen because

---

[33] Voorhees with Adams, THIS JOURNAL, 44, **1397 (1922).**

they are not directly connected to the 1,4-system:  $O=\overset{|}{C}-\overset{|}{C}=O$, and because they are joined to a double bond which retains the same position in the hydroquinone. In a *p*-naphthoquinone, on the other hand, the substituents are attached to the 1,6-conjugated system to the ends of which hydrogen adds.[34] The substituents, to a degree depending upon their size and character, retard the velocity of the addition of hydrogen because the 1,6-system suffers rearrangement as a result of the process of reduction and the double bond between the substituted carbon atoms becomes a single bond. Ring formation between the substituent groups decreases somewhat the hindrance of these groups.

In conclusion, I wish to express my thanks to Dr. Samuel C. Hooker for generously supplying me with a number of compounds for this investigation, and to acknowledge my indebtedness to the Cyrus M. Warren Fund of the American Academy of Arts and Sciences for a grant which has aided this work.

Summary

The constant of the equilibrium between the tautomers, hydroxy-α-naphthoquinone and hydroxy β-naphthoquinone, depends upon the reduction potentials of these two forms, according to the equation

$$\log K = (E_0^{\beta} - E_0^{\alpha})/0.0296$$

where $K = [\alpha\text{-Form}]/[\beta\text{-Form}]$. In order to estimate the value of K, the reduction potentials of a number of ethers of the α and β forms have been determined, with the result that, as an approximation, $K = 502$.

In order to test the principle that that tautomer will predominate which has the lower reduction potential, the potentials of the two tautomeric forms of naphthopurpurin have been estimated from the values for certain related compounds, and it has been found that the actual potential of naphthopurpurin corresponds closely with the value estimated for the tautomer of lower potential. Similar analysis of the results of Clark for two indophenols furnishes additional support of the point at issue.

The reduction potentials of a number of compounds of the type represented by lapachol are consistent with this principle and, with one exception, the electrochemical results are consistent with all other known properties of these substances. It is considered that, contrary to the views of the discoverer of the compound, *iso*-β-lapachol is a *p*-quinone.

The variation of the tautomeric equilibrium constant with the hydrogen-ion concentration has been formulated, and it has been shown that the

The 1,6-addition to *p*-quinones of the magnesium subiodide of Gomberg and Bachmann, *ibid.*, 49, 236 (1927), as well as the 1,4-addition of this reagent to *o*-quinones, has been established by boiling the dark green suspension which results with acetyl chloride, when the hydroquinone diacetate is formed in good yield.

ratio of the equilibrium constant of the undissociated tautomers to the constant for the completely ionized substances is equal to the ratio of the dissociation constants of the two hydroxy quinones.

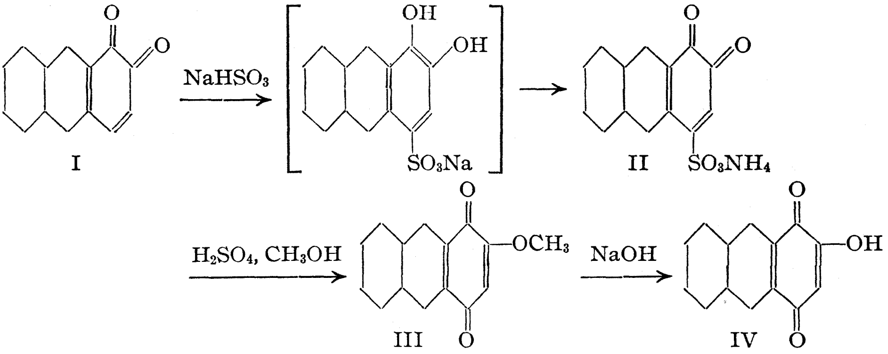
2-HYDROXY-1,4-ANTHRAQUINONE

BY LOUIS F. FIESER

RECEIVED SEPTEMBER 16, 1927 PUBLISHED FEBRUARY 4, 1928

The interest attaching to the properties of hydroxynaphthoquinone, in particular with regard to the abnormal course of its alkylation reactions[1] and the position of the equilibrium between its tautomeric forms,[2] renders it a matter of some importance to examine the hitherto unknown compound named in the title. The chemistry of anthracene is so different from that of naphthalene that it should be possible to determine, in this way, if the phenomena referred to are at all general.

The most satisfactory method found for the preparation of 2-hydroxy-1,4-anthraquinone is indicated as follows



The conversion of II into III involves hydrolysis of the sulfonate group, tautomeric change to IV, and esterification. Good yields were obtained in all of the reactions when pure materials were employed, but it was found most convenient to use crude 1,2-anthraquinone,[3] when the over-all yield from β-anthrol was only 23% of the theoretical. The sulfonate, II, was also obtained from 1-nitroso-2-anthrol.[3] This was converted, by acidifying its solution in sodium bisulfite solution, into 1-amino-2-anthrol-4-sulfonic acid, and the latter was easily oxidized to the quinone, II, by nitric acid. The yield, however, was very poor.

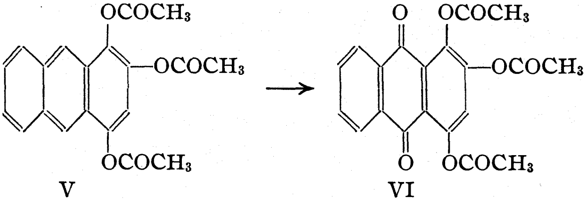
[3] Lagodzinski. Ann., 342, 59 (1905).

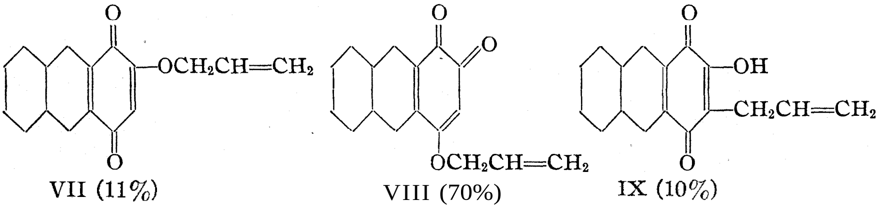
The structure of this hydroxyanthraquinone was established by oxidizing its hydroquinone triacetate, 1,2,4-triacetoxy-anthracene (V), with chromic



acid. The resulting substance was found to be identical with a sample of triacetylpurpurin, VI, prepared from purpurin.

2-Hydroxy-1,4-anthraquinone resembles the corresponding naphthoquinone to a marked degree. The only noteworthy difference between the two substances is that the former does not form a bisulfite addition product and, therefore, unquestionably has the *p*-quinonoid structure. The compound, which crystallizes in yellow needles, displaces even acetic acid from solutions of its salts, it reacts readily with amines and it is esterified by methyl alcohol in the presence of mineral acids to give II. This ether, together with 4-methoxy-1,2-anthraquinone, is produced in the ratio of 33% of the former to 62.5% of the latter by the action of methyl iodide on the silver salt of 2-hydroxy-1-4-anthraquinone. The isomers exhibit all of the properties characteristic of the corresponding methoxynaphthoquinones;[1a] the o-quinone ether, for example, forms a soluble bisulfite compound and is converted into the isomer by the action of methyl alcohol and hydrogen chloride.

Allyl bromide reacts with the silver salt of 2-hydroxy-1,4-anthraquinone with the formation of three isomers in the proportions indicated.



According to views previously expressed,[1a,b] VII is the result of simple methathesis, VIII is produced as a result of the 1,4-addition of the alkyl halide, while IX, which can also be prepared by the rearrangement of VIII, here results from the 1,2-addition of the alkyl halide. The relative yields of the isomers are very nearly the same as in the allylation of hydroxynaphthoquinone, and this is also true of the results of methylation.

All of these facts indicate that the presence of the additional benzene ring is of little consequence; the dominant feature in the structures of these hydroxy quinones of the naphthalene and anthracene series is the grouping, $O{=}\overset{|}{C}{-}CH{=}\overset{|}{C}{-}OH$, which, as Claisen first observed,[4] is almost equivalent to a carboxyl group.

The normal reduction potentials of some of the quinones here described are given in Table I. The determinations were carried out by electrometric titration of the quinone with titanous chloride or of the catalytically prepared hydroquinone solution with an oxidizing agent according to a procedure previously described.[2] Solvent "C" was employed in the cases noted because, being essentially neutral, it does not cause hydrolysis of the o-quinone ether. ΔE_1 and ΔE_2 indicate the slope of the titration curve; the theoretical value is 17.8 mv.

TABLE I

REDUCTION POTENTIALS AT 25°

Solvents: A, 0.1 N HCl; B, 50% alcohol, 0.1 N in HCl and 0.2 N in LiCl; C, 37% alcohol, 0.047 M in KH_2PO_4 and 0.047 M in Na_2HPO_4.

Compound	Solvent	Titrated with	E_0, v.			ΔE_1, mv.	ΔE_2, mv.	E_0 (av.)
2-Hydroxy-1,4-anthraquinone	B	$TiCl_3$	0.275	0.275		18.5	18.2	0.275
2-Methoxy-1,4-anthraquinone	C	$K_4Fe(CN)_6$	.272	.273		19.0	19.4	.272
4-Methoxy-1,2-anthraquinone	C	$K_4Fe(CN)_6$	,347	.345	0.346	18.8	18.5	.346
1-Methyl-5,6-(P,P-naphtho)-3,4-coumarane-quinone	B	$TiCl_3$	.304	.306	.304	18.1	17.9	.305
1,2-Anthraquinone-4-sulfonic acid	A	$TiCl_3$	.530	.530		18.6	18.2	.530
1,2-Anthraquinone	..	....	....	....	....	....	....	.490[5]
1,4-Anthraquinone[6]	B	$TiCl_3$	,401	.404	.399	17.4	17.8	.401

In Table II is given a comparison of these values with the normal potentials under similar conditions of the corresponding naphthoquinones.

TABLE II

DIFFERENCE IN POTENTIAL BETWEEN α- AND β-NAPHTHOQUINONES AND α- AND P-ANTHRAQUINONES IN MILLIVOLTS

Substituent	None	OH	OCH_3	SO_3H	$—CH_2CH(CH_3)O—$
a-Quinones	82	81	81	...	...
β-Quinones	89	..	87	98	101

The a- and β-anthraquinones are lower in potential than the similarly constituted naphthoquinones by from 81 to 101 mv., which, considering that seven pairs of compounds of different types are compared under a variety of solvent conditions, represents a fairly constant quantity and is suggestive of some fundamental relationship.

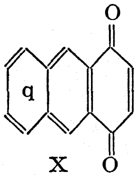
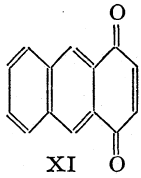
[5] Conant and Fieser, THIS JOURNAL, 46, 1858 (1924), determined this value for 95% alcohol 0.5 N in HCl.

[6] The sample was prepared according to Dienel, *Ber.*, **39, 931** (1906).

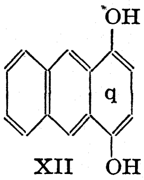
If the para-bond structure is disregarded, there are two possible formulas for a compound'such as 1,4-anthraquinone. Formula X does not explain



X



XI



XII

the observed relationship because it contains an o-quinonoid nucleus which should render the substance more, rather than less, reactive than α-naphthoquinone, in which a stable benzene ring is fused to the P-quinone group. It is not easy to judge of the properties of a compound possessing the structure of XI, but it does not seem at all likely that the substance would be any less reactive than α-naphthoquinone. Thus it does not appear that the difference in the potentials of these bi- and tricyclic quinones is connected with the structures of these quinones and an explanation must be sought by considering the structures of the reduction products.

In terms of the o-quinonoid theory of the structure of anthracene, XII should possess an added reactivity as a result of its o-quinonoid nucleus and it should be, in this respect, comparable with 9,10-anthrahydroquinone. This would mean that the corresponding quinone should have a lower reduction potential than quinones which are similar to it but which do not pass into anthracene derivatives on reduction, and this is, indeed, the case. The low reduction potential of 9,10-anthraquinone has been attributed to this same factor[7] and it is interesting to see how the potentials of the two *p*-quinones of the anthracene series compare. 9,10-Anthraquinone differs from 1,4-anthraquinone essentially in that both of its quinonoid linkages are members of benzene rings, while with the isomer only one linkage is so involved. The same relationship exists between a-naphthoquinone and *p*-benzoquinone, and the difference in their potentials is 0.224 v. It would be expected, then, if the quinone structures are of relatively little significance, that 1,4- and 9,10-anthraquinone would differ in potential by about this same amount, and the actual difference, 0.246 v., is not far from this value. This seems to establish the correctness of the interpretation adopted, namely, that 1,4-anthraquinone is comparable with 1,4-naphthoquinone and that its reduction product is comparable with 9,10-anthrahydroquinone. The o-quinonoid formula, X, hardly expresses the similarity to α-naphthoquinone, while, if Formula XI is adopted, it must be considered that the compound has at least no **very** pronounced added reactivity as a result of the tetraketone structure.

Regarding the question of the possible tautomerism of 2-hydroxy-1,4-

---

[7] Fieser and Ames, THIS JOURNAL, 49, 2604 (1927).

anthraquinone, the chemical properties of the substance clearly show that the less stable β-anthraquinone form must be present in only a very small concentration in the equilibrium mixture, though it is necessary to consider that this form is capable of at least transitory existence. Assuming that the difference in potential of the two tautomers is equal to the difference in the potentials of the corresponding ethers, the constant of the tautomeric equilibrium may be calculated with the use of the equation previously developed.[2] It is found that $K = 316$, which means that 99.7% of the substance is present at equilibrium in the α-anthraquinone form. It is clear that the chemical and electrochemical evidence are in good agreement with each other, and that in this respect, also, the bi- and tricyclic quinones are very similar.

Experimental Part

1,2-Anthraquinone-4-sulfonic Acid.—A slight modification of the usual procedure* for the reduction of sodium anthraquinone-β-sulfonate greatly shortened the time required for the operation. A mixture of **150** g. of this salt,[9] **90** g. of zinc dust, 800 cc. of ammonia solution (sp. gr. **0.90**) and **350** cc. of water was placed in a flask equipped with a reflux condenser and a mechanical stirrer. The mixture was warmed on the water-bath to such a temperature that only slight frothing occurred, the temperature being increased as reduction proceeded. After about four hours reduction was complete and the precipitated product was separated from the brown filtrate while the latter was still hot. By suspending the precipitate in **3** liters of water and allowing the zinc to settle to the bottom, the greater part of the metal could be separated mechanically and the sodium anthracene-β-sulfonate obtained was suitable for conversion into β-anthrol. For this purpose the anthracene sulfonate from **200** g. of the quinone was fused with **900** g. of potassium hydroxide according to the directions of Lagodzinski;[3] yield, **80–90** g.

The 1,2-anthraquinone[10] prepared in the manner described by Lagodzinski was found to contain considerable inert material which is not easily removed on a large scale, but which does not greatly interfere with the reaction of the quinone with sodium bisulfite. The quinone obtained from **60** g. of β-anthrol, while still moist, was made into a paste with **500** cc. of water, **35** g of sodium bisulfite was added and the mixture was stirred mechanically for two hours. The quinone rapidly dissolved while a fine

[8] Liebermann, **Ann.,** 212, **57 (1882).**

[9] I am indebted to the E. I. du Pont de Nemours & Co. for a large supply of this material.

[10] Attempts to convert this quinone into a dihydroxy derivative by the action of calcium oxychloride, following the methods employed for the preparation of isonaphthazarin, were unsuccessful. In no case was there any evidence of the formation of such a quinone; the sole product isolated. separated from considerable black material by extraction with dilute hydrochloric acid, was a colorless acid, very readily soluble in water and melting at 232°. It is probably the lactone acid,  $C_{10}H_6\begin{array}{l}\diagup\\ \diagdown \mathrm{CHCHOHCOOH}\end{array}$, corresponding to the oxidation product of β-naphthoquinone obtained by Zincke, *Ber.*, 25, **405 (1892).**

Anal. Calcd. for $C_{14}H_{10}O_5$: C, **65.11;** H, **3.91.** Found: C, **65.33;** H, **3.80.**

suspension of black material remained unaltered. The mixture was then warmed to the boiling point and a solution of 25 cc. of sulfuric acid in 80 cc. of water was slowly added. A few drops of caprylic alcohol served to prevent foaming due to the evolution of sulfur dioxide. The hot solution was filtered through a large folded paper and to the dark brown filtrate, after cooling to room temperature, was added a solution of 21 g. of chromic acid in a small volume of water. The solution became deep red in color and, after adding 200 cc. of saturated sodium chloride solution, the sodium salt of 1,2-anthraquinone-4-sulfonic acid separated in the form of a fine, crystalline powder. It was washed with dilute sodium chloride solution and dried at 120°; yield, 50 g. (52%, based on the weight of β-anthrol). When pure 1,2-anthraquinone was employed for this reaction instead of the crude material, the yield of the sulfonate, which was isolated in the form of the ammonium salt in the manner described below, was 74% of the theoretical quantity.

The sodium salt is readily soluble in water and crystallizes in the form of small, dark red needles.

Anal.[11] Calcd. for $C_{14}H_7O_5SNa$: Na, 7.41. Found: 7.27.

Neutral solutions of this compound do not undergo decomposition as readily as is the case with β-naphthoquinone sulfonate, but the substance is rapidly converted into brown products in the presence of alkali. The quinone forms a colorless bisulfite addition product and readily reacts with aromatic amines to give red, alkali-soluble anilino-quinones.

The ammonium salt was obtained by adding an excess of saturated ammonium nitrate solution to a solution of the sodium salt in hot water. The two salts are easily distinguished, for, when each is precipitated by salting out, the sodium derivative separates in the form of a bright red suspension which is very difficult to filter and dry, while the ammonium salt forms a compact, dull red precipitate. The conversion is nearly quantitative when the sodium salt employed is pure; the crude material described above apparently contained considerable sodium chloride for it yielded only 58% of the theoretical quantity of the ammonium salt. The ammonium sulfonate dissolves readily in alcohol or water but the solutions rapidly undergo decomposition. Crystallized from a dilute ammonium nitrate solution, it formed small, dark red prisms.

Anal.[11] Calcd. for $C_{14}H_{11}O_5NS$: S, 10.50. Found: 10.14.

The β-anthraquinone sulfonate was also obtained from nitroso-β-anthrol, though the process was less satisfactory than that given above. The nitroso compound, in the form of its sodium salt, was treated with a solution of sodium bisulfite (2 molecular equivalents), the solution was filtered from a rather considerable quantity of black material, and a large excess of sulfuric acid was added. After standing at 30–40° for one week, the separation of yellow crystals of 1-amino-2-anthrol-4-sulfonicacid had ceased, the yield being 10–15% of the theoretical. The low yield is probably due both to a partial destruction of the nitroso compound by the bisulfite and to incomplete reduction of the intermediate product by sulfur dioxide. The sulfonic acid derivative, which is insoluble in water, crystallized from 10% bisulfite solution in the form of yellow needles containing combined water which was not eliminated on drying in *vacuo* at 100°.

Anal.[11] Calcd. for $C_{14}H_{11}O_4NS\ {}^1/_2H_2O$: S, 10.75. Found: 10.49.

On stirring this compound into 25% nitric acid, oxidation rapidly took place and crystallization of ammonium 1,2-anthraquinone-4-sulfonate occurred.

2-Hydroxy-1,4-anthraquinone.—To a suspension of 10 g. of β-anthraquinone ammonium sulfonate in 100 cc. of methyl alcohol, 15 cc. of concd. sulfuric acid was

---

[11] Analysis of Dr. F. H. Case.

slowly added while the mixture was well shaken. The salt rapidly dissolved, the solution warmed and became deep red in color, sulfur dioxide was given off and suddenly a yellow substance separated and the flask was soon filled with a thick, crystalline paste. After allowing the mixture to cool, the product was collected and washed well with methyl alcohol. Addition of water to the filtrate causes the precipitation of only a negligible quantity of impure material. The yellow product, 2-methoxy-1,4-anthraquinone (see below), was nearly pure; yield, 6.6 g. (85%). It was boiled with 600 cc. of water and 5 cc. of 6 *N* sodium hydroxide solution until most of the material had dissolved, the orange-yellow solution was filtered and the residue boiled with sufficient dilute alkali to dissolve it. The sodium salt of hydroxyanthraquinone was precipitated by adding 15 cc. of 6 N alkali to the combined filtrates. It separated from the solution while still hot in the form of a red powder. On acidifying the solution of this salt in boiling water, 2-hydroxy-1,4-anthraquinone separated in the form of very slender, bright yellow needles, and in very pure condition; yield, 5.7 g. (92%).

2-Hydroxy-1,4-anthraquinone is moderately soluble in glacial acetic acid or in alcohol, sparingly soluble in benzene, ether or water, and dissolves only to a very slight extent in bisulfite solution. The solution in concd. sulfuric acid is claret red, the sodium hydroxide, carbonate or acetate solution is pale orange-yellow, while the vat is orange-red. The substance condenses with aromatic amines in glacial acetic acid solution to give alkali-insoluble anilino-quinones. It crystallizes from toluene or glacial acetic acid in the form of yellow needles which melt with decomposition at 243°, a red color being imparted to the glass capillary even above the point of fusion.

Anal. Calcd. for $C_{14}H_8O_3$: C, 74.99; H, 3.60. Found: C, 74.81; H, 3.76.

The sodium salt, prepared as described above and crystallized from water, formed orange micro-needles which dissolve readily in water but which are very sparingly soluble in dilute sodium hydroxide solution.

Anal. Calcd. for $C_{14}H_7O_3Na$: Na, 9.35. Found: 9.36.

The silver salt was prepared by precipitation from a solution of the ammonium salt at 60°; the material was at first gelatinous but in a few seconds it changes into a crystalline, dark red powder.

Anal. Calcd. for $C_{14}H_7O_3Ag$: Ag, 32.59. Found: 32.42.

The acetyl derivative was obtained by the action of acetic anhydride and a small quantity of concd. sulfuric acid on the quinone. Crystallized from alcohol, in which it is sparingly soluble, or from benzene, which readily dissolves the material, it forms yellow plates melting at 195°.

Anal. Calcd. for $C_{16}H_{10}O_4$: C, 72.17; H, 3.79. Found: C, 72.02; H, 3.86.

1,2,4-Triacetoxy-anthracene was prepared by boiling for ten minutes a mixture of 2 *g.* of the hydroxyanthraquinone, 5 g. of sodium acetate, **6** *g.* of zinc dust and 40 cc. of acetic anhydride. The solution was filtered while hot, the residue washed with hot glacial acetic acid and water was added to the hot filtrate. The acetyl derivative separated in crystalline form and in nearly quantitative yield. It is moderately soluble in benzene or glacial acetic acid, and the solutions, particularly when dilute and when viewed in thin layers, exhibit pronounced blue fluorescence. It is best crystallized from benzene-ligroin, forming colorless needles; m. p. 191".

Anal. Calcd. for $C_{20}H_{16}O_6$: C, 68.16; H, 4.58. Found: C, 68.06; H, 4.62.

On boiling a solution of 1 g. of this anthracene derivative in glacial acetic acid with 0.8 g. of chromic acid for five minutes, adding a little water and cooling, triacetyl purpurin was obtained. After repeated crystallization from alcohol, the melting point of the yellow needles remained constant at 202–203°, and no depression of the melting point was produced on admixture of a sample of the triacetyl derivative (m. p. 202–203°) prepared from purpurin. Schunck and Roemer[12] report a melting point of 198–200°.

Anal. Calcd. for $C_{20}H_{14}O_8$: C, 62.82; H, 3.69. Found: C, 62.75; H, 3.85.

Methylation

A mixture of 4 g. of 2-hydroxy-1,4-anthraquinone silver salt, 2 g. of methyl iodide and 40 cc. of benzene was shaken mechanically until the red salt had disappeared (about ten hours), and the product was then extracted with benzene and the solvent evaporated under diminished pressure. The finely-powdered material was first triturated with ammonia solution to remove a small quantity (0.14 g.) of the hydroxy compound and then with successive portions of bisulfite solution to remove the o-quinone isomer formed. This was precipitated from the solution by the addition of sodium carbonate; yield, 1.71 g. (62.5% of the theoretical amount, allowing for the hydroxy compound recovered); m. p., 197°. The residue insoluble in bisulfite solution was the somewhat impure p-quinone ether; yield, 0.9 g. (33%).

4-Methoxy-1,2-anthraquinone.—Crystallized from benzene, in which it is moderately soluble, the compound formed clusters of fine, yellow needles melting at 198°.

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.61; H, 4.23. Found: C, 75.52; H, 4.48.

The ether dissolves readily in bisulfite solution, gives a claret-red solution in concd. sulfuric acid, and is readily hydrolyzed by boiling with dilute alcoholic hydrochloric acid or with alkali. On boiling for a short time a solution of the substance in methyl alcohol containing a small quantity of concd. sulfuric acid it is completely converted into the isomeric p-quinone ether.

2-Methoxy-1,4-anthraquinone.—The material obtained directly from ammonium β-anthraquinone sulfonate is nearly pure but contains a trace of a dark-colored by-product which is best removed by crystallization from toluene with the use of animal charcoal. Small, yellow needles melting at 217° are thus obtained.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.61; H, 4.23. Found C, 75.54; H, 4.53.

This ether is moderately soluble in benzene, toluene or glacial acetic acid, insoluble in bisulfite solution, and it dissolves without change in concd sulfuric acid with a claret-red color. It is not readily hydrolyzed by dilute alcoholic hydrochloric acid. The material prepared in the above manner was compared with samples obtained by esterifying hydroxyanthraquinone with methyl alcohol and hydrogen chloride and by methylation with methyl iodide. The substances were identical.

Allylation

Three products are formed in the reaction of hydroxyanthraquinone silver salt with allyl bromide and they may be readily separated by taking advantage of the solubility of the o-quinone ether in bisulfite solution and of the acidic nature of the C-alkyl derivative. A mixture of 8.9 g. of the silver salt, 150 cc. of benzene and 3.5 g. of allyl bromide was boiled for one-half hour and the silver bromide separated. Most of the o-quinone ether crystallized from the filtrate; the mother liquor, diluted with ether, was extracted with ammonia solution and then with bisulfite solution and the products were recovered in the usual way. From the mother liquor, dried and concentrated, the *p*-quinone ether was obtained by the addition of petroleum ether; it was somewhat dark in color but melted only a few degrees below the correct temperature. The other isomers were nearly pure. Yields: *o*-quinone ether, 4.9 g. (70%); p-quinone ether, 0.8 g. (11%); C-alkyl derivative, 0.7 g. (10%).

---

[12] Schunck and Roemer, Ber., 10, 553 (1877).

4-Alloxy-1,2-anthraquinone.—This compound is best crystallized from benzene, in which it dissolves readily; it separates in the form of flat, yellow needles; m. p. 173". It readily undergoes rearrangement, as indicated below.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 77.22; H, 4.78.

2-Alloxy-1,4-anthraquinone.—In order to remove dark-colored by-products it was necessary to precipitate the crude material several times from its solution in glacial acetic acid by the addition of water; the ether was then crystallized repeatedly from benzene-ligroin and obtained in the form of light yellow blades melting at 139°.

And. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 77.28; H, 4.67.

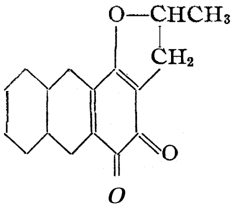
2-Allyl-3-hydroxy-1,4-anthraquinone.—This compound dissolves readily in glacial acetic acid and crystallizes from this solvent in the form of beautifully lustrous, flat, yellow needles melting at 215°. It is readily soluble in benzene, moderately soluble in alcohol, and the alkaline or alkali carbonate solution is orange in color.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 76.90; H, 4.68.

The same substance is easily obtained by the rearrangement of 4-alloxy-1,2-anthraquinone. Three and one-half g. of the ether was heated in an oil-bath maintained at 175°. As soon as fusion was complete the temperature of the melt rose rapidly to 220° and the vessel was at once removed from the oil-bath. The melt quickly solidified and now failed to fuse at 175". The product was extracted with ammonia solution and crystallized once from alcohol; yield, 3 g.; m. p. 214°.

1-Methyl-5,6-(β,β-naphtho)-3,4-coumaranquinone.—One g. of allylhydroxyanthraquinone was dissolved in 7 cc. of concd. sulfuric acid and after one-half hour the claret-red solution was poured into water. The somewhat oily, red precipitate was dissolved in bisulfite solution and recovered by acidification of the solution, when it separated in crystalline condition. After several crystallizations from benzene-ligroin the melting point remained constant at 186–187°, and small, orange-red needles were obtained.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 77.01; H, 4.85.



This coumaran derivative is attacked only very slowly by dilute alkali in the cold but on warming it is rapidly dissolved, giving an orange-red solution from which acids precipitate a yellow substance in crystalline condition The compound crystallizes from benzene, in which it is only moderately soluble, in the form of small, yellow needles, m. p. 211–212°. The acidic character and the color of the material, together with the analysis, indicate the structure of **2-(β-hydroxypropyl)-3-hydroxy-1,4-anthraquinone.**

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00. Found: C, 72.05; H, 5.34

Summary

2-Hydroxy-1,4-anthraquinone has been prepared and its structure established by conversion into triacetylpurpurin. The silver salt of this quinone reacts with a saturated alkyl halide to give a mixture of the products of metathesis and of 1,4-addition, while with allyl bromide a C-alkyl derivative, the product of 1,2-addition, is also formed. These and other results show that the properties and reactions of 2-hydroxy-1,4-anthraquinone are strikingly similar to those of 2-hydroxy-1,4-naphthoquinone.

The reduction potentials of α- and β-anthraquinones are from 81 to

101 mv. lower than those of the corresponding naphthoquinones, while α-anthraquinone is 246 mv. higher in potential than 9,10-anthraquinone. These facts are consistent with the conception that a-anthraquinone is in every way comparable to a-naphthoquinone, but that its reduction product should be compared with 9,10-anthrahydroquinone.

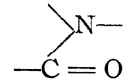
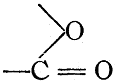
THE ISOMERISM OF PHENYLPHTHALIMIDE AND A STUDY OF THE NITRO AND CHLORO DERIVATIVES

By Mary L. Sherrill, Florence L. Schaepfer and Elizabeth P. Shoyer

Received September 16, 1927 Published February 4, 1928

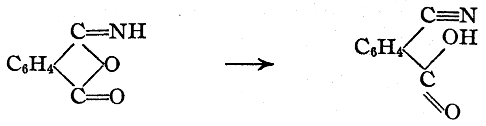
A critical study of the extensive work which has been done on phenylphthalimide or phthalanil, and its derivatives shows not only conflicting theoretical interpretations but contradictory experimental results. In addition to the closely related compounds the phthalanils, the phthalanilic acids, and the phthalamides which have not always been completely separated from one another, there are the two isomeric phthalimides—the symmetrical type —C = O and the asymmetrical type —C = N—





These isomers differ so slightly in their physical and chemical properties that the separation and identification have been difficult and this accounts for much of the confusion and inaccuracy in the reported results. In the present study a complete survey of the literature was made and much of the experimental work repeated, duplicated in some cases and in the case of disputed points additional evidence has been obtained. The more general methods of preparation of the phthalanils and the phthalanilic acids have not been a matter of controversy, but this is not true of the preparation and isolation of the isomeric phthalanil derivatives.

The first evidence of the existence of an isomeric phthalimide was reported by Hoogewerff and van Dorp.[1] They found that o-cyanobenzoic acid was obtained by the action of ammonia on phthalyl chloride. Since neither phthalimide nor the phthaldiamide can be transformed by ammonia into the o-cyanobenzoic acid, they assumed the formation of an asymmetrical phthalimide as an intermediate compound—this evidently was unstable in alkaline solution and rearranged to the acid, thus



---

[1] Hoogewerff and van Dorp, *Rec. trav. chim.*, **11, 84 (1892).**

A year later the same authors[2] prepared compounds isomeric with the substituted camphorimides by treating the proper camphoramic acid with acetyl chloride or phosphorus oxychloride. These camphor-iso-imides were found to react with ammonia to give the corresponding cyano acid and therefore were assumed to have the following structure,  giving the acid  Iso-imides of other dicarboxylic acids could not be prepared but the iso-imide of phthalic acid was evidently obtained although not in a pure state; the substance obtained did give, with ammonia, o-cyanobenzoic acid. This work was one of the most important proofs of the existence of iso-imides and of the asymmetrical structure of the compounds obtained by the action of acetyl chloride on a dibasic acid. It stimulated interest in the preparation of various substituted iso-imides and phthalmethyl-iso-imide and phthalbenzyl-iso-imide were prepared in this way.[3] These iso-imides were crystalline products whose melting points were much lower than those of the ordinary imides; they were bases, but the salts were easily decomposed in the presence of water forming the corresponding acid. In 1896 van der Meulen,[4] working in the same laboratories, prepared the phthalphenyl-iso-imide by the action of acetyl chloride on phthalanilic acid. He isolated a crystalline compound which melted at 115–117°, while the melting point of the ordinary phenylphthalimide was 208°. These results were duplicated by other investigators.[5] Van der Meulen[6] found that when iso-imides were heated they were converted into the ordinary imides, that alcohols transformed them and their hydrochlorides into amidoic esters, sometimes into iso-esters and that amines formed with the iso-imides di-amides.

In 1901 Kuhara and Fukui[7] claimed to have prepared a substance isomeric with phthalanil which they called a-phenylphthalimide. This work was repeated by Kuhara and Komatsu;[8] the a-phenylphthalimide, however, was not isolated but normal phenylphthalimide, phthaldiphenyl-

diamide and a hydrated di-amide were obtained. Then these investigators repeated the work of van der Meulen[4,6] and reported that they could not duplicate his work. They obtained two substances isomeric with phthalanil; one, yellow in color, they called the iso-imide; the other, white in color, they designated as β,α-phenylphthalimide.

Since the work of Kuhara is the last publication dealing with these isomers of phthalanil, his conclusions and results have remained unchallenged. A study of his methods seemed to indicate that the two isomers he reported were mixtures, so it was thought advisable to repeat the experiments of van der Meulen, Hoogewerff and van Dorp, Pummerer and Dorfmuller on the one hand and those of Kuhara, Fukui, Komatsu on the other, in order to prove as far as possible the existence or nonexistence of the various isomers mentioned above. Especial attention was given to the preparation of van der Meulen's phthalphenyl-iso-imide and to the preparation and isolation of the β,α-phenylphthalimide and the isomeric phenylphthalimide reported by Kuhara.

Early in the work in this Laboratory it was found that phenylphthalimide and phthalanilic acid could be completely separated from each other by a difference of solubility in chloroform. By this method it was found that a compound reported by Gabriel and Thorpe[9] as phthalanilic acid (m. p. 192°) was a mixture of phenylphthalimide (m. p. 208°) and phthalanilic acid (m. p. 169°, decompd.). It was found possible by the use of chloroform to separate phenylphthalimide from phthaldiphenyldiamide and thus some very clean cut separations were made possible. The results show that van der Meulen's phthalphenyl-iso-imide is the true isomer of phthalanil, that the iso-phthalanil of Kuhara and Fukui, designated as a-phenylphthalimide, is a mixture of phthaldiphenyldiamide, that the β,α-phenylphthalimide of Kuhara is a mixture of phthalphenyl-iso-imide and phthalanilic acid and that the yellow product obtained by Kuhara (m. p. 125–126") was a mixture of the true isophthalanil (m. p. 116°) and small amounts of *n*-phthalanil.

The literature showed also some conflicting data with regard to the o-m-p-nitrophthalanils and indicated that investigation of some of the methods might prove of value. Accordingly, the work of various investigators, including Pawlewski, Dobreff and Kuhara was repeated in this Laboratory with the result that much of the confusion has been eliminated. The p-chlorophthalanilic acid and the *p*-chlorophthalanil[10] have been prepared but no reference is given in the literature to the corresponding *ortho* and *meta* compounds. These compounds, as well as the para compounds, have been prepared in this work.

Experimental

Phthalanilic acid was prepared[11] by the reaction of chloroform solutions of phthalic anhydride (50 g.) and aniline (31.4 g.). There was considerable heat of reaction and the white phthalanilic acid which precipitated out was found to be practically pure; it melted at 169° with evolution of steam, the residue resolidified and remelted at 207°, the melting point of phthalanil.

The effect of alcohol on phthalanilic acid has been studied[12] and the final product has been proved to be phthalanil. In this process, however, the alcohol solutions become yellow and this color has not been definitely accounted for. Since one of the isomers of phthalanil is yellow,[6] it was thought that some of the isomeric compound might be formed as an intermediate. A series of experiments was carried out in which the action of alcohol (95% and absolute) on the acid was studied. The concentration, temperature, length of contact and light conditions were varied. The color of the solution increased from pale yellow to a deep red directly as there was an increase in the temperature, in the concentration of the solution, in the length of time of reaction and in the volume of air above the solution. The results seemed to indicate a slow oxidation and the change was most rapid and extensive in the presence of an oxidizing agent, as shown by the addition of a small amount of hydrogen peroxide to the solution. No trace of the isomer could be obtained. The products isolated after the reaction were only phthalanilic acid and phthalanil, the quantity of the latter increasing with the time. The ultraviolet absorption spectra of alcoholic solutions of phthalanil and phthalanilic acid were also investigated and showed that even very dilute solutions of phthalanilic acid were gradullay transformed into phthalanil.

Phthalanil was prepared by the fusion of phthalic anhydride (50 g.) with aniline at a temperature of 250–260°.[13] The product was washed with alcohol, dissolved in chloroform and precipitated by alcohol in the form of glistening white needles (m. p. 207°). On account of the extreme solubility of phthalanil in chloroform and the complete insolubility of phthalanilic acid in this solvent it was found possible to make a complete separation of the two and the method was used throughout this investigation. There is no indication in the literature that chloroform would serve for this separation. Repetition of the work of Gabriel and of Thorpe[9,14] showed that the product they obtained of melting point 192°, thought to be pure phthalanilic acid, could be separated into pure phthalanil (m. p. 207") and pure phthalanilic acid (m. p. 169°) by extraction with chloroform.

Isomeric **Phthalanils**

The fundamental reaction involved in the preparation of the iso-imides[2] consisted in the action of acetyl chloride on phthalamic acid. Therefore, before any duplication of the methods used by previous investigators was undertaken, this reaction was carried out under varying conditions of time and temperature and a careful separation and identification of the products were made. A pale yellow product (melting between 160 and 203°) resulted from the action of acetyl chloride on phthalanilic acid either at ordinary temperature or at 40°. If the yellow product was allowed to stand in the air or dried at a temperature of 80°, the yellow color disappeared entirely. If, however, the product was dried in a vacuum desiccator and then kept in an atmosphere of carbon dioxide, the yellow color persisted for several weeks. The reaction product was extracted with ether and the ether extract gave a white crystalline substance melting with decomposition between 157 and 202°. By extraction of this substance with chloroform, phthalanil was isolated (m. p. 207°), phthalanilic acid (m. p. 169°) was obtained and some phthalic acid, colorless plates (m. p. 184° with decomposition forming phthalic anhydride, m. p. 129–130°). The identification of these substances was checked by comparison with the pure substance; in each case mixed melting points showed no depression. The phthalic acid was further identified by the fluorescein test; phthalanil and phthalanilic acid gave negative tests under the same conditions. The residue left after the ether extraction was treated with chloroform, which removed a small amount of phthalanil and the residue melted at 237° with decomposition. This proved to be the phthaldiphenyldiamide,[6,5a,15] for when heated with glacial acetic acid it was transformed into phthalanil. These results show that the yellow product contained the hydrochloride of phthalphenyl-iso-imide. This hydrochloride was unstable in the air (more stable in dry air or in carbon dioxide), giving off hydrogen chloride and leaving the iso-imide. This iso-imide has been shown to be easily transformed into phthalanil.[5b] The presence of phthalic acid indicated the decomposition of some of the phthalanilic acid into phthalic acid and aniline. The reaction of aniline with the phenyl-iso-imide would account for the small amount of diamide formed.

An effort was made to prepare the α-phenylphthalimide of Kuhara.[7] The work was repeated in every detail, as follows. To an ethereal solution of 93 g. of aniline cooled to —10°, an ethereal solution of 50.75 g. of phthalyl chloride, also cooled to —10°, was added drop by drop. The temperature was kept below —6°. Hydrogen chloride was evolved and a white precipitate separated. The reaction mixture was kept in a freezing mixture for two hours. The precipitate was filtered and washed suc-

---

[15] Rogow, *Ber.*, **30, 1442 (1897).**

cessiuely with hydrochloric acid, ammonia and water, as described by Kuhara. The product obtained melted at 215–219°. A chloroform extraction separated a very small amount of phthalanil (m. p. 207°); the main portion of the material was insoluble in chloroform and slightly soluble in alcohol. By recrystallization from alcohol a white crystalline product was obtained, m. p. 231° with decomposition. This was soluble in hot glacial acetic acid but was thereby converted into phthalanil and was therefore phthalanilide. This confirms the work of Hoogewerff and van Dorp,[5a] Chambers,[16] and Dunlap and Cummer,[17] who found that ethereal solutions of aniline and phthalyl chloride at low temperature formed, in the main, phthalanilide. Therefore, the original product, m. p. 215–219°, proved to be a mixture of n-phthalanil and phthalanilide and not an isomeric phthalanil.

Phthalphenyl-iso-imide, m. p. 116°, was prepared by careful duplication of the work of van der Meulen.[4] Five grams of phthalanilic acid was treated with 30 g. of acetyl chloride and the mixture heated at a temperature of 60° for seven minutes; the mixture turned yellow almost immediately. The cooled mixture was treated with carbon disulfide, the insoluble hydrochloride of phthalphenyl-iso-imide was filtered and immediately transferred to anhydrous ether. The iso-imide was freed by 30% potassium hydroxide, the flask was kept cold and the potash added only to bare alkalinity. The product was then practically all dissolved and the ether solution, yellow in color, was separated from the water layer and dried over solid potassium hydroxide for ten minutes. From this solution, filtered and evaporated in a desiccator over sulfuric acid, yellow needle crystals (m. p. 112–115°) were obtained. After one recrystallization from anhydrous ether, the crystals melted at 116°. This agreed with the results of van der Meulen[4] and Pummerer and Dorfmüller[5b] although Hoogewerff and van Dorp[5a] gave the melting point as 120–122°. Kuhara and Komatsu[S] claimed that they could not obtain the product which van der Meulen reported but that, on distillation, of part of the ether solution and then on spontaneous evaporation of the remainder phthalanil crystallized out first and then an amber-colored substance. The latter, on repeated recrystallization from anhydrous ether, gave amber-colored rhombic crystals, m. p. 125–126°. Kuhara also evaporated, as quickly as possible, the ethereal solution of the reaction product and obtained an almost colorless crystalline substance which, after one recrystallization from anhydrous ether, melted at 83–84°. This he designated as β,α-phenylphthalimide and believed both this and the amber-colored substance to be the true isomers of phthalanil rather than the yellow needles, m. p. 116°, of van der Meulen. In order to clear up these points the phthalphenyl-iso-imide was prepared as given above; a portion of the ether solution was evaporated in a desiccator over sulfuric acid and the yellow crystals, m. p. 116°, were obtained. A second portion of the same ether solution was partially distilled and then allowed to evaporate. The first product crystallizing out was phthalanil, m. p. 207"; further evaporation gave a very pale yellow residue which melted from 70–80°, resolidified and melted at 207°. A chloroform extraction of this mixture was made; the residue insoluble in chloroform proved to be pure phthalanilic acid, m. p. 169". It melted with evolution of gas, resolidified and remelted at 207°. The chloroform extract evaporated in a desiccator over sulfuric acid gave clusters of yellow needles, m. p. 116°; therefore the reaction prod-

---

[17] Dunlap and Cummer, *ibid.*, 25,612 (1903).

uct, m. p. 70–80°, was a mixture of phthalphenyl-iso-imide and phthalanilic acid. This mixture obtained on heating the ethereal solution was probably caused by traces of alkali hydrolyzing the iso-imide into the acid.

The fact that a low melting reaction product (70–80°) was obtained in this Laboratory on repetition of Kuhara's work and that this proved to be a mixture indicates definitely that what Kuhara and Komatsu really had in the case of the substance melting at 83–84°, called β,α-phenylphthalimide was a mixture of van der Meulen's iso-imide and phthalanilic acid. Further confirmation lies in the fact that whenever the phenyl-iso-imide melting at 116° was mixed with phthalanilic acid, the mixture melted between 70 and 85°. Kuhara also states that when heated by itself β,α-phenylphthalimide was converted into the normal phenylphthalimide; this would be true of a mixture of phthalphenyl-iso-imide and phthalanilic acid since, on heating, both of these substances are converted into the ordinary phenylphthalimide.

Whenever the phthalphenyl-iso-imide prepared in this Laboratory was exposed to the air, it was found that the melting point became gradually higher, due to the fact that it was slowly transformed into the normal phthalanil. It was also proved that a mixture of a small amount of phthalanil with the iso-phthalanil melted at 120–126°, which accounts for the product of higher melting point obtained by Hoogewerff and van Dorp (120–122') and that obtained by Kuhara (125–126°). When the phthalphenyl-iso-imide was allowed to stand in the presence of acid fumes, however, long, white needle crystals could be observed on the surface of the iso-imide. These were collected and found to be phthalic anhydride. The residue was found to consist of a mixture of the normal phenylphthalimide, the phthalphenyl-iso-imide and the phthaldiphenyldiamide. The two former substances were separated from the latter by extraction with ether and were then separated from each other by fractional crystallization from the ether solution.

Nitrophenylphthalimides

Preliminary to the checking of the work of various investigators on the isomeric nitrophenylphthalimides, nitro phthalanilic acids were prepared.

p-**Nitrophthalanilic** acid (m. p. 192° with decomposition) was prepared by the reaction of acetic ester solutions of *p*-nitraniline and phthalic anhydride.[18] The solvent was distilled off and the residue, after recrystallization from alcohol, gave a crystalline product which melted at 190–192° with evolution of gas, resolidified and melted again at 260° (melting point of *p*-nitrophthalanil, 262–263°). The method used in the preparation of phthalanilic acid was found to give better yields and more satisfactory material. Chloroform solutions of equimolecular quantities of p-nitraniline and phthalic anhydride were mixed and heated until the yellow color of the solution gradually faded. When cool the product was filtered, washed with cold chloroform and then recrystallized

---

[18] (a) Meyer and Lüders, *Ann.*, **327**, 52 (1903); (b) *Ann.*, **415**, 29 (1917).

from hot chloroform. It formed white crystals which melted at 192°, evolved a gas, resolidified and melted at 262–263°.

m-**Nitrophthalanilic** acid (m. p. 202° with decomposition) was prepared by the reaction of acetic ester solutions of m-nitraniline and phthalic anhydride. Chloroform solutions of the reagents gave, as for the para compound, a theoretical yield and the product washed with chloroform consisted of white needles which melted at 202°, resolidified and melted at 240–242°.

o-Nitrophthalanilic acid (m. p. 149–151°) was also prepared by the action of *o*-nitraniline on phthalic anhydride in ethyl acetate solution and in chloroform solution. The acid is very soluble in both acetic ester and chloroform, so it did not precipitate out as in the case of the para and meta compounds. In order to isolate the o-nitrophthalanilic acid it was necessary to evaporate the solvent in each case to a small volume and stir until the acid crystallized. The product, washed with ether, was purified by precipitation with hydrochloric acid from a solution in sodium hydroxide. It formed yellow needles which melted at 149–151° (Meyer and Lüders[18b] give 146–148°) without evolution of gas and the liquid did not resolidify on further heating as in the case of the para and meta acids. If the melted product was cooled, however, and heated again it began to melt at 150° and water vapor came off at 200°, the melting point of the *o*-nitrophthalimides.

The normal nitrophenylphthalimides, *p*-nitrophenylphthalimide (m. p. 262–264°), m-nitrophenylphthalimide (m. p. 242–244") and o-nitrophenylphthalimide (m. p. 202–203") were prepared by the fusion of the proper nitraniline with phthalic anhydride. according to Meyer and Maier.[19] These corresponded in properties and melting points to the values given by other investigators[m] for their normal compounds, but did not correspond to the compounds reported by Dobreff.[21]

Since Kuhara, Komatsu and Nishiyori claimed to have obtained both the symmetrical and asymmetrical forms of the o-, *m*- and *p*-nitrophenylphthalimides by the reaction of ether solutions of the corresponding nitraniline and of phthalyl chloride at —10°, and since the work of van der Meulen and that done in this Laboratory showed that under these conditions the phthaldiphenyldiamides were formed, the work of Kuhara and that of Dobreff was carefully repeated.

According to Kuhara,[20c] ethereal solutions of 10 g. of *p*-nitraniline and 14.6 g. of phthalyl chloride were cooled and the chloride was added slowly to the aniline. After five minutes a precipitate gradually separated and the yellow color of the ether solution faded. The precipitate was almost white, faintly tinged with yellow. It was filtered, washed with hydrochloric acid, then with ammonia, whereupon it became deep yellow in color and some of it dissolved and then crystallized in the pores of the filter plate. It was finally washed with water and dried. Then the entire mass was extracted with alcohol. From the deep yellow alcoholic solution there crystallized first a small amount of a white substance, m. p. 262–263°. This was normal p-nitrophenylphthalimide; a mixed melting point with the pure compound showed no depression. A large quantity of this compound was obtained from the ether filtrate of the original reaction mixture. Next from the alcoholic solution a mass of fine, white needles crystallized

[21] Dobreff, Ber., 28, 940 (1895).

which melted at 192'. This substance was reported by Kuhara to be pale yellow and to be the asymmetrical p-nitrophenylphthalimide, identical with the product obtained by Dobreff.[21] It was noted in this Laboratory, however, that the product melted with the evolution of gas, resolidified and melted again at 262–263°, which indicated that it was probably the p-nitrophthalanilic acid. It dissolved in alkalies, giving a deep yellow solution from which the acid was reprecipitated as a white powder. A mixture of this compound with p-nitrophthalanilic acid (m. p. 192°), prepared as indicated above, showed no change in the melting point. The appearance of the yellow color on washing the reaction product with ammonia was due to the formation of an ammonium salt and it was traces of this which colored the Kuhara product and that of Dobreff. This ammonium salt was obtained in this Laboratory as a yellow, crystalline product which finally crystallized from the alcohol solution.

The portion of the original reaction product insoluble in alcohol was a pale yellow powder which melted at 232° and when dissolved in hot glacial acetic acid was converted into the p-nitrophenylphthalimide. This compound was, therefore, *p*-nitrophenylphthalamide, which had been obtained by Pawlewski[22] by the action of two molecules of p-nitraniline on one molecule of phthalyl chloride. Therefore, by following the exact details of Kuhara's work, the products obtained were white *p*-nitrophenylphthalimide, m. p. 262–263°, white p-nitrophthalanilic acid, m. p. 192°, yellow *p*-nitrophenylphthalamide, m. p. 232°, and the yellow ammonium salt of *p*-nitrophthalanilic acid. When the experiment was repeated and the original reaction product washed with ether instead of hydrochloric acid and ammonia the product did not change color and from it were isolated, as above, p-nitrophenylphthalimide, p-nitrophthalanilic acid and p-nitrophenylphthalamide.

Similarly the work of Dobreff[21] was repeated. The p-nitraniline (10 g.) and the phthalyl chloride (14.6 g.) were heated on a steam-bath until the mixture changed from brown to tan. A portion of the filtered product was boiled, according to Dobreff, a long time with water and then recrystallized from alcohol. The yellow substance, insoluble in alcohol, melted at 230–232° and was p-nitrophenylphthalamide. From the alcohol solution a small amount of normal *p*-nitrophenylphthalimide (m. p. 262–263°) crystallized first, then a creamy white powder (m. p. 192" with decomposition) which proved to be the p-nitrophthalanilic acid. A second portion of the filtered product was washed with ether and extracted with alcohol and exactly the same products were obtained as from the first portion except that in this case there was much more of the normal p-nitrophenylphthalimide and much less of the p-nitrophthalanilic acid. This work showed that Dobreff's method gives largely the normal p-nitrophenylphthalimide but that boiling with water hydrolyzed this to the acid and that the 190–190.5° yellow compound of Dobreff is the p-nitrophthalanilic acid. The yellow color must have been due to traces of the yellow nitrophthalanilide.

Kuhara[23] stated that the asymmetrical nitrophenylphthalimides could be obtained by the action of acetyl chloride on the corresponding nitrophthalanilic acid but gave no details. The Hoogewerff-van Dorp method[a] was carried out with the utmost care. The p-nitrophthalanilic acid and acetyl chloride were heated for twenty minutes at 60–75°. There was no color change. The product, however, was washed with carbon disulfide, filtered and added directly to anhydrous ether. A drop or two of 30% potassium hydroxide temporarily changed the white solid into the orange potassium salt. This color disappeared, however, as long as the mixture was slightly acid. The only substance which could be isolated was the p-nitrophthalanilic acid, m. p. 192°, which was recovered practically quantitatively. Variations in temperature and time of reaction

---

[22] Pawlewski, Ber., 28, 1118 (1895).

[23] Ref. 20 c, p. 346.

gave no other results. Therefore, the asymmetrical *p*-nitrophenylphthalamide cannot be prepared by the method used in the preparation of phenylphthal-iso-imide.

Kuhara[24] prepared a mono-silver salt of p-nitrophthalanilic acid from a water solution of the ammonium salt by precipitation with silver nitrate. The ammonium salt was prepared in this Laboratory by passing dry ammonia gas into an alcoholic solution of the acid. A solution of this salt was treated with silver nitrate and the silver salt, pale yellow in color, was dried and analyzed.

Anal. Calcd. for $C_{14}H_9O_5N_2Ag$: Ag, **27.46.** Found: **27.20, 27.26.**

A di-silver salt of *p*-nitrophthalanilic acid was also prepared. The di-potassium salt was first formed by the reaction of alcoholic potash on an alcoholic solution of the p-nitrophthalanilic acid. The potassium salt was washed with alcohol and dried, then dissolved in a large volume of alcohol and to this solution alcoholic silver nitrate was added. A yellow precipitate was first formed but on addition of the calculated amount of silver nitrate the precipitate became brown. This brown di-silver salt was difficultly soluble in alcohol but could be recrystallized from it.

Anal. Calcd. for $C_{14}H_{18}O_5N_2Ag_2$: Ag, **43.17.** Found: **43.20, 43.12.**

The action of phthalyl chloride on m-nitraniline according to the Kuhara method was investigated as in the case of the para compound. One product crystallizing from the alcoholic extract was white and melted at **243°.** This substance agreed in melting point and properties with the symmetrical m-nitrophenylphthalimide of other investigators.[20a,20c,22] The substance which crystallized next was m-nitrophthalanilic acid, colorless needles melting at **202"** with evolution of gas, resolidifying and melting again at 243°. This was identical with the acid previously prepared.[18b,25] A large amount of the acid was also obtained from the ether filtrate of the original reaction product. The portion least soluble in alcohol was pale yellow in color and melted at 230–232°. This was reported by Kuhara[23] as the asymmetrical m-nitrophenylphthalimide. It proved to be the m-nitrophenylphthalamide and when heated with glacial acetic acid it was converted into the asymmetrical *m*-nitrophenylphthalimide.[22]

The Dobreff method was repeated in this case too.'' The product, after being boiled with water, was crystallized from hot alcohol and found to be a mixture of *m*-nitrophenylphthalamide, m. p. 230–232°, and *m*-nitrophthalimide, **m.** p. **240–245".** This mixture was separated by treatment with chloroform; the amide was insoluble and the imide dissolved and was recrystallized from alcohol. Phthalic anhydride was obtained from the original ether solution and red crystals of the hydrochloride of *m*-nitraniline separated from the water extract. The evidence of this work shows that the yellow compound reported by Dobreff and the asymmetrical m-nitrophenylphthalimide of Kuhara were identical and were the m-nitrophenylphthalamide.

The reaction of acetyl chloride on the m-nitrophthalanilic acid was studied as in the case of the para compound, but no trace of an asymmetrical compound could be obtained. The acid was recovered practically quantitatively. At high temperatures small amounts of the symmetrical m-nitrophthalanil were obtained.

The Kuhara work[20c] on the asymmetrical o-nitrophenylphthalamide was repeated. The following products were isolated from the alcoholic solution: first colorless needles, m. p. 198–200°, which proved to be the *o*-nitrophenylphthalimide;[18b,20b,22] then yellow crystals, m. p. 149–151°, which proved to be the o-nitrophthalanilic acid, and on the sides of the beaker yellow crystals of the hydrochloride of o-nitraniline, which melted from **140–150"** with evolution of gas. The original ether filtrate when evaporated gave a yellow mixture that melted between 108–145° with evolution of a gas. This was

---

[24] **Ref. 20** c, p. **362.**

[25] Tingle and Rolke, THIS JOURNAL, **30,** 1882 (1908).

extracted with dilute sodium hydroxide and from the alkali solution o-nitrophthalanilic acid was obtained. The residue, insoluble in alkali, was washed with alcohol from which yellow crystals of the hydrochloride of o-nitraniline were obtained. The residue, insoluble in alcohol, dissolved completely in chloroform and proved to be *o*-nitrophenylphthalimide. Efforts to prepare an asymmetrical o-nitrophenylphthalimide as in the case of the other nitro compounds proved unsuccessful. No trace of an isomeric compound could be obtained.

Chlorophthalanilic Acids

The *p*-chlorophthalanilic acid was prepared by the action of chloroform solutions of phthalic anhydride on p-chloro-aniline. The acid crystallized out in white needles and was filtered, washed with chloroform and found to melt at 187.5'; after cooling, it resolidified and when reheated melted at 192°, the melting point of *p*-chlorophthalanil. Recrystallization of the acid did not change its melting point. In properties it corresponded with the p-chloro acid reported by Tingle and Brenton[26] (m. p. 180°).

The m-chlorophthalanilic acid was prepared in a similar way. It formed white crystals which melted at 183–184° with evolution of gas. When cooled it resolidified and remelted at 157'. The acid is very soluble in ethyl acetate, glacial acetic acid and dilute alkalies. It can be recrystallized from alcohol, chloroform or benzene, but if prepared in chloroform solution this is unnecessary as the product is obtained pure. Since this compound is not given in the literature an analysis was made.

Anal. Calcd. for $C_{14}H_{10}O_3NCl$: N, 5.08. Found: 4.94.

The o-chlorophthalanilic acid was obtained by the same method. The acid is somewhat soluble in ether and in chloroform. It can be recrystallized from chloroform or benzene but the best product was obtained by precipitation from a solution of the acid in dilute alkali. It crystallizes in white needles, m. p. 147–148°. If it is heated to 155° a gas is gradually evolved.

Anal. Calcd. for $C_{14}H_{10}O_3NCl$: N, 5.08. Found: 4.91.

Chlorophenylphthalimides

The chlorophenylphthalimides were prepared by the fusion of the corresponding chloro-aniline with phthalic anhydride. The p-chloro compound was dissolved from the reaction mass by chloroform and precipitated by alcohol in the form of long, white. silky needles, m. p. 192°, unchanged by recrystallization from hot alcohol. It agreed in properties with the *p*-chlorophthalanil of Gabriel? The m-chlorophenylphthalimide was isolated by dissolving it in chloroform and precipitating it with alcohol. It is very soluble in chloroform, ether, benzene and ethyl acetate and insoluble in glacial acetic acid. It can be recrystallized from hot alcohol and the crystals melt at 183–184° with evolution of gas.

Anal. Calcd. for $C_{14}H_8O_2NCl$: N, 5.43. Found: 5.47, 5.39.

The o-chlorophenylphthalimide was found to be too soluble in alcohol to be precipitated by it from a chloroform solution. The residue obtained by evaporation of the chloroform solution could be recrystallized from hot alcohol. The product consisted of long, white, silky needles which melted at 132–140°. It was found to be soluble in chloroform, glacial acetic acid, benzene, ethyl acetate and ether.

Anal. Calcd. for $C_{14}H_9O_2NCl$: N, 5.43. Found: 5.34.

Attempts to prepare isomeric forms of these chlorophenylphthalimides by the action of acetyl chloride on the acids were not successful.

---

[26] Ref. 10a, p. 1161.

p-Chlorophenylphthalamide was obtained by the action of *p*-chloro-aniline on phthalyl chloride. By benzene and alcoholic extraction of the reaction product, p-chlorophthalanil was recovered. The residue, insoluble in alcohol, was a white powder that melted at 233°. When it was recrystallized from hot alcohol or boiled with glacial acetic acid it was transformed into the imide. This indicates that it is the amide but because of the difficulty of getting a pure sample no analysis was made.

Summary

The results of these investigations lead to the following conclusions.

1. The phthalphenyl-iso-imide prepared by van der Meulen is the true asymmetrical phenylphthalimide. The α-phenylphthalimide of Kuhara is a mixture of phthalanil and diphenyldiamide. The β,α-phenylphthalimide (83–84°) of Kuhara is a mixture of phthalphenyl-iso-imide and phthalanilic acid. The a-phenylphthalimide (m. p. 125') of Kuhara is a mixture of the iso-imide and the normal phenylphthalimide.

2. The p-isonitrophenylphthalimide of Kuhara and of Dobreff is *p*-nitrophthalanilic acid. The m-isonitrophenylphthalimide of Kuhara and of Dobreff is a mixture of m-nitrophenylphthalamide and *m*-nitrophenylphthalimide. The o-isonitrophenylphthalimide of Kuhara is *o*-nitrophthalanilic acid with traces of o-nitrophthalanil and the hydrochloride of o-nitraniline. The asymmetrical o-, m- and *p*-nitrophenylphthalimides could not be obtained by the action of acetyl chloride on the corresponding phthalanilic acid.

3. The o-, m- and *p*-chlorophthalanilic acids can be prepared best by the reaction of chloroform solutions of phthalic anhydride on the corresponding chloro-aniline. The o- and *m*- acids have not been previously recorded. The o-, m- and *p*-chlorophthalanils can be prepared by the fusion of the chloro-aniline with phthalic anhydride. The *ortho* and ***meta*** compounds have not been previously recorded.

THE MECHANISM OF CARBOHYDRATE OXIDATION. VII. THE ACTION OF POTASSIUM HYDROXIDE ON DIHYDROXY ACETONE

BY WILLIAM LLOYD EVANS AND WILLIAM ROBERT CORNTHWAITE

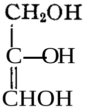
RECEIVED SEPTEMBER 22, 1927 PUBLISHED FEBRUARY 4, 1928

The studies of Hass and one of us[1] on the behavior of crystalline glyceric aldehyde in potassium hydroxide solutions, in which the concentration of the base varied from 0.2 to 6 N at 25 and 50°, showed that the amounts of the products obtained under the variable conditions employed were dependent on both the temperature and the normality of the alkali used. Pyruvic aldehyde, lactic, acetic and formic acids were the reaction products studied in the work on glyceric aldehyde. It was pointed out[2] that solutions of glyceric aldehyde[3] in the presence of potassium hydroxide should form an equilibrated system in the same manner as that which Lobry de Bruyn and Alberda van Ekenstein found existed in alkaline solutions of d-glucose and d-galactose. Furthermore, the active component of such a solution should be an enediol or its dissociation products similar to the systems postulated by Nef and his collaborators in the case of certain hexoses.

If these views are correct then it is clear that the following reaction represents the equilibrated condition existing between the three carbon atom compounds in an alkaline solution of glyceric aldehyde.

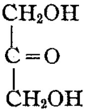
$$\begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CHO \end{array}$$

Glyceric aldehyde



$$\begin{array}{l} CH_2OH \\ | \\ C{-}OH \\ \| \\ CHOH \end{array}$$

Triose enediol



$$\begin{array}{l} CH_2OH \\ | \\ C{=}O \\ | \\ CH_2OH \end{array}$$

Dihydroxy acetone

On the basis of this discussion it is expected that dihydroxy acetone should react in aqueous solutions of potassium hydroxide in the same general manner that glyceric aldehyde does. To determine this point was one of the principal objects of these experiments by reason of the importance of dihydroxy acetone in carbohydrate chemistry, especially in its structural relation to fructose.

Experimental Part

Reagents.—The potassium hydroxide, alcohol, phenylhydrazine, zinc carbonate, phosphoric and hydrochloric acids were of the same degree of purity as those used in the work on glyceric aldehyde. The dihydroxy acetone was purchased under the name of "Oxantin." Before using, it was kept in a vacuum desiccator over soda lime and calcium chloride for at least one week. It melted at 78–79° (corr.).[4]

[4] Bertrand, *Ann. chim.*, [8] 3,255 (1904); Piloty, *Ber.*, 30, 3165 (1898).

Procedure.—In order that our data might be comparable with those obtained from the action of aqueous solutions of potassium hydroxide on glyceric aldehyde, every experimental detail of the work recorded in this report was an exact duplicate of that employed in the study of glyceric aldehyde, save that dihydroxy acetone was used instead of the aldehyde.

Products of the Reaction.—At various stages qualitative examination of our reaction mixtures was made for pyruvic aldehyde, acetol, lactic, acetic and formic acids.

Data.—Our quantitative data are shown in Figs. 1, 2, 3, 4, 5 and 6. For the sake of comparison the data by Evans and Hass from glyceric aldehyde are shown in the drawings by means of dotted lines.

Theoretical Part

The results obtained in these experiments were found to be in complete qualitative agreement with those obtained by the action of aqueous solutions of potassium hydroxide on glyeeric aldehyde. The suggestions offered for the reaction mechanism involved in the formation of pyruvic aldehyde, lactic, acetic and formic acids from glyceric aldehyde"are in accord with the data obtained by us in these experiments with dihydroxy acetone under precisely similar conditions. In addition to the discussion previously given concerning the general reaction involved in the formation of the above compounds, we wish to supplement it with the following brief statements with reference to our own data.

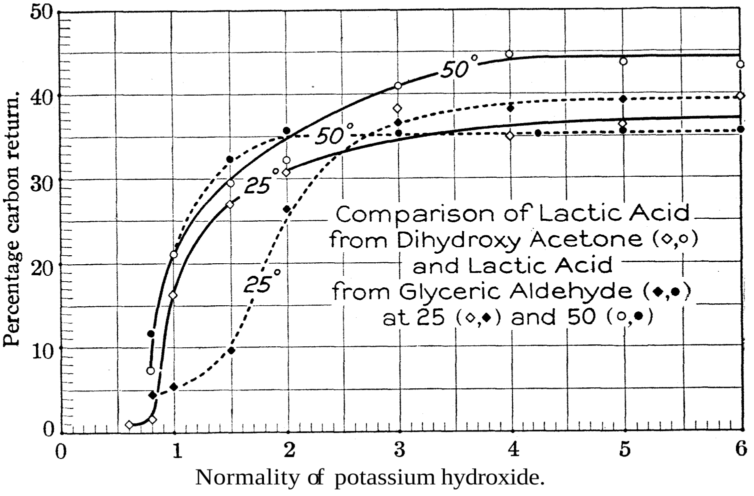

Fig. 1.

Lactic Acid.—If dihydroxy acetone and glyceric aldehyde form one and the same triose enediol, then it follows that lactic acid may be formed according to the following series of steps:[5]

Dihydroxy acetone ↘
or ⇄ Triose enediol ⟶ Pyruvic aldehyde ⟶ Lactic acid
Glyceric aldehyde ↗

---

[5] Ref. 1, p. 2710; compare Neuberg, *Biochem.* Z., 71,250 (1915).

The molecular mechanism of this series of changes may be regarded as an application of the suggestion offered by Miss Marjorie Pickard Benoy and one of us[6] for the formation of saccharinic acid lactones from the enediols of glucose and galactose. The comparative yields of lactic acid from the two trioses are shown in Fig. 1. No lactic acid (zinc lactate) was found at 25° in potassium hydroxide solutions at either 0.2 or 0.4 N, but appreciable amounts were present at 0.6 *N*. It is clear from the graph of our data that our quantitative results are also in general agreement with the assumption that the lactic acid formation from glyceric aldehyde and dihydroxy acetone is following the same course.

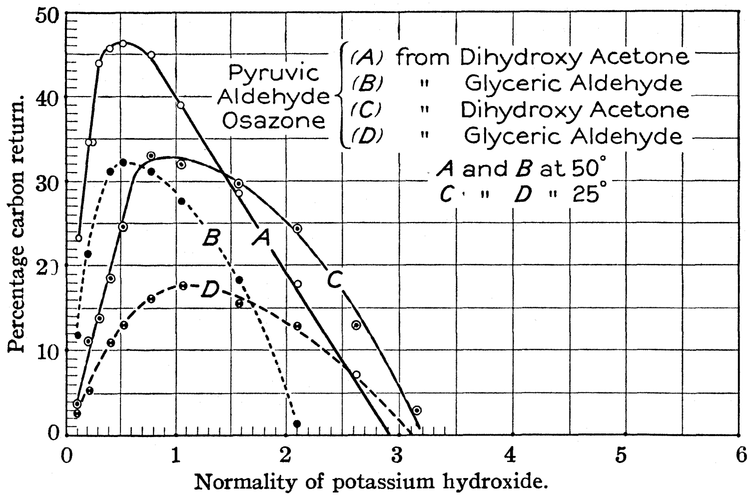

Fig. 2.

Pyruvic Aldehyde.—The percentage of dihydroxy acetone carbon obtained as pyruvic aldehyde is shown in Fig. 2. The data obtained from glyceric aldehyde are also given with certain correction factors applied which were previously omitted.[7] An examination of these curves shows in a very clear way the effect of temperature on the reaction by reason of the fact that the maximum yield of pyruvic aldehyde from both of these trioses occurs at a lower normality at 50° in each case than it does at 25°. Furthermore, it should be noted that the maximum yield of pyruvic aldehyde osazone from both compounds occurs at approximately the same normality for a given temperature. The fact that the maximum production of pyruvic aldehyde in dihydroxy acetone and glyceric aldehyde solutions occurs at practically the same alkali normality and that the general effect of temperature is also the same in each case, point very strongly to the assumption made above that a common intermediate

[6] Evans, Edgar and Hoff, This journal, 48, 2675 (1926).

[7] *See* Ref. 1, p. 2710.

compound, namely, the triose enediol, is formed in each case. Furthermore, the differences obtained in the yields of pyruvic aldehyde osazone from these two trioses at any given alkalinity under these experimental conditions seem to indicate that a condition exists in alkaline solution of these two carbohydrates similar to that observed by de Bruyn and van Ekenstein in alkaline solutions of glucose, mannose and fructose, that is, an equilibrated system in which the ratio of the amounts of the components present varied with the hexose used. It has been shown in this Laboratory[8] that the oxalic acid–carbon dioxide ratio obtained in the oxidation of these three well-known hexoses in strongly alkaline solutions of potassium permanganate tends toward the same value as the temperature and normality of the alkali are increased.

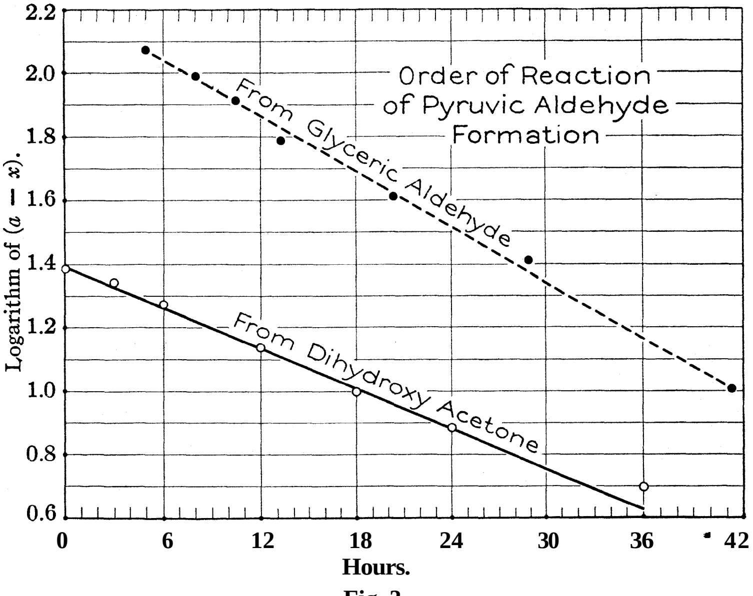

Fig. 3.

If alkaline solutions of glyceric aldehyde and dihydroxy acetone form a common triose enediol as an intermediate in the formation of pyruvic aldehyde osazone, and if the amounts of the components in the solutions varied according to the triose used, then the order of the reaction in the formation of the aldehyde from both compounds at a given alkalinity should be the same and the rate of the reaction should be different in each case. In Fig. 3 this is shown to be the case, that is, the reaction is monomolecular. The temperature used was 25°. The bearing of the recent experiments of Fischer, Taube and Baer[9] on the interpretation

---

[8] Evans, Buehler, Looker, Crawford and Holl, This Journal, 47, 3085 (1925).

[9] Fischer, Taube and Baer, Ber., 60B, 479485 (1927).

of our experimental data is very important. These investigators have shown that crystalline glyceric aldehyde may be converted into dihydroxy acetone in boiling pyridine to the extent of 49%.[3]

In the work on glyceric aldehyde the view was expressed that acetic and formic acids resulted from a dissociation of pyruvic aldehyde into acetaldehyde and carbon monoxide. These two acids increase in amount with the alkalinity until a maximum has been reached, after which their amounts diminish due to the fact that the pyruvic aldehyde at that point is now being converted into lactic acid at a speed which increases with the alkalinity. This inter-relation of the formation of lactic, acetic and formic acids to the pyruvic aldehyde involved in the reaction of an aqueous solution of potassium hydroxide on dihydroxy acetone is clearly seen in Fig. 4. According to our experimental methods of measurement, the

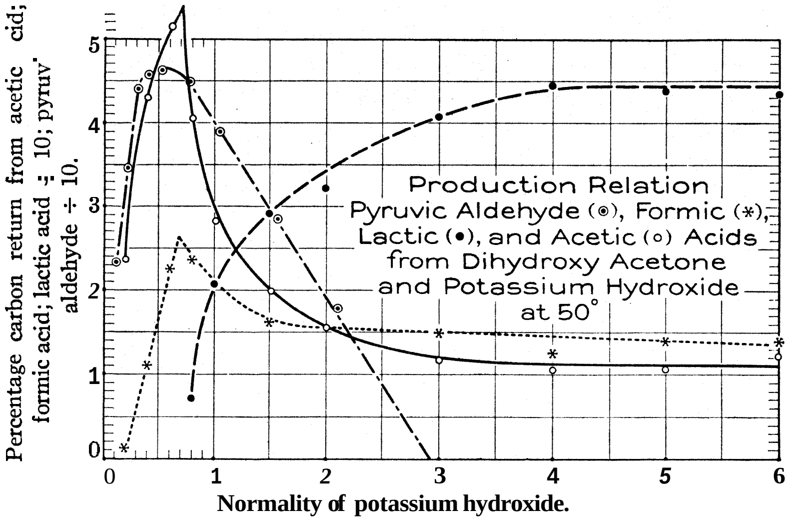

Fig. 4.

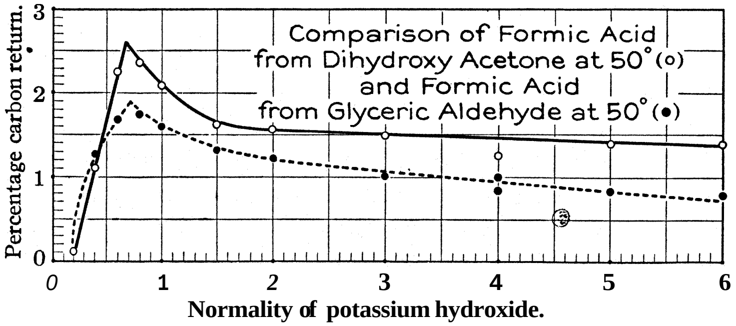

Fig. 5.

maximum yield for pyruvic aldehyde, acetic and formic acids and the minimum yield for lactic acid occur at approximately the same point of alkalinity. The maximum yield of dihydroxy acetone carbon as pyruvic aldehyde is approximately the same as the maximum for that of lactic acid. The formic and acetic acid yields are given in Figs. 5 and 6, respectively. The differences in the yields of these two acids from the two sources are not very great. It is also conceivable that the triose enediol of these reactions may undergo dissociation into the active forms of glycolic and formaldehydes, which in turn may react to yield other substances, among which would be formic acid. Our reaction mixtures were not examined for either glycol or glycolic acid. The view that a 1,2-enediol may undergo such a dissociation with subsequent chemical change has received much support in the recent experiments of Gustus and Lewis[10] on the action of alkaline hydrogen peroxide solution on 2,3,4,6-tetramethyl-d-glucose.

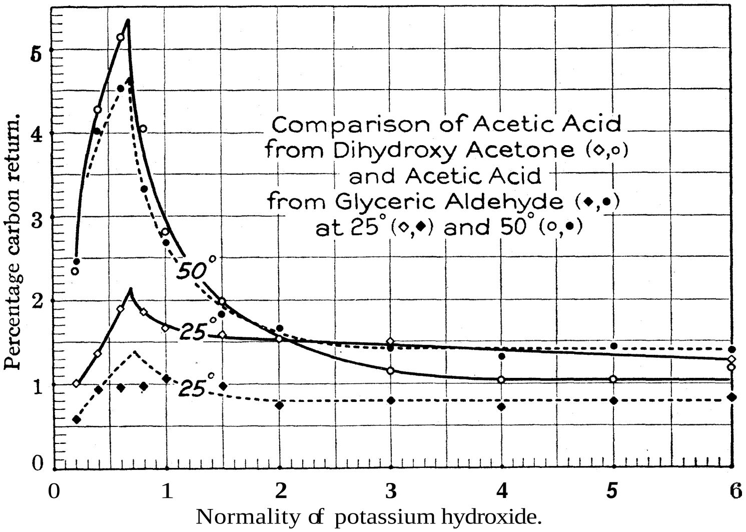

Fig. 6.

Summary

1. Molar solutions of dihydroxy acetone were treated with various concentrations of potassium hydroxide from 0.2–6 N at 25 and 50°. The resulting acetic, formic and lactic acids were measured quantitatively (Figs. 1, 5 and 6).

2. The yields of formic and acetic acids at 50° increased with the increasing alkali concentration until a maximum point was reached,

---

[10] Gustus and Lewis, THIS JOURNAL, 49, 1512 (1927); see also Baly, *The Rice Institute Pamphlet, 12,* 93 (1925).

after which they diminished. The same effect was observed for acetic acid at 25°.

3. Molar solutions of dihydroxy acetone were treated with alcoholic phenylhydrazine solutions in the presence of various concentrations of alkali. The yield of pyruvic aldehyde osazone increased with the alkalinity to a maximum at both 25 and 50°, after which it diminished. Increasing temperature increased the yield of the osazone (Fig. 2).

4. The maximum yield of pyruvic aldehyde osazone from both trioses occurs at the same alkali normality for a given temperature. This maximum is attained at a lower alkali normality at 50° than at 25°.

5. The yields of lactic acid at 25 and 50° increased to a constant maximum with both the increasing alkalinity and temperature. The maximum point is practically the same as that for the pyruvic aldehyde at these temperatures.

6. The data obtained are shown graphically in comparison with a similar study on glyceric aldehyde. The results seem to indicate that both dihydroxy acetone and glyceric aldehyde in alkaline solutions form systems similar to those observed by de Bruyn and van Ekenstein in alkaline solutions of the hexoses.

7. The differences observed in the yields of pyruvic aldehyde osazone are thought to be due to the differences in the equilibrium existing between glyceric aldehyde, dihydroxy acetone and triose enediol in alkaline solutions. This point of view is supported by the fact that the order of the reaction is the same in both cases, while the rate of the reaction is different (Fig. 3).

8. Since both trioses are thought to form one and the same enediol, then the lactic acid must be derived from the pyruvic aldehyde arising from this common enediol. The acetic and formic acids are thought to be derived from a dissociation of pyruvic aldehyde into acetaldehyde and carbon monoxide. The minimum point for lactic acid yields is therefore related to the maximum yields for pyruvic aldehyde, acetic and formic acids. This inter-relation is shown in Fig. 4.

CATALYTIC OXIDATIONS IN AQUEOUS SOLUTIONS. II. THE OXIDATION OF PRIMARY ALCOHOLS

BY NICHOLAS A. MILAS[1]

RECEIVED SEPTEMBER 24, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

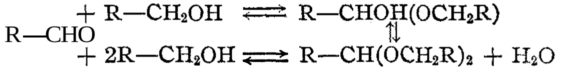
In a recent paper[2] of this series the author has shown that metallic oxides such as osmium tetroxide and vanadium pentoxide can be used, in aqueous solutions, to induce the oxidation of furfural and pyromucic acid by means of chlorates. The present paper describes several additional experiments in which vanadium pentoxide has been used to induce the oxidation of six of the primary alcohols.

The oxidation of alcohols has been the subject of a vast number of investigations which have occupied a period of more than a century. It is well established, therefore, that when primary alcohols are oxidized under ordinary conditions, the principal products which result from the oxidation are either aldehydes, or acids, or both. However, certain controlled oxidations of ethyl,[3] *n*-butyl,[4] isobutyl[5] and *iso*-amyl[6] alcohols yield esters as the principal products when the alcohols are present in excess. But such methods of oxidation are not applicable to all alcohols and any attempt to explain the formation of esters in these oxidations might lead to erroneous conclusions.

In the present paper a new catalytic method is described whereby the primary alcohols are simultaneously oxidized and esterified. It consists in the treatment of the alcohols, under proper care, with chlorates in dilute acid solution and in the presence of vanadium pentoxide as the catalyst.

Notwithstanding the great number of investigations published during the past hundred years on the oxidation of alcohols, comparatively little attention has been paid to the mechanism of the oxidation and subsequent esterification of these alcohols when the two reactions are taking place simultaneously in the same medium. Such a mechanism may be briefly postulated by the following equations

$$R—CH_2OH \xrightarrow{O} R—CHO + H_2O \qquad (1)$$



$$R—CHO \begin{cases} + R—CH_2OH \rightleftharpoons R—CHOH(OCH_2R) \\ \qquad\qquad\qquad\qquad\qquad \updownarrow \\ + 2R—CH_2OH \rightleftharpoons R—CH(OCH_2R)_2 + H_2O \end{cases} \qquad (2)$$

$$R{-}CHOH(OCH_2R) \xrightarrow{O} R{-}CO(OCH_2R) + H_2O \qquad (3)$$

It is quite obvious that the primary addition products of aldehydes when alcohols are present in excess would be unstable alcoholates or "hemiacetals," which may be regarded as secondary alcohols and therefore should be easily oxidized to the corresponding carbonyl derivatives before they are hydrolyzed. Although this assumption is purely hypothetical, at present, its justification is supported by the fact that, in the experiments to be described later, ester formation precedes acid formation. The organic acids formed during the reaction seem to result from the slow hydrolysis of the esters under the influence of the mineral acids. Furthermore, experiments in which acetaldehyde was used with the catalytic mixture failed to show an appreciable oxidation to acetic acid. However, when mixtures of equimolecular proportions of acetaldehyde and ethyl alcohol or acetaldehyde and n-butyl alcohol were used, instead of the aldehyde alone, ethyl and n-butyl acetates were formed, respectively.

In addition to hemiacetals, acetals might be formed as intermediate products of the oxidation of alcohols. Quite recently Adkins and his students[7] have carried out a series of experiments in which they found that the formation of acetals from mixtures of alcohols and aldehydes was markedly accelerated by certain salts and acids while the yields of acetals were greatly diminished with increased dilution. The latter observation of Adkins was more recently substantiated by Skrabal and Mirtl[8] who found that mineral acids act as catalysts in acetal hydrolysis which increases proportionately with increased dilution, while Skrabal, Brunner and Airoldi[9] assumed that such an hydrolysis takes place in steps hemiacetals being first formed. If this be the case, the acetals formed, during the oxidation of alcohols are immediately hydrolyzed under the influence of the mineral acids to hemiacetals which are then oxidized to the corresponding carbonyl derivatives. To confirm this view acetal, instead of ethyl alcohol, was used with the catalytic mixture. Ethyl acetate was the principal product of the oxidation.

Experimental Part

General Method.—The alcohols are oxidized very slowly, even at the boiling point of water, by a neutral aqueous mixture of sodium chlorate and vanadium pentoxide. However, in the presence of dilute sulfuric acid, the oxidation proceeds somewhat rapidly at first and slowly toward the end of the reaction. The appearance of a blue color, due to the reduction

---

[7] (a) Adkins and Nissen, THIS JOURNAL, 44, 2749 (1922); (b) Adams and Adkins, *ibid.*, 47, 1358 (1925).

[8] Skrabal and Mirtl, *Z. physik. Chem.*, 111, 108 (1924).

[9] Skrabal, Brunner and Airoldi, ibid., 111, 118 (1924).

of vanadium pentoxide to vanadium trioxide,[2] is a proof of the absence of chlorates and consequently of the end of the reaction.

After several preliminary experiments the following general method, which is applicable to alcohols higher than methyl alcohol, was adopted. Solutions of 5% sulfuric acid containing the calculated amount of sodium chlorate and 5–10% in excess necessary to oxidize half of the alcohol present completely to the corresponding acid were mixed with small amounts of vanadium pentoxide and the alcohol in question, in a suitable container provided with a reflux condenser and a dropping funnel, and the mixture was heated slowly to 75–80°. A rise of temperature above 80° at this stage of the reaction should be avoided since it causes a rapid evolution of chlorine dioxide, which forms an explosive mixture with the alcohols. During the progress of the reaction some of the sulfuric acid is used up and should be replaced by adding the calculated amount of 6 N sulfuric acid, assuming that all of the original acid is consumed after a heating of five hours. In some cases it was found necessary to make even a second addition of the acid. After the final addition, the temperature was raised to the boiling point of the mixture and kept there till the end of the reaction.

Method of Analysis.—The esters were hydrolyzed by refluxing each for two hours with an excess of about 0.5 *N* alcoholic potash solution. The excess alkali was titrated with a solution of 0.2 N hydrochloric acid, using phenolphthalein. Therefore, the results are expressed in terms of 0.2 N potassium hydroxide solution. A blank was run with each analysis to check the strength of the alkali.

The yields of organic acids were estimated by titration according to Richardson and Bowen.[10] For the sake of comparison, a blank was run with the estimation of each organic acid. The yields of both esters and organic acids, as expressed below, represent the results of several experiments performed with each alcohol.

I. Oxidation of Methyl Alcohol with Sodium Chlorate and Vanadium Pentoxide

The general method described above is not applicable to the oxidation of methyl alcohol because of the explosive violence of the reaction between the formaldehyde formed and the chlorine dioxide liberated during the reaction. Therefore, the following modification of the method was finally adopted.

Seventy-three g. of sodium chlorate (Merck's U. S. P. grade) was dissolved in 130 cc. of 2.5% sulfuric acid and the mixture was slowly dropped by means of a dropping funnel at the rate of about 1 cc. per minute into a flask fitted with an efficient reflux condenser and containing 64 g. of methyl alcohol (Merck's "C. P." grade, free from acetone), 50 cc. of water and 0.3 g. of vanadium pentoxide.[11] The mixture was heated to 75–80°. At first the solution becomes orange-yellow and changes to blue at the end of the reaction. After ten hours of heating, 36 cc. of *6* N sulfuric acid was slowly dropped into the mixture and heating continued until the blue color appeared. This took thirty-six hours longer. During the progress of the reaction a large quantity of carbon dioxide was evolved. At the end of the reaction the mixture was found to contain traces of

---

[10] Richardson and Bowen, J. *Soc.* Chem. *Ind.,* 25,836 (1906).

[11] For the preparation of this catalyst, see Milas, ref. **2,** p. 2007.

chloroform, as shown by the carbylamine test,[12] methyl formate, formic acid and small quantities of a condensation product the identity of which was not determined.

Isolation of Methyl Formate.—The reaction mixture from the above experiment was subjected to fractional distillation. The fraction boiling between 30 and 60° was collected, dried over anhydrous sodium carbonate and refractionated, the fraction distilling between 34 and 38° being collected and analyzed; yield, 5–6 g., or 8–10% of the alcohol taken.

Anal. Subs., 0.8372: required 68.8 cc. of 0.2 N KOH. Calcd. for $C_2H_4O_2$: 69.7 cc.

The aqueous solution was distilled once to free it from sulfuric acid and the blue color of vanadous oxide, which interferes with the end-point of the titration. The distillate was made up to a definite volume and lots of 50 cc. were titrated against 0.2 N sodium hydroxide (methyl orange, phenolphthalein). These indicated a yield of 8–9 g. of formic acid. No attempt was made to recover the unoxidized alcohol.

II. Oxidation of Ethyl Alcohol, Acetal and a Mixture of Equimolecular Proportions of Paraldehyde and Ethyl Alcohol with Sodium Chlorate and Vanadium Pentoxide

(*a*) Oxidation of Ethyl Alcohol.—Ninety-two g. of ethyl alcohol (abs.), 74 g. of sodium chlorate, 0.5 g. of the catalyst and 92 cc. of a 5% solution of sulfuric acid were brought together in a 500cc. Erlenmeyer flask provided with a reflux condenser and a dropping funnel. The mixture was heated very slowly to 75–80° and, after five hours of heating, 19 cc. of 6 N sulfuric acid was added very slowly and the temperature raised to the b. p. of the mixture. The blue color appeared after ten to twelve hours of heating. The mixture had separated into two layers, the upper of which was mostly ethyl acetate and some unconverted alcohol, while the lower contained alcohol, small quantities of acetaldehyde (forms a silver mirror in the cold with Tollens' reagent) and acetic acid. The entire mixture was subjected to fractional distillation; the fraction boiling between 70 and 90° was collected, dried over sodium carbonate, refractionated and the fraction distilling between 74 and 80° collected (74 g.) and analyzed by hydrolysis. This fraction proved to be 70–73% ethyl acetate, which is 60–61% of the total alcohol taken.

The entire aqueous solution, mixed with the fractions boiling above 80°, was distilled and the distillate made up to a definite volume. Samples of 50 cc. of this were titrated, indicating a total yield of 13.5–15.9 g. of acetic acid.

(b) Oxidation of Acetal.—One hundred g. of acetal (Kahlbaum's) was mixed with 62 g. of sodium chlorate, 0.3 g. of the catalyst and 100 cc. of 5% sulfuric acid and the mixture heated very slowly under a reflux condenser to 75–80°, this temperature being maintained till the end of the reaction, which took nine hours. The experiment yielded 45 g. of ethyl acetate, 36 g. of acetic acid and some alcohol which had presumably resulted from the hydrolysis of the ester.

(c) Oxidation of an Equimolecular Mixture of Paraldehyde and Ethyl Alcohol.—When acetaldehyde alone was treated with the oxidizing mixture in presence of 5% sulfuric acid, paraldehyde was chiefly formed, and when this mixture was further heated at 75–80° for thirty-four hours, no additional change was noticed. This mixture yielded only traces of acetic acid, as shown by the ferric chloride test.[13] However, when the aldehyde was mixed with equimolecular proportions of alcohol, oxidation occurred immediately, with ethyl acetate resulting as the main product of the reaction.

Fifty g. (1.14 moles) of paraldehyde (Kahlbaum's) was mixed with 52.3 g. (1.14 moles) of absolute alcohol, 50 g. of sodium chlorate, 0.3 g. of the catalyst and 100 cc. of

---

[12] Hofmann, *Ann.*, 146, 107 (1868).

[13] Weston, "A Scheme for the Detection of the More Common Classes of Organic Compounds," Longmans, Green and Co., 1912, p. 27.

5% sulfuric acid and the mixture was heated very slowly, under a well-cooled reflux condenser, to 30°. In the beginning the temperature of the reaction mixture should not be allowed to rise above 40°, otherwise the reaction will become too violent and uncontrollable. After five hours the reaction has somewhat moderated and the temperature may now be raised to 75–80", and 19 cc. of 6 N sulfuric acid slowly added to the mixture and the heating continued for six additional hours before the blue color appears. The experiment yielded 54 g. of ethyl acetate and 21.3 g. of acetic acid. Small quantities of unconverted alcohol and aldehyde were also recovered.

During the above reactions the active form of the aldehyde is presumably the monomolecular, which is regenerated under the influence of sulfuric acid. This is well shown by the work of McLeod[14] on the polymers of acetaldehyde.

These results, while not absolutely conclusive, indicate the plausibility of the view presented in the early part of this paper.

III. Oxidation of n-Propyl Alcohol with Sodium Chlorate and Vanadium Pentoxide

Ninety g. of n-propyl alcohol (Kahlbaum's) was mixed with 58 g. of sodium chlorate, 0.5 g. of the catalyst and 90 cc. of 5% sulfuric acid and the mixture slowly heated to 75–80° until the violent reaction moderated; then the temperature was raised to boiling. After five hours of heating, the first portion of 18 cc. of 6 *N* sulfuric acid was added, the heating continued for ten hours longer when a second portion of 22 cc. of the acid was slowly added, and the heating again continued until the blue color appeared. Twenty to twenty-two hours were required for the completion of the reaction. The mixture was then cooled and the ester layer separated from the aqueous layer. The former consisted chiefly of propyl propionate, propyl alcohol, propionic acid, small quantities of propionaldehyde and a chlorinated ester. It was shaken several times with a 4% solution of sodium hydroxide to remove the acid and most of the alcohol, washed twice with water, dried over anhydrous sodium carbonate and fractionated. The fraction distilling between 121 and 124° (4245 g.) consisted of pure propyl propionate free from any chlorinated products. The ester yield was 48–51% of the total alcohol taken.

Anal. Subs., 1.2983: required 56.25 cc. of 0.2 N KOH. Calcd. for $C_6H_{12}O_2$: 55.96 cc.

A small quantity of the chlorinated ester boiling between 140 and 150° with decomposition was isolated but not analyzed.

The washings from the ester layer were mixed with the aqueous layer, treated with dilute sulfuric acid in excess and distilled. The distillate was made up to a liter, and a portion of it was exactly neutralized and evaporated to dryness on the water-bath. The dry salt, treated with absolute alcohol and a few drops of concd. sulfuric acid, gave a decided odor of ethyl propionate. Fifty-cc. samples of the distillate were then titrated and the total yield of propionic acid estimated. These indicated a total yield of 22–24 g. of propionic acid.

IV. Oxidation of n-Butyl Alcohol with Sodium Chlorate and Vanadium Pentoxide[15]

Eighty-nine g. of n-butyl alcohol (b. p. 116.5–118°) was mixed with 48 g. of sodium chlorate, 0.5 g. of the catalyst and 90 cc. of 5% sulfuric acid and the mixture heated

---

[14] McLeod, Am. Chem. Jour., 37, 27 (1907).

[15] I am indebted to William L. Ruigh of this Laboratory for the preliminary experiments on this alcohol.

slowly, under a reflux condenser, to 75–80° for two hours, then to the b. p. for three hours longer, when **18** cc. of **6** N sulfuric acid was slowly added and the heating continued for five hours longer. A second portion of **22** cc. of the acid was then added and the heating continued till the blue color appeared. Fifteen to eighteen hours were required for the completion of the reaction. The mixture was then cooled and the layers separated. The ester layer was washed several times with a **4%** solution of sodium hydroxide, twice with water, dried over sodium carbonate and fractionated. After two fractionations the fraction distilling between **164** and 166° **(4143** g.) was collected and analyzed; yield, 47–49% of the total alcohol taken.

Anal. Subs., **1.0892:** required **38.22** cc. of **0.2** N **KOH.** Calcd. for $C_8H_{16}O_2$: **37.85** cc.

Besides the ester, small quantities of chlorinated products boiling with decomposition from 10–15° higher than the ester were isolated but not analyzed. From **20–25** g. of unoxidized alcohol was recovered. Small quantities of butylaldehyde were also isolated.

The washings from the ester layer were combined with the aqueous layer, treated with sulfuric acid and distilled, and the distillate was made up to a liter. A portion of this was exactly neutralized, and evaporated to dryness. The salt, treated with calcium chloride in the hot, formed a white precipitate which persisted only in cloudy form when the mixture was cooled. The odor of the free acid was characteristic of that of butyric acid. Fifty-cc. samples of the distillate were then titrated and indicated a yield of 5–6.5 g. of n-butyric acid.

V. Oxidation of *iso*Butyl Alcohol with Sodium Chlorate and Vanadium Pentoxide

Eighty-nine g. of isobutyl alcohol (Kahlbaum's) was mixed with **48** g. of sodium chlorate, **0.5** g. of the catalyst and **90** cc. of 5% sulfuric acid. The mixture was treated in exactly the same manner as in the case of normal butyl alcohol except that the number of hours to complete the reaction was only 15–16. The ester layer was also treated similarly, fractionated twice, and the fraction distilling between **147** and 150° (40–42 g.) collected and analyzed; yield, **46–48%** of the alcohol taken.

Anal. Subs., **1.0282:** required **36.15** cc. of **0.2** N **KOH.** Calcd. for $C_8H_{16}O_2$: **35.71** cc.

During the above oxidation large quantities of carbon dioxide were evolved, and some of the alcohol was oxidized to acetone, considerable quantities of which were detected by the iodoform reaction. Isobutylaldehyde and small quantities of chlorinated products were also isolated.

Isobutyric acid was identified by preparing its sodium salt, which was found to decolorize instantly dilute potassium permanganate. Acetone was identified as one of the oxidation products. Neither the salt nor the free acid formed a precipitate with calcium chloride either in the hot or in the cold. The total yield of isobutyric acid, as determined by titration, was 4–5 g.

VI. Oxidation of *iso*-Amyl Alcohol with Sodium Chlorate and Vanadium Pentoxide

Seventy-five g. of iso-amyl alcohol (Kahlbaum's pyridine free) was mixed with **40** g. of sodium chlorate, 0.5 g. of the catalyst and 150 cc. of a **5%** solution of sulfuric acid and the mixture heated slowly to 75–80° for one hour; then the temperature was raised to boiling. After four hours **36** cc. of **6** N sulfuric acid was added and the heating continued for eight hours longer before the blue color appeared. The ester layer was shaken several times with a 4% solution of sodium hydroxide, washed twice with water, dried over sodium carbonate and fractionated. After three fractionations the fraction distilling between 190 and 195" (33–35 g.) was collected and analyzed; yield of iso-amyl *iso*-valerate, 45–48% of the alcohol taken.

Anal. Subs., 2.0247: required 59.40 cc. of 0.2 *N* KOH. Calcd. for $C_{10}H_{20}O_2$: 58.85 cc.

Besides iso-amyl isovalerate, isovaleric aldehyde, some unoxidized alcohol, small quantities of chlorinated products, acetone and carbon dioxide were identified.

When the washings from the ester layer were mixed with the aqueous layer and the mixture was treated with sulfuric acid, a layer of isovaleric acid separated out. The mixture was extracted with 300 cc. of ether and the ether extract dried over anhydrous sodium sulfate and subjected to fractionation. Most of the high-boiling liquid distilled between 175 and 177°. This was almost pure isovaleric acid; yield, 12–13 g. The acid had a very rancid odor and gave a gelatinous precipitate with a solution of zinc sulfate.

Summary

1. Vanadium pentoxide, in dilute sulfuric acid solution, induces the oxidation of methyl, ethyl, *n*-propyl, n-butyl, isobutyl and iso-amyl alcohols, acetal and mixtures of equimolecular proportions of paraldehyde and ethyl alcohol and paraldehyde and n-butyl alcohol with chlorates to give esters as the principal products.
2. Organic acids, small quantities of aldehydes and chlorinated products, acetone and carbon dioxide were isolated as by-products in the oxidation of some of the alcohols.
3. A tentative mechanism of the oxidation is presented.

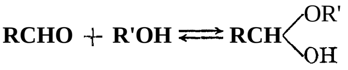
HEMIACETAL FORMATION AND THE REFRACTIVE INDICES AND DENSITIES OF MIXTURES OF CERTAIN ALCOHOLS AND ALDEHYDES

BY HOMER ADKINS AND A. E. BRODERICK

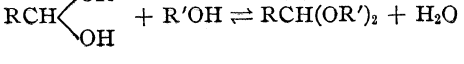
RECEIVED OCTOBER 10, 1927 PUBLISHED FEBRUARY 4, 1928

Heat is evolved when certain alcohols and aldehydes are mixed with each other. The addition of a catalyst such as hydrogen chloride or calcium chloride to the solution results in acetal formation. Presumably the pure alcohol and aldehyde react by addition according to the equation



$$RCHO + R'OH \rightleftharpoons RCH\begin{cases}OR' \\ OH\end{cases}$$

The hemiacetal in the presence of a catalyst may then react with alcohol to form an acetal and water



$$RCH\begin{cases}OR' \\ OH\end{cases} + R'OH \rightleftharpoons RCH(OR')_2 + H_2O$$

Our investigations of the reactivities of alcohols and aldehydes in acetal formation have led us to seek more precise evidence as to the justifiability of this hypothesis. We have therefore measured the refractive indices and the densities of mixtures of certain alcohols and aldehydes. A summary of the results is presented in the table.

TABLE I

REFRACTIVE INDICES OF MIXTURES OF VARIOUS ALCOHOLS AND ALDEHYDES[a]

Acetaldehyde and ethanol		Acetaldehyde and isopropanol		Heptaldehyde and *iso*propanol		Heptaldehyde and ethanol

[a] The readings of refractive indices are believed to be reproducible to within less than 0.0001. The concentration of the aldehyde was accurate to within less than 1% for all mixtures except those having a high content of acetaldehyde, for which an accuracy of less than 2% is claimed.

The percentages given in the table represent the per cent. by weight of aldehyde contained in the aldehyde-alcohol mixture. All measurements were made at 25° except for those mixtures containing acetaldehyde, which were made at 8°. The densities $(d^{25°}_4)$ for the benzaldehyde-ethanol mixtures are also given in the table. The results of a few significant determinations on mixtures other than the seven noted in the table are as follows.

74.4% Anisaldehyde, 25.6% ethanol: d_4^{25}, 1.0135; n_D^{25}, 1.50432.
60.7% Butyraldehyde, 39.3% ethanol: d_4^{25}, 0.8442; n_D^{25}, 1.39134.
100% Anisaldehyde: d_4^{25}, 1.1192; n_D^{25}, 1.57031.
50% Acetaldehyde, 50% *tert.*-butyl alcohol: n_D^8, 1.37470.
100% *tert.*-butyl alcohol: n_D^8, 1.38684.

The refractive indices were determined by means of a Pulfrich refractometer. The densities were determined by the use of a pycnometer. The alcohols and the acetaldehyde were purified as described elsewhere;[1] ethanol, b. p. 77.8–78.0°; *iso*propyl alcohol, b. p. 82.1–82.5°; *tert.*-butyl alcohol, b. p. 82.5–82.7°, m. p. 25°. The bisulfite derivative of butyraldehyde was made from the liquid products of the air oxidation of butanol over copper. The aldehyde was liberated from the bisulfite compound by sodium carbonate and steam distilled. The aqueous mixture was repeatedly dried over calcium chloride and then fractionated. The portion boiling between 73 and 74° was collected and used within two or three days. All samples of butyraldehyde recovered from the commercial product or allowed to stand for a time in the laboratory boiled 6 or 7° too high. The benzaldehyde was fractionated and had a boiling point of 168.4" and $d_4^{20°}$, 1.04885. The heptaldehyde was fractionated from the product of the Eastman Kodak Company; b. p. 175.0–175.5°. The anisaldehyde was similarly obtained and distilled at 130–131° at 15 mm. No cinnamic aldehyde could be obtained sufficiently colorless so that it could be used in this work, although the compound is usually so described.

The refractive indices of mixtures of ethanol and acetaldehyde, ethanol and heptaldehyde and isopropanol and acetaldehyde have been plotted in Fig. 1. The curved lines pass through the experimentally determined points, while the straight lines represent what would be the refractive indices if the alcohol and aldehyde did not react. It is obvious that reaction has taken place between the alcohols and aldehydes. The curve for heptaldehyde and isopropanol is similar to that for *iso*propanol and acetaldehyde, although the divergence of the curve from the straight line is not so great. The single mixture of butyraldehyde and ethanol whose constants were measured shows a divergence similar to that of acetaldehyde and ethanol.

The refractive indices of mixtures of benzaldehyde and ethanol, anisaldehyde and ethanol and of tertiary butanol and butyraldehyde are quite different from what they would be if the alcohol and aldehyde did not react with each other. However, in the case of these pairs the experimental curve is below the straight line rather than above it, as is the case with the data shown in Fig. 1.

The refractive index is, of course, a function of the density of the liquid as well as of the constitution of the compound or compounds which com-

---

[1] Adkins and Broderick, This Journal, 50, 178 (1928).

pose the liquid. The densities of all of the benzaldehyde-ethanol mixtures, of a single mixture of butyraldehyde-ethanol and of an anisaldehyde-ethanol mixture have been determined. These data have a relationship to the densities of the corresponding alcohols and aldehydes similar to that found to exist between the index of refraction of the mixtures and of the corresponding alcohol and aldehyde. However, the change in refractive index is not due solely to the change in density. This is evidenced by the fact that if one calculates the refractive index of a mixture of 74.4% anisaldehyde and 25.6% ethanol upon the assumption that these compounds are present as such, but that the mixture has the observed density of 1.0333, the value 1.51605 is obtained. The experimental value for this mixture is 1.50432, indicating that a constitutional change has taken place. However, in the case of butyraldehyde and ethanol, the change in refractive index parallels the density change. The molecular refraction based upon the observed indices of refraction of an equimolecular mixture of the alcohol and aldehyde was 33.24. The value calculated upon the assumption that the alcohol and aldehyde are present but have the observed density (0.8044) is 33.22. The calculated value for the molecular refraction of the hemiacetal is 32.02, the value 2.501 being taken for each carbon, 1.051 for each hydrogen, 1.521 for the hydroxyl oxygen and 1.603 for the ether oxygen.

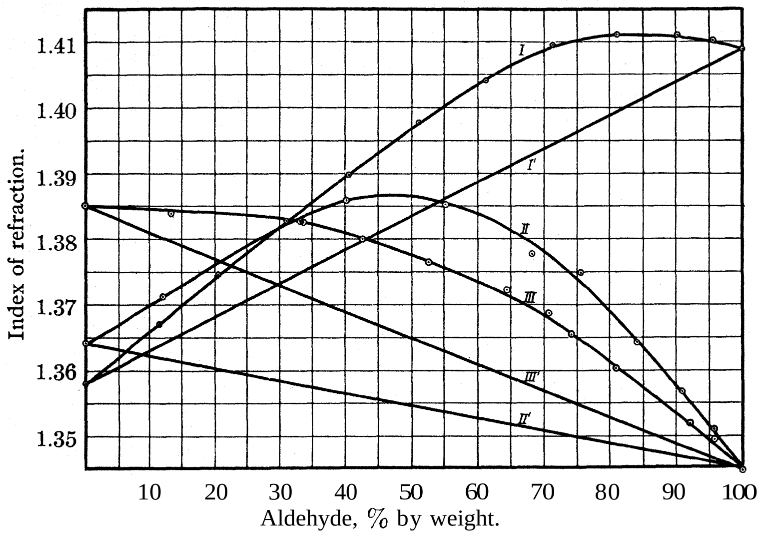

Fig. 1.—Refractive indices of mixtures of certain aldehydes and alcohols. The per cent. by weight of aldehyde in the mixture is plotted (abscissa) against the refractive index of the mixtures (ordinate). Curve I is for heptaldehyde and ethanol at 25°; Curve II, acetaldehyde and ethanol at 8°; Curve III, acetaldehyde and isopropanol at 8°. The straight lines show refractive indices of ideal solutions.

Success in detecting reaction between an alcohol and an aldehyde through determinations of the refractive indices of mixtures of the two is dependent upon whether or not the refractive index of the reaction product differs considerably from that of the ideal mixture. A small or even a total lack of difference of the constants from those of ideal mixtures does not prove that no reaction has taken place. It must also be kept in mind that two distinct questions may be asked with regard to the reaction under consideration. First, do certain aldehydes react with certain alcohols, and, second, how far to the right is the equilibrium point in those cases where reaction occurs? The first question is answered in the affirmative by the data for all nine of the pairs of compounds investigated. An answer to the second question can only be attempted in those cases where the observed values lie on a line having a pronounced curvature. This is true for only two or perhaps three of the seven complete sets of data, that is, for acetaldehyde-ethanol and heptaldehyde-ethanol and perhaps for acetaldehyde-isopropanol.

It should be emphasized that in a consideration of the experimental data from this point of view, the significant thing is not the point at which the refractive index is at a maximum but is the point at which there is the maximum *deviation* of the curve from the straight line representing the refractive indices of ideal solutions. For example the maximum deviation for heptaldehyde-*iso*propyl alcohol is for concentrations of between 60 and 70% heptaldehyde. These compounds are in molecular proportions when there is 65% heptaldehyde present. The maximum deviation for acetaldehyde-ethanol is for concentrations between 50 and 55% acetaldehyde. The equimolecular mixture contains 49% of acetaldehyde. The maximum deviation for acetaldehyde-isopropyl alcohol is almost constant over a wide range of concentrations from 35 to 60% aldehyde. The equimolecular mixture contains 42% of acetaldehyde. Thus it is seen that in the case of these three mixtures the maximum deviation of refractive indices from those of ideal solutions comes at approximately the concentration of reactants necessary for the formation of a hemiacetal, thus indicating that the equilibrium point of the reaction for these compounds is quite far to the hemiacetal side of the equation.

Summary

The refractive indices and densities of mixtures of several pairs of alcohols and aldehydes have been determined over the range from pure alcohol to pure aldehyde. All the data obtained indicate that chemical reactions took place and that, at least in some cases, one mole of alcohol and one mole of aldehyde reacted almost quantitatively to form what is presumably a hemiacetal.

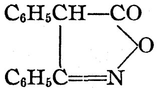
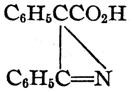
DIPHENYL ISOXAZOLONE
A STUDY OF THE TAUTOMERISM OF ISOXAZOLONES

BY E. P. KOHLER AND A. H. BLATT

RECEIVED OCTOBER 13, 1927 PUBLISHED FEBRUARY 4, 1928

Diphenyl isoxazolone was first described by Beckmann and Paul,[1] who in 1891 obtained it incidentally while studying the action of sodium on desoxybenzoin. Realizing that the substance must be an anhydride of the oxime of phenyl benzoyl acetic acid, they considered the two formulas

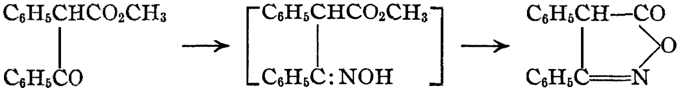




When they found that it could be titrated with a standard base of which it neutralized exactly one equivalent, they decided in favor of the second formula and named it "anhydro oximido benzoyl acetic acid."

Six years later Walther and Schickler[2] came across the substance again while examining the action of hydroxylamine on the amide of phenyl benzoyl acetic acid. They were unaware of the earlier work, made a faulty analysis of their product and, impressed by its acidity, formulated it as the oxime of phenyl benzoyl acetic acid.

Quite recently the same substance turned up again, this time as a product of the oxidation of 3,4-diphenyl-5-hydroxy-5-benzoyl isoxazoline with sodium peroxide.[3] It was then made synthetically by the most general reaction available for the preparation of isoxazolones:



The isoxazolone was described as a substance capable of existing in two modifications—the ordinary form first mentioned by Beckmann and Paul, and an unstable, lower-melting, more acidic form which immediately yielded a copper derivative when its ethereal solution was shaken with aqueous copper acetate. This conclusion led to the present investigation. If correct, it would mean that diphenyl isoxazolone is the only isoxazolone derivative—perhaps the only heterocyclic compound—of which desmotropic modifications can be isolated, and it would also mean that diphenyl isoxazolone would be the best material for the study of the structure of solid isoxazolones, and of their tautomerism in solution.

This conclusion now appears to us to be doubtful because we have been unable to prepare a sample of isoxazolone that does not immediately yield

---

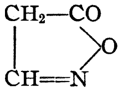
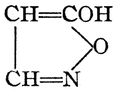
[3] Kohler, THIS JOURNAL, 46, 1741 (1924).

a copper derivative. The analytical sample (0.5 g.) left from the earlier work gave an ethereal solution which, when shaken with aqueous copper acetate, at first produced only a faint opalescence. Then, very gradually, apparently as a consequence of rearrangement, it deposited the deep blue copper derivative, complete deposition requiring several hours. Numerous attempts to prepare another sample showing this behavior were all unsuccessful; we are therefore unable to exclude the possibility that lower-melting preparations contain a small quantity of an impurity which does not materially change the composition.

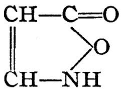
Rut even though we failed to isolate desmotropic modifications we nevertheless secured reliable evidence on the structure of the isoxazolone, both as solid and in solutions. The various methods by which alkyl and aryl isoxazolones have been prepared leave no doubt as to the nature of the carbon chain or the position of the hydrocarbon residues; the only uncertainty is the location of one hydrogen atom. This is created by the fact that various isoxazolone derivatives correspond to three tautomeric forms of the parent substance



I



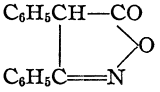
II



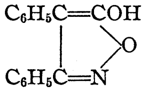
III

Most authors represent alkyl and aryl isoxazolones as derivatives of form I—largely, doubtless, because this form is most closely related to the substances from which these isoxazolones are usually obtained. Uhlenhuth,[4] who made the most extensive investigation of mono- and di-alkyl isoxazolones, adopted Formula III because he found that phenyl isoxazolone, when methylated by way of the silver salt, gave an N-methyl derivative—evidence that would not now be regarded as weighty. Formula III was also preferred by Moureu and Lazennec[5] because in their opinion it agrees best with all methods of preparation.

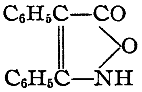
The corresponding formulas for the possible modifications of diphenyl isoxazolone are



IV



V



VI

In order to get a basis on which to distinguish between these formulas we have titrated solutions of the substance with bromine by the Kurt Meyer method, examined the behavior of the substance itself as well as that of its acyl and alkyl derivatives towards ozone, and determined both the

[4] **Uhlenhuth, Ann., 296, 36** (1897).

[5] Moureu **and** Lazennec, *Bull. soc. chim.*, [4] **1**, 1092 (1907).

quantity of gas evolved and the amount of reagent consumed when the substance reacts with methyl magnesium iodide.

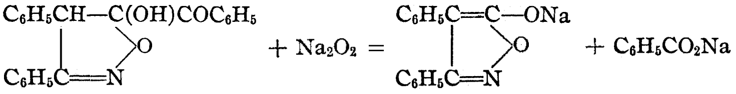
The bromine titrations show quite conclusively that solutions of diphenyl isoxazolone contain at least two forms. Unless prepared in a special manner, alcoholic solutions give bromine values which indicate 90% of "enolic" modifications. Since these solutions are strongly acidic, give color reaction with ferric chloride and copper derivatives with copper salts, this "enolic" modification must be the hydroxy isoxazol represented by V. In addition to this hydroxylic form the solution must contain 10% of one or both of the other modifications. In order to distinguish between these forms we subjected solutions of the isoxazolone to the action of ozone.

The forms represented by IV and V would not be expected to yield ozonides and neither of these forms would be likely to give definite products when oxidized with concentrated ozone, because the former contains no ethylenic linkage and the second is essentially aromatic. The modification represented by VI, on the other hand, would be expected to form an ozonide like every other phenylated ethylene derivative. Experiments showed that the isoxazolone is very slowly attacked by 6% ozone but neither forms an ozonide nor yields any of the normal decomposition products of ozonides. It can safely be concluded, therefore, that solutions of diphenyl isoxazolone contain a mixture of the "ketonic" modification IV and the "enolic" modification V; there is no evidence of the presence of form VI.

The bromine titrations also supply conclusive evidence that the solid isoxazolone is not the enolic modification. When these titrations were made as speedily as possible, with the purest materials that could be prepared, in apparatus that had been carefully steamed, they always gave values far below the usual 90% and in one case even below 50% of enol. The freshest solutions therefore contain the least enol, and since there is no evidence whatsoever of the presence of the imino form, even in the most concentrated solutions, it seems necessary to conclude that the solid substance is the "ketonic" modification V. The "keto-enol" system differs from most others only with respect to the rapidity with which it attains equilibrium.

II. Preparation

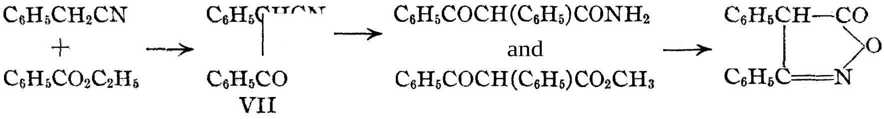
Of the various methods of formation enumerated in the introduction, two merit consideration as methods of preparation: the oxidation of hydroxy benzoyl diphenyl isoxazoline and the action of hydroxylamine on phenyl benzoyl acetic ester. The first is represented by the equation



This method gives an excellent yield but the hydroxy isoxazoline can be obtained only by a long series of reactions[6] starting with phenyl nitro methane. The preparation of this is in itself an arduous task. Our procedure for the oxidation was as follows.

To a solution of 70 g. of sodium peroxide in 810 g. of ice and 700 cc. of water is added, gradually, 35 g. of the hydroxy isoxazoline. This mixture is stirred for eight hours, then left overnight. The next day the sodium salt is collected on a filter and washed with dilute sodium carbonate, filtrate and washings being discarded. The sodium salt is dissolved in 600–800 cc. of water, the solution filtered, the clear filtrate acidified and left to itself until the precipitation is complete. The precipitate is thoroughly washed with water, dried and boiled with ether. This removes benzoic acid and small quantities of other impurities and leaves a crude product that melts at 150–155°; yield, 90%.

The successive steps in the second method of preparation are as follows:



Here the principal difficulty lies in the first step. By a modification of the procedure of Bodroux it was found possible to effect this condensation on a large scale and since, contrary to the observations of Walther and Schickler, the isoxazolone can be made from the amide as well as from the ester, this method of preparation proved to be the more convenient.

Phenyl Benzoyl Aceto Nitrile (VII).—After preliminary trials with the various agents that have been used for condensing ethyl benzoate with benzyl cyanide[7] we decided in favor of Bodroux's method but, possibly owing to the quality of our sodamide, our yield was only 35%. By changing the procedure and also the proportions of reactants this was increased to 60% which is still much lower than the 85% reported by Bodroux. Our procedure was as follows.

In a one-liter flask fitted with a dropping funnel, reflux condenser and motor stirrer, 40 g. of finely powdered sodamide is placed under 500 cc. of absolute ether. To this is added in the course of half an hour, during which the mixture is stirred constantly, 60 g. of benzyl cyanide. The mixture, which during the addition acquires a dark red color, is boiled for half an hour, then cooled in an ice-bath while 75 g. of ethyl benzoate is added. This requires about half an hour and is accompanied by the separation of a yellow solid. The mixture is then kept at room temperature for several hours.

The products from two or three such operations are combined and slowly poured into cold 50% alcohol. The resulting solution is diluted with water until it separates into two layers. The aqueous layer is thoroughly extracted with ether, then acidified with a mixture of ice and concentrated hydrochloric acid. This precipitates the nitrile as an oil which slowly solidifies. After washing with chilled methyl alcohol and drying,

---

[7] (a) Walther and Schickler, ref. 2, p. 308; (b) Ghosh, *J. Chem. Soc.*, 109, 116 (1916); (c) Bodroux, *Bull. soc. chim.*, [4] 9,651 (1911); (d) *ibid.*, p. 726. After we had prepared our material, Wislicenus, Eichert and Marquart, *Ann.*, 436, 92 (1925), described a preparation in which they used metallic potassium as a condensing agent. This gave a yield of 80%.

the yield of crude solid is 120–130 g. from 120 g. of benzyl cyanide, or 55–60%. The crude nitrile—m. p. 90–92°—is readily purified by crystallization from dry methyl alcohol, but this is unnecessary if it is to be used for making the isoxazolone.

For the purpose of converting the nitrile into diphenyl isoxazolone it was first esterified with methyl alcohol and hydrochloric acid, essentially as described in earlier papers. The result was a mixture of ester and amide in proportions that depended on the conditions. Each of these was turned into the isoxazolone. To this end a methyl alcoholic solution of the substance and 20% excess of hydroxylamine hydrochloride was boiled—for two hours in the case of the ester, four hours in the case of the amide. Most of the isoxazolone crystallized on cooling; the balance was precipitated by diluting the solution with water. Both ester and amide gave practically quantitative yields of a crude washed and dried product which melted and decomposed at 150°. For most purposes this was simply boiled with dry ether which removed small quantities of impurities and thereby raised the melting point to 155–157°. The purest product was obtained by careful recrystallization from benzene. This melted and decomposed sharply at 159°.

3,4-Diphenyl isoxazolone is readily soluble in methyl and ethyl alcohols, sparingly soluble in chloroform, carbon tetrachloride and benzene, almost insoluble in ether. Its resistance to hydrolytic agents is impressive; neither prolonged boiling with saturated methyl alcoholic potassium hydroxide nor protracted heating to 110–115° with concentrated hydrochloric acid produced any effect at all, and more than 85% of it was recovered after long boiling with a 60% solution of sulfuric acid in methyl alcohol. It likewise resists the action of hydroxylamine and phenyl hydrazine and a sample which had been boiled for five hours with zinc dust and glacial acetic acid was recovered almost quantitatively by diluting the solution with water.

III. Salt Formation

Inasmuch as diphenyl isoxazolone is strongly acidic, there is no difficulty in preparing its salts. Beckmann and Paul[8] analyzed the silver salt and found that its composition corresponds to that of a metallic derivative. Walther and Schickler,[9] unaware of the earlier work, repeated the analysis and reported values corresponding to a salt of the open chained oximido acid. Since then so many salts of other disubstituted isoxazolones have been found to be metallic derivatives that there now can be scarcely any question that the salts of these isoxazolones are formed by replacement of hydrogen by a metal. We analyzed a sample of the silver salt which had been dried at 120° and confirmed the values obtained by Beckmann and Paul, but we also found that the salt tenaciously retains considerable amounts of water. Thus a salt which had been dried to constant weight in a vacuum desiccator gave low values for silver and lost water when heated to 120°. The loss, however, was less than half of that required for a salt of the open chained acid.

In addition to the silver and sodium salts we found the copper acetate and magnesium bromide salts useful, the former as a means of detection and identification and the latter for operations in ethereal solution. For our purpose the sodium salt was made by dissolving 5 g. of the isoxazolone

[8] Ref. 1, p. 20.

[9] Ref. 2, p. 316.

in 50 cc. of saturated sodium carbonate diluted with an equal volume of water. This solution when chilled deposited a hydrated form that melted at 50° and resolidified at 120°. The thoroughly dried salt is very hygroscopic.

The Copper Salt, $C_{15}H_{10}ONOCuOCOCH_3$.—The mixed copper salt was made by shaking an ethereal solution of the isoxazolone with aqueous copper acetate and also by adding the acetate to an aqueous solution of the sodium salt The products are identical. The salt separates as a deep blue or purple crystalline precipitate, As it is insoluble alike in water and in organic solvents it serves well as a means of detecting small quantities of the isoxazolone. For the purpose of analysis it was washed with water and acetone and dried to constant weight.

Anal. Calcd. for $C_{17}H_{13}O_4NCu$: Cu, 17.75. Found: 17.47.

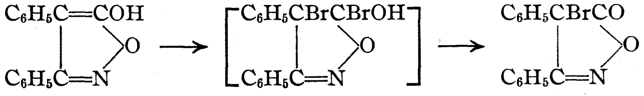
The analysis indicates a mixed salt and the presence of the acetic acid residue was confirmed by warming the salt with alcohol and concentrated sulfuric acid.

The Magnesium Bromide Salt.—An ethereal solution of this mixed salt was made by adding the isoxazolone to an excess of ethyl magnesium bromide and warming the mixture until the evolution of gas ceased. Owing to the insolubility of the isoxazolone in ether the reaction is slow but a quantitative experiment with methyl magnesium iodide in *iso*-amyl ether showed that even after prolonged heating only one molecule of reagent had been consumed and that one molecule of methane was liberated. The ethereal solutions are generally yellow and sometimes they develop a brown color but direct experiment showed that the isoxazolone is recovered quantitatively when the solutions are acidified. The color is doubtless due to a small quantity of iron compounds in the reagent; it disappears on addition of water. No attempt was made to isolate the mixed salt; it was used only in ethereal solution immediately after it had been prepared.

IV. Halogenation and Oxidation

Halogenation and oxidation are grouped together here because diphenyl isoxazolone is so easily oxidized that, unless special precautions are taken, operations intended to give halogen compounds give, instead, large quantities of the oxidation product. For this reason it is best to prepare the chlorine compound by the action of phosphorus pentachloride. The bromine compound can be made by adding bromine to solutions of the ketone but both the bromine and the solvent must be thoroughly dry.

Since the halogen compounds behave neither like hypo halides nor like imine halides they must be derived from the carbonyl form of the isoxazolone. Brominations which are carried out in solutions in which the substance is largely enolic doubtless start with the usual addition reaction



V VIII

4-Bromo-3,4-diphenyl Isoxazolone (VIII).—The finely powdered solid isoxazolone was suspended in dry carbon tetrachloride and treated with a slight excess of bromine which had been distilled from phosphorus pentoxide. The solid dissolved with evolution of hydrogen bromide. The solution, on evaporation under diminished pressure, left an oil that solidified when rubbed with methyl alcohol. After recrystallization from methyl alcohol the solid melted at 72°; yield, 90%. The same bromine compound was formed when dry bromine was added to a chilled ethereal solution of the magnesium derivative. It is not attacked by ozone and it is insoluble in alkalies, but prolonged heating with methyl alcoholic potassium hydroxide destroys it.

Anal. Calcd. for $C_{15}H_{10}O_2NBr$: C, 56.96; H, 3.2. Found: C, 56.66; H, 3.25.

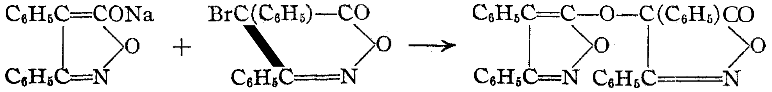
4-Chloro-3,4-diphenyl Isoxazolone.—Three g. of phosphorus pentachloride was added to 3 g. of the isoxazolone suspended in 40 cc. of chloroform. After the vigorous initial reaction had subsided, the mixture was boiled for forty-five minutes, then filtered and evaporated under diminished pressure. It left an oil which was dissolved in ether. The ethereal solution deposited the solid which after purification melted at 77–78°; yield, 50%.

Anal. Calcd. for $C_{15}H_{10}O_2NCl$: C, 66.3; H, 3.7. Found: C, 65.9; H, 3.85.

One of the conspicuous properties of diphenyl isoxazolone is the ease with which it is oxidized. The solid form is stable in the air but its solutions develop color and gradually deposit a sparingly soluble, colorless oxidation product. This is formed rapidly when solutions in suitable solvents are treated with ferric chloride, bromine that has not been carefully dried, nitrous and nitric acids. It is formed also from the sodium salt by such oxidizing agents as bromine, potassium permanganate and potassium ferricyanide. Its composition and molecular weight indicate that its formation involves the removal of two atoms of hydrogen from two molecules of the isoxazolone. In agreement with this it was found that in the oxidation with permanganate only one atom of oxygen is required to oxidize two molecules of the salt and that the product is insoluble in alkalies.

A similar dimolecular oxidation product was obtained by Volhard[10] from 3-benzyl-4-phenyl isoxazolone. From the composition of this substance and its insolubility in alkalies, Volhard concluded that it is formed from two molecules of the "ketonic modification"[1] by removing two atoms of hydrogen and adding one atom of oxygen. The resulting formula seemed to us a *priori* rather improbable. Carbon and hydrogen determinations do not with certainty establish the presence or absence of an additional oxygen atom, but the quantity of permanganate required to form the substance from the sodium salt shows conclusively that the oxygen consumption corresponds to one atom for two molecules of isoxazolone.

Since an ether formed by removing one atom of hydrogen from the carbonyl, the other from the enolic modification would likewise be insoluble in alkalies, we undertook the synthesis of such a compound. We found that the oxidation product can be obtained by the interaction of the bromo compound and the dry sodium salt in absolute ether



IX

---

[10] Volhard, *Ann.*, 296, 9 *(1897)*.

While we do not regard this evidence as conclusive, we deem it likely that the oxidation products which are so readily formed from the disubstituted isoxazolones are ethers of the type represented by IX. The process of oxidation thus appears to be quite similar to that of phenols; in alkaline solutions these likewise are readily oxidized to dimolecular products in which one half of the molecule is aromatic, the other half alicyclic.[11]

Preparation.—From the isoxazolone the oxidation product is very easily obtained with nitrous acid. Thus 15 g. of sodium nitrite was added little by little to a solution of 5 g. of the isoxazolone in acetic acid. After the addition the solution was left to itself for forty-five minutes, then made alkaline with sodium carbonate and extracted with ether. The ethereal solution gave 3.6 g. of crude product melting at 148°—a yield of 70%. By the same procedure, nitric acid which had been freed from nitrous acid gave a yield of 60%; as there were no nitro compounds the substance is evidently more easily oxidized than nitrated.

The best method of preparation is by oxidation of the sodium salt. A solution of the isoxazolone in the minimum quantity of half saturated sodium carbonate is treated with finely powdered permanganate until the color persists. The excess of permanganate and the oxides of manganese are removed with bisulfite and acid, leaving the product as a finely divided solid which is easily purified by recrystallization from a mixture of acetone and methyl alcohol; yield, 90%.

The only method of preparation that gave any clue as to the structure of the oxidation product was carried out as follows. Equivalent quantities of the thoroughly dried sodium salt and the bromine substitution product were suspended in dry ether. Reaction is slow and incomplete. The mixture was boiled for ten hours, then filtered. The solid was washed with methyl alcohol to remove unchanged bromo compound and with water to free it from bromide. The crude product melted with decomposition at 152–155° and a mixture of this and the pure substance at 154–156°.

Anal. Calcd. for $C_{30}H_{20}O_4N_2$: C, 76.2; H, 4.3. Found: C, 76.3; H, 4.4.

In boiling acetone the molecular weights found were 467 and 473 instead of 473 calculated for the dimolecular compound.

The oxidation product is sparingly soluble in ether and in methyl alcohol, readily soluble in acetone. It is insoluble in alkalies. On prolonged boiling with methyl alcoholic potassium hydroxide it is altered but does not yield isoxazolone. Towards constant boiling hydriodic acid it shows the normal behavior of an oxygen ether. Thus when 1.18 g. was boiled for two hours with the calculated quantity of acid, it gave 0.4 g. of isoxazolone and an oil that was insoluble in alkalies but readily soluble in organic solvents.

V. Titration with Bromine

The first titrations were made by the procedure which is commonly used for determining by the Kurt Meyer method the quantity of enolic modification in a keto-enol mixture. The isoxazolone was dissolved in about 50 cc. of absolute alcohol, bromine in excess was added to the solution, then β-naphthol and finally potassium iodide. After two to three minutes the liberated iodine was titrated with standard thiosulfate, using the disappearance of the iodine color as end-point, The values are shown in the following table.

---

[11] Pummerer, Putffarcken and Schopflocher, *Ber.*, 58, 1808 (1925).

TABLE I

TITRATION VALUES WITH BROMINE

	Substance, g.	Thiosulfate, (0.1026 *N*) cc.	Iodine, g. per mole	Enol, %
1	0.2303	17.20	230.5	90.8
2	.2810	20.50	225.3	88.7
3	.1634	11.82	223.3	87.9
4	.1634	12.30	232.3	91.5
5	.1634	11.80	223.3	87.8

The first two values were obtained in determinations which were parallel except that the first was made at 24°, the second with chilled reagents at −5°. The remaining three values were obtained with an alcoholic solution which had been kept in the dark for fifteen days. Of these three values the last two represent parallel determinations made after adding a drop of dilute hydrobromic acid and allowing the solutions to stand for several minutes. These values indicate that solutions of diphenyl isoxazolone contain about 90% of "enolic" modification and that they reach equilibrium with great rapidity, but before this interpretation could be accepted it was necessary to establish that the missing material could not be accounted for by oxidation or the formation of a bromine compound that is not readily reduced by hydrogen iodide.

For the purpose of determining whether an appreciable amount of oxidation occurs during the titrations we repeated the operation with a larger quantity of material and in the absence of β-naphthol which interferes with the detection of the oxidation product. To a solution of 1.084 g. of the isoxazolone was added first a slight excess of bromine, then potassium iodide in excess. After three minutes the liberated iodine was removed with the dilute thiosulfate, the solution diluted and extracted with ether. The ethereal solution was washed in succession with calcium chloride, half saturated sodium carbonate and water, and then evaporated. It left a small wet residue which was dissolved in 2–3 cc. of methyl alcohol. This solution was inoculated with oxidation product, but beyond a slight cloudiness no solid appeared. Since this procedure should detect at least 0.04 g. of the oxidation product, the titration values are not vitiated by oxidation.

In order to test the rapidity and completeness with which the bromo isoxazolone is reduced by potassium iodide in acid solution, a drop of dilute hydrobromic acid was added to a solution of 0.4471 g. of the bromo isoxazolone. Potassium iodide was then added in excess and after two minutes the liberated iodine was titrated. It required 27.10 cc. of the standard thiosulfate solution, equivalent to 98.25% of the bromo compound.

In view of the rapidity with which the equilibrium is established it seemed improbable that the nature of the solid substance could be established by the Kurt Meyer method but, since no other could be used with a substance having so high a melting point, it was tried. To this end the titrations were repeated with materials purified with great care in apparatus that had been thoroughly steamed immediately before use. The values now were:

TABLE II

Substance, g.	Thiosulfate, (0.1021 N) cc.	Iodine, g. per g. m.	Enol, %
0.1109	6.70	185.6	73.1
.1402	5.49	120.2	47.3
.1903	10.50	185.6	66.7

The variations in the values obtained in such shifting systems are, inevitably, large but the consistently low results show that the solid cannot be the enolic modification.

VI. Alkylation and Acylation

The most interesting reactions of diphenyl isoxazolone are alkylation and acylation. For the study of the former we selected methylation and benzylation. Methylation can be accomplished in a great variety of ways, all of which lead to the same methyl derivative. This was formed when methyl iodide was added to a solution of the isoxazolone in methyl alcoholic sodium methylate, when methyl iodide was allowed to react with the dry sodium salt suspended in benzene or the dry silver salt suspended in ether, by the action of dimethyl sulfate on the sodium salt in water or on the magnesium bromide salt in ether, and by boiling a pyridine solution of the isoxazolone with methyl iodide.

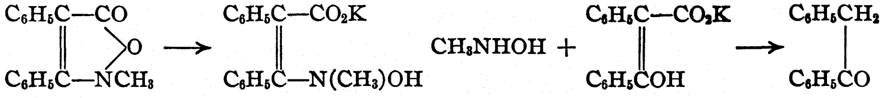
Little is known about the course of alkylation of isoxazolones. Uhlenhuth[12] made the methyl and ethyl derivatives of phenyl isoxazolone from the silver salt. By boiling the methyl compound with alcoholic potash he obtained a small quantity of a volatile base which he caught in hydrochloric acid and turned into a chloroplatinate. The analysis of the chloroplatinate gave a value for platinum from which he concluded that the base was methyl amine and, therefore, that the methylation product was an N-methyl derivative. The evidence seems inconclusive because the value for platinum lies almost exactly midway between that of an ammonium and a methyl ammonium chloroplatinate.

We degraded our methyl derivative in accordance with Uhlenhuth's procedure but obtained only traces of a volatile base—far too little for identification. The principal degradation product was desoxybenzoin but we also obtained a small quantity of benzoic acid. These substances could not arise from a C-methyl but they might be formed equally well from an O-methyl or an N-methyl derivative. A Zeisel methoxyl determination which gave a negative result eliminated the oxygen ether and ozonization finally supplied positive evidence that the substance is an N-methyl ester. The degradation with bases doubtless is represented by the

---

[12] **Uhlenhuth, ref. 4, p. 46.**

following scheme which shows that methyl amine, if formed at all, would be a secondary product.



X

N-Methyl-3,4-diphenyl Isoxazolone (X).—For preparing the ether in quantity we prefer the following method. The isoxazolone (47.4 g.) was dissolved in 120 cc. of methyl alcoholic sodium methylate containing 7 g. of sodium. To this solution was added 56.8 g. of methyl iodide. The mixture was boiled until neutral, then made strongly alkaline with sodium methylate and while still hot diluted with much water. On cooling it deposited 27 g. of the methyl derivative, and ether extracted 4 g. more. The alkaline solution contained 16 g. of unchanged isoxazolone which was recovered by acidification; yield, 91%. The ether was purified by recrystallization from ether and petroleum ether, or methyl alcohol and water. It crystallizes in needles and melts at 92°.

Anal. Calcd. for $C_{16}H_{13}O_2N$: C, 76.5; H. 5.2. Found: C, 76.4; H, 6.3.

The methyl ether was not affected by heating for twelve hours at 110–115° with concentrated hydrochloric acid, and heating with hydriodic acid in the Zeisel apparatus gave no methyl iodide. It was insoluble in aqueous alkali but when boiled with strong methyl alcoholic potassium hydroxide for two hours, 1.8 g. left an oil from which 0.5 g. of pure recrystallized desoxybenzoin and 0.1 g. of benzoic acid were extracted.

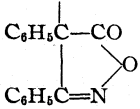
Ozonization.—Ozonized oxygen containing about 6% of ozone was passed for 3 hours through a solution of 2.6 g. of the methyl ether in 35 cc. of carbon tetrachloride. The solvent was removed under diminished pressure and the ozonide first treated with water, then warmed with dilute sodium hydroxide and finally distilled with steam in order to remove nitrogenous products. From the residue ether extracted a small quantity of unchanged substance. The alkaline layer was acidified and treated with phenyl hydrazine. It deposited the phenyl hydrazone of benwyl formic acid, which was identified by comparison with a sample on hand.

The N-benzyl Ether.—The benzyl derivative was made in the hope that it might be more suitable for studying the action of bases on the N-alkyl derivatives. This proved not to be the case. It melts at 123' and its behavior towards alkalies and ozone is exactly like that of the methyl derivative.

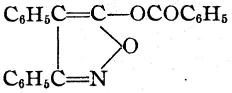
Anal. Calcd. for $C_{22}H_{17}O_2N$: C, 80.7; H, 5.2. Found: C, 80.4; H, 5.3.

Acylation was first studied with benzoyl chloride and then, since ozonization of the benzoate did not clearly exclude the possibility that the acyl group might go to carbon atom 4, it was repeated with chloro formic ester, which almost invariably forms O-acyl derivatives. Benzoylation in pyridiie, in water by the Schotten-Baumann reaction, and in ether by the action of benzoyl chloride on the magnesium bromide derivative gave the same benzoate.

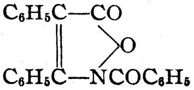
It is difficult to secure absolutely explicit evidence as to the structure of the acyl derivatives. The three possible formulas of the benzoate are



XI



XII



XIII

The third of these formulas is definitely excluded by the results of ozonization. A substance with this structure should, like the ethers, form an ozonide which on decomposition with water would give phenyl glyoxylic acid as one of the products. The benzoate does not form an ozonide. It is slowly attacked by concentrated ozone, but no treatment of the resultant oil yields even a trace of phenyl glyoxylic acid which can be detected with the very delicate color reaction of this substance.

A substance with the structure represented by XII would be expected to behave towards ozone essentially like triphenyl isoxazol which, as has been shown by Meisenheimer,[13] can be oxidized to a derivative of benzilmonoxime. Despite many attempts we were never able to isolate benzil, its monoxime or any other definite oxidation product. The experiments with ozone, therefore, do not serve to distinguish between formulas XI and XII. There remains only the behavior towards hydrolytic agents. Both acids and bases regenerate the isoxazolone much more easily than they would be expected to hydrolyze a substance like that represented by XI. Indeed, one would be inclined to predict that the primary action of strong bases on such a substance would be ring-opening, and that the final product would be triphenyl isoxazol. In the absence of more explicit evidence, however, the detailed structure of the acylation products of isoxazolones must be regarded as unknown.

The Benzoate.—The crude benzoate obtained in pyridine or by the Schotten-Baumann reaction melted at 126–127°, while that from the magnesium bromide derivative melted at 135°. It was at first suspected that the lower-melting preparation might contain isomeric benzoates, but careful fractional crystallization failed to disclose such isomerism. The benzoate crystallizes well both from ether and from alcohol in needles melting at 138–139°.

Anal. Calcd. for $C_{22}H_{15}O_3N$: C, 77.4; H, 4.4. Found: C, 77.5; H, 4.4.

The Ethyl Carbonate.—Twice the calculated quantity of chloro carbonic ester was added to 5 g. of the dry sodium salt suspended in absolute ether. The mixture was boiled for an hour, then poured into water. The ethereal layer, washed with sodium carbonate and water, dried and evaporated, gave 4.3 g. of ester—a yield of 85%.

Anal. Calcd. for $C_{18}H_{15}O_4N$: C, 69.9; H, 4.9. Found: C, 69.8; H, 4.9.

The ester crystallized well but always softened at 103° before it melted at 109–110°. The ester was rapidly hydrolyzed by bases, yielding 90% of isoxazolone after it had been heated for fifteen minutes with methyl alcoholic potassium hydroxide. Its behavior towards ozone was precisely like that of the benzoate.

Summary

The paper contains a method for preparing 3,4-diphenyl isoxazolone in quantity and an account of the experiments made for the purpose of establishing the structure of the solid form, the equilibrium in solution and the structure of the bromination, acylation and alkylation products.

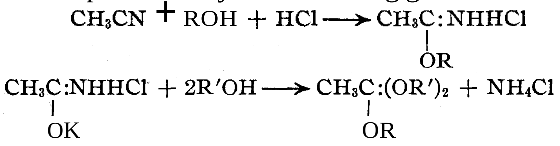
ESTERS OF ORTHO-ACETIC ACID[1]

BY PETER P. T. SAH

RECEIVED OCTOBER 15, 1927 PUBLISHED FEBRUARY 4, 1928

Although a number of esters of orthoformic acid, simple and mixed, were prepared by Pinner[2] through the action of alcohols on form-imino-ether hydrochlorides, their corresponding homologs, the various esters of ortho-acetic acid, with the exception of triethyl ortho-acetate, were not described in the literature. This only known ester of ortho-acetic acid was first synthesized by Geuther[3] in 1871 from methyl chloroform and sodium ethoxide. Since methyl chloroform is hard to prepare in available amounts in the laboratory, this method is only of theoretical interest. In 1907, Reitter and Hess[4] allowed ethyl alcohol to react with Pinner's acet-imino-ethyl-ether hydrochloride and isolated triethyl ortho-acetate. The reaction was not further developed and the various esters of ortho-acetic acid remained unknown. It is the purpose of this communication (1) to relate how triethyl ortho-acetate was prepared in large quantities in the laboratory by a simplified and improved procedure of Reitter and Hess and (2) to describe a few simple physical constants of the various new ortho-acetates produced by the following general reaction



$$CH_3CN + ROH + HCl \longrightarrow \underset{OR}{\underset{|}{CH_3C}}{:}NHHCl$$

$$\underset{OK}{\underset{|}{CH_3C}}{:}NHHCl + 2R'OH \longrightarrow \underset{OR}{\underset{|}{CH_3C}}{:}(OR')_2 + NH_4Cl$$

Experimental Part

Acet-imino-ethyl-ether Hydrochloride.[5]—This was prepared according to Pinner's method. Into a cooled mixture of anhydrous acetonitrile (135 g., b. p. 82°), absolute ethyl alcohol (200 cc.) and absolute ether (120 cc.), there was introduced a slight molecular excess of dry hydrogen chloride. This mixture, after standing in the icebox overnight, solidified into a hard cake of white, shining plates. The ether was decanted. The hydrochloride was dried in a vacuum over soda lime for twenty-four hours to remove the excess of hydrogen chloride; yield, 86–95%. By using methyl alcohol in place of ethyl alcohol in the above reaction, acet-imino-

methyl-ether hydrochloride was obtained as white, shining plates; yield, 71.6%.

Triethyl Ortho-Acetate.—Three hundred and fifty g. of acet-imino-ethyl-ether hydrochloride, absolutely dry and free from hydrogen chloride, was treated with 750 cc. of absolute ethyl alcohol. The mixture was allowed to stand in a tightly stoppered bottle in a dry place for two weeks with occasional shaking. The ammonium chloride separating out was filtered. This was preserved, since the reaction of alcohol with imino-ether hydrochloride was very slow and the solid precipitate still contained a large amount of the unreacted hydrochloride. The filtrate was treated with 2 g. of fused potassium carbonate to remove any trace of free hydrogen chloride. The solution was then fractionated under reduced pressure of 40–60 mm. The first fraction boiled over between 25 and 35°, consisted of absolute alcohol with some ortho-acetate and was used again in the further treatment of the precipitate of ammonium chloride as well as the fresh portion of acet-imino-ethyl-ether hydrochloride. The fraction from 55 to 75° at 50 mm. was collected and refractionated at atmospheric pressure. Pure triethyl ortho-acetate boiled very constantly at 144 to 146° at atmospheric pressure without any decomposition. Prom four runs 750 cc. of pure product was obtained.

[6] The slightly high values of molecular refraction and carbon content of these two ortho-esters seemed to indicate that they were contaminated, respectively, by traces of **tri-*n*-propyl** and tri-n-butyl ortho-acetates from which they could not be separated by fractional distillation.

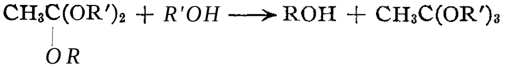
TABLE II

PHYSICAL PROPERTIES OF ORTHO-ACETATES

Ortho-acetates	B. p., °C.	d_4^{25}	n_D^{25}	Mol. ref. (G. and D.) Obs.	Calcd.	Mol. ref. (L. and L.) Obs.	Calcd.
Trimethyl	107–109	0.94375	1.38585	49.10	49.14	29.88	30.166
Dimethylethyl	123–126	.91915	1.38885	56.73	56.79	34.49	34.769
Methyldiethyl	135–136	.90085	1.39185	64.43	64.44	39.14	39.372
Ethyldi-*n*-propyl[6]	190–194	.87129	1.40635	88.70	87.39	53.66	53.181
Ethyldi-*n*-butyl[6]	220–225	.86461	1.41485	104.70	102.69	63.18	62.387

The ester is a colorless liquid with a pleasant odor, similar to that of ethyl acetate but stronger. The following constants were noted: b. p. 144–146°; n_D^{25}, 1.39485; d_4^{25}, 0.8847; molecular refraction (Gladstone and Dale), 72.33 (obs. val.), 72.09 (calcd. val.); molecular refraction (Lorenz and Lorentz), 43.91 (obs. val.), 43.975 (calcd. val.). The liquid is insoluble in cold water, but is miscible with ethyl alcohol, ether, ethyl acetate, chloroform and carbon tetrachloride. It is highly volatile with ethyl alcohol when distilled with the latter at atmospheric pressure.

By allowing various alcohols to react with acet-imino-ether hydrochloride, five new esters of ortho-acetic acid were isolated. Their method of preparation and physical properties are described in the following tables. In the case of a higher alcohol reacting on a lower alcohol derivative of imino-ether hydrochloride, there was always observed, in perfect accord with Pinner's experiments,[2] the formation of a by-product, a simple ortho-ester, in small amounts. The lower alcohol radical had a tendency toward being replaced by the higher alcohol, which was in excess.



$$\underset{\displaystyle |\atop OR}{CH_3C}(OR')_2 + R'OH \longrightarrow ROH + CH_3C(OR')_3$$

Summary

1. A simple procedure for the preparation of triethyl ortho-acetate is described.

2. Five new esters of ortho-acetic acid were prepared through similar reactions and their physical constants studied

THE PREPARATION AND PROPERTIES OF *l*-MANNONIC AND *l*-GLUCONIC LACTONES[1,2]

BY FRED W. UPSON, LILA SANDS AND CARRELL H. WHITNAH

RECEIVED OCTOBER 17, 1927 PUBLISHED FEBRUARY 4, 1928

Pischer[3] first prepared crystalline *l*-mannonic lactone from d-arabinose while van Ekenstein and Blanksma[4] isolated it later in the preparation of *l*-mannose.

The *l*-gluconic acid was isolated by Fischer in the form of a sirup. Nef[5] and also Hedenburg[6] prepared two crystalline modifications of d-mannonic lactone and also of d-gluconic lactone. The two modifications of d-mannonic lactone are fully described by Hedenberg.[6] One, which is undoubtedly the γ-lactone, possesses an initial specific rotation of $+51.8°$ in water and melts at 151°. The rotation changes only very slowly. The second lactone possesses an initial rotation of $+111.8°$ which diminishes very rapidly in water solution to a value of $+84.8°$ in less than two hours and to $+29.5°$ at the end of twenty-six hours Hedenburg gave to this lactone provisionally a propylene oxide structure. As shown in another part of this paper this lactone should be formulated in all probability as an amylene oxide or 6-lactone.

The present paper gives an account of the properties of the corresponding lactones of *l*-mannonic and *l*-gluconic acids prepared from *l*-arabinose by the Kiliani reaction. *l*-Gluconic acid lactone has been prepared for the first time in a crystalline state and a tetramethyl mannonic acid lactone prepared and its properties determined.

Experimental Part

Addition of Hydrogen Cyanide to *l*-Arabinose.—*l*-Arabinose was treated with hydrogen cyanide according to the directions of Fischer.[3] The resulting nitriles were converted to the mixed acids by the usual process through hydrolysis with barium hydroxide. The sirup obtained after precipitation of the barium as sulfate yielded two fractions (A) of nearly pure crystalline *l*-mannonic lactone. The residual sirups were thoroughly extracted with absolute alcohol, leaving behind a thick, colloidal residue. The alcoholic extracts yielded two more fractions (B) of crystalline products which were mixtures of *l*-mannonic and *l*-gluconic lactones. The filtrates (C) resulting here were converted to the brucine salts and yielded crude brucine *l*-gluconate, from

[6] Hedenburg, THIS JOURNAL, 37, 345 (1915).

which crystalline *l*-**gluconic lactone** was first obtained. The various fractions of brucine salt were subjected to fractional crystallization either from water or alcohol. There were obtained from **100** g. of I-arabinose **58.8** g. of pure I-mannonic **lactone** and **8.8** g. of crystalline *l*-**gluconic lactone.** Fischer obtained a yield of 40 g. of *l*-**mannonic lactone,** but *l*-**gluconic lactone** was isolated only in sirupy form.

l-Mannonic Lactones

***l*-Mannonic-γ-lactone.**—The crystalline fractions **(A)** described in the first part of this paper, which consisted of almost pure 1-mannonic **lactone,** were purified by recrystallization from absolute alcohol and then glacial acetic acid and converted to the γ-**lactone** according to the procedure of **Nef.**[5] **A** pure white crystalline **lactone** melting sharply at 150.5–151° and possessing a specific rotation of **—51.8'** was obtained. No significant change in rotation occurred during a period of two days.

Titration.—The **lactone** reacted very slowly with alkali at room temperature and required a temperature of approximately 100° to complete the titration.

Anal. **0.2064** g. required **11.85** cc. of **0.0972** *N* NaOH; calcd. for $C_6H_{10}O_6$: **11.93** cc. Calcd. for $C_6H_{10}O_6$: H, **5.61; C, 40.45.** Found: H, **5.57;** C, **40.69.**

The properties of this **lactone** show it to be the enantiomorph of the d-mannonic γ-**lactone** obtained by Nef and by Hedenburg. The fact that neutralization proceeds very slowly at room temperature and also the slow change in rotation prove that these lactones, the one a d- and the other an *l*-**mannonic lactone,** possess in all probability the stable or butylene oxide structure.7

Tetramethyl-*l*-mannonic γ-Lactone.—The *l*-mannonic 7-lactone obtained as described above was methylated by means of methyl iodide and silver oxide according to the method of Purdie and **Irvine.**[8] The process required two treatments with methyl iodide and silver oxide using methyl alcohol as a solvent and a further treatment with methyl iodide as the solvent. This process gave a tetramethyl *l*-**mannonic** methyl ester. The ester group was hydrolyzed by boiling for half an hour with a slight excess of **0.5** N sodium hydroxide. Hydrochloric acid exactly equivalent to alkali was added and the whole distilled under **reduced** pressure to complete dryness at 100°. The methylated **lactone** was extracted from the sodium chloride with ether and the ether solution dried. Upon evaporation this solution deposited the methylated **lactone** in a crystalline condition. This compound was shown by analysis to be a tetramethylated **lactone.**

Titration.—The compound **titrated** like a **lactone,** that is, only a very small amount of alkali was taken up at room temperature and complete neutralization could be accomplished only on heating to 100°.

Anal. **0.1820** g. required **7.43** cc. of **0.103** N NaOH. Calcd. for $C_{10}H_{18}O_6$: **7.54** cc. Calcd. for $C_{10}H_{18}O_6$: H, **7.71;** C, **51.28.** Found: H, **7.8;** C, **50.88.**

Methoxyl determination: Calcd. for $C_{10}H_{18}O_6$: methoxyl, **52.99.** Found: **53 7.**

This tetramethyl *l*-**mannonic lactone** crystallizes in long, narrow, colorless plates which melt at 109°. It is readily soluble in ether and alcohol, less soluble in water.

The specific rotation in water solution six minutes after solution was **—65.51';** after thirty-four hours −64.11°; while at the end of five days the rotation had changed to −60.6°, becoming constant after eighteen days with $[\alpha]^{20}_{D} = -47.4'$. This slow change in specific rotation, together with the fact that the titration could not be com-

---

[7] Pryde, **J** *Chem. Soc.*, *123,* **1811 (1923).**

[8] Purdie and Irvine, **J.** ***Chem. Soc.*, *83,* 1026 (1903).**

pleted at 25°, is evidence that the compound possesses the butylene oxide or γ-lactone structure.

Tetramethyl *d*-Mannonic γ-Lactone.—For purposes of comparison this compound was prepared by direct methylation of d-mannonic y-lactone, m. p. 151'. The methylation was carried out using methyl iodide and silver oxide as already described for the *l*-mannonic lactone. The compound was obtained in the form of colorless plates; m. p. 107°.

Anal. Methoxyl determination, calcd. for $C_{10}H_{18}O_6$: methoxyl, 52.99. Found: 52.34.

Titration.-4.2120 g. required 9.1 cc. of 0.1 *N* NaOH. Calcd. 9.05 cc. The specific rotation of this compound in water solution was found to be +66.6° immediately after solution. After six hours the value was +64° and after twenty-four hours +63°. A graph in Fig. 1 shows the change of rotation with time.

The High Rotating Mannonic Lactones.—Hedenburg,[6] by the action of oxalic acid on calcium d-mannonate, prepared a second lactone of d-mannonic acid, characterized by a high initial specific rotation of +111.8° which diminished in the course of twenty-six hours to the value of +29.3°. This lactone also was neutralized much more readily with alkali. These facts indicate an unstable lactone and led Hedenberg to formulate it as a propylene oxide or β-lactone. The evidence obtained in this investigation leads to the conclusion that this lactone is in all probability an amylene oxide or δ-lactone.

The Active *l*-Mannonic Lactone.—This lactone was prepared according to Hedenburg's method and found to consist of microscopic, colorless plates which melt at 160–162°.

And. Calcd. for $C_6H_{10}O_6$: H, 5.62; C, 40.45. Found: H, 5.71; C, 40.68. The substance titrated more readily than did the y-lactone; 0.1020 g. required 5.5 cc. of 0.103 *N* NaOH. Calcd. for $C_6H_{10}O_6$: 5.6 cc.

The lactone in aqueous solution has a high initial specific rotation, −113.6°, this diminishing to the value −102.5 after an hour and twenty minutes. At the end of three and one-half hours the value had become −78.5°. At the end of thirty-two and one-half hours the minimum value of −30.9' was reached, after which it slowly increased to the value −40.9 after twenty-eight days. The change in rotation of this I-mannonic lactone is thus shown to parallel the change of rotation of the active d-lactone as observed by Hedenberg. A curve in Fig. 1 shows more concretely the nature of the change.

Active Tetramethyl *d*-Mannonic Lactone.—Tetramethyl *d*-mannose was prepared according to the method of Haworth[9] by means of methyl sulfate and sodium hydroxide. This compound was oxidized by means of bromine as described by Pryde.[10] After removal of hydrobromic acid by means of lead carbonate and silver oxide in the usual way, the methylated oxidation product was extracted with ether and the ethereal solution subjected to fractionation finally at a pressure of 1–2 mm. The tetramethyl d-mannonic lactone was obtained as a colorless oil which showed no tendency to crystallize.

Anal. Calcd. for $C_{10}H_{18}O_6$: H, 7.77; C, 51.28; methoxyl, 52.99. Found: H, 7.76; C, 50.62; methoxyl, 52.83.

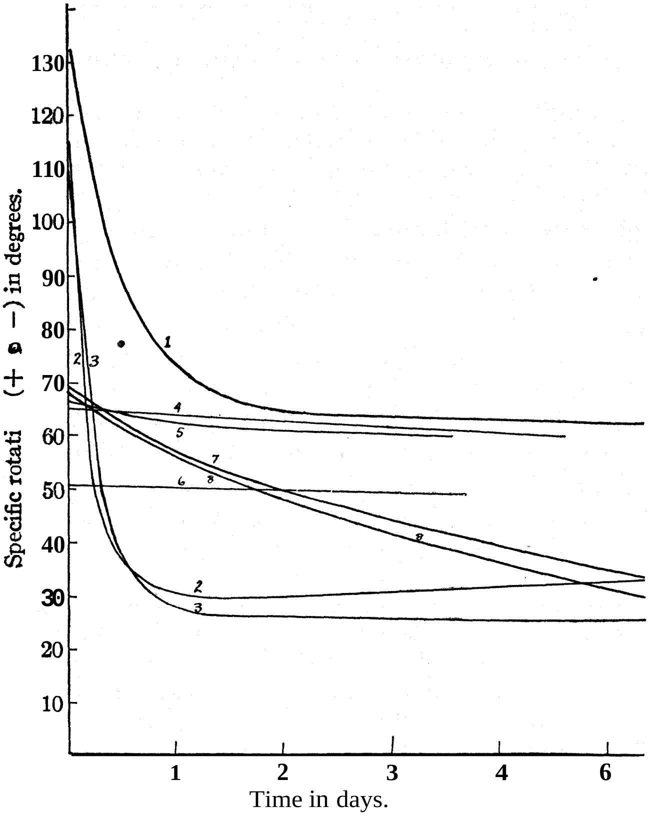
---

[9] Haworth, J. Chem. *Soc.*, 107, 8 (1915).

[10] Ref. 7, p. 1808.

The titration proceeded rapidly in the cold until about three-fourths complete; 0.2282 **g.** required **9.75** cc. of **0.0972** *N* **NaOH;** calcd. for $C_{10}H_{18}O_6$, **9.9 cc.**

The **initial** specific rotation five minutes after solution was +132.3°. The specific rotation diminished rapidly, changing to the value **+113.6°** after four and one-half hours and to **−76.3'** after twenty-two hours. It reached a minimum value of +59.5°



1. Tetramethyl d-mannonic 8-lactone; **2.** d-mannonic δ-lactone; 3. I-mannonic δ-lactone; **4.** tetramethyl d-mannonic y-lactone; **5.** tetramethyl Lmannonic γ-lactone; **6.** *d*-mannonic and *l*-mannonic γ-lactones; 7. I-gluconic y-lactone; 8. d-gluconic y-lactone.

Fig. 1.--Curves showing change of rotation of various lactones with time.

after about six days and at the end of nine days the value had become +63.6°. A curve in Fig. **1** shows more concretely the change of rotation with time. An inspection of the graph brings out the fact that the curves belong to two distinct types. Those belonging to the normal lactones of d- and *l*-mannonic acids, as well as the methylated derivatives, are almost horizontal and show little falling off. The rotations of the two abnormal lactones and of the methoxyl derivative of the *d*- variety have a much higher initial value and the slope of the curves is very steep at first, becoming more nearly horizontal after twenty hours.

Structure of the Active Mannonic Lactones.—The common lactones of the sugar acids are formulated as butylene oxides of γ-lactones because of their comparative stability towards alkalies and because of the slow change in rotation which they undergo in water solution. Evidence of this view is presented by Hedenberg[6] and by Pryde,[7] and the theory is further supported by Hudson's rule.[11]

According to the rule of Hudson the position of the lactone bridge in the sugar acid lactones determines the sign of rotation. Pryde has shown in the case of galactonic lactone that the two tetramethyl derivatives, the one obtained by the oxidation of methylated galactose and the other by direct methylation of the lactone, differ in sign of rotation. According to Hudson's rule the 1-5 lactone should rotate to the right and the 1-4 to the left. In the case of the lactones of mannonic acid both the 1-4 and the 1-5 should be dextro-rotatory. It seems certain, therefore, that the active d-mannonic lactone of Nef and Hedenburg as well as the active *l*-mannonic lactone here reported together with the tetramethyl lactone obtained by oxidation of tetramethyl mannose, all possess the amylene oxide or 1-5 lactone structure. This leads logically to the conclusion that crystalline mannose possesses the amylene oxide or 1-5 lactone structure. Levene and Meyer[12] have reached the same conclusion based on a study of these same methylated lactones. The constants of their tetramethyl 1,4-lactone agree closely with those determined by us. The second compound of Levene and Meyer, obtained on oxidation of tetramethyl mannose, shows a lower specific rotation, +105°, than the value found in this Laboratory, +132°. It is possible that their product contained some free acid, which accounts for the lower rotation. They give no data showing the change of rotation with time.

Lewis and Greene[13] have recently prepared tetramethyl mannose in a crystalline form. From this they have obtained by oxidation with bromine a tetramethyl lactone in the form of a sirup which shows an initial specific rotation of +136.4° and a final value of +62.4°. These results correspond closely with those found in this Laboratory and their lactone is undoubtedly identical with the one reported above.

It should be noted that Nef[14] in 1914 first suggested that other lactone bridges than those of the γ or butylene oxide type are possible among the members of the sugar group and that Nef and also Hedenburg[6] were the first to obtain representatives of these abnormal lactone types in their studies of mannonic and gluconic lactones. The methylation studies on the mannonic lactones both in this Laboratory and elsewhere connect

definitely the one lactone type of the acid with that of its parent sugar. As pointed out by Charlton, Haworth and Peat,[15] the normal lactone type of the sugar apparently belongs to the γ or amylene oxide form, while the stable normal lactones of the monobasic sugar acids belong to the γ or butylene oxide type. In only one other case, that of glucose, has the unmethylated acid lactone been obtained which corresponds to the normal lactone type of the sugar.[16]

l-Gluconic Lactone

l-Gluconic lactone, as already indicated in the first part of this paper, has been isolated for the first time in a crystalline condition. The mother liquors (C) obtained as already described, from which no more crystalline mannonic lactone could be obtained were converted to brucine salt in the usual way. On crystallization of the brucine salts from absolute alcohol, several fractions melting at temperatures ranging from 150–180° were obtained. As the larger portion of the mannonic lactone had already been removed by crystallization, the crystalline brucine salts obtained here contained very little brucine *l*-mannonate. The whole of the crystalline brucine salt was converted to the free lactone in the usual way through treatment with barium hydroxide and subsequent removal of the barium through precipitation as sulfate. The gluconic lactone was obtained first as a thick gum which showed evidence of crystallization after standing for some days under absolute alcohol. On long standing there was obtained a considerable quantity of crystalline lactone, which could be removed by filtration with vacuum. After the lactone was once obtained it was readily recrystallized from absolute alcohol or glacial acetic acid. The latter solvent was found to give a pure product. The lactone was obtained in the form of colorless plates melting at 134–135°. The initial specific rotation in 3.79% solution was −68.7°. The rotation diminished to the value of −62.5° after twenty-four hours, to the value −58.2° after two days and continued to diminish for some days. The minimum value −13.7' was reached after a period of fifteen days, after which there was a slow increase in the value. This change in rotation closely paralleled that for the d-gluconic lactone as recorded by Hedenburg,[6] who found an initial value of −67.2'.

Titration.-4.2017 g. of lactone required 11.24 cc. of 0.0972 N NaOH; calcd., 11.48 cc.

A number of derivatives of *l*-gluconic lactone were prepared. Two g. of lactone was converted to the brucine salt. After recrystallization from 90% alcohol and drying in *vacuo* the salt melted sharply at 181–182°; $[\alpha]^{20}_{\mathrm{D}} = -25.43$ in 4.01% solution.

The brucine salt of Lmannonic acid was also prepared for purposes of comparison. Its melting point was found to be 161–162° and $[\alpha]^{20}_{\mathrm{D}} = -15.78$" in 3.98% solution.

The phenylhydrazide of *l*-gluconic acid was prepared in the usual way. On recrystallization from water it melted sharply at 200" and $[\alpha]^{20}_{\mathrm{D}} = -11.7$' in water solution of 2.97%. The melting point of the hydrazide of d-gluconic acid is 200° and the specific rotation is +12". The results recorded above indicate very definitely that the compound is the phenylhydrazide of I-gluconic acid. The properties of the lactone, together with those of its brucine salt and phenylhydrazide, indicate clearly that the above-described compound is the crystalline lactone of *l*-gluconic acid.

Summary

1. The lactones of I-mannonic and I-gluconic acids were prepared from I-arabinose in a somewhat better yield than had been obtained previously.

2. Two lactones of l-mannonic acid were prepared: the common lactone having a butylene oxide ring and the less stable lactone having an amylene oxide ring.

3. Evidence for the structure of the two lactones was substantiated by the preparation of two distinct tetramethyl mannonic lactones.

4. *l*-Gluconic lactone was prepared for the first time in crystalline form and its constants were determined.

THE MOLECULAR WEIGHTS OF PHYCOERYTHRIN AND OF PHYCOCYAN

BY THE SVEDBERG AND N. B. LEWIS[1]

RECEIVED OCTOBER 27, 1927 PUBLISHED FEBRUARY 4, 1928

Phycoerythrin and phycocyan are closely related proteins of the globulin type which occur together in certain algae. They are both fluorescent and have characteristic colors; the color and fluorescence are quite strong even in 0.01% solution. On account of this strong light absorption both in the visible and the ultraviolet and of the relative ease of preparing them in a pure crystalline state they appeared to be particularly suitable for molecular weight determinations by means of the ultracentrifuge.

There is a series of references in the literature to these substances dating back to that of Kützing;[2] but they appear to have first been prepared in a pure state by Kylin.[3] In this paper he gives an account of their preparation from *Ceramium rubrum*, of their chemical properties, absorption spectra and a quantitative analysis of phycoerythrin. It also includes a complete list of the earlier references.

Kitasato[4] used another alga, *Porphyra tenera* (the sun-dried material being an article of commerce in Japan) as raw material, and the substances were prepared by a method analogous to that of Kylin. His observations in general, and his analysis of phycoerythrin, agree with those of Kylin. Further, he was able to make an analysis of phycocyan, which occurs in much smaller quantities (Ceramium *rubrum*, according to Kylin, about $^1/_{10}$ of that of phycoerythrin); his figures for this are very close to those for phycoerythrin.

Experimental

Preparation of Material.—*Ceramium rubrum* was extracted with water as described by Kylin. The extract, consisting of a solution of the mixed substances as well as

numerous impurities (slimy carbohydrates, etc.), was treated with about 20% of its weight of ammonium sulfate. The proteins thus precipitated were brought into solution by washing with distilled water. This solution was then treated with increasing amounts of ammonium sulfate up to 20% of its weight. After each addition it was allowed to stand for a day, filtered and the precipitate redissolved. In this way were formed four fractions with differing relative amounts of the two substances. The first fraction (the largest), consisting mainly of phycoerythrin, was recrystallized until the resulting crystals, as seen under the microscope, were seen to be entirely free from phycocyan; and the third and fourth, consisting almost entirely of phycocyan, recrystallized until they were free from phycoerythrin. The precipitate from Fraction 2, consisting of a mixture in which phycoerythrin predominated, was shaken with a little water and centrifuged. The deposit was found to be free from phycoerythrin crystals, which evidently dissolve more rapidly. The various mother liquors obtained, if dilute were discarded, if not, were separated into fractions in a similar manner. As these substances are decomposed on exposure to daylight, the liquids in all cases were kept in the dark, with toluene added as a preservative.

The pure crystalline substances were dissolved in as small a quantity of water as possible and dialyzed in collodium bags against water at 0° for periods of not less than a week, at the end of which time the specific conductivity at 20° had fallen to less than 10^{-4} ohm^{-1}, and the substances had commenced to precipitate in an amorphous form. The phycocyan was dissolved in a dilute sodium phosphate-potassium phosphate buffer solution (PH = 7.0). The phycoerythrin dissolved again when the liquid was poured into a glass vessel (due probably to traces of alkali from the glass). This solution was filtered and part kept without buffer; the remainder in phosphate buffer (PH = 6.8).

Specific Volume.—The partial specific volume at 19.4° of phycoerythrin was determined pycnometrically. The concentration of the sample was determined by drying to constant weight at 105°. The value for a dilute (0.84%) solution was found to be 0.746 which is very close to

that for egg albumin and hemoglobin. For phycocyan, concentration was determined (a) by precipitating a weighed amount of solution with acid, filtering on a Gooch crucible and drying at 105°; (b) by drying at 105° and subtracting the calculated weight of phosphate in the volume of solution used. The two values agreed satisfactorily. The value found for the partial specific volume at 19.6° was 0.761 but this is rather inaccurate owing to the dilute solution used.

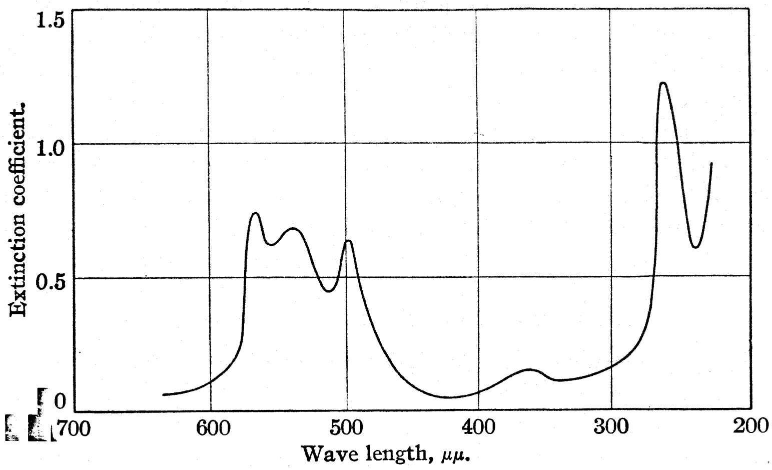

Fig. 1.—Light absorption for phycoerythrin (0.0097% solution).

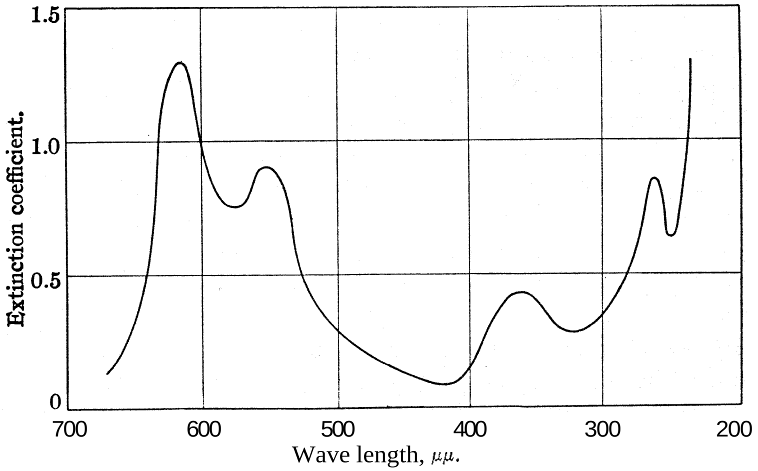

Fig. 2.—light absorption for phycocyan (0.0293% solution).

Light Absorption.—(In dilute phosphate buffer solution, PH = 6.8 and 7.0.) The absorption in the visible spectrum was measured with a Konig-Martens spectrophotometer and the results are given in Tables

I and II; for the ultraviolet a Judd-Lewis spectrophotometer was used; the values being of a lower order of accuracy they are not tabulated. The absorption curves obtained are shown in Figs. 1 and 2.

With phycoerythrin the absorption band in the visible was found to have three maxima, at 566, 540 and 497.5$\mu\mu$, agreeing with those obtained by Kylin[3] (569–565,541–537 and 498–492$\mu\mu$) and Kitasato[4] (562,526 and 495 $\mu\mu$, respectively). With phycocyan the maxima were found to be at 615 and 553$\mu\mu$, agreeing with those of Kylin (618–613 and 553–549$\mu\mu$, respectively) and Kitasato (614 and 546$\mu\mu$). In the ultraviolet both substances have bands with maxima at 262$\mu\mu$, and feebler, less well-defined ones at about 360$\mu\mu$ (Kitasato, approximately 270 and 330$\mu\mu$). With phycoerythrin the former band is much stronger than with phycocyan.

Determination of the Molecular Weight

A. By the Method of Sedimentation Equilibrium.—The apparatus and procedure have already been described.[5,6,7] With phycoerythrin photographs were taken in the visible spectrum (Wratten K3 filter), long-waved ultraviolet (Wratten or Corning nickel-glass filter), and short ultraviolet (quartz optical system, chlorine and bromine filters), the arrangements being as previously described.[5,6,7] In order to cut down the intensity of the mercury line 366$\mu\mu$ so as to get suitably long times of exposure, it was found convenient to insert a ground-glass screen between the mercury lamp and the water filter.

As standards, to correct for variation in intensity of the mercury lamp, solutions of potassium chromate of suitable strength were used, both for the long-waved and short-waved ultraviolet.

With phycocyan consistent results were not obtained with the short ultraviolet, possibly owing to a certain amount of decomposition during the run, so that the products formed would have absorption in the short ultraviolet, but not in the long ultraviolet or the visible, and hence the results would be affected only in experiments with the short ultraviolet. To increase the absorption in the long ultraviolet (since only a dilute solution of phycocyan was available), it was found necessary to use a cell of 8 mm. in thickness, as against 2 mm. in all other cases.

B. By the Method of Sedimentation Velocity.—The centrifuge and the method used have already been described.[8,9] Parallel light from the Pointolite lamp was used, with an Ilford three-color, green filter for phycoerythrin and a Lifa yellow filter for phycocyan. The plates used were Ilford

concentrations at distances x_2 and x_1, respectively, from the axis of rotation and ω the angular velocity.

The results of typical runs are given in Tables III and IV; the results for all the runs are summarized in Tables V and VI. It will be seen from Tables III and IV, and it was also the case in the other experiments, that there is no systematic variation in the values of the molecular weight with varying distance from the axis of rotation; in other words, the solutions consist of molecules of uniform size.

B. Sedimentation Velocity.—The molecular weight is given by[8]

$$M = \frac{RT}{D(1 - V\rho)} \cdot \frac{1}{\omega^2 x} \cdot \frac{dx}{dt} = \frac{RT}{D(1 - V\rho)} \cdot s$$

where s is the specific sedimentation velocity, D the diffusion constant, x the distance from the axis of rotation and the other symbols have the same meaning as before. D can be calculated from the amount of blurring of the boundary as previously described.[8,9] It must be pointed out that in these experiments, more particularly those with phycoerythrin, the values of D obtained are not very accurate, first, because the color-sensitized plates used do not appear to be as uniform, especially for **green** light, as the non-sensitized plates, thus making the determinations of concentration not so reliable; second, because with the relatively large sedimentation velocity and low diffusion constant, the time of centrifuging is shorter and thus the amount of diffusion much less; and third,

because the value of D depends on the square of this quantity, so that any error in the determination of the latter has a correspondingly larger effect. The value of s, on the other hand, can be determined with a much higher degree of accuracy.

Details of typical runs are given in Tables VII and VIII and they are summarized in Table IX.

Fig. 3 gives a reproduction of the photographs taken during the centrifuging of the phycoerythrin at 39,000 r.p.m., that is with a mean centrifugal force of 90,000 times that of gravity, and shows the condition of the solution at 20, 40, ... and 140 minutes after the start of the run; the top row is the scale of concentrations.

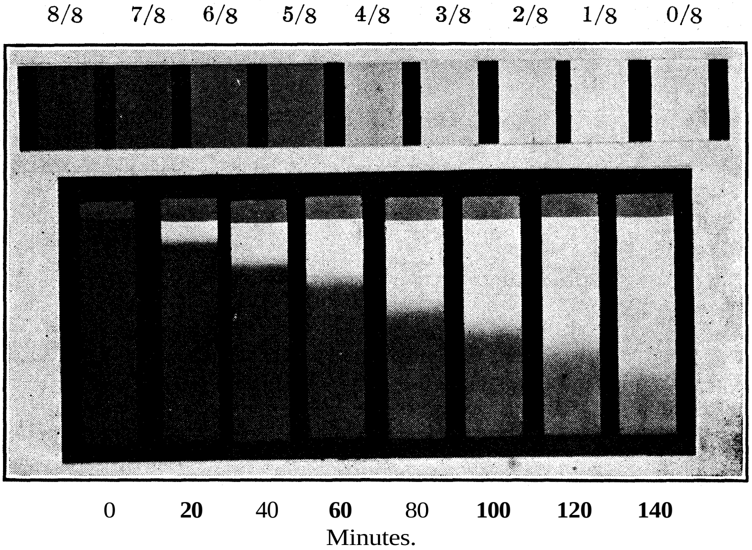

Fig. 3.

Fig. 4 shows the variation of concentration with distance after $^1/_2$, 1,. . . . . and $3^1/_2$ hours of centrifuging of phycocyan; the curves have been corrected for the decrease of concentration of the solution with time. The dotted curves for two and three hours represent the theoretical diffusion curves of a substance of only one molecular species. The deviation from the experimentally determined distribution is small and probably within the limits of experimental error. The same statement was also found to be true for the runs with phycoerythrin; that is, within the limits of experimental error, the molecules of both substances are uniform.

Examination of a Sample of Phycoerythrin Seventeen Years Old

A sample of Kylin's original phycoerythrin, which had also been prepared from *Ceramium rubrum*, was obtained through the courtesy of Professor Morner of the Biochemical Department. It had been kept for seventeen years in crystalline form under a saturated solution of ammonium sulfate covered with toluene.

Some of this substance was dialyzed for two weeks in a collodium bag against phosphate buffer solution ($P_H = 6.8$). The results of one run with this are shown in Fig. 5, which gives the variation of concentration with distance after 40, 65, 80 and 100 min. of centrifuging (speed 41,000–42,000 r. p. m.). The curves show marked divergences from those of a pure molecular species (see Fig. 4); Curve A shows the calculated curve for the pure substance after 80 minutes of centrifuging under the same conditions.

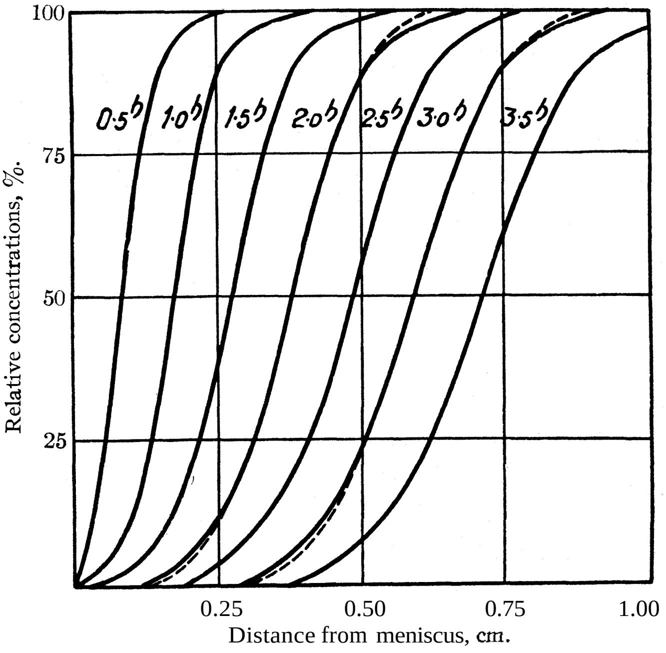

Fig. 4.

The curves show a point of inflection and evidently represent the distribution for a mixture of molecules of the normal size and of a smaller proportion of smaller ones so that the upper part corresponds to the distribution of the normal molecules and the lower to that of the smaller ones. From the amount of sedimentation corresponding to the lower part, it can be seen that these molecules were of $^1/_6$ or $^1/_8$ the weight of the normal ones. If we assume that the light absorption (in the green) per unit weight of these is the same as that for the normal molecules, an estimate can be made as to their proportion in the mixture. The values of s, the specific sedimentation velocity and of D, the diffusion constant for the normal molecules, were taken from the results of the previous experiments and were corrected for any difference of temperature from 30°; those of s and D for molecules of $^1/_6$ and $^1/_8$ the size were calculated (assuming spherical molecules and the validity of Einstein's law) and the theoretical distribution curves for various mixtures then obtained. The experimental accuracy is, however, not great enough to decide whether the smaller molecules are those of $^1/_6$ or $^1/_8$ the normal size. In Fig. 5 the dotted curves show the calculated distributions for a mixture of 70% of molecules of weight 208,000 and 30% of 208,000/8. A mixture of 67% of 208,000 and 33% of 208,000/6 was found to agree equally well with the experimental results. A second run at 41,000 r. p. m. gave similar results, as did also one at 28,000 r. p. m.

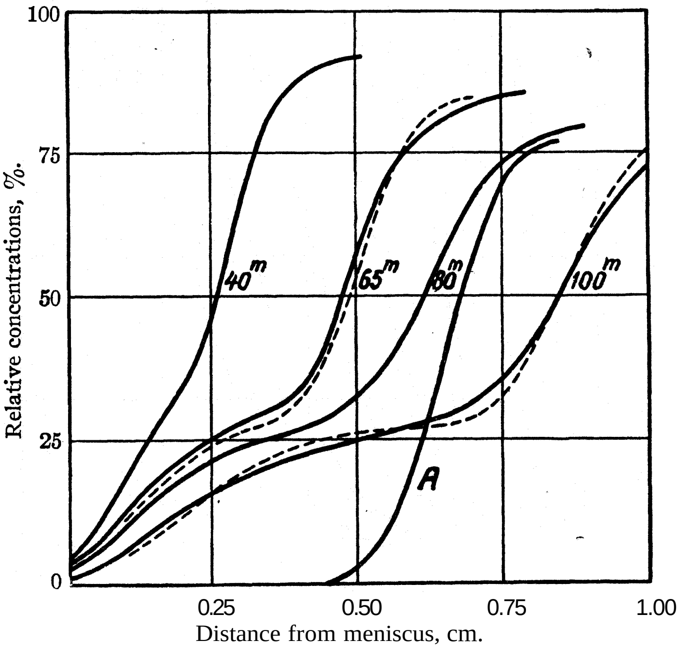

Fig. 5.

It was thought that the two kinds of molecules might be separable by recrystallization. Accordingly the material was recrystallized 6 times and the experiment repeated. The distribution curves still showed the presence of from 25 to 30% of the smaller molecules, so that very little, if any, separation had taken place.

Toward the end of the investigation the centrifuge was arranged so that photographs could be taken with short ultraviolet light. Under these conditions the recrystallized material gave qualitatively the same results as before, but the results were not suitable for quantitative information as to the composition of the mixture.

Discussion of Results

From the results it is considered that the most probable value of the molecular weight of phycoerythrin is 208,000 ± 8000 and of phycocyan 106,000 ± 5000, the former within the limits of experimental accuracy being double the latter. It is interesting to compare these values with those of the other two proteins already investigated in this Laboratory, namely, egg albumin and hemoglobin. We have for the molecular weight of egg albumin,[6] 34,500 ± 1000; for hemoglobin[10] it is 68,500 = 34,500 X 1.99; for phycocyan, = 34,500 × 3.07; and for phycoerythrin, = 34,500 X 6.03. The smaller molecules in the old sample of phycoerythrin may be of weight 208,000/6, that is, also approximating to 34,500.

The diffusion constant for phycoerythrin can be calculated from the Einstein formula

$$D = \frac{RT}{N} \cdot \frac{1}{6\pi r\eta}$$

where R is the gas constant, N the number of molecules in one gram molecule, η the viscosity of the solution at temperature, T (for the dilute solutions used this was taken as the same as that for pure water, that is, 0.0080 gm. cm.$^{-1}$ sec.$^{-1}$ at 30°), r the radius of the molecule (assumed spherical); r is calculated from the molecular weight M by the formula $M/N = {}^4/_3\, \pi r^3 \rho$; ρ, the density, was assumed to be the reciprocal of the specific volume, the value being taken as 1.33. On this assumption $r = 3.95 \times 10^{-7}$ cm. The value of D calculated in this way is 0.061 cm.^{2}/day at 30°; experimental values were 0.061, 0.054 and 0.053, and the value obtained from the mean values of the molecular weight and specific sedimentation velocity was 0.061.

Thus the results agree very well with the assumption that the phycoerythrin molecule is spherical and has a density of 1.33. On the other hand, with phycocyan, which has practically the same diffusion constant and only half the molecular weight, the molecule must diverge widely from the spherical shape. Now Kitasato[4] found that these two substances had practically the same elementary composition, so that one could conclude that the phycoerythrin molecule is some sort of aggregation of two phycocyan molecules; or that it consists of an approximately spherical aggregation of smaller molecules and that phycocyan consists of an elongated-shaped aggregation of half the number of these smaller molecules.

Summary

1. The centrifugal sedimentation equilibrium and sedimentation velocity methods have been used to determine the molecular weights of phycoerythrin and phycocyan in dilute buffer solutions, using various

---

[10] Mean of determinations by Svedberg, Fåhraeus and Nichols.

hydrogen-ion concentrations and protein concentrations, and using visible, long-waved ultraviolet and short-waved ultraviolet light.

2. Within the limits of experimental error none of these factors influenced the values found for the molecular weight, the value of phycoerythrin being 208,000 ± 8000, and for phycocyan 106,000 ± 5000.

3. Within the limits of experimental error both of these substances consisted of a pure molecular species.

4. A sample of phycoerythrin 17 years old was found to consist of molecules of weight 208,000, together with about 30% of molecules of $^1/_6$ or $^1/_8$ of this weight; no marked separation of the two sizes of molecule was effected by recrystallization.

5. It was pointed out that the molecular weights of phycoerythrin and phycocyan, as well as that of hemoglobin, approximately were multiples of that of egg albumin.

PURE ARSENOBENZENE AND THE MOLECULAR COMPLEXITY OF ARSENOBENZENE AND ARSENOMETHANE

BY CHARLES SHATTUCK PALMER AND ALBERT B. SCOTT[1]

RECEIVED OCTOBER 28, 1927 PUBLISHED FEBRUARY 4, 1928

The structure of arseno compounds, which are probably the most important therapeutically and interesting chemically of all organic arsenicals, is not definitely known, although it has been quite generally accepted that they are analogous to the azo compounds, R—N=N—R. However, compounds of the two groups are quite different in solubility, ease of oxidation and reduction, action with chlorine and sulfur, etc. The published results on the molecular weights of symmetrical arseno compounds are conflicting and inadequate. The purpose of this investigation, therefore, was to determine the molecular weights of arseno compounds in associating and non-associating solvents in order to throw more light on the nature of their molecular structure.

Molecular weights for only three symmetrical compounds with the arseno linkage have been published. The first was for arsenomethane to which Auger,[2] in 1904, assigned the formula $(CH_3As)_4$ (I) from cryoscopic determinations on a solution of the yellow oil in benzene. But in 1926 Steinkopf, Schmidt and Smie[3] pointed out an error in his work and gave the

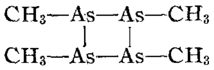
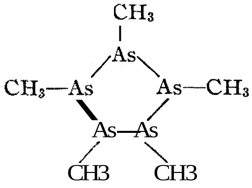
formula as $(CH_3As)_5$, which they represented structurally (II) as a cyclic compound with a ring of five arsenic atoms, never before known. The



I



II

molecular weight of arsenobenzene in benzene solution was determined by Michaelis and Schäfer[4] and a single value of 399.8 is reported. Although the calculated molecular weight for $C_6H_5—As{=}As—C_6H_5$ is 304, these authors state that their value proves that the molecule has the azo-type structure and that arsenobenzene is a true analog of azobenzene. The same investigators found widely divergent values for *p*-arsenotoluene.

Arsenomethane and arsenobenzene were chosen as the first compounds to be utilized in this investigation because the two values for the molecular weight of the former do not agree and the single value for the latter does not conform satisfactorily to the azo-type structure that it is supposed to demonstrate. Because of the ease with which arseno compounds are oxidized by air, special precautions, including the use of an inert atmosphere (carbon dioxide or nitrogen), are necessary in their preparation and in molecular weight determinations. For the latter, standard ebullioscopic and cryoscopic methods were used in this investigation and, as a check on their accuracy, compounds of known molecular weight were run under conditions the same as those used for the arseno compounds.

The method of Binz, Bauer and Hallstein[5] for the reduction of phenylarsonic acid to arsenobenzene by means of hypophosphorous acid was improved by changing the time and temperature of the reaction and introducing two alkali extractions and a final recrystallization; pure arseno benzene melting at 195° was thus obtained. Because of its slight solubility, the use of very dilute solutions was necessary in the molecular weight determinations, with some corresponding sacrifice of precision. By the ebullioscopic method in carbon disulfide and benzene mean values of 334 and 402, respectively, were obtained; while cryoscopic determinations in very dilute naphthalene solution gave an average value of 642. These results indicate the existence of the normal or azo-type structure, $C_6H_5—As{=}As—C_6H_5$, in a non-associating solvent (carbon disulfide), but distinct association in benzene (recognized as a common associating solvent) and especially in naphthalene, possibly with complete conversion into a double molecule in the latter solvent. The average value of 402

[5] Binz, Bauer and Hallstein, Ber., **53A,** 427 (1920).

in benzene solution confirms the work of Michaelis and Schäfer who found **309.8;** but their interpretation that arsenobenzene is normal in such a solution is probably wrong, since a mean value of 334, much nearer the theoretical, was found in carbon disulfide. The individual values obtained in naphthalene were widely divergent, due, probably, to the necessary use of an extremely dilute solution with consequent magnification of errors in thermal control. The mean value given was obtained after rejecting extremely high and extremely low values and may be regarded only as an indication of association.

Great care was necessary in the preparation of arsenomethane as the yellow oil because it is readily oxidized and also passes rapidly to red or brown-black, solid modifications of hitherto unknown molecular complexity. The preparation and molecular weight determinations were carried out in an inert atmosphere and the ebullioscopic solvents were saturated with nitrogen. The theoretical value of 450 suggested by Steinkopf, Schmidt and Smie for the molecular weight of the yellow oil was checked to within 5.3% by a mean value of 474 in carbon disulfide solution. A value of 476 (mean of two determinations giving 491 and 461) was found in benzene solution for the molecular weight of a mixture of about equal amounts of the red solid and yellow oil obtained by allowing the yellow oil to stand for four days in an inert atmosphere in a sealed ampule. The close agreement between the values obtained for the mixture and for the yellow oil alone makes it appear that the red solid has the same molecular weight, at least in solution, as the oil.

Experimental Part

Preparation of Arsenobenzene ($(C_6H_5—As=As—C_6H_5)_x$).—Analyses showed that the method of Binz, Bauer and Hallstein[5] for the reduction of phenylarsonic acid by hypophosphorous acid resulted in impure arsenobenzene. A satisfactory method of preparation was worked out as follows. A mixture of 1 liter of 50% hypophosphorous acid with a solution of 100 g. of recrystallized phenylarsonic acid[6] in 700 cc. of water was vigorously stirred in a flask fitted with a mercury-sealed stirrer in a water-bath at 55–60°. If a hard cake formed during the reaction it was pulverized in a mortar and returned to the flask. After four and one-half hours the reaction mixture was forced by carbon dioxide pressure into an anaerobic filter and the precipitate washed on the filter with 500 cc. of 10% sodium hydroxide solution followed by 500 cc. of warm 5% sodium hydroxide. During this filtration and during the entire subsequent purification process, all contact of the arseno compound with air was avoided by the maintenance of the compound or of the solution containing it in an atmosphere of carbon dioxide. The crude arsenobenzene was removed from the filter and vigorously stirred with two successive 200-cc. portions of 10% sodium hydroxide solution, the yellow powder being filtered off after each extraction and finally washed on the filter with 500 cc. of warm 5% sodium hydroxide followed by 1 liter of distilled water and dried for two days over phosphorus pentoxide in an evacuated carbon dioxide atmosphere. For **recrystallization,** the dry, crude product was dissolved in the minimum quantity of boiling chlorobenzene and the hot, filtered solution allowed to cool.

Palmer with Adams, THIS JOURNAL, 44,1361 (1922).

The first crop of crystals only was utilized. These were filtered off, washed with absolute ether, recrystallized as before and again washed with ether. The final product (weight about 12 g.) consisted of perfectly white needles melting at 195" when heated in the usual capillary tube at the rate of 1° per minute near the melting point. Other preparations described in the literature have melted at 196°,[7] 208°,[5] 212°.[4] Crystallographic examination of the arsenobenzene prepared in this investigation showed it to consist of strongly birefringent needles, all of one type.

Anal. Subs., 0.0995, 0.1051: 26.79 cc. iodine (a), 28.17 (b) [1 cc. (a) = 0.001839 g. As, (b) = 0.0018501. Calcd. for $C_{12}H_{10}As_2$: As, 49.31. Found: 49.51, 49.59.

Preparation of Arsenomethane $(CH_3As)_5$.—Following the general method of Auger,[2] arsenomethane was prepared as a bright yellow oil by stirring 100 g. of sodium methylarsonate with 350 cc. of 50% liypophosphorous acid for three hours in a water-bath at 70°. Traces of impurities in the sodium methylarsonate were found to cause immediate formation of brown and red solid modifications of arsenomethane, but the intermediate can be prepared in adequate purity by Quick and Adams'[8] modification of "Meyer's reaction," the product from the second recrystallization from alcohol being thoroughly washed with a mixture of equal volumes of alcohol and water to remove any trace of the original materials as well as all of the sodium iodide. The immiscible oil was transferred to a small separatory funnel, washed 5 times with 25-cc. portions of 5% sodium hydroxide solution followed by similar portions of water, and then sealed in ampules, all in an atmosphere of carbon dioxide; yield, good. The clear, yellow oil boiled at 178° under 15mm. pressure, but all attempts to purify it further by fractional distillation under reduced pressure resulted in the immediate formation of some of the red, solid modification, so the material was finally used without further purification.

Anal. Subs., 0.0553, 0.0563: 21.44, 21.48 cc. iodine (1 cc. = 0.002126 g. As). Calcd. for $(CH_3As)_5$: As, 83.30. (Auger found 82.50.) Found: 82.42, 81.11.

Molecular Weight Determinations.—In the ebullioscopic molecular weight determinations the apparatus and procedure of McCoy[9] were used. In the case of arsenomethane the solvents were previously saturated with nitrogen. In order to avoid undue dilution it was found desirable to dissolve the samples of arsenobenzene in the minimum amount of the desired solvent before the inner tube of the apparatus was placed in its final position. The usual apparatus and technique, with slow but continuous mechanical stirring, were employed for the cryoscopic determinations. As the temperature differences to be measured in the case of arsenobenzene are small, because of its slight solubility, particular care must be taken in thermal control. All temperatures were measured by an accurate Beckmann thermometer. Of the solvents used in the molecular weight determinations, the naphthalene was purified by two recrystallizations from alcohol followed by a fractional sublimation at about 70°; the benzene was the C. P., thiophene-free grade of the Eastman Kodak Company; and the carbon disulfide was obtained in exceptional purity by treating the technical product with ceresin wax according

Summary

1. A method for preparing pure arsenobenzene from phenylarsonic acid is given in detail.

2. Arsenobenzene has been found to have a molecular weight corresponding to the monomolecular, azo-type structure, $C_6H_5—As{=}As—C_6H_5$, in a non-associating solvent, but to be distinctly associated in benzene and naphthalene solutions.

3. $(CH_3As)_5$ and not $(CH_3As)_4$, the first formula suggested, has been confirmed as the molecular formula of arsenomethane in the form of the yellow oil, and the red, solid form may have the same molecular weight.

4. The custom of representing all arseno compounds by the general formula $R—As{=}As—R$ is unjustified.

THE ACTION OF SODIUM-POTASSIUM ALLOY ON PETROLEUM[1]

BY J. B. CONANT[2] AND A. H. BLATT[3]

RECEIVED OCTOBER 31, 1927 PUBLISHED FEBRUARY 4, 1928

When a sample of crude Pennsylvania petroleum, diluted with anhydrous ether, is shaken with sodium-potassium alloy in an inert atmosphere an intense brown solution and precipitate result. The color is discharged by introducing moisture or dry carbon dioxide. In the latter case large amounts of the gas are absorbed and a white precipitate is formed. This precipitate is evidently the sodium (or potassium) salt of an organic acid since it readily dissolves in water, and on acidifying the aqueous solution a solid organic acid is precipitated.

The behavior of the highly colored reaction mixture obtained by the action of the alloy on petroleum clearly indicates that an organo-sodium (or potassium) compound is present. Such a compound might be formed either by the cleavage of a highly substituted ethane[4] or by the addition of the metal to an unsaturated system.[5] The preliminary results which are reported below point to the latter alternative.

We have found that samples of a variety of crude oils (Mid-Continent, California and Colombia, S. A.) and a sample of "cracking-coil residue" from a Mid-Continent gas oil behave in a similar fashion when treated with sodium-potassium alloy. On the other hand, there was no reaction with a sample of "cracking-coil distillate" from Mid-Continent gas oil. Twelve to twenty-four hours of vigorous shaking appeared to complete the reaction as further treatment of the recovered oil gave no metallic derivative. We hope in a later investigation to isolate the highly colored metallic derivative and from it obtain the corresponding saturated hydrocarbon by treatment with moisture. For the present we have confined ourselves to a preliminary study of the acids which are produced by the action of carbon dioxide on the reaction mixture.

---

[1] This paper contains preliminary results obtained in an investigation on "Isolation and Investigation of Thermo-Labile Hydrocarbons Present in Petroleum," listed as Project No. 16 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by the Universal Oil Products Company. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

The Preparation of Acids from Petroleum by the Action of the Alloy and Carbon Dioxide

After the petroleum-ether mixture had been shaken with sodium-potassium alloy for twenty-four hours, dry carbon dioxide was admitted. The gas was absorbed as the mixture was gently agitated and the brown color disappeared. During the absorption of the gas considerable heat was evolved. The excess alloy was decomposed with moist ether and alcohol and the mixture extracted with water. The aqueous layer was then acidified with hydrochloric acid,[6] which precipitated the organic acids as brown, amorphous powders. The details of a typical run are given in the experimental portion of this paper.

In order to determine how much, if any, "naphthenic acids"[7] were extracted from the petroleum by our treatment, we carried out a blank determination. A sample of the petroleum was shaken with alloy in the usual way. Then, instead of admitting carbon dioxide, moist ether was added. This lightened the color at once, presumably due to the decomposition of the metallic derivative by the water thus added. The reaction mixture, after decomposition of the excess alloy with alcohol, was extracted with water in exactly the same way as in the runs in which the acids were prepared. The aqueous solution was then acidified. In the case of the Pennsylvania and Colombia oils only the barest perceptible trace of precipitate was formed. In the case of the Mid-Continent cracking-coil residue a considerable amount of material was present at this point in the blank determination. This material was filtered, dried and weighed. It amounted to 2.5 g. per liter of oil. This is about 11% of the weight of the acid which was obtained when the reaction mixture from the same oil was treated with carbon dioxide.

These experiments, in which the reaction mixture was decomposed with moisture instead of carbon dioxide, serve to prove that the acids which we have prepared from the Pennsylvania and Colombia oils are practically free from naphthenic acids. In the case of the acids from the Mid-Continent cracking-coil residue, however, they were contaminated with about 11% of naphthenic acids. As we have no assurance that our method of purification would eliminate the naphthenic acids, we shall confine our attention in this paper to the acids prepared from the Pennsylvania and Colombia oils.

The crude acids are brown, amorphous solids without sharp melting points and may be mixtures of several compounds. They can be partially

---

[6] It is of some interest that with California and Colombia oils, which are known to contain considerable sulfur, hydrogen sulfide was evolved on acidification of the aqueous layer. Apparently the alloy had removed at least a portion of the sulfur as metallic sulfides. This reaction may be of use in the study of the sulfur compounds of crude oils.

[7] We have used the term "naphthenic acids" to designate acidic material originally present in the oil and not formed by the action of alloy and carbon dioxide on the oil.

purified by solution in sodium carbonate, boiling the solution with decolorizing carbon and reprecipitation with hydrochloric acid. All attempts at further purification have so far failed. The acids could not be crystallized because in contact with organic solvents they formed thick oils. Distillation at 0.01 mm. was unsuccessful as the material decomposed before distilling. The substances contain no nitrogen, halogen or sulfur. (With the acids from the Colombia oil a faint sulfur test was obtained.) They are insoluble in boiling water and only slightly soluble in organic solvents. They dissolve in sodium hydroxide, sodium carbonate and sodium bicarbonate solutions. The samples for analysis were dried in a vacuum over phosphorus pentoxide.

TABLE I

Sample of oil	Condition of treatment	Yield,[a] g. per liter	Color	Melting point, °C.	Yield of "naphthenic acid" in blank run, g. per liter
Pennsylvania Crude[b]	Room temperature	10	Light tan	90–100, dec. at about 150	trace

California Crude[c]	Room temperature	4.5	Light brown	125–130, dec. at about 150	.65
Colombia Crude[c]	Room temperature	17	Tan	110–120, dec. at about 140	trace

[a] Treated at room temperature.

[b] Kindly supplied by the Kendall Refining Company, Bradford, Pa. This oil is from the Bradford Field, near Bradford, Pa., and is obtained from a Devonian sand found at a depth of about 1500 feet.

[c] Kindly supplied by the Standard Oil Company of New Jersey. The cracking coil distillate and residue are from an oil which is a mixture of various Mid-Continent oils. The Mid-Continent Crude is also a composite sample. The California Crude is a so-called Southern California oil of gravity **26.3.** The Colombia Crude is a representative of the tank ship deliveries from Colombia, South America. It has the gravity **27.4.**

Table I summarizes the yield of acids obtained from different oils and the amount of naphthenic acids obtained in the blank determinations.

Analyses and Combining Weight

The acid from the crude Pennsylvania oil was studied in most detail. A number of samples prepared in different experiments were analyzed for carbon and hydrogen. The values for carbon varied between 75 and 77%. An average sample taken from a great many different runs, purified as carefully as possible and dried to constant weight in a vacuum, gave the following analysis which we consider the most significant: C, 76.0; H, 7.3. The combining weight was determined by titration in 50% alcohol solution with sodium hydroxide using a hydrogen electrode; the addition of the alcohol made the "break" somewhat sharper. The acid was dissolved in a known excess of standard alkali, half the volume of alcohol added, and titrated back with hydrochloric acid using the "break" of the titration curve, as determined by the hydrogen electrode, as the end-point. The combining weight thus found was 240 ± 10. The simplest empirical formula for the Pennsylvania acid from the analysis is C_6H_7O; this unit has the molecular weight of 95. Five times this unit would correspond to a dibasic acid with a molecular weight of 475 and a combining weight of 238. Thus the composition and combining weight correspond to an acid with the formula $(C_{28}H_{33}O)(COOH)_2$.

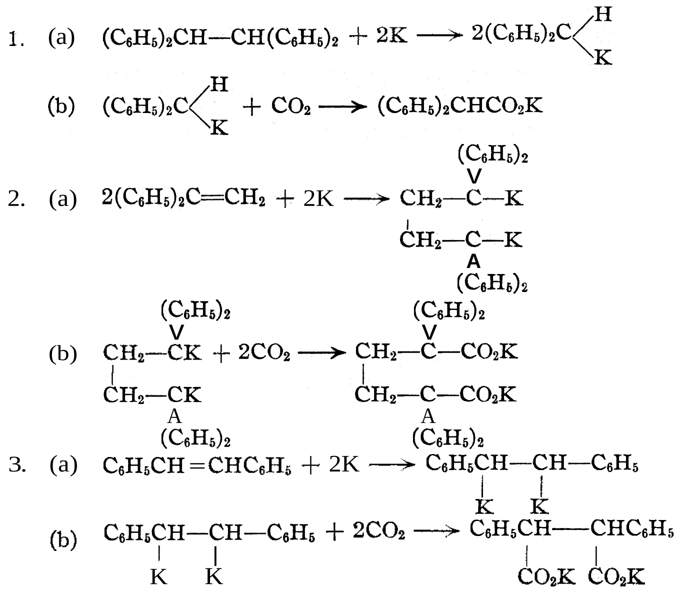
The composition of the Colombia acid was C, 75.8; H, = 8.0; its combining weight was 248. These numbers correspond to a unit $C_{6.3}H_8O$, with the molecular weight of 100. Five times this unit gives a dibasic acid $(C_{30}H_{38}O)(COOH)_2$, with the combining weight of 260.

Because of the insolubility of the acids in the usual solvents we have no direct determinations of their molecular weights. Indeed, considering the tendency of acids to associate in solution, significant molecular weight determinations could only be performed with some derivatives. Attempts to obtain solid esters have so far failed. On treating the Pennsylvania acid with thionyl chloride and then ammonia an amide was obtained as an amorphous solid. It was separated from any unchanged acid by extraction with sodium hydroxide, in which it was insoluble. It was insoluble in all the solvents tried and could not be further purified. The analysis points to an imide of a dibasic acid, but the results are far from conclusive. (Calcd. for $(C_{28}H_{33}O)(CO)_2NH$, N, 3.07. Calcd. for $C_{14}H_{36}CONH_2$, N, 6.0. Found: N, 4.54.)

While one cannot attach much significance to analytical data obtained with substances which are probably mixtures, one or two points are perhaps worthy of discussion. The formulas derived above are at best representative of the mean composition of the mixture. If the acids are mixtures of several isomeric substances, this representation may be very near the ultimate truth in regard to the composition of the components. It is evident that the substances are not aliphatic acids. An acid $C_nH_{2n+1}COOH$ with a combining weight of 256 is $C_{15}H_{31}COOH$. This has the composition C, 75.0; H, 12.5. Both the Pennsylvania acid (H, 7.3) and the Colombia acid (H, 8.0) contain far less hydrogen than an aliphatic acid. If we assume that the fifth atom of oxygen in our acids is a ketonic oxygen then the parent acid is $(C_{28}H_{35})(COOH)_2$ in the case of the Pennsylvania product, and $(C_{30}H_{40})(COOH)_2$ in the case of the Colombia product. These formulas are of the type $C_nH_{2n-21}(COOH)_2$ and $C_nH_{2n-20}(COOH)_2$, respectively. A dibasic acid with two phenyl groups, for example, diphenylsuccinic aid $(C_6H_5CH)_2(COOH)_2$ is of the type $C_nH_{2n-16}(COOH)_2$; with four phenyl groups $[(C_6H_5)_2C]_2(COOH)_2$, the type is $C_nH_{2n-32}(COOH)_2$. It will be evident from this that our acids contain less hydrogen than corresponds to one phenyl group per carboxyl and more hydrogen than corresponds to two phenyl groups per carboxyl. If the assumption were made that the extra atom of oxygen in our acids was linked as an ether, the type formulas would be for the Pennsylvania acid $C_nH_{2n-23}(COOH)_2$ and for the Colombia acid $C_nH_{2n-22}(COOH)_2$, and our tentative conclusion as to the degree of unsaturation of these acids would not be affected.

The inference that our acids contain at least one phenyl group per carboxyl group is substantiated by a consideration of the reactions in which organo-metallic derivatives, capable of yielding acids with carbon dioxide, are formed.[8]

These reactions are as follows



$$1.\ (a)\quad (C_6H_5)_2CH{-}CH(C_6H_5)_2 + 2K \longrightarrow 2(C_6H_5)_2C{<}^{H}_{K}$$

$$(b)\quad (C_6H_5)_2C{<}^{H}_{K} + CO_2 \longrightarrow (C_6H_5)_2CHCO_2K$$

$$2.\ (a)\quad 2(C_6H_5)_2C{=}CH_2 + 2K \longrightarrow \begin{array}{l} \qquad (C_6H_5)_2 \\ \qquad\ \ V \\ CH_2{-}C{-}K \\ | \\ CH_2{-}C{-}K \\ \qquad\ \ A \\ \qquad (C_6H_5)_2 \end{array}$$

$$(b)\quad \begin{array}{l} \quad (C_6H_5)_2 \\ \qquad V \\ CH_2{-}CK \\ | \\ CH_2{-}CK \\ \qquad A \\ \quad (C_6H_5)_2 \end{array} + 2CO_2 \longrightarrow \begin{array}{l} \quad (C_6H_5)_2 \\ \qquad V \\ CH_2{-}C{-}CO_2K \\ | \\ CH_2{-}C{-}CO_2K \\ \qquad A \\ \quad (C_6H_5)_2 \end{array}$$

$$3.\ (a)\quad C_6H_5CH{=}CHC_6H_5 + 2K \longrightarrow \begin{array}{l} C_6H_5\underset{K}{\underset{|}{CH}}{-}\underset{K}{\underset{|}{CH}}{-}C_6H_5 \end{array}$$

$$(b)\quad C_6H_5\underset{K}{\underset{|}{CH}}{-}\underset{K}{\underset{|}{CH}}{-}C_6H_5 + 2CO_2 \longrightarrow C_6H_5\underset{CO_2K}{\underset{|}{CH}}{-\!-}\underset{CO_2K}{\underset{|}{CH}}C_6H_5$$

It will be noted that all of these reactions give rise to phenylated acids. Reactions 1 and 2 yield acids with two phenyl groups per carboxyl group, while Reaction 3 yields acids containing one phenyl group per carboxyl group. In some work with synthetic hydrocarbons of known structure,[9] we have found that while Reaction 1 (cleavage) will not take place unless there are two phenyl groups on each carbon atom, Reaction 2 (dimolecular addition) will take place with compounds of the types $C_6H_5CH{=}CHR$ and $C_6H_5CH{=}CR_2$ (R = alkyl) and yields acids contain-

---

[8] The possibility that the metallic derivatives were formed by the replacement of an active hydrogen atom by metal is removed by the fact that in none of our experiments was there any gas evolved. The amount of acid formed in a typical run of Pennsylvania oil would correspond to the liberation of about 50 cc. of hydrogen; in a typical run of Colombia oil to about 85 cc. of hydrogen. The gas volume in the reaction flask was about 100 cc. Consequently the increase in pressure due to the liberation of such volumes of hydrogen would be easily detected.

[9] Conant and Blatt, THIS JOURNAL 50, 551 (1928).

ing one phenyl group per carboxyl group. Therefore all of these possibilities must be reckoned with in the further study of this problem.

High Temperature Treatment of Pennsylvania Oil

The reaction with sodium-potassium alloy at low temperature in ether is complete in twelve hours, because further treatment failed to yield more material. Furthermore, at even 150° (in the absence of ether, of course) sodium-potassium alloy was without action on a sample of oil which had been put through the low temperature treatment.

Samples of the Pennsylvania oil which had been put through the low temperature treatment with sodium-potassium alloy were pumped free from ether and low-boiling constituents and treated with sodium-potassium alloy in the presence of carbon dioxide at 250". At this temperature two materials are formed, a dark brown, neutral substance insoluble in water and all organic solvents, and the sodium or potassium salt of some acid. The latter material was dissolved in water and the acid precipitated and dried in the same way as the acid from the low temperature runs. The yield in three hours was 10 g. of neutral material per liter of original oil and 3 g. of the acid material. The loss in volatilization during the pumping between the low temperature run and the high temperature run was 25 to 30% of the original oil.

The acid from the high temperature runs was a very dark, amorphous solid with the same intractable properties as the low temperature acids. A carefully purified sample was analyzed and the following numbers were obtained: C, 71.0; H, 5.9. A titration with the hydrogen electrode as the indicator showed a combining weight of 190. The analyses correspond to a unit $C_{4.1}H_{4.1}O$ with the weight of 69. The neutral material was insoluble in all solvents, except acetylene tetrabromide, in which it was slightly soluble on boiling. A certain amount of coloring material could be removed by boiling with ether. The material thus "purified" and dried was analyzed. It contained 15.6% of ash. The carbon and hydrogen analyses after correction for the ash were as follows: C, 85.6; H, 6.9.

It is impossible at present to suggest the nature of the reaction between the oil and the alloy at 250°. Not only may the reactions previously outlined be involved, but in addition dehydrogenation of alicyclic and saturated systems may take place.

Experimental Part

Treatment of Oils with Sodium-Potassium Alloy at Room Temperature

The general directions given for the Pennsylvania crude oil were followed in all the other cases. Consequently details will be given only when there was some variation in the procedure. In every case a sample of 100 cc. of oil, diluted with ether, was shaken first with a solution of sodium carbonate, then with 20% sodium hydroxide, and the alkaline extracts thus obtained were acidified. In no case was there evidence of more than traces of acids or phenols.

Low Temperature Treatment of Pennsylvania Crude with Alloy.[10]—Crude Pennsylvania petroleum was kept at room temperature under a vacuum of 15 mm. until no more

---

[10] The alloy is prepared by melting together under xylene five parts of potassium and two parts of sodium. It is liquid above −10°.

gas was evolved. One hundred cc. of the petroleum thus treated was placed in a 250cc. distilling flask, then 6 cc. of alloy and 50 cc. of dry ether were added. The flask was stoppered, then alternately evacuated and filled with dry, purified nitrogen, through the side arm, five times. After the last filling with nitrogen the side arm of the flask was stoppered and the flask placed on a shaking machine. In the course of the first few minutes of shaking the reaction began and an intense, dark brown precipitate was formed. After twelve hours of shaking, the flask was repeatedly evacuated and filled with pure, dry carbon dioxide until no more was absorbed. The absorption of carbon dioxide was very vigorous and the contents of the flask warmed up almost to the boiling point of ether.

Ordinary ether was now added and the contents of the flask were transferred to a large beaker. The unused alloy was removed, and alcohol and finally water were added. The mixture of oil, ether, alcohol and water separated into layers. The water layer was removed and the ether layer extracted once with a dilute solution of sodium carbonate. The combined aqueous layers were extracted once with ether,[11] heated on the steam-bath to remove ether and alcohol, then boiled down to a small volume.

The resulting dark-brown, aqueous solution of the alkali salts was cooled and extracted twice with alcohol-free ether. The ether was removed from the water layer by an air blast and then the solution was acidified with dilute hydrochloric acid. The crude low-temperature acid was thus obtained as a brown, amorphous solid. It was filtered and dried. One gram of crude acid was obtained.

The acid was purified by solution in dilute sodium carbonate and repeated boiling with bone black. It was finally precipitated with hydrochloric acid, dissolved in dilute sodium hydroxide, filtered, precipitated with hydrochloric acid, filtered, washed with water, then dried. The dry powder was ground to insure homogeneity and dried to constant weight for analysis.

Anal. I. Subs., 0.1137: CO_2, 0.3173; H_2O, 0.0750. II. Subs., 0.1246: CO_2, 0.3472; H_2O, 0.0814. Found: I. C, 76.1; H, 7.4. II. C, 76.0; H, 7.3. Combining weight by titration in 50% alcohol: I. Subs.: 0.2983 g. required 5.99 cc. of 0.2 N NaOH. II. Subs.: 0.2983 g. required 6.37 cc. of 0.2 N NaOH. Found: I, 248; II, 234.

The purified acid softens on heating to 70–80°, and melts at about 100°. It is slightly soluble in the common organic solvents. Qualitative tests show the absence of nitrogen, sulfur and halogen.

When the acid is heated with thionyl chloride and the resulting acid chloride poured into ammonia, an imide is formed. The imide is insoluble in all the solvents tried. For analysis it was purified by extraction with dilute sodium hydroxide, then washed with water and dried.

Anal. Subs., 0.2504: 10.4 cc. of N_2, 28°, 761 mm. Found: N, 4.54.

Blank Run to Determine the Amount of Napthenic Acids Obtained from Crude Pennsylvania Oil.—One hundred cc. of oil was placed in a 250cc. distilling flask, then 6 cc. of alloy and 50 cc. of ether were added. The flask was filled with nitrogen, stoppered and shaken exactly as in the runs to prepare acid. After the shaking was completed the contents of the flask were poured onto moist ether, which discharged the color of the metallic derivative. The succeeding decomposition of excess alloy and extraction of the alkali salts were carried out exactly as in the carbon dioxide runs. On acidifying the alkaline aqueous solution there was only the barest preciptible precipitate.

Mid-Continent Crude Oil.—The yield of crude, dried acids from this oil was 0.5

---

[11] The ether and the oil layers are combined and worked up to recover the oil. This process is described under the high temperature treatment.

g. per hundred cc. In the blank determination, decomposing with moist ether, the acid obtained from 100 cc. of oil amounted to 0.123 g.

The acids obtained by the carbon dioxide treatment were purified by solution in sodium carbonate, filtration to remove traces of non-acidic material and reprecipitation with hydrochloric acid. They were thus obtained as a brown, amorphous powder, free from nitrogen, halogen and sulfur, which, on heating, began to darken and shrivel at about 100°, melted at 120–130°, and decomposed with evolution of gas at about 170°.

Cracking Coil Distillate from Mid-Continent Oil.—This material gave practically no precipitate after shaking with alloy for twelve hours.

Cracking Coil Residue from Mid-Continent Oil.—This sample, a thick brown oil, gave the maximum yield of acids, 2.3 g. per 100 cc. of oil. In the blank determination 0.25 g. of naphthenic acids was obtained per 100 cc. of oil. The crude acids from the carbon dioxide runs were heated twice in carbonate solution with decolorizing carbon, the solution filtered, acidified and the precipitate filtered off and dried.

The purified acids thus obtained were chocolate brown in color and contained no sulfur, nitrogen or halogen. On heating they darkened at about 130°, melted at about 150" and some thirty degrees higher started to decompose with evolution of gas.

California Crude Oil.—On shaking with alloy the oil set to a stiff paste so that in each run it was necessary to use 100 cc. of ether for 100 cc. of oil. When the solution of the alkali salts of the acids was first acidified large amounts of hydrogen sulfide were evolved. The crude acids were purified by solution in alkali, filtration and precipitation with hydrochloric acid. The yield of crude, dry acid was 0.45 g. per 100 cc. of oil. In the blank run 0.065 g. of naphthenic acids per 100 cc. of oil was obtained.

Anal. Subs., 0.01326, 0.01411, 0.01498: CO_2, 0.03643, 0.03851, 0.04090; H_2O, 0.00826, 0.00871. Found: C, 74.95, 74.4, 74.5; H, 6.9, 6.7. Combining weight: Subs., 0.3100 g. required 6.89 cc. of 0.2 N NaOH. Found: 225.

The purified acids, light brown in color, contained neither nitrogen nor halogen. They gave a faint test for sulfur when fused with potassium and treated with sodium nitroprusside, but no color or precipitate with lead acetate. On heating to about 80" the acids began to shrivel and turn dark. At 125–130" they melted and at 140–150° decomposition with evolution of gas began.

Colombia Crude.—This oil, like the California crude, set to a paste on treatment with alloy so that it was necessary to use 100 cc. of ether with each 100 cc. of oil. On acidifying the alkaline solution of the acids for the first time there was much hydrogen sulfide evolved. The yield of crude acids in the carbon dioxide runs was 1.7 g. per 100 cc. of oil. In the blank determination, using the same volume of oil, only a bare trace of naphthenic acids was obtained. For purification the acids were treated in carbonate solution with decolorizing carbon, filtered, precipitated with hydrochloric acid, filtered and dried.

Anal. Subs., 0.1460, 0.1344, 0.1150: CO_2, 0.4068, 0.3730, 0.3175; H_2O, 0.0977, 0.0982, 0.0832. Found: C, 76.0, 75.9, 75.6; H, 7.5, 8.0, 8.0. Combining weight by titration in 50% alcohol: Subs., 0.2840 g. required 6.12 cc. of 0.2 N NaOH. Found: 232.

The acids contained neither nitrogen nor halogen. After fusion with potassium they gave a faint, positive test for sulfur with sodium nitroprusside, but no color or precipitate with lead acetate. They were light tan in color, amorphous and when heated began to shrivel and darken at about 75°. About 50° higher they melted, while at 140° decomposition, with evolution of gas, commenced.

High Temperature Treatment of Pennsylvania Oil with Alloy.—The mixture of oil, ether and alcohol recovered from the low temperature treatment was heated on the steam-bath, at ordinary pressure, then under a vacuum of 15 mm. to remove all low-boiling material and to dry the oil. One hundred cc. of the oil thus prepared, which did not differ in appearance from the crude oil, was placed in a 500cc. flask fitted with an inlet for pure, dry carbon dioxide, a stirrer with mercury seal, and a reflux condenser. Preliminary experiments showed that there was no reaction when the oil was heated to 150° in a current of carbon dioxide, and that there was a reaction at 250° with formation of neutral and acidic products. At 200° there is formation of acidic products but not of neutral products. We have worked at 250°.

The oil, 100 cc. with 10 cc. of alloy, was heated for three hours at 250° in a current of carbon dioxide, cooled, then worked up in a fashion similar to the low temperature runs, save that in the present case the insoluble product was separated by filtration.

The high temperature acid obtained in this fashion was a dark, almost black, amorphous solid. It was purified for analysis by reprecipitation, then dried. The purified material was very dark brown in color.

Anal. I. Subs., 0.2048: CO_2, 0.5336; H_2O, 0.1084. II. Subs., 0.2402: CO_2, 0.6260; H_2O, 0.1284. Found: I. C, 71.0; H, 5.9. II. C, 71.0; H, 5.9.

The acid was moderately soluble in acetone and alcohol, and slightly soluble in ether and benzene. On heating it decomposed at about 200°. Qualitative tests showed the absence of nitrogen, sulfur and halogens.

The neutral product was also dark brown in color. It was insoluble in all solvents tried, except in acetylene tetrabromide in which it dissolved to a small extent and separated as an oil on cooling. For purification it was boiled repeatedly with ether and dried. This material contained a large portion of ash, but no nitrogen or sulfur.

Anal. Ash: 0.1668 gave 0.0260 of non-combustible residue, or 15.6%. Subs., 0.1408 (corrected for ash): CO_2, 0.4419; H_2O, 0.0863. Found: C, 85.6; H, 6.9.

Summary

1. Samples of various crude petroleums and a cracking coil residue were treated with sodium-potassium alloy in dry ether in an atmosphere of nitrogen. Highly-colored metallic derivatives were formed which on treatment with carbon dioxide yielded alkali salts of organic acids. On acidifying the water solution of these salts, complicated mixtures of acids were precipitated.

2. The analysis of the mixed acids from the Pennsylvania and Colombia oils indicated that they contained one aromatic group per carboxyl group. They were free from nitrogen, halogens and sulfur.

3. A sample of the Pennsylvania oil which had reacted completely with the alloy at room temperature yielded alkali salts of acids when heated with the alloy and carbon dioxide at 250°. A considerable amount of amorphous, neutral material was also formed.

THE ACTION OF SODIUM-POTASSIUM ALLOY ON CERTAIN HYDROCARBONS[1]

BY J. B. CONANT[2] AND A. H. BLATT[3]

RECEIVED OCTOBER 31, 1927 PUBLISHED FEBRUARY 4, 1928

We have found that sodium-potassium alloy reacts with various samples of petroleum forming highly colored organometallic compounds. These on treatment with carbon dioxide yield the salts of a mixture of acids.[4] In order to throw more light on this interesting reaction we have studied the action of the alloy on certain pure hydrocarbons which have not been hitherto investigated from this standpoint. The analysis of the mixture of acids obtained from petroleum indicated the presence of one aryl group per carboxyl group. We have therefore turned our attention to two classes of hydrocarbons which might conceivably react with the alloy and carbon dioxide with the formation of acids similar to those obtained by us from petroleum.

Derivatives of Dibenzyl

The first class of substances prepared and investigated were derivatives of dibenzyl which may be represented by the general formula I. We prepared dimethyldiphenylethane ($R=CH_3$), di-isopropyldiphenylethane, ($R= (CH_3)_2CH-$), di-*n*-butyldiphenylethane ($R= C_4H_9$) and di-*tert.*-butyldiphenylethane ($R= (CH_3)_3C-$).

$$C_6H_5\underset{R}{CH}\underset{R}{CH}C_6H_5$$

I

Ziegler has shown[5] that tetraphenylethane ($R = C_6H_5$, Formula I) reacts with sodium-potassium alloy in ether forming the metallic derivative of diphenylmethane [$(C_6H_5)_2CHK$]. Dibenzyl itself does not undergo this reaction.[6] It was, therefore, a matter of considerable theoretical interest, quite aside from the petroleum problem, to see whether or not the derivatives containing alkyl groups would behave like dibenzyl or like tetraphenylethane,

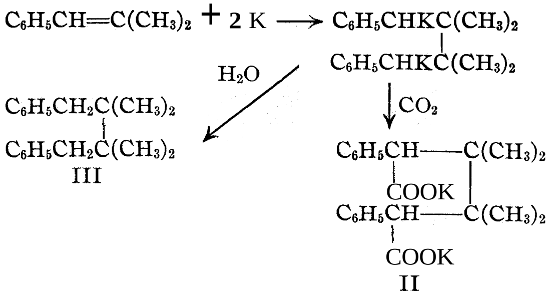
The results were all negative. After shaking the ethane with the alloy in ether in the usual way, more than 90% of the compound was recovered unchanged; there was no color produced and no evidence of a reaction. Even boiling the di-isopropyl and the di-*tert.*-butyl compounds, with the alloy in dioxane was without effect. It may be concluded, therefore, that the metallic compounds formed in the petroleum reaction were not produced as a result of the cleavage of di-aryl-di-alkyl ethanes. It is also evident that even the isopropyl and *tert.*-butyl groups are not equivalent to a phenyl group in increasing the reactivity of tetra-substituted ethanes toward sodium-potassium alloy. Considering the effectiveness of the branched alkyl groups in promoting dissociation in the dixanthyl series,? this is somewhat surprising. Since, however, even a tetra-aryl ethane reacts with sodium-potassium alloy and not with 40 per cent. sodium amalgam we are obviously dealing with about the limits of reactivity which can be estimated by the methods developed in this Laboratory.= Even if the dissociating influence of *sec.* and *tert.*-alkyl groups (as indicated by studies in the dixanthyl series)? is exerted in the tetra-substituted ethanes, a di-aryl di-*tert.*-alkyl ethane might just fall short of reacting with the alloy.

Derivatives of Styrene

Schlenk[8] has shown that unsymmetrical diphenylethylene $(C_6H_5)_2C{=}CH_2$ reacts with the alkali metals with the formation of the compound $(C_6H_5)_2CKCH_2CH_2CK(C_6H_5)_2$, (written as the potassium compound). A similar reaction has not been reported with unsaturated hydrocarbons containing one phenyl group, although Schlenk found that styrene $(C_6H_5CH{=}CH_2)$ reacts very slightly and then polymerizes. Using sodium-potassium alloy in ether we have found that propylstyrene $(C_6H_5CH{=}CHC_3H_6)$ and dimethylstyrene $(C_6H_5CH{=}C(CH_3)_2)$ yield metallic derivatives corresponding to the reaction characteristic of unsymmetrical diphenylethylene. On treatment with carbon dioxide, the salt of a dibasic acid is formed (II); with water a saturated hydrocarbon (III) is produced.



$$C_6H_5CH{=}C(CH_3)_2 + 2\,K \longrightarrow \begin{array}{c} C_6H_5CHKC(CH_3)_2 \\ | \\ C_6H_5CHKC(CH_3)_2 \end{array}$$

$$\begin{array}{c} C_6H_5CHKC(CH_3)_2 \\ | \\ C_6H_5CHKC(CH_3)_2 \end{array} \xrightarrow{H_2O} \begin{array}{c} C_6H_5CH_2C(CH_3)_2 \\ | \\ C_6H_5CH_2C(CH_3)_2 \end{array}\ \text{III}$$

$$\begin{array}{c} C_6H_5CHKC(CH_3)_2 \\ | \\ C_6H_5CHKC(CH_3)_2 \end{array} \xrightarrow{CO_2} \begin{array}{c} C_6H_5CH{-}C(CH_3)_2 \\ |\qquad\quad | \\ COOK\quad | \\ C_6H_5CH{-}C(CH_3)_2 \\ | \\ COOK \end{array}\ \text{II}$$

---

[7] Conant, Small and Sloan, THIS JOURNAL, **48, 1743 (1926).**

[8] Schlenk, *et al., Ber.,* **47,473 (1914).**

The composition of the resulting acids, which have one phenyl group per carboxyl group, is similar to the composition of our petroleum acid. This reaction must, therefore, be considered among the possibilities. It might be noted in this connection that the color of the metallic derivatives is bright red while the compounds from petroleum are nearly black; the only dark metallic derivative that we have met in working with hydrocarbons of known structure is from stilbene. This is an indication (but not proof) that the organometallic compounds from petroleum are of the type

$$\text{Aryl-}\underset{\overset{|}{R}}{C}K\ \underset{\overset{|}{R}}{C}K\text{-aryl}$$

The hydrocarbon formed by the action of water on the reaction mixture from dimethylstyrene is tetramethyldibenzylethane (III above). It is a representative of a class of substances—the hexa-alkyl-ethanes—of which very few representatives are known. (The benzyl group is essentially a primary alkyl group.) We have been very anxious to prepare members of this class as we believe that if the alkyl groups are branched the hydrocarbons will be reactive and tend to disproportionate on heating. We are now investigating the action of the alloy on di-isopropylstyrene with the hope of preparing dibenzyl-tetra-isopropylethane.

Sodium potassium alloy is without action on di-benzyl-tetramethylethane (III) as would be expected since there are only primary groups attached to the ethane carbon atoms.

The results of the analyses of the hydrocarbons and certain of the acids were very irregular when the combustion was performed in the usual way. The percentages of both carbon and hydrogen were low. That the difficulty lay with the analysis and not with the purity of the compounds was shown by the irregularities with a given sample and by the fact that repeated crystallization from varied solvents was without effect. After repeated trials it was found possible to obtain results which were only 1 to 1.5% low in carbon. This was accomplished by burning the sample mixed with a large amount of copper oxide wire much as a Dumas nitrogen determination is carried out. In spite of these somewhat unsatisfactory analyses, the formulas of the compounds have been established without doubt. The hydrocarbons were shown to contain no nitrogen, sulfur or halogen and were not changed by boiling with zinc and acetic acid.. The molecular weights of all the substances were determined by the micro method using camphor. The formulas we have assigned are the only ones possible on the basis of these molecular weights and the analytical data. Our difficulties with the analyses seem to be connected with predominance of methyl groups in the compounds. It seems probable that methane (or formaldehyde) was formed in the combustion tube and escaped further oxidation.

Experimental

Preparation of the Carbinols

The phenyl alkyl carbinols were prepared by a uniform procedure. Benzaldehyde (in one case acetaldehyde) was added to an excess of the appropriate Grignard reagent, cold and free from excess magnesium. After standing overnight the reaction mixture was decomposed with ice and a slight excess of sulfuric acid, the ether layer separated and the aqueous layer extracted once with ether. The combined ether layers were washed with water, sodium carbonate, then water and dried over sodium sulfate. After removing the ether on the steam-bath, the residual material was distilled under reduced pressure. The yields given are based on the amount of aldehyde employed.

Phenylmethylcarbinol.[9]—Forty-four grams (1.0 mole) of acetaldehyde was added to the Grignard reagent (1.2 moles) prepared from 28.8 g. of magnesium, 190 g. of bromobenzene and 600 cc. of ether. The product boiled at 110–111° at 28 mm.; yield, 97 g. or 80%.

Phenyl*iso*propylcarbinol.[10]—Seventy-four grams (0.7 mole) of benzaldehyde was added to the reagent (1.0 mole) from 24 g. of magnesium, 130 g. of isopropyl bromide and 500 cc. of ether. The resulting carbinol boiled at 101–104° at 7 mm.; yield, 87 g. or 83%.

Phenylbutylcarbinol.[11]—Eighty-five grams (0.8 mole) of benzaldehyde was added to the reagent from 24 g. of magnesium, 100 g. of butyl chloride and 500 cc. of ether. The product boiled at 129–130° at 13 mm.; yield, 112 g. or 85%.

Phenyl-*tert*.-butylcarbinol.[12]—One hundred and twenty-seven grams (1.2 moles) of benzaldehyde was added to the reagent prepared from 72 g. of magnesium and 324 g. of *tert*.-butyl chloride and 1 liter of ether. On distillation the product boiled over a wide range but all the material which came over above 95° at 7 mm. solidified promptly in the receiving flasks. The yield was 118 g.; 60%. There was considerable residue which did not distil at a pressure of 7 mm. and bath temperature of 220°.

Preparation of the Bromides

The bromides were obtained by passing dry hydrogen bromide into the carbinols, which were kept cold by means of an ice-bath. Two layers soon formed: an upper one of organic bromide, a lower one of saturated aqueous hydrobromic acid. The reaction mixture was transferred to a separatory funnel, the lower layer drawn off, the organic bromide then placed in a beaker containing fused sodium sulfate and left in a desiccator over potassium hydroxide until free from hydrogen bromide. Finally, the product was distilled *in vacuo*.

The purity of the bromides was controlled by Volhard analyses for bromine. A weighed sample of bromide was boiled for two hours with an excess of halogen-free sodium methylate then acidified with nitric acid. From this stage the regular Volhard procedure was followed.

All of the bromides were lachrymators.

Phenylmethylbromomethane.[13]—From 63 g. of carbinol there was obtained 70 g. of bromide, boiling at 92–94° under 8 mm.; yield, 74%.

Phenylisopropylbromomethane, $C_6H_5CHBrCH(CH_3)_2$.—Seventy-five grams of carbinol gave 68 g. of bromide, boiling at 116–119° at 17 mm.; yield, 64%. Calcd. for $C_{10}H_{13}Br$: Br, 37.6. Found: Br, 37.9.

Phenylbutylbromomethane, $C_6H_5CHBrC_4H_9$.—From 96 g. of phenylbutylcarbinol was obtained 96 g. of the bromide; boiling point 120–123° at 10 mm.; yield, 70%. Calcd. for $C_{11}H_{15}Br$: Br, 35.2. Found: Br, 34.2.

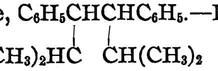
Phenyl-*tert*.-butylbromomethane.[12a]—From 65.6 g. of carbinol there was obtained 50 g. of the bromide, boiling point 106–112° at 9 mm.; yield, 55%.

Preparation of the Ethanes

The ethanes were prepared by adding a solution of the bromide in anhydrous ether (500 cc. ether per mole of bromide) to magnesium turnings, in the usual fashion of preparing a Grignard reagent. After the addition the solution was boiled for one and one-half hours, then cooled in an ice-bath while anhydrous cupric chloride (one mole per mole of bromide) was added. At this stage a vigorous reaction took place. The reaction mixture was left overnight, then decomposed with ice and hydrochloric acid, the ether layer separated, the aqueous layer extracted once with ether and the combined ether extracts were washed with water, carbonate solution, then water and dried over calcium chloride. On concentrating the ether the ethane was obtained.

Diphenyldimethylethane.[12a,13a]—From 74 g. of phenylmethylbromomethane, 9.6 g. of magnesium, 200 cc. of ether and 53 g. of anhydrous cupric chloride there was obtained 8.3 g. of ethane; yield, 20%. Considerable amounts of the oily isomer were formed at the same time. For use in the cleavage tests the ethane was crystallized four times from alcohol; m. p. 124–125'.

Diphenyl-di-isopropylethane,



$C_6H_5CH(CH(CH_3)_2)CH(CH(CH_3)_2)C_6H_5$

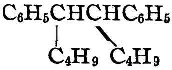
.—From 42.6 g. of phenyl-*iso*propylbromomethane, 4.8 g. magnesium, 100 cc. of ether and 27 g. of cupric chloride there was obtained 8 g. of the ethane; yield, 30%. The material is moderately soluble in cold ether and ethyl acetate, only slightly soluble in cold ethanol and acetic acid. It was purified by two crystallizations from glacial acetic acid, followed by a find crystallization from ethanol. From all of these solvents the ethane separates in very fine, white needles which melt at 150–150.5°.

Anal. Calcd. for $C_{20}H_{26}$: C, 90.2; H, 9.8. Found: C, 88.1; H, 9.7.

Mol. wt.: subs., 0.0138: camphor, 0.1359; depression, 15.5°. K = 40,000. Calcd. for $C_{20}H_{26}$: mol. wt., 266. Pound: 262.

---

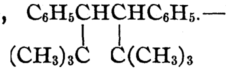
[13] (a) Radziszewski, *Ber.*, 7, 142 (1874); (b) Engler and Bethge, *Ber.*, 7, 1126 (1874).



Diphenyl-di-n-butylethane, $C_6H_5\underset{C_4H_9}{CH}\underset{C_4H_9}{CH}C_6H_5$.—Much difficulty was encountered in securing this ethane as a solid since small amounts of phenylamylene formed in the course of its preparation prevented crystallization. On evaporation of the ether after working up the reaction mixture an oil was invariably obtained. This was subjected to steam distillation, which removed the phenylamylene. The residue from the steam distillation when taken up in petroleum ether (2040°) and repeatedly evaporated gave a mushy solid mixed with oil. The solid and oil were separated by means of a sintered glass filter and the solid was then left on a porous plate. Finally it was crystallized from ethanol until it had a sharp and constant melting point at 80°. The yield of crude material dried on porous plate is small, about 10%. Once free from oil the ethane is only slightly soluble in alcohol, moderately soluble in ethyl acetate and quite soluble in ether.

Anal. Calcd. for $C_{22}H_{30}$: C, 89.8; H, 10.2. Found: C, 88.4; H, 10.6.

Mol. wt.: subs., 0.0280; camphor, 0.2838; depression, 13°. Calcd. for $C_{22}H_{30}$: mol. wt., 294. Found: 305.



Diphenyl-di-*tert.*-butylethane, $C_6H_5\underset{(CH_3)_3C}{CH}\underset{C(CH_3)_3}{CH}C_6H_5$.—From 45.4 g. of phenyl-*tert.*-butylbromomethane, 4.8 g. of magnesium, 125 cc. of ether and 27 g. of cupric chloride there was obtained 7 g. of the ethane, a yield of 24%. The ethane is moderately soluble in ether, only slightly soluble cold in ethanol, acetic acid and ethyl acetate. For use in the cleavage tests it was twice crystallized from glacial acetic acid, then once from ethyl acetate: stout prisms, on very slow crystallization rectangular plates; m. p. 180–181°.

Anal. Calcd. for $C_{22}H_{30}$: C, 89.8; H, 10.2. Found: C, 88.7; H, 10.2.

Mol. wt.: subs., 0.0171; camphor, 0.1588; depression, 14°. Calcd. for $C_{22}H_{30}$: mol. wt., 294. Found: 308.

Treatment of the Ethanes with Alloy

In each experiment 0.0005 mole of purified ethane, 10 cc. of ether ("absolute" ether dried over phosphorus pentoxide, then sodium potassium alloy) and 1 cc. of alloy were sealed in glass tubes under nitrogen. After shaking for forty-eight hours and then standing for an additional 120 hours there was no evidence of reaction. The tubes were opened in an atmosphere of carbon dioxide, moist ether was added and the excess alloy removed. After the addition of water, the resulting ether layer and alkaline aqueous layer were worked up separately. In each case the ethane was recovered and its identity proved by a melting point and mixed melting point. With the dimethylethane 75% of the material was recovered, with the di-isopropylethane, 80%. In the cases of the di-*n*-butyl- and di-*tert.*-butylethanes, the recovery was over 90%. There were no acidic products formed.

Finally the di-isopropyl- and the di-*tert.*-butylethane were heated with alloy in dioxane at the boiling point of the solvent for ten minutes. No color developed and over 90% of the ethanes were recovered unchanged.

Action of Sodium-Potassium Alloy on Mono- and Di-alkyl Substituted Styrenes

a–Phenylamylene (7-Propylstyrene).[14]—The ethylene was prepared from phenylbutylbromomethane by boiling with sodium methylate solution. From 100 g. of crude bromide there was obtained 50 g. of α-phenylamylene, b. p. 212–215".

α,α′-Diphenyl-β,β′-dipropyladipic Acid.—When the alloy (5 cc.) is added to the phenylamylene (7.3 g.) there is no reaction. On addition of dry ether, 150 cc., there is immediate formation of a thin film of cherry-red metallic derivative over the surface of the alloy. The reaction mixture was sealed off under an atmosphere of purified nitrogen and shaken for twenty-four hours, then dry carbon dioxide admitted until the color of the metallic derivative disappeared.

Moist ether was next added and the excess of alloy removed. Finally water was added and the alkaline solution thus obtained was extracted twice with ether and heated on the steam-bath to remove dissolved ether. On cooling and acidifying with hydrochloric acid the organic acid separated as a white, slimy mass. It was dissolved in ether, the ether dried, concentrated and petroleum ether added. From this mixture the acid crystallized in small white cubes. These were purified by crystallization from alcohol. The melting point of the acid is 278°, uncorrected.

Anal. Calcd. for $C_{24}H_{30}O_4$: C, 75.4; H, 7.85. Found: C, 74.9; H, 8.0.

Phenyldimethylethylene and Alloy.—The ethylene was first prepared according to the procedure of Tiffeneau.[15] It is more convenient to heat the alcohol and oxalic acid in a flask fitted with a wide glass tube, 50 cm. long, at such a temperature that the water formed distils out of the top of the condenser. After the water has been removed, the temperature rises and anhydrous oxalic acid begins to sublime into the condenser. At this point the dehydration is complete.

α,α′ - Diphenyl - β,β,β′,β′ - tetramethyladipic Acid, $C_6H_5CH(COOH)C(CH_3)_2$-$C(CH_3)_2CH(COOH)C_6H_5$.—When the alloy (2 cc.) is added to 3.2 g. of the ethylene there is no reaction. Upon the addition of ether the formation of a cherry-red metallic derivative starts at once. The reaction mixture was shaken under nitrogen for thirty-six hours, then decomposed with dry carbon dioxide and worked up in the usual manner. From the alkaline layer over 2 g. of acid was obtained. The ether layer yielded a small amount of neutral material (see below—decomposition with water).

The acid was purified by crystallization from ether-petroleum ether, when it was obtained as white crystals melting at 238–240° with evolution of gas. For analysis it was vacuum dried at 80°.

Anal. Calcd. for $C_{22}H_{26}O_4$: C, 74.6; H, 7.34. Found: C, 73.6; H, 7.5.

Mol. wt.: subs. 0.0101; camphor, 0.1113; depression, 10.5°. Calcd. for $C_{22}H_{26}O_4$: mol. wt., 354. Found: 346.

Dibenzyltetramethylethane, $C_6H_5CH_2C(CH_3)_2C(CH_3)_2CH_2C_6H_5$.—A mixture of 3.2 g. of ethylene, 3 cc. of alloy and 150 cc. of dry ether was shaken in an atmosphere of nitrogen for seventy-two hours, then decomposed with moist ether. On working up the ether layer there was obtained 2.2 g. of neutral material, identical with that found in small amounts in the carbon dioxide run. The neutral material was purified by crystallization from alcohol, from which it separated in fern-shaped aggregates of very fine, white needles, melting at 131–132°. For analysis it was dried in *vacuo* at 80°.

Anal. Calcd. for $C_{20}H_{26}$: C, 90.2; H, 9.8. Found: C, 89.0; H, 9.85.

[15] Tiffeneau, *Ann. chim.*, [8] 10, 365 (1907).

Mol. wt.: subs., 0.0090; camphor, 0.0893; depression, 15°. Calcd. for $C_{20}H_{26}$: mol. wt., 264. Found: 263.

Dibenzyltetramethylethane is very soluble in ether, moderately soluble in alcohol and ethyl acetate. It is unaffected by treatment with sodium-potassium alloy in dioxane at 100°. On heating 0.133 g. of the substance with alloy in dioxane at the boiling point for ten minutes no color was developed and on working up the products over 90% of the ethane was recovered unchanged.

Summary

1. Sodium-potassium alloy was found to be without action on diphenyldimethylethane, diphenyldibutylethane, diphenyl-di-isopropylethane and diphenyl-di-*tert.*-butylethane. The last three hydrocarbons are new.

2. Propylstyrene and dimethylstyrene add sodium and potassium alloy and undergo condensation. By the action of carbon dioxide derivatives of adipic acid were formed. The action of water on the metallic compound from dimethylstyrene yielded a hexa-alkyl ethane (dibenzyltetramethylethane).

THE SYNTHESIS OF α,β,γ-TRIMETHYLGLUTARIC ACID

BY FRANCIS EARL RAY

RECEIVED NOVEMBER 7, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

In 1913 Noyes and Littleton[1] studied the decomposition of the methyl ester of *iso*-aminocamphonanic acid with nitrous acid. The only product isolated was the cis-camphonololactone. Later Noyes and Skinner[2] studied the same reaction and fractionated the decomposition products under reduced pressure. The fraction boiling at 86–88° (21 mm.) contained unsaturated acids. It was saponified and submitted to oxidation with alkaline permanganate, giving an acid which lost carbon dioxide at its melting point and supposedly formed α,β,β-trimethylglutaric acid.

Dr. Friedrich Richter in revising Beilstein's "Handbuch" found that α,β,β-trimethylglutaric acid had been previously obtained by Balbiano[3] and synthesized by Perkin and Thorpe[4] and kindly called Professor Noyes' attention to the oversight. The α,β,β-trimethylglutaric acid had a melting point of 88–89°. In view of this discrepancy, it seems evident that the acid melting at 111° obtained by Noyes and Skinner was not the α,β,β trimethylglutaric acid.

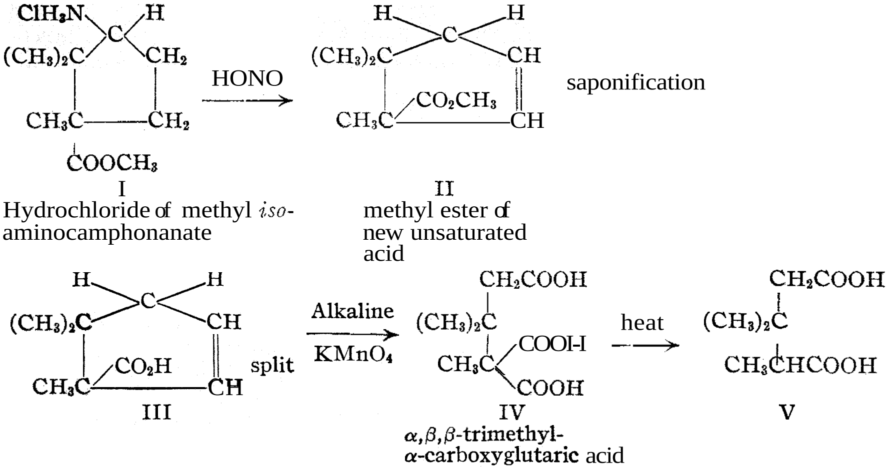
[4] Perkin and Thorpe, J. *Chem.* SOC., 75, 65 (1899).

The formation and constitution of the compound obtained by Noyes and Skinner was explained by the following reactions



I Hydrochloride of methyl *iso*-aminocamphonanate

II methyl ester of new unsaturated acid

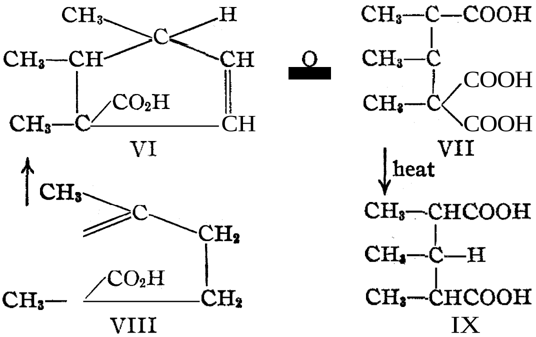
III

IV α,β,β-trimethyl-α-carboxyglutaric acid

V

Discussion

It was thought possible, therefore, that the reaction involved a rearrangement similar to the shift of the methyl group observed in the formation of lauronolic acid, which was also obtained in this decomposition and isolated in a higher-boiling fraction. If a migration of one of the gem methyl groups to the adjacent primary carbon atom occurs during the decomposition with nitrous acid, the compound VI might be formed. On this assumption oxidation would give α,β,γ-trimethyl-α-carboxyglutaric acid, VII, which would split off carbon dioxide and give α,β,γ-trimethylglutaric acid, IX. A shift of the double bond in lauronolic acid, VIII, might also give VI.



VI

VII

VIII Lauronolic acid

IX

A search of the literature failed to reveal the previous synthesis of α,β,γ-trimethylglutaric acid and its preparation was accordingly undertaken.

An attempt was made to prepare it by the Knoevenagel[5] reaction, which involved condensing 1 mole of acetaldehyde with 2 moles of malonic ester and then methylating the product in the a and γ positions. On hydrolysis with 1–1 hydrochloric acid, α,β,γ-trimethyl-α,γ-dicarboxyglutaric acid was obtained. This melted at 190° with decomposition. The liquid obtained by heating to split off carbon dioxide did not solidify and seemed by the wide range of its boiling point to be a mixture.

Other condensations tried were acetaldehyde and cyano-acetic ester, acetaldehyde and aceto-acetic ester, ethylidene chloride and cyanoacetic ester and ethylidene malonic ester and malonic ester. From all of these the tetracarboxylic acid was obtained but on decomposition the desired glutaric acid could not be isolated.

It was thought that the symmetrical character of the molecule militated against its successful decomposition. Accordingly, the attempt was made to prepare a derivative of an unsymmetrical nature. It might be supposed that such an acid would melt (with evolution of carbon dioxide) at a lower temperature than the tetracarboxylic acid and so avoid the profound change that seemed to take place when an attempt was made to split off carbon dioxide from the tetrabasic acid.

The synthesis adopted was as follows: ethylmethylacetic acid was prepared from malonic ester in the usual manner. This was brominated, and esterified and then unsaturated by boiling with quinoline. Cyanoacetic or malonic ester was condensed with this unsaturated ester by means of sodium ethylate. The product so obtained was methylated and hydrolyzed by prolonged boiling with potash. The α,β,γ-trimethyl-a-carboxyglutaric acid so obtained melted with evolution of carbon dioxide at 144° and the α,β,γ-trimethylglutaric acid, after repeated recrystallization, melted at 134°. A mixed melting point determination with Dr. Skinner's acid melted at 95–100".

It seems, therefore, that the acid obtained by Noyes and Skinner was not α,β,γ-trimethylglutaric acid.

Dr. Richter has also called attention to an α,α,β-trimethylglutaric acid prepared by Perkin and Thorpe,[6] which has a melting point of 112°. The supposed α,β,β acid of Noyes and Skinner melted at 111°. The similarity of melting points suggested the preparation of the α,α,β compound. The acid obtained was not fully purified but on comparison with the compound supplied by Dr. Skinner by a mixed melting point, the two were found to be identical. Dr. Skinner in a private communication has expressed the opinion that during the decomposition of the α,β,β-trimethyl-a-carboxyglutaric acid, one of the β methyl groups migrates to the a position, forming α,α,β-trimethylglutaric acid.

X XI

Experimental Part

Ethylidene **Dimalonic** Ester.—One hundred and sixty g. of malonic ester and 22 g. of acetaldehyde, both freshly distilled, were mixed and cooled to 0°. Five g. of **diethylamine** was added slowly with stirring and the mixture allowed to stand overnight. It was heated for five to six hours and then twice distilled; b. p. 200–210° (20 mm.), 170-175" (1 mm.), yield 18–20 g.

α,β,γ-Trimethyl-α,γ-dicarboxyglutaric Ester.—The above-mentioned product was added to 2.6 g. of sodium dissolved in 28 cc. of absolute alcohol and then treated with 16 g. of methyl iodide. After heating for three to four hours on the water-bath the alcohol was distilled off and the ester extracted and distilled; b. p. 190–195° (2–3 mm.), yield about 5 g. Considerable tar always remained in the flask after the distillation.

α,β,γ-Trimethyl-α,γ-dicarboxyglutaric Acid.—Five g. of the ester was boiled over the free flame with 25 cc. of 1–1 hydrochloric acid for twenty-four hours. The tar was removed by filtration and the filtrate on concentration deposited the crystalline acid. After one recrystallization from alcohol it melted sharply at 190°.

Anal. Subs., 0.0414: 6.34 cc. of 0.1 *N* alkali. Calcd. for $C_{10}H_{14}O_8$: 6.34 cc. Subs., 0.0933: CO_2, 0.1585; H_2O, 0.0541. Calcd. for $C_{10}H_{14}O_8$: H, 5.38; C, 45.79. Found: H, 5.4; C, 46.3.

0.8662 g. of this tetracarboxylic acid was heated to 190–200° and the products were aspirated through calcium chloride and soda lime. After twenty-five minutes the weight of the carbon dioxide bulb became constant and showed a gain of 0.2750 g. or 31.75%; theoretical, 33.6%.

The liquid residue was boiled with a few drops of 1–1 hydrochloric acid to destroy any anhydride formed but no crystals were obtained on evaporation of the ether extract. On distillation the product boiled over a range of 142–180°. It was evidently a mixture of various products.

Bromo-ethylmethylacetic Acid.—Ethylmethylacetic acid was prepared from malonic ester in the usual manner. Fifty g. was obtained. One hundred and twenty g. of phosphorus pentachloride and 80 g. of bromine were used to brominate the acid. It was then esterified, washed and distilled. Ninety g. boiling at 75–80" (25 mm.) was obtained.

Tiglic Ester.—The bromo ester was boiled with 65 g. of quinoline for two hours and allowed to stand overnight. The unsaturated tiglic ester was decanted and distilled; yield, 35 g. boiling at 100° (30 mm.).

Condensation of Tiglic Ester **and Cyano-acetic** Ester.—Ten g. of tiglic ester and 15 g. of cyano-acetic ester were boiled with 0.25 g. of sodium in 4 cc. of absolute alcohol for eight hours. The mass was then poured into ice-cold, acidulated water, extracted, dried and distilled; yield 8 g. boiling at 150–170° (30 mm.).

Methylation of **β,γ-Dimethyl-α-cyanoglutaric** Ester.—This product was methylated by 0.7 g. of sodium dissolved in 15 cc. of absolute alcohol and 5 g. of methyl iodide. After extraction and distillation 6 g. of α,β,γ-trimethyl-α-cyanoglutaric ester was obtained boiling at 140–150° (1–2 mm.).

α,β,γ-Trimethyl-α-carboxyglutaric Acid.—The ester was hydrolyzed with 10 g. of potash dissolved in 10 cc. of water. It was heated on the water-bath and the evolved ammonia collected in acid. After forty-eight hours only about 50% of the theoretical amount of ammonia had been evolved. It was then boiled over a small flame for sixteen hours until over 90% of the calculated ammonia had been collected and no further appreciable amount was given off. Two methods of isolating the free acid were used with about equal success. The first consisted in acidifying and extracting with ether and the second in preparing the barium salt by adding a concentrated solution of barium chloride to the alkaline solution of the acid. The barium salt, which is less soluble in hot than in cold solution, was washed with hot water, acidified with hydrochloric acid, dried and extracted with alcohol. The extracts from both procedures on spontaneous evaporation were clear, colorless sirups which crystallized after standing for several days. It was difficult to find a suitable solvent for recrystallization, After many experiments a mixture of benzene and acetone was used. It was generally necessary to allow the solution to stand overnight before crystals were deposited. After several recrystallizations the acid melted at 144–145° with decomposition.

Anal. Subs., 0.0063: Ag, 0.0038. Calcd. for silver salt: 60.1. Found: 60.3. Subs., 0.0222: 2.55 cc. of 0.1 N alkali. Calcd. for $C_8H_{14}O_4$: 2.54.

α,β,γ-Trimethylglutaric Acid.—The a-carboxy acid, in a test-tube immersed in an oil-bath, was heated at 150–160° for twenty minutes to split off carbon dioxide. On cooling the mass solidified and after ten recrystallizations from benzene the melting point was raised from 107 to 134°.

Condensation of Tiglic Ester with **Malonic** Ester.—In a manner precisely similar to the foregoing 20 g. of tiglic ester was condensed with 30 g. of malonic ester and the product methylated; boiling point 181° (25 mm.).

Anal. Subs., 0.1093: H_2O, 0.0870; CO_2, 0.2412. Calcd. for $C_{15}H_{26}O_6$: H, 8.61; C, 60.0. Found: H, 8.83; C, 60.1.

The ester was hydrolyzed with concentrated potash but the acid did not crystallize. It was distilled to split off carbon dioxide and the anhydride so formed was hydrolyzed by warming with a few drops of dilute hydrochloric acid. On evaporation α,β,γ-trimethylglutaric acid melting at 134° was obtained.

α,α,β-Trimethylglutaric Acid.—This acid was prepared according to the methods given by Perkin and Thorpe.[4] The acid after twelve recrystallizations melted at 103–104°. Lack of material prevented its further purification. A mixture of approximately equal amounts of this α,α,β-trimethylglutaric acid and of Dr. Skinner's acid melted at 105°.

Conclusion

It seems probable that α,α,β-trimethylglutaric acid is formed from α,β,β-trimethyl-α-carboxyglutaric acid by a shift of one of the 8-methyl groups to the α position upon loss of carbon dioxide, as Dr. Skinner suggests.

The writer wishes to express his sincere appreciation to Professor W. A. Noyes for the help and encouragement received during the progress of this investigation which was conducted in the latter's laboratory at Urbana, Illinois.

Summary

The decomposition of the methyl ester of *iso*-aminocamphonanic acid with nitrous acid gives a fraction boiling at 86–88' (21 mm.), which consists of unsaturated acids. On saponification and oxidation of this ma-

terial with alkaline permanganate and loss of carbon dioxide an acid was obtained by Noyes and Skinner which was thought to be α,β,β-trimethylglutaric acid.

The possibility of this acid being α,β,γ-trimethylglutaric acid has been eliminated by the synthesis of this compound and direct comparison with a sample of the original acid. The α,β,γ- is a new acid and completes the trimethylglutaric acid series.

It has been shown also that the compound obtained by Noyes and Skinner is α,α,β-trimethylglutaric acid.

LOCAL ANESTHETICS DERIVED FROM JL-PIPERIDYL CARBINOL

BY L. T. SANDBORN[1] WITH C. S. MARVEL

RECEIVED NOVEMBER 10,1927 PUBLISHED FEBRUARY 4, 1928

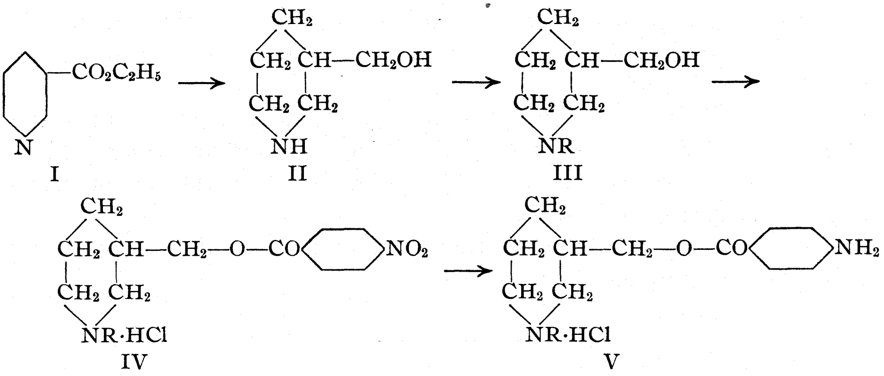
Some of the molecular structures which produce local anesthetic action are very well known. Numerous compounds have been prepared in the attempt to find the best combination of high anesthetic value and low toxicity which is desirable for this type of drug. The earlier synthetic substitutes for cocaine were usually esters of cyclic amino alcohols; then with the discovery of novocaine the esters of open chain amino alcohols became more important. Recently McElvain[2] has shown that in a series with very closely related structures the closed ring derivatives are much more efficient in anesthetic action.

In connection with some other researches, a method for the preparation of 8-piperidyl carbinol (II) was developed. The fact that it was a cyclic amino alcohol at once suggested its use for the synthesis of a compound which should have local anesthetic action. The very favorable properties which were shown by this substance led to a more complete study of the derivatives of β-piperidyl carbinol with a view to producing a drug that might have properties better than any of those now available. @-Piperidyl carbinol was obtained in about 43% yields by the reduction of ethyl nicotinate (I) with sodium and absolute alcohol. It was also obtained in 50% yields by a similar reduction of ethyl nipecotate, but the difficulties involved in the preparation of nipecotic ester make the former method more practical. It has the properties that would be expected of an amino alcohol of this type.

---

[1] This communication is an abstract of a thesis submitted by L. T. Sandborn in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[2] McElvain, THIS JOURNAL, 46, 1721 (1924).



The common local anesthetics are p-aminobenzoates of tertiary amino alcohols. 0-Piperidyl carbinol (a secondary amino alcohol) was therefore first alkylated on the nitrogen by treatment with an alkyl halide. The N-alkyl derivatives (III) obtained were the methyl, ethyl, isopropyl, *n*-butyl and allyl compounds. All of the alkyl derivatives boiled very close to the original carbinol and there was some difficulty on this account in obtaining them in a pure condition. The scheme finally adopted for their purification was to titrate the mixture of alkylated and unalkylated carbinol with standard acid and to obtain a mean molecular weight. From this value the amount of unalkylated carbinol was calculated. Then enough benzoyl chloride was added to react with the secondary amine to form the benzoyl amide. The alkylated carbinol was then extracted from this mixture with dilute acid, reprecipitated with alkali and extracted with benzene. An attempt was made to purify the carbinols by converting them to the hydrochlorides and crystallizing these derivatives. The salts were too hygroscopic for easy crystallization.

The N-alkyl-0-piperidyl carbinols were converted to the *p*-nitrobenzoyl ester hydrochlorides (IV) by the action of p-nitrobenzoyl chloride. The nitro ester hydrochlorides were reduced to the corresponding amino ester hydrochlorides (V) with hydrogen in the presence of a platinum-oxide platinum black catalyst.[3] This process could not be used on the allyl derivative and reduction with iron and hydrochloric acid was tried. The reduced product was not isolated in a crystalline condition either as a free base or as a salt.

Pharmacological Tests[4]

A 1% solution of the monohydrochloride of each amino ester was used. The toxicity was determined by intravenous injection in rabbits and the

---

[3] Adams and Shriner, THIS JOURNAL, 45,2171 (1923).

[4] The pharmacological tests were performed by H. J. Cannon at the Abbott Laboratories. The authors desire to take this opportunity of expressing their thanks to the Abbott Laboratories for their kind assistance in this investigation.

onset time and duration of anesthesia by application to the cornea of a rabbit's eye.

TABLE: I

PHARMACOLOGICAL PROPERTIES

Alkyl carbinol	Average onset time in min.	Average duration of anesthesia in minutes	Minimum lethal dose in mg. per kg. of body weight
Methyl	2	25	15
Ethyl	1.5	4,550	16
Isopropyl	3.5–3.75	30–35	16
n-Butyl	1.75	25-30	15

These pharmacological properties compare very favorably with those of the local anesthetics now in common use.

Experimental Part

β-Piperidyl Carbinol.—In a 5-liter two-necked, round-bottomed flask fitted with a large bore condenser and a mechanical stirrer, was placed 800 cc. of absolute alcohol (dried with sodium or magnesium methylate) and 45.3 g. (0.3 mole) of ethyl nicotinate. The solution was stirred and heated to boiling over a flame. The flame was then removed and 92 g. (4 atoms) of sodium was added through the condenser as rapidly as possible.

In our experiments several rather characteristic color changes were noticed during the reduction. A green color appeared when the first portion of sodium was added. This color then quickly disappeared and the mixture turned yellow. At this point moderate foaming occurred. As the reaction continued, there was a gradual change in color from yellow to reddish brown and then back to light yellow. With this last change the sodium, which was usually in fairly large pieces up to this stage, melted and was broken up into fine globules which were suspended in the alcohol. A vigorous reaction set in, foaming occurred and it was often necessary to cool the flask with wet towels to prevent loss of material through the condenser. On the other hand, if this vigorous reaction did not set in by the time all of the sodium had been added, the flask was heated until it did occur. Occasionally it was necessary to add a 100-cc. portion of absolute alcohol to keep the sodium ethylate in solution.

The reaction mixture was heated for about a half hour after the sodium had dissolved and was then cooled to room temperature. About 250 cc. of water was added to decompose the sodium ethylate and the alcohol was removed by distillation under reduced pressure. When the solution became quite concentrated another 50 cc. of water was added and distillation continued until all of the alcohol was removed. The strong sodium hydroxide solution containing the β-piperidyl carbinol was extracted with five 500-cc. portions of ether. The ether was distilled off and the residual amino alcohol was distilled under reduced pressure. The yield was 14–15 g. (4043% of the theoretical amount) of a product which is a thick, viscous oil; b. p. 106–107° (3.5 mm.); d_4^{20} = 1.0263; n_D^{20} = 1.4964; M_D, calcd., 32.74; observed, 32.69.

Anal. Subs., 0.1853: H_2O, 0.1908; CO_2, 0.4254. Calcd. for $C_7H_{18}ON$: H, 11.45; C, 62.61. Found: H, 11.52; C, 62.61.

In a similar way 47.1 g. of ethyl nipecotate in 450 cc. of absolute ethyl alcohol was reduced with 46 g. of sodium to give 17–19 g. (49–55% of the theoretical amount) of β-piperidyl carbinol.

General Procedure for the Preparation of **N-Alkyl-β-piperidyl Carbinols.**—In a 500-cc. three-necked, round-bottomed flask, fitted with a reflux condenser, a mechanical stirrer and a separatory funnel, was placed 23 g. (0.2 mole) of β-piperidyl carbinol dissolved in 100 cc. of benzene, and 0.1 mole of alkyl bromide or iodide dissolved in about 75 cc. of benzene was added through the separatory funnel. With methyl iodide, ethyl iodide and allyl bromide the reaction went rapidly and heat was liberated. The reaction mixture was then stirred at room temperature for about eight hours to complete the reaction. When isopropyl bromide or *n*-butyl bromide was used the reaction was much less vigorous and the reaction mixture was stirred and heated on the steam cone for about five hours. During the mixing of the halide and the amine, a gummy material consisting of a mixture of the hydrochlorides of β-piperidyl carbinol and the N-alkyl-β-piperidyl carbinol separated from the solution.

When the reaction was complete, the mixture was made strongly alkaline by the addition of 30% sodium hydroxide solution. The benzene layer was separated and the aqueous layer was extracted with two 100-cc. portions of benzene. The benzene was distilled and the residue distilled under reduced pressure. A sample of the distillate was titrated with standard acid to determine the mean molecular weight of the mixture of alkylated and unalkylated carbinol. Then sufficient benzoyl chloride was added to the benzene solution of this mixture to react with the unalkylated material to form an amide. After standing for a few hours to allow complete reaction to occur, the N-alkyl-β-piperidyl carbinol was extracted from the benzene with dilute hydrochloric acid solution. The N-alkyl carbinol was then liberated as the free base by the addition of sodium hydroxide solution and was extracted with two 100-cc. portions of benzene. The benzene was distilled off and the residue then distilled under reduced pressure. The average yield of the alkylated carbinol was about 60% of the theoretical amount. The physical properties and analyses of the N-alkyl-β-piperidyl carbinols are given in Table II.

TABLE II

PROPERTIES AND ANALYSES OF N-ALKYL-β-PIPERIDYL CARBINOLS

Alkyl group	B. p., °C.	d_4^{20}	n_D^{20}	M_D, calcd.	M_D, obs.	Subs. g.	Cc. of 0.1116 N HCl	% N, calcd.	Found

Preparation of the **N-Alkyl-β-piperidyl *p*-Nitrobenzoate** Hydrochlorides.—To 0.1 mole of N-alkyl-β-piperidyl carbinol dissolved in 100 cc. of benzene in a 500-cc. two-necked flask, fitted with a reflux condenser and a mechanical stirrer, was added 0.15 mole of *p*-nitrobenzoyl chloride. The mixture was heated on the steam cone and stirred for three hours, during which time a gummy mass separated. About 200 cc. of water containing a little hydrochloric acid was added and the benzene layer was separated. The water layer was extracted with two 100-cc. portions of ether and then made alkaline by the addition of cold sodium hydroxide solution. The oily *p*-nitrobenzoic acid ester which separated was collected in ether and the ether solution acidified with alcoholic hydrogen chloride. The nitro ester hydrochlorides usually separated as gummy solids and were purified by crystallization from absolute alcohol. The yields were about 50% of the theoretical amount. The properties of the compounds are indicated in Table III.

TABLE III

PROPERTIES AND ANALYSES OF THE N-ALKYL-β-PIPERIDYL CARBINOL *p*-NITROBENZOATE HYDROCHLORIDES

Alkyl group	M. p., °C. (corr.)	Subs., g.	Cc. of 0.09744 *N* $AgNO_3$	Empirical formula	Cl, calcd.	Cl, found
Methyl	187–190	0.1598	5.13	$C_{14}H_{19}N_2O_4Cl$	11.27	11.09
Ethyl	194–195	.1537	4.83	$C_{15}H_{21}N_2O_4Cl$	10.79	10.86
Isopropyl	196–200	.1566	4.62	$C_{16}H_{23}N_2O_4Cl$	10.34	10.19
n-Butyl	197–198	.1537	4.36	$C_{17}H_{25}N_2O_4Cl$	9.94	9.80
Allyl	186–187.5	.1491	4.5	$C_{16}H_{21}N_2O_4Cl$	10.41	10.43

Preparation of the N-Alkyl-p-piperidyl Carbinol *p*-Aminobenzoate Hydrochlorides.—To a solution of 0.05 moles of the nitro ester hydrochloride in 200 cc. of absolute alcohol was added 0.25 g. of platinum oxide catalyst[3] and then this mixture was treated with hydrogen at about two atmospheres' pressure. The pressure gage indicated that the theoretical amount of hydrogen was absorbed in ten minutes but the reducing conditions were maintained for about forty-five minutes. The mixture was filtered to remove the catalyst and the alcoholic solution was concentrated under reduced pressure to about 75 cc. About 300 cc. of dry ether was added and the solution was cooled in an ice-salt bath. A gummy solid separated which was obtained crystalline by recrystallization from alcohol-ether mixtures. These crystals were usually slightly yellow. The color could not be removed by treating the alcoholic solution with decolorizing carbon (Norit) but by treating a second time with hydrogen in the presence of the platinum catalyst, white or only slightly yellowish products were obtained. In every case a considerable amount of gummy material which could not be crystallized was obtained. The average yield of crystalline material was about 45% of the theoretical amount. The physical properties and analyses of the products are listed in Table IV.

TABLE IV

PROPERTIES AND ANALYSES OF THE N-ALKYL-β-PIPERIDYL CARBINOL *p*-AMINOBENZOATE HYDROCHLORIDES

Alkyl group	M. p., °C. (corr.)	Subs., g.	Cc. of 0.0999 *N* $AgNO_3$	Empirical formula	Cl, calcd.	Cl, found

Summary

1. Methods for the preparation of β-piperidyl carbinol and its N-alkyl derivatives have been devised.
2. The *p*-aminobenzoate hydrochlorides of these alkyl carbinols have been prepared.
3. Pharmacological tests show that these aminobenzoyl ester hydrochlorides have relatively low toxicity and strong local anesthetic action.

STUDIES IN AUTO-OXIDATION. I. CYCLOHEXENE PEROXIDE. (PRELIMINARY COMMUNICATION)[1]

BY H. N. STEPHENS

RECEIVED NOVEMBER 18, 1927 PUBLISHED FEBRUARY 4, 1928

'She formation of peroxides, or moloxides, as intermediate products in auto-oxidation processes was suggested almost simultaneously, in 1897, by the theory of Bach[2] and that of Engler and Wild.[3] Although in some cases experimental confirmation of their views has not been as specific as might be desired, their fundamental ideas have grown in favor up to the present time. In numerous cases of substances undergoing auto-oxidation, tests characteristic of peroxides have been obtained, but in nearly all cases the isolation of the particular substances responsible for these tests has not been realized. One notable exception is offered by the intermediate product in the oxidation of benzaldehyde, which was recently isolated by Jorissen and Van der Beek.[4] Although this substance, benzoyl hydroperoxide, had been known for some years,[5] previous attempts to isolate it in the auto-oxidation of benzaldehyde had resulted in failure.

In the case of substances containing the ethenoid linkage, the isolation of intermediate peroxides has presented still more difficulty, and repeated failures by various investigators to isolate these products have gradually strengthened the view that the primary auto-oxidation products are unisolable. Substances which corresponded in empirical composition to peroxides have been isolated by Engler and Frankenstein[6] and Staudinger[7] but in neither case were the characteristic reactions of peroxides shown. According to Staudinger, his product was formed from the monomolecular peroxide by polymerization, through oxygen-to-oxygenlinkages, to a product of indefinitely large molecular weight.

For complete confirmation of the theory of peroxide formation, it is, of course, necessary to isolate the primary intermediate products, and with this end in view the present research was started about four years ago. In choosing an unsaturated hydrocarbon for use as a starting material the main requisites were simplicity of structure and reasonable activity toward gaseous oxygen and it was found that cyclohexene fulfilled the

latter requirement to a greater extent than the simple, open chain hydrocarbons.

Continuous bubbling of oxygen through this hydrocarbon was obtained by means of a circulator previously described by the writer.[8] By this means exposure of a fresh surface of liquid was assured at all times. Oxidation was carried out at room temperature under an average pressure of about 1 atmosphere of oxygen and the duration of experiments varied between one and four months.

The crude product of oxidation in each case showed only a faint yellow coloration and its viscosity varied with the time of oxidation. It was at once noted that the liquid gave a pronounced peroxide reaction but it was evidently a mixture containing a considerable amount of unchanged cyclohexene. After distilling the latter off under reduced pressure, a sirupy residue was obtained from which it was attempted to separate the peroxide. After several unsuccessful attempts it was found that the liquid showed very little tendency to decompose on moderate heating, so distillation under very low pressures was attempted. By using a pressure of about 0.5 mm., it was found that even early in the distillation a peroxide test was given by the distillate. By following the intensity of the color produced by one drop of the distillate with 2 cc. of titanic sulfate solution, the fraction richest in peroxide was secured and this submitted to further fractional distillation. Finally a liquid was obtained which boiled, under 0.5 mm. pressure, at 54–56°. The quantities of this liquid, obtained from various experiments, were always very small, the largest amount being approximately 6 g. This latter amount was the product from 800 g. of cyclohexene which had been oxidized over a period of four months.

Cyclohexene peroxide is a colorless, mobile liquid with a pungent odor strongly reminiscent of oxidizing substances such as ozone, nitrogen pentoxide, hypochlorous acid, etc. It has a corrosive action on the skin, which manifests itself after contact for only a few seconds. If allowed to remain on the skin for some time, it produces burns which take several days to heal. The peroxide colors titanic sulfate solution instantly, liberates iodine from acidified potassium iodide and decolorizes indigo solution; in brief, it behaves as a typical organic peroxide. Analysis of the peroxide gave values as follows.

Anal. Calcd. for $C_6H_{10}O_2$: C, **63.16;** H, 8.77. Found: C, **63.26, 63.22; H.** 8.88, **8.86.**

A molecular weight determination in benzene, by the Maass modification of the Beckmann cryoscopic method,[9] gave a value of 119, while the theoretical value is 114. Determination of active oxygen iodimetrically was unsatisfactory, as the liberated iodine apparently reacted with the reduc-

---

[9] Maass, *Trans. Roy. Soc. (Canada) 13,* Sec. iii, 97 (1919).

tion product. Reduction with stannous chloride also failed to give the expected results but the values obtained by the latter method were concordant. Analysis of three different samples of peroxide gave values corresponding to 78.7 – 79.8% of the theoretical amount of active oxygen. The agreement between these different analyses must indicate either a constant amount of impurity or a constant amount of side reactions during reduction. The latter does not seem very plausible, as one would expect slight variations in technique to cause variations in the extent of side reactions.

The analytical values for carbon and hydrogen require that any impurity present have the same composition as the peroxide and there are two possible ways of accounting for the existence of such an impurity. First, polymerization or some similar reaction may take place in the vapor phase and the impurity may thus be carried over into the distillate. Second, if we accept the existence of two modifications of the peroxide,[10] one labile and one stable, we might assume that their boiling points were so close together as to render them inseparable by distillation. The possibility of the existence of two forms of cyclohexene peroxide is one which will be studied in this Laboratory in the near future.

The other possibility, that of polymerization, is one which has already been investigated in a preliminary way. After each fractionation of cyclohexene peroxide, it was noticed that a considerable residue of sirupy liquid remained which could not be distilled. An examination of the empirical composition of this liquid showed it to be practically identical with the peroxide.

Anal. **Calcd. for** $C_6H_{10}O_2$: C, 63.16; H, 8.77. **Found:** C, 63.17, 62.58; H, 8.46, 8.53.

Determination of the molecular weight in benzene as above, gave a value of 215, whereas $(C_6H_{10}O_2)_2$ requires 228. It seems probable, then, that at the temperature of distillation, two molecules of peroxide may combine, by polymerization or condensation, to form a product or products of the same empirical composition. It is rather interesting to note, in passing, that Harries[11] obtained two ozonides of cyclohexene, only one of which was distillable.

In examining further the sirupy liquid obtained from the peroxide, it was found that, although it produced no coloration of titanic sulfate at room temperature, except after long contact, a strong color developed on heating the mixture. As the substance is very slightly soluble in water, the function of the heat may be to increase the solubility or to cause the dissociation of an unstable polymer. If this product were a single substance, formed from two molecules of peroxide, it would be expected that one peroxide group would be left as such and therefore one would ex-

---

[10] Staudinger, *J. prakt. Chem.*, 85, 330 (1912).

[11] Harries, *Ann.*, 410, 25–26 (1915).

pect to find $^1/_2$ the amount of active oxygen required by the monomolecular form. The actual value obtained was 34% instead of 50% but, as will be brought out in detail in later papers, there are possible reactions which would use up active oxygen without changing the empirical composition and there is no reason for believing the sirupy liquid to be the product of a single reaction. However, the existence in the product of a considerable proportion of a substance having peroxide properties seems to point to the possibility of a condensation of two molecules of the simple peroxide, in which one peroxide group is left as such. This would involve an entirely different type of reaction from that postulated by Staudinger to account for his polymeric peroxide.

Investigations in this field are being extended along a number of different lines and further communications will be published in the near future.

Summary

1. For the first time, a true peroxide has been isolated as a product of auto-oxidation of an unsaturated hydrocarbon. Thus, specific confirmation has been obtained for the Bach-Engler interpretation of the action of oxygen on the ethenoid linkage.

2. Evidence has been obtained which shows that there is a tendency for two molecules of peroxide to combine, forming a new substance with peroxide properties.

A PREPARATION METHOD FOR BENZOPHENONE

BY GREGG DOUGHERTY

RECEIVED DECEMBER 5, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction and Discussion

It is well known that simple carboxylic acids yield hydrocarbons to a greater or less extent when they are heated with finely divided metals, particularly copper and nickel.

$$R{-}\overset{\overset{O}{/\!/}}{C}{-}O{-}H \longrightarrow R{-}H + CO_2$$

In the case of aliphatic acids the reaction is usually difficult to effect. Acetic acid, for example, when heated with copper at 390–411°, gives mainly acetone and when nickel is used as the catalyst a considerable portion of the acid is decomposed into complex carbonaceous substances.[1] With aromatic acids the decomposition is usually easier but frequently, as with benzoic acid and nickel,[2] the reaction temperature is so high that the resulting hydrocarbons are largely transformed into other substances.

---

[1] Sabatier and Senderens, *Ann. chim. phys.*, [8] 4, 467 (1905).

[2] Sabatier and Mailhe, *Compt.* rend., 159, 217 (1914).

It has been found that this process of eliminating carbon dioxide from an acid can be used to advantage in the preparation of benzophenone from o-benzoylbenzoic acid.

$$C_6H_5—C(=O)—O—C_6H_4—C(=O)—O—H \longrightarrow C_6H_5—C(=O)—C_6H_5 + CO_2$$

The yields, 80–90% of the theoretical, exceed the average of those obtained by the Friedel and Crafts synthesis, in which benzene and benzoyl chloride react in the presence of aluminum chloride, by about 10%. Furthermore o-benzoylbenzoic acid, which is the intermediate in the synthetic anthraquinone process, is manufactured on a large scale and should be obtained without difficulty. It can also be prepared easily and inexpensively from phthalic anhydride, benzene and aluminum chloride.[3] This reaction goes nearly to completion, 95–97%, so that the yield of benzophenone based on the phthalic anhydride is still somewhat better than that obtained when benzoyl chloride and benzene are used, and the cost of the materials is much less.

When o-benzoylbenzoic acid is heated alone to about 300° some carbon dioxide is eliminated and benzophenone can be detected among the products. The yield, however, is negligible. The catalysts which accelerate the reaction most efficiently are metals such as copper, nickel, iron and the o-benzoylbenzoic acid salts of these metals. It is not necessary that the metals be particularly finely divided as they go into solution in the acid, and the only apparent advantage in having a fine state of subdivision is to increase the rate of solution. The preferred catalysts are finely divided copper and the copper salt of o-benzoylbenzoic acid. The latter is easily made by adding a copper sulfate solution to a solution of the sodium salt of the acid, washing, filtering and drying the precipitate at 110°. The velocity of the reaction increases with the amount of catalyst used, but too large a quantity causes inconvenience in getting out the product. It has been found that a satisfactory ratio is **1-3** g. of copper, or an amount of the copper salt of o-benzoylbenzoic acid containing an equivalent weight of copper, to 100 g. of the acid. In the presence of these catalysts carbon dioxide elimination begins at about 150° and increases as the temperature rises until 306° is reached, when the reaction mixture begins to boil. The speed of the reaction below 200° is too slow for practical purposes and above 280° there is decomposition, the formation of anthraquinone and unidentified tarry substances. The optimum temperature range is about 250–270°.

Preparation Procedure

Three hundred grams of pure o-benzoylbenzoic acid was placed in a distilling flask with a low side tube. To this was added 20 g. of the copper salt of the acid. The flask was fitted with a mechanical stirrer

---

[3] Cain, "The Manufacture of Intermediate Products for Dyes," Macmillan and Co., London, 1918, p. 240.

arranged through a mercury seal, and a thermometer the bulb of which was immersed in the liquid when the material melted. The mixture was heated with stirring; carbon dioxide evolution was appreciable at 200°, and it was allowed to escape through the side tube of the flask and to bubble through water, which gave an indication of the progress of the reaction. The temperature was allowed to rise and was maintained at 260° until carbon dioxide evolution ceased (about four hours). It is necessary to continue until the carbon dioxide evolution has completely stopped. If a distillation is attempted before this point, a considerable quantity of anthraquinone is formed, which contaminates the product. The stirrer was taken from the flask, a short air condenser attached to the side tube and the thermometer raised out of the liquid as for distillation. The crude benzophenone was distilled over until the drops of distillate became dark in color; the weight of this crude product was 209 g., 86.6% of the theoretical. One crystallization from 95% alcohol gave pure benzophenone, m. p. 47-48', in an amount corresponding to 82-84% of the theoretical based on the o-benzoylbenzoic acid. The crystallization may be replaced by distillation in a vacuum.

Summary

A method for the preparation of benzophenone has been described.

THE ACTIVE PRINCIPLES OF THE POSTERIOR LOBE OF THE PITUITARY GLAND.[1] I. THE DEMONSTRATION OF THE PRESENCE OF TWO ACTIVE PRINCIPLES. II. THE SEPARATION OF THE TWO PRINCIPLES AND THEIR CONCENTRATION IN THE FORM OF POTENT SOLID PREPARATIONS

BY OLIVER KAMM, T. B. ALDRICH, I. W. GROTE, L. W. ROWE AND E. P. BUGBEE

RECEIVED DECEMBER 31, 1927 PUBLISHED FEBRUARY 4, 1928

Introduction

The manifold physiological activities of extracts of the posterior lobe of the pituitary gland are now well known; namely, their effect in stimulating uterine contractions (oxytocic activity), their ability to raise the blood pressure (pressor activity), and their diuretic-antidiuretic effects (renal activity). These three types of activity have led the way to three definite and important medical applications; these are illustrated respectively by the use of pituitary solutions in obstetrics, in the treatment of surgical shock, and in the control of diabetes insipidus.

---

[1] Presented before the Detroit meeting of the American Chemical Society, September, 1927.

On the other hand, chemical information concerning the physiologically active constituents of pituitary extracts is rather meager; in fact it has not been shown definitely whether the above enumerated pharmacological activities are due to a single chemical substance (hormone) or to the presence of several different compounds. The American investigators, and this is true especially of the Johns Hopkins and the U. S. Hygienic Laboratory groups, have defended the evidence favoring a single active principle, whereas the English workers have argued for two or three principles, while the Germans at one time claimed the separation of even a larger number.

Our own work has been directed towards the isolation of the active principle (or principles) in pure form in the hope that something might be learned concerning its chemical nature. Assuming the presence of a single hormone, it is obvious that the same result will be attained irrespective of the particular method chosen for analysis. In our own experience the pressor assay method is capable of an accuracy of 10%, the oxytocic assay method of 10 to 20%, while the diuretic method is scarcely adapted to quantitative work. Because of its greater accuracy we adopted the pressor assay method and proceeded with the concentration of the active principle.

As a result of a new method of manipulation to be described presently, we succeeded in preparing a very potent product—in fact when this fraction was tested by the pressor assay method it appeared to be many times as potent as the very active product reported by Abel, Rouiller and Geiling,[2] although an accurate comparison could not be made. However, when this potent product was subjected to an accurate assay by the oxytocic method it was found that most of the smooth-muscle-stimulating principle had disappeared—either it had been eliminated in the fractionation process or it had been destroyed. Accordingly the work was repeated and all fractions, residues and solutions normally discarded were carefully reexamined. As a result an efficient method was developed for the separation of the pressor from the oxytocic activity.

This illustrates the necessity of applying more than one quantitative assay method in any attempt at fractionation and concentration of extracts of the posterior lobe—a requirement that has been disregarded by most workers in this field. However, in demonstrating the presence of more than one active principle it is necessary not merely to obtain fractions that differ from each other when subjected to two or more methods of assay (since this result might be due to the partial injury of a single active principle), but it is necessary to obtain complete quantitative evidence to demonstrate that a separation can be effected, and by recombining the fractions in the original proportions it should be possible to obtain again a pituitary solution indistinguishable from the original, thus proving that

---

[2] Abel, Rouiller and Geiling, *J. Pharmacol.*, 22, 289 (1923).

no injury of any active principle has taken place. This is exactly what we have done and, in addition, by continuing our fractionation process, we have effected the first substantially complete separation of two principles. Our diuresis experiments on rabbits seem to indicate that the diuretic principle is the same as the pressor principle, thus eliminating one of the complicating possibilities. In addition, we have obtained both principles (oxytocic and pressor) in highly potent form as solid preparations although not yet in crystalline condition. No definite chemical information is available at the present time concerning the chemical nature of these principles but they appear to be basic in character. For this reason we have designated them as alpha- and beta-hypopharnines[3] (amines derived from the hypophysis).

Historical Part

The pressor action of extracts of the pituitary gland was discovered by Oliver and Schafer[4]; and later Howell" and Schafer and Vincent%-ere able to demonstrate that the pressor action is confined to the posterior lobe.

The Epinephrine Theory.—Since epinephrine (adrenaline) was the most active pressor compound known to occur in the animal organism, it was logical to suspect that pituitary extracts owe their blood-pressure-raising effect to an action on the suprarenal glands, whereby an increased amount of epinephrine is discharged into the circulation, or that a compound similar to epinephrine or that epinephrine itself occurs in the pituitary gland. In spite of the fact that Dale[7] had concluded in 1909 that epinephrine and the active principle of the posterior lobe are two different substances, the epinephrine theory was not readily abandoned; in fact, as recently as 1916 Watanabe and Crawford[S] concluded that "pituitary extracts when prepared by certain methods, yield color reactions which would suggest the presence of epinephrine or an epinephrine-like compound."

The Histamine Theory.—In 1919 Abel and Kubota[g] isolated histamine from a quantity of whole pituitary gland and on the basis of their chemical and pharmacological studies concluded that "histamine is the plain-muscle-stimulating and depressor constituent of the posterior lobe of the pituitary gland. The physiological and chemical evidence in favor of identity of

[3] These products are already being manufactured for experimental clinical use a-Hypophamine is being supplied under the trade name of Oxytocin (designating quick birth) and β-Hypophamine under the trade name Vasopressin (designating elevation of blood pressure). They were first supplied for clinical use in August, 1927.

[9] Abel and Kubota, *ibid.,* 13,243–298 (1919).

the two principles coincide at every point." A separate pressor principle of minor importance was also recognized.

The claims of Abel and Kubota were promptly and effectively disproved by Dudley[10] in a masterly piece of experimental work. Histamine is stable towards alkali; it is unacted upon by trypsin; it is soluble in boiling chloroform but not readily extracted from acid solutions by butyl alcohol. The pituitary uterine stimulant exhibited exactly the opposite behavior in each one of these tests. In a subsequent paper by Abel and Nagayama[11] the Histamine Theory was withdrawn.

The Single versus the Multiple Hormone Theories.—In addition to the three primary physiological responses that have been obtained by the administration of pituitary extracts (oxytocic, pressor and renal activities) a number of additional effects have been reported, as for example the melanophore action, the galactagog action, the effect on coagulability of the blood, the effect on intestinal peristalsis, inhibition of gastric secretion, mydriasis, etc. It was natural therefore to consider the possibility of the presence of a variety of active principles and such a possibility has not been overlooked by the earlier workers.

Schafer and Vincent[12] showed that pituitary extracts contain a depressor as well as a pressor substance, and as early as **1900** Osborne and Vincent[13] called attention to the fact that the central portion of the posterior lobe appeared to contain more activity than the periphery. Herring[14] and more recently, Hogben and De Beer,[15] have sought to trace the active principles to physiologically distinct parts of the posterior lobe.

Führer[16] in **1913** claimed to have isolated four crystalline principles from the posterior lobe but this work has never been verified by others.[17] It is likely that these crystalline fractions consisted of inorganic salts containing in admixture appreciable and variable amounts of physiologically active material.

Not only did Dudley[10,18] overthrow the "histamine theory," but he went farther and offered evidence suggesting the presence of more than one active principle. By means of butyl alcohol extraction of dilute aqueous pituitary solutions, Dudley was able to secure what appeared to be a partial separation of the oxytocic and pressor activities, although considerable decomposition took place.

[18] **Dudley, J.** *Pharmacol.*, **21,** 103 (1923).

In contrast to the claims of Fühner, Guggenheim[19] offered evidence in favor of the unitarian theory. He found that the various physiological activities of pituitary extracts (the vasomotor, respiratory and oxytocic) are all destroyed equally readily upon exposure to alkali.

Since 1920 Abel and his co-workers have been the enthusiastic advocates of the unitarian theory. Although they refer to three products, A, B and C derivable from the posterior lobe, the latter two, a histamine-like substance and histamine itself, appear in animal extracts of all kinds. However, in respect to Compound A they concluded[20] that "the infundibulum contains but one active specific substance, or hormone, and that this in its uninjured state is not only a blood-pressure-raising but also a plain-muscle-stimulating substance." Their most recent publication[2] states that "we therefore conclude that all the evidence at hand is greatly in favor of our belief that the oxytocic?, pressor, diuretic and respiratory activities referred to above are properties of one and the same substance."

The wealth of evidence presented in favor of the unitarian nature of Compound A is almost incontrovertible. Subjected to four different agencies, namely, heat, tryptic digestion, hydrochloric acid decomposition and alkaline hydrolysis, both the pressor and oxytocic activities disappeared as in the decomposition of a single compound. Finally, even more convincing evidence is claimed in the statement that in their highly purified products the pressor, oxytocic and diuretic activities stand in the same relationship as in an ordinary pituitary extract.

Recently Smith and McClosky[21] demonstrated the parallel destruction of the oxytocic and pressor activities by heat and thus claimed to have affirmed the evidence advanced by Abel in favor of chemical unity. Finally, in a study "On the Dialysis of the Physiologically Active Constituents of the Infundibulum" the same workers[22] summarized the situation thus: "The identical diffusion rate of the oxytocic, pressor and renal activities present in infundibular extracts argues in favor of their chemical identity, and confirms the view held by Abel and his collaborators on this matter."

The controversy between Dudley and Abel has been submitted to analysis by Hogben, Schlapp and MacDonald,[23] and although these investigators were not disposed to regard Abel's preparation as a pure homogenous substance, they likewise stated that "we cannot regard Dudley's conclusions as fully established until his fractions have been standardized by a method of comparison such as we here propose."

[23] Hogben, Schlapp and MacDonald, *Quart. J. Exp. Physiol.*, 14,315 (1924).

In subsequent publications by Schlapp[24] and more recently by Draper[25] an account is given of a successful repetition of Dudley's experiment and an additional new method is presented by Schlapp in support of the multiple hormone theory. "By producing precipitates of lead sulfide in extracts by the passage of sulphuretted hydrogen gas through suitable concentrations of lead acetate all the active principles are to some extent absorbed. But the quantity of pressor and melanophore substance absorbed exceeds that of oxytocic absorbed by a significant amount."

Dreyer and Clark[26] as well as Fenn[27] have considered the melanophore stimulant as a separate principle but according to Schlapp[24] there is insufficient quantitative evidence that the pressor and melanophore responses are due to distinct substances.

It has been suggested that several pressor principles are present in posterior lobe pituitary extracts. Crawford[28] was primarily interested in the concentration of this type of activity but even in 1916 when he was still investigating the possibility of the presence of epinephrine he suggested that "in pituitary extracts there must be one or two depressor compounds, and one or more pressor compounds." Dudley[LY] has also presented evidence suggesting the presence of a second pressor principle.

The present status of the work on the isolation of the active principles of the posterior lobe is thus expressed by Dudley:[29] "I am driven, therefore, to the conclusion that Abel and Rouiller's preparation, like my own, contained at least three, and possibly more, active substances mixed with an unknown quantity of inert material."

"My conclusion, I am aware, shows the prospect of isolating the pituitary active principles in a far less encouraging light than theirs; but the experience of the past few years has given me so strong an impression of the difficulties entailed in the search for this group of extremely active, unstable substances, present in relatively minute proportions in the scarce and costly material of the posterior lobe of the pituitary gland, that I feel it a duty to make clear, for the benefit of other workers on the subject, my own reading of the facts at present available."

General Discussion

In reading over the extensive experimental work that has been reported in connection with the search for the active principle (or principles) of the posterior lobe of the pituitary gland one is impressed by the great number of uncorrelated experiments. For this reason we shall attempt to present

only the essential parts of our work but we shall endeavor to describe our experiments in sufficient detail so that the results can readily be duplicated.

Obviously it will be impossible to present here the hundreds of kymograph charts upon which our work is based even if it were desirable to do so. We can assure the reader, however, that none of our assays are based upon one or two contractions of a muscle in comparison with a standard solution or upon one or two blood-pressure readings. Samples submitted for assay were treated as unknowns and often checks were required from two workers. A brief account of the assay methods is given below.

Fortunately there is now available from the U. S. Bureau of Chemistry a Standard Powdered Pituitary Product and all oxytocic results can be expressed in terms of this standard. The official Solution of Pituitary of the Pharmacopeia of the United States represents in each cc. the activity derived from **3** mg. of this standard powder. The potency of this solution may be expressed in terms of International Units,[30] each cc. being equivalent to 10 International Oxytocic Units. It follows, therefore, that one milligram of the U.S.P. Standard Powdered Pituitary is equal to 2 International Units of oxytocic activity.

In all of our work we refer to the U.S.P. Standard Powdered Pituitary as possessing a potency of 100%. A product, therefore, that is reported as 1000% is 10 times as potent as the U.S.P. standard and contains 20 Units per milligram.

A Pressor Standard

The Pharmacopeia fixes only an oxytocic standard and obviously this would be sufficient if all of the activity of pituitary extracts were due to a single principle, as has been supposed by several of the leading investigators. In view of the fact that we have definitely separated two principles, the need of a Pressor Standard becomes apparent.

In working with fairly fresh pituitary glands we find that there is a surprising constancy in the relative amounts of pressor and oxytocic activities present in the gland, and indeed it is this constancy that has aided in promulgating the ideas of a single principle.

For the present we propose that the pressor standard be expressed also in terms of the U.S.P. Standard Powdered Pituitary Product, one milligram of this powder being considered as containing 2 Pressor Units. The official solution of pituitary would therefore be designated as containing 10 International Units of Oxytocic activity and also 10 Pressor Units.

In the subsequent work we shall refer to the U.S.P. Standard Powdered Pituitary as possessing a pressor potency of 100%. A fraction, therefore, that is reported by us as 5000% is fifty times as potent as the U.S.P. standard and contains 100 Pressor Units per milligram.

The Oxytocic Assay Method

The oxytocic method of assaying pituitary solution depends upon the measurement of the contraction caused in a strip of uterine muscle when it is immersed in Locke's solution to which has been added some of the solution to be tested. This method was first suggested by Dale and Laidlaw.[31] The apparatus consists of a water-bath in which a temperature of 37.5° is maintained by an electric heating unit controlled by a thermostatic regulator. Partly immersed in the water-bath stands a vertical tube of about 150 cc. capacity marked at the 100cc. level. Locke's solution, previously heated to 37.5°, is run into the vertical tube up to the 100cc. level through a small tube near the lower end. The Locke's solution may be drained off conveniently through a second small tube in the lower end of the vertical tube. Air is bubbled slowly through the Locke's solution from a small glass tube which enters the upper and open end of the vertical tube and extends down almost to the bottom of the solution. The extreme tip of the air tube is bent into a hook shape. This hook furnishes a convenient place for the attachment of one end of a strip of muscle. A thread is attached to the other end of the muscle and in turn is attached to a light lever which bears against the smoked paper of a kymograph. In this way the contractions and relaxations of the muscle are recorded on the smoked paper. The most satisfactory uterine muscles are taken from virgin guinea pigs weighing from 200 to 250 g. Two strips are obtained from each guinea pig.

In making an oxytocic test a measured amount of a pituitary solution is added to the 100 cc. of Locke's solution in which the uterine muscle is immersed. The muscle contracts very quickly and relaxes again in a few minutes. The Locke's solution is then drained away and fresh Locke's solution is admitted up to the 100cc. mark. After a few minutes' rest the muscle may be used for another test. Various quantities of a standard pituitary solution of known strength are tried on the muscle until the dosage has been determined which is required to cause a contraction slightly less than the maximum contraction of that muscle. Then various quantities of the unknown solution are tried until the quantity has been found which will give a sub-maximum contraction equal to that produced by the standard solution. Then tests are made alternately with quantities of the standard and unknown solutions until the relationship between their activities has been determined.

In this Laboratory so many oxytocic tests have to be made that the original one- or two-tube apparatus proved inadequate. The apparatus has been increased in capacity by making the water-bath large enough to hold twelve vertical tubes so that twelve muscles can be used at the same time. Accurate assays are secured by testing a single extract on from three to six muscles.

---

[31] Dale and Laidlaw, *J. Pharmacol.*, **4**, 75 (1912).

The Pressor Assay Method

The pressor method of assay for posterior pituitary extracts depends upon the fact that consecutive injections of the same quantity of an active extract when given intravenously to a dog—a very definite technique being followed—cause the same amount of increase in blood pressure. Some of the details of the technique are similar to those necessary for the proper standardization of adrenaline.

The procedure is briefly as follows.

A medium-sized, healthy, normal dog is deeply anesthetized with chloretone[32] by intraperitoneal administration of a dose of a 40% solution of chloretone in 40% alcohol, amounting to 0.4 g. per kg. body weight of the dog (1 cc. of the 40% solution per kg.). Cannulas are inserted into one femoral vein and one carotid artery, the former for receiving the intravenous doses of diluted extract and the latter for connection to a mercury manometer for recording arterial blood pressure. Under this deep anesthesia–all reflexes destroyed except a slight conjunctival reflex—0.04 cc. (1 cc. of a **1–25** dilution) of a standard U.S.P. Pituitary Extract is injected. Every 15 minutes, not oftener, alternately there are injected intravenously the small doses of sample and standard until comparable doses of the two are found which will produce the same rise in blood pressure on the same dog in at least two series. The result should be checked on another dog if there is any doubt about the first test.

Pituitary extracts of the posterior lobe cause a rise in arterial pressure due to constriction of peripheral blood vessels. If the above technique is rigidly followed, there will be no preliminary fall in blood pressure or development of tolerance such as occurs if larger doses are given too frequently. Special emphasis is placed upon the requirement of using only 0.4 unit for the intravenous dose.

Experimental Part

The activity (both pressor and oxytocic) of the posterior lobe of the pituitary gland may be removed almost quantitatively by extracting the gland with water containing a small amount (0.1 to 1%) of acetic acid.[33] This method, originally proposed by one of the present writers (Aldrich),[34] is now a part of the official method in the Pharmacopeia and is in quite general use by manufacturers. Nevertheless, some of the scientific workers in the field have employed ordinary aqueous extracts and apparently have failed to recognize the importance of using acidified water. This is

[32] Rowe, J. *Pharmacol.*, 9, *107* (1916); Hamilton, J. Am. *Pharm. Assocn.*, 1, 1119 (1912).

[33] The use of a highly ionized acid such as hydrochloric acid even in as low a concentration as 0.5% results in destruction of the active principles. Recent work on this point has been reported by Stasiak, J. *Pharmacol.*, 28, 1 (1926).

[34] Aldrich, *Am.* J. *Physiol.*, 21, Proc. XXIII (1908).

true, unfortunately, of the important work of Schlapp,[24] of Draper[25] and possibly of Dudley.[10]

The Importance of *P*H Control in Making Aqueous Extracts

Adams[35] has shown that considerable loss of oxytocic activity takes place when pituitary solutions are heated at a PH of 3. We find that the reaction of extracts prepared without the use of acetic acid is near a PH of 6, and that the loss of pressor activity is even more pronounced than the loss of oxytocic activity. Extracts prepared with the use of 0.25% acetic acid possess a PH of about 3.8 to 4.4 and are comparatively stable.

The following summary gives the results of extraction of 1-g. samples of acetone-desiccated posterior lobe both with 0.25% acetic acid and with distilled water, the extracts being heated during only one-half hour as in the method described below.

TABLE I

ASSAYS BASED ON 1-G. SAMPLES OF DESICCATED POSTERIOR LOBE

(a)	Extracted with 0.25% acetic acid	= 1000 units (Oxytocic)
(b)	Extracted with 0.25% acetic acid	= 800-1000 units (Pressor)
(c)	Extracted without acetic acid	= 800 units (Oxytocic)
(d)	Extracted without acetic acid	= 250 units (Pressor)
(e)	Reëxtraction of residue from (d) with 0.25% acetic acid	= 30 units (Pressor)

It is evident that more than one-half of the pressor activity was lost and, although the oxytocic activity is more stable, a 20% loss was detected here also. A significant point is that the loss of pressor activity is not recoverable by reëxtracting the gland residue—it has actually been destroyed.

The above experiment was duplicated in work on a manufacturing scale although unintentionally. In Table II, Experiments (a), (b), (c) and (d) illustrate the uniformity with which the activity is extracted under

TABLE II

YIELDS OF ACTIVITY ON A MANUFACTURING SCALE

	1 No. units pressor according to assay	2 No. units pressor extracted	3 No. units in salted out product
(a)	1,650,000	1,900,000[a]	1,300,000
(b)	1,650,000	1,650,000	1,630,000
(c)	1,650,000	1,460,000	1,600,000
(d)	1,650,000	1,800,000[a]	1,530,000
(e)	1,650,000	800,000	600,000
(f)		40,000	

[a] These two values indicate yields of more than 100%, due no doubt to errors in the assay. This is verified by the values recorded in Col. 3, which represent the yields in the next step in the process.

---

[35] Adams, J. Biol. Chem., **30**, 235 (1917).

specified conditions. In Expt. (e) the acetic acid was accidentally omitted and, although the error was detected a half-hour later after the solution had been heated, and the acid was then promptly added, a considerable loss of pressor activity had taken place. Expt. (f) shows that reextraction of the gland residue failed to yield the activity that had been lost.

Loss of Activity Due to Acetone Desiccation

The acetone liquors recovered from the desiccation process contain a negligible amount of pressor activity but a considerably larger amount of oxytocic activity.

Fifty posterior lobes were dropped in 200 cc. of acetone, which is the volume prescribed in preparing the standard powder. Several hours later the acetone was poured off and replaced with fresh acetone, as prescribed. The acetone liquors were evaporated at a low temperature and the residue extracted with dilute acetic acid. The acid solution was then assayed by both oxytocic and pressor methods; 160 oxytocic units, but only 40 pressor units, were found. The desiccated gland material which was not completely defatted and not separated from coarse material by sifting assayed 50% of U.S.P. standard and contained a total of 2000 International Units.

In the above experiment the pituitary glands were collected during the afternoon, kept in the refrigerator overnight without freezing them, and dissected on the following morning.

Smith and McClosky[36] have not recorded a study of the acetone liquors obtained in connection with the preparation of their standard powder but we are informed in a private communication from Dr. M. I. Smith that only 0.4% of the oxytocic activity was lost

It appears, therefore, that there is very- little loss if the glands are desiccated within a few minutes after the death of the animal but a number of hours later sufficient acidity is developed to permit the acetone to extract 2% of the pressor activity and 8% of the oxytoric activity.

The Depressor Activity of Pituitary Extracts

Schafer and Vincent[12] not only demonstrated the presence of a depressor substance but showed that it is extractable from the glands by means of alcohol. Recent workers[37] have attached considerable significance to this depressor product, some referring to it as histamine.

When acetone-desiccated glands are extracted with absolute ethyl alcohol in a Soxhlet extractor, this depressor product is readily removed. We have tested it by three methods, as is shown in the following table.

---

[36] Ref. 21, p. 16.

[37] For references see the excellent paper by Sharpey-Schafer and Macdonald, *Quart. J. Exp. Physiol.*, 16, 251–280 (1926).

TABLE III

ASSAYS BASED ON EXTRACT FROM 1 G. OF DESICCATED POSTERIOR LOBE

(a)	Colorimetric assay for histamine	<1 mg.
(b)	Blood pressure assay for histamine	<1 mg.
(c)	Oxytocic assay	80 Oxytocic units ≈ 100 mg. histamine

According to the oxytocic assay, approximately 100 mg. of histamine is indicated as being extractable from 1 g. of gland material. The blood pressure assay, however, indicates the presence of even less than 1% of this large quantity of histamine and the colorimetric test agrees in demonstrating that histamine is present only in small amounts. Two conclusions might be drawn: first, the depressor principle is not histamine but rather a substance much more potent than histamine in its oxytocic action; second, a small amount of histamine is present in the gland but in the process of alcohol extraction there is extracted simultaneously some of the true oxytocic principle.

We believe that the second conclusion is correct. Since the oxytocic principle is soluble in alcohol, there is no reason why it should not be extracted and our results show that in six hours' extraction approximately 10% of the oxytocic principle is removed.

Freshly collected pituitary glands contain very little histamine, but if this impurity is present it may be removed advantageously by salting-out methods. This is illustrated by the following experiment, in which a known quantity of histamine was intentionally added.

A pituitary extract was prepared so as to contain 20 mg. of pituitary proteins per cc. To this solution, which according to colorimetric assay contained material equivalent to less than 0.02 mg. of histamine per cc., there was added 0.5 mg. per cc. of histamine in the form of hydrochloride. Sufficient solid sodium chloride was then added to salt out the pituitary proteins and the precipitate was removed by centrifuging and purified merely by washing with a very small volume of saturated salt solution. The filtrate as well as the precipitate was then assayed colorimetrically for histamine with the following results:

Precipitate dissolved in water to original volume	0.02 mg. histamine per cc.
Filtrate (calcd. to original volume)	0.45–0.50 mg. histamine per cc.

It is apparent that histamine is readily removed by the salting-out method, the variation from the theory being within the limits of accuracy of the colorimetric method of assay when conducted in the presence of salts.

The Concentration of the Active Principles

In our choice of methods for the concentration of the active principles of the posterior lobe, we have been guided by the results obtained from a study of the dialysis of pituitary extracts. The active principles dialyze more slowly than does the known substance, adrenaline, and the suggestion has been advanced that the pituitary principles may possess a molecular weight in the neighborhood of 600.[38] Although this conclusion is specula-

---

[38] Kamm, *Science*, Feb., 1928.

tive, it has proved a reliable guide. The active principles are relatively simple when compared with the protein-like material present in pituitary extracts. On the other hand, they are relatively complex when compared with most of the simpler glandular extractives, such as the inorganic salts, creatinine,[39] histamine, amino acids, etc.

The process may be illustrated by the separation of the active principles B from the mixture A B C, in which A represents low molecular weight substances and *C* represents the high molecular weight substances, such as proteins. In the absence of a specific precipitant for B, two methods of separation suggest themselves: first, *A* B can be separated from *C* and subsequently B can be fractionated from *A;* or, second, *A* can be separated from B *C* and subsequently B can be fractionated from *C*.

The method that we attempted to use for the separation of A B from C was that of fractional dialysis. Another method was based upon the use of uranium acetate[34] for the precipitation of C. Although most protein precipitates appear to adsorb the active principles, the use of uranium acetate appears to be the least objectionable. However, since these methods of attack are not used in our final method, we refrain from recording the hundreds of experiments that have been conducted in these directions.

Our final method involves the separation of B C from *A*. Although this first step may be partly accomplished by the use of effective protein precipitants such as tannic acid and phosphotungstic acid, the subsequent recovery, particularly from the phosphotungstate, requires rather heroic methods that might injure the active principles[40] and consequently we have used the more gentle process of salting out the proteins, together with the active principles, by means of salts such as sodium chloride or ammonium sulfate.

Salting-out Methods

Although Osborne and Vincent[41] had observed in 1900 that a part of the pressor activity of pituitary solutions is present in the salted-out fraction obtained by the addition of ammonium sulfate, no practical development resulted from this observation until 1913, when Clover[42] attempted to isolate the active principle by fractional precipitation by salting-out methods. Although mistaken in his conclusion that his potent salted-out fraction was an approximation of the active principle itself, Clover's work led to the first water-soluble pituitary preparations in solid, stable form.

[39] Dudley, J. *Pharmacol.*, 21, 111 (1923). isolated a considerable amount of creatinine from his extracts.

[40] Ref. 39, p. 104.

[41] Osborne and Vincent, Brit. Med. J., 1, 502 (1900).

[42] Clover, U. S. Patent Application of March 3, 1918; see No. 1,373,551.

Recently we have standardized by both pressor and oxytocic methods one of the best specimens of this "Proto-pituitrin," prepared by Clover in 1913, with the following results.

TABLE IV

Assay in *1913* *0.5* mg. per cc. yielded a pituitary extract equal to the *1913* standard
Assay in *1927* *0.5* mg. = 8.5 Oxytocic units
Assay in *1927* *0.5* mg. = *7.5* Pressor units

Two results are apparent: (1) this solid preparation remained stable for a period of fourteen years, and (2) the oxytocic and pressor activities are present approximately in the proportion in which they occur in the pituitary gland.

All of our work on products obtained by salting-out methods from relatively *concentrated* solutions has led to the conclusion that both principles are carried down into the precipitate in substantially the proportions in which they occur in the gland. Quite a different result is obtained in working with dilute solutions.

Comparison of the figures in Col. 1 of Table II with those in Col. 3 illustrates the completeness with which the activity is recovered by salting out in a fairly concentrated solution containing 50 to 100 units per cc. When relatively dilute solutions are treated with salt, a considerable loss of activity occurs, due to incomplete precipitation, as is illustrated by the following experiment.

One hundred cc. of a posterior lobe extract assaying *10* oxytocic units and *10* pressor units per cc. and containing 0.5% chloretone was treated with *30* g. of solid sodium chloride. The protein fraction together with the precipitated chloretone was removed with the centrifuge. The solution as well as the salted-out precipitate was then subjected to assay by both methods with the following result.

TABLE V

	No. of pressor units	No. of oxytocic units
Original solution	*1000*	*1000*
Salted-out fraction	*500*	*700*
Filtrate	*400*	*250*

The above results show not merely that dilute solutions are incompletely precipitated by salting-out methods, but also that the two activities are carried down with the protein fraction in unequal amounts. We have here another bit of evidence which disagrees with the theory that both types of activity are due to a single hormone.

The Separation of the Pituitary Hormones from Proteins: Separation of the Fraction B C into B and C

The hormones of the posterior lobe of the pituitary gland are not readily separated from foreign gland tissue and are carried along with the protein fractions. In this respect they resemble insulin and the parathyroid hormone rather than the simpler hormone, adrenaline. However, the method of manipulation of these protein extracts that has proven successful with insulin, namely, iso-electric precipitation, and which can be applied also to the purification of the parathyroid hormone, fails when applied to pituitary extracts. A new method of manipulation was required and has been devised.

After partial purification by salting out, the pituitary protein fraction is much more susceptible to fractionation than is the crude gland extract. However, the usual organic solvents used for such fractionation purposes, as for example alcohol, do not yield very satisfactory results.

An essential part of our method consists in the choice of an organic solvent which acts chemically with the active principles, due possibly to salt formation, and which acts simultaneously as a solvent for the salts of the active principles but is a relatively poor solvent for foreign protein material. An important prerequisite for such a solvent is that it must not injure the active principles.

The ideal solvents have been found in the aliphatic monocarboxylic acids of low molecular weight. Our work has been chiefly with acetic, propionic, and butyric acids, all of them being used in relatively high concentration and in the case of acetic acid in practically anhydrous form. The solvent action of propionic acid containing 5% of water and butyric acid containing about 10% of water is practically equivalent to 98–100% acetic acid. Since the results with acetic acid are highly satisfactory and since this solvent is also the cheapest one, the experiments to he described will deal with this particular acid.

The solution of the active principles in glacial acetic acid at room temperature (25°) is stable for days. After a month a perceptible loss of activity is observed, but in the following experiments the material need be exposed to the acid during only an hour. The advantages of such a method are in obvious contrast to methods involving reactive agents such as mercuric chloride and barium hydroxide.

The pituitary proteins are relatively insoluble in glacial acetic acid, whereas the active principles are readily extracted by this solvent. The amount of foreign protein extracted, however, is dependent upon the moisture content of the acid—for example, 98% acetic acid will extract appreciable quantities of protein, whereas 100% acetic acid will dissolve very little protein but it will extract the physiologically active compounds although with more difficulty than when the 98% acid is used. More dilute acid than 98% may be used as, for example, a solvent containing 10 to 20% (or even more) of water, but in this case the proteins and contaminating salt will dissolve completely and the subsequent fractionation by the addition of organic precipitants will be more tedious.

We find that the acetic acid extract may be subjected profitably to fractional precipitation by the gradual addition of acetone, ether, and petroleum ether in the order specified. When this is done, the first few fractions are found to be relatively inert, but successive fractions show an increasing potency. Acetone is the best precipitant for the inert proteins; subsequently the pressor principle, together with varying quantities of the oxytocic principle, is precipitated in a series of fractions by the addition of sulfuric ether, and finally complete precipitation is secured by the addition of a hydrocarbon precipitant such as petroleum ether.

By several repetitions of the fractionation process, it is possible to obtain the active principles in very potent form.

The steps involved in this concentration of the active principles and their separation are as follows:

(1) Extraction of the gland material according to the known method, using dilute aqueous acetic acid.

(2) Concentration of the dilute extract at a low temperature.

(3) Separation of the activity. together with proteins, by the addition of salt.

(4) Extraction of the salted-out fraction with glacial acetic acid.

(5) Fractionation of the acetic acid extract by the addition of organic liquids such as acetone, ether and petroleum ether.

The U. S. P. pituitary powder is prepared under special conditions[43,21] from pituitary glands collected within thirty minutes after the death of the animal. We have already designated the potency of this powder as 100%. In four preparations we were able twice to duplicate material possessing this potency, but two other lots, for some unexplained reason, possessed a potency of only 70%.

Commercial desiccated posterior lobe obviously is less potent than the standard powder and in actual practice a good technical product will test 40 to 60% of standard. A satisfactory method of separating the active principles, however, should be independent of the potency of the starting material and, indeed, we have found this to be true of the method to be described.

Experimental Procedure

(1) An aqueous extract of the posterior lobe of the pituitary gland is prepared by extracting 100 g. of the commercial acetone-desiccated gland material testing 50% of U. S. P. standard with 10 liters of 0.25% acetic acid. The mixture is gradually heated to a temperature of about 95° during a half-hour period, cooled quickly and then filtered to remove the insoluble gland residue, which is reextracted with one liter of the acidified water in order to secure a fairly complete extraction. The combined filtrates should contain 100,000 units of oxytocic activity and an equal number of units of pressor activity.

(2) The filtrate is then concentrated at a low temperature to a volume

---

[43] *U. S. P.*, X, page 220.

of one liter. Since the active principles in acid solution are stable toward oxidation by air, evaporation with the aid of a current of warm air is permissible,

(3) The concentrated extract is treated with 550 g, of c. p. ammonium sulfate. The precipitate is filtered on a hardened filter paper, pressed, dried and powdered. The weight of salted-out product will be 20 to 40 g. according to the amount of salt present, an excess of which is not objectionable.

(4) The salted-out product is extracted with successive portions of glacial acetic acid (99–100%) a total volume of 500 cc. of acetic acid being used.[44] The amount of glacial acetic extracted material will be approximately 5 to 8 g., provided care is taken to prevent undue exposure to the moisture of the air during the extraction process.

(5) The acetic acid extract is now treated with 1250 cc. of sulfuric ether and then immediately with 2500 cc. of petroleum ether, which treatment precipitates the active material completely. The precipitate is filtered off by suction, washed with ether and dried. Its weight should be 5 to 10 g. varying with the water content of the acetic acid, and a potency test by both the pressor method and the oxytocic method should demonstrate the presence of 80 to 90% of the activity contained in the original 100 g. of desiccated gland material. Ninety to ninety-five per cent. of the inert material has thus been removed by our process up to this stage. Assay shows the product to possess a potency of 450 to 900% of standard according to the weight, the oxytocic and pressor activities being practically balanced.

The uniformity of this extraction and purification method is illustrated by the following four practical experiments conducted on a manufacturing scale.

TABLE VI

SEPARATION OF ACTIVE PRINCIPLES FROM INERT MATERIAL ON A MANUFACTURING SCALE

Expt. no.	No. of pressor units in desiccated gland	No. of oxytocic units in desiccated gland	No. of pressor units extracted	Yield of final product, g.	Potency by pressor test, %	Potency by oxytocic test, %
1	3,500,000	3,620,000	3,180,500	203	625	625
2	3,500,000	3,620,000	3,470,000	237	500	600
3	3,500,000	3,620,000	3,450,000	258	500	600
4	3,500,000	3,620,000	3,180,500	250	500	625

---

[44] In order to secure an efficient extraction the following method may be applied. The salted-out product is divided into four equal part lots A, B, C and D. Part Lot A is extracted with seven times its weight of acid and this first extract set aside. A is then reextracted with a second portion of acid but this second extract is used for extraction of Part Lot B after which the second extract is combined with the first. In making the third extract Lots A, B and C are extracted in this respective order and the procedure is continued in this manner until each fraction has been extracted four times before being discarded and a total of seven portions of acetic acid have been used.

Partial Separation of the Two Active Principles

As a next step it is advantageous to remove a part of the oxytocic activity by the following simple process. A complete separation at this stage is not feasible because of the tendency of the protein fractions to adsorb the oxytocic fraction.

Five g. of the material assaying 500–900% of the U. S. P. powder is dissolved in 250 cc. of 98% acetic acid at a temperature of 40" and precipitated immediately by the addition of 2.5 volumes of sulfuric ether previously warmed to 30°. The flocculent precipitate is allowed to settle rapidly (not over five minutes) and is filtered by suction, washed with ether and dried.

The precipitate is immediately redissolved in 250 cc. of 98% acetic acid and precipitated as before. The recovered material will weigh 4.5 to 4.7 g.

The ether filtrate contains oxytocic activity together with traces of salts such as ammonium acetate. The active fraction may be precipitated by the addition of petroleum ether but the resultant solution is usually so difficult to filter that the following procedure is preferred.

The two ether-acetic filtrates (above) are combined and refiltered through hardened filter paper and the *clear* filtrate is treated with 10 cc. of water (which must dissolve completely) and two volumes (about **3** liters) of petroleum ether. A fine mist is thrown out which carries down practically all the oxytocic activity and usually collects as a varnish on the sides and bottom of the container after standing for several hours or overnight. The *clear* liquid is decanted and the gummy precipitate dissolved in 50 cc. of water and filtered free from fat. Based on solid content, this petroleum ether precipitate contains oxytocic material of a potency of 5000 to 12,000% and not more than 3–4% of pressor activity per 100% oxytocic activity.

The following practical result has been duplicated many times. Ten g. of a partially purified solid assaying 600% oxytocic and 500% pressor activity yielded by this process 9.6 g. of a fraction assaying 500% pressor but only 325–375% oxytocic activity. However, the petroleum ether precipitate, taken up in 100 cc. of water, had a solid content of 350 mg. and contained 50,000 to 60,000 units of oxytocic activity, thus accounting for the oxytocic activity removed from the precipitate. Such a solution is suitable for subsequent use in the purification of the oxytocic principle and also, after suitable dilution, for practical clinical use, since it contains only small amounts of pressor activity.

Fractionation of the Pressor Principle

(a) Five g. of partially separated material testing 500–900% by the pressor test but only approximately one-half this potency according to the oxytocic test, is dissolved in 100 cc. of 98% acetic acid at room temperature and the solution is filtered by suction from a small amount of salt and other insoluble impurities.

(b) To the filtrate is added 40 cc. of acetone. The precipitate, consisting mainly of protein containing only a small amount of active material, is filtered off, washed with ether and dried.

(c) The filtrate from (b) is treated with an additional 40 cc, of acetone and a second protein fraction is obtained as before, although this fraction contains a slightly more active material.

(d) The filtrate from (c) is treated with about 25 cc. of sulfuric ether and the precipitate filtered off and dried as before. This fraction is more potent than (c) by both the pressor and oxytocic tests.

(e) The filtrate from (d) is treated with 125 cc. of ether and the precipitate filtered off and dried. This fraction is very active by the pressor test but less active by the oxytocic test, thus plainly showing a separation of the active principles.

(f) The filtrate from (e) is treated with an excess (about 500 cc.) of sulfuric ether in order to precipitate the remainder of the pressor activity.

(g) The filtrate from (f) contains only a trace of pressor activity but contains the bulk of the oxytocic activity. The latter may be obtained by the addition of petroleum ether as already described. Due to the presence of moisture this fraction may precipitate as a gummy mass but can be obtained in the form of a white solid by dissolving in absolute alcohol and precipitating with an excess of ether. If it precipitates as a liquid it must be concentrated at a low temperature.

The results obtained by this fractionation method are shown in the following experiment selected at random from a large number of similar results.

Thirty g. of material assaying 750% by pressor and 375% by oxytocic test was treated with 600 cc. of 98% acetic acid and fractionated with the following results.

TABLE VII

FRACTIONATION OF PRESSOR PRINCIPLE AND SEPARATION OF A POTENT OXYTOCIC FRACTION

Fraction number	Amount and kind of solvent added	Assay of fraction. %	Weight of fraction, g.
1	Acetic acid	Practically inert	5.4
2	225 cc. Acetone	300 Pressor, 150 oxytocic	7.7
3	225 cc. Acetone	400 Pressor, 200 oxytocic	8.4
4	150 cc. Ether	750 Pressor, 250 oxytocic	1.9
5	750 cc. Ether	3125 Pressor, 700 oxytocic	4.2
6	4000 cc. Ether	1875 Pressor, 1625 oxytocic	1.0
7	Petroleum Ether	120 Pressor, 5000 oxytocic	0.8
		Total	29.4

In the above experiment 220,000 pressor units were recovered from a total of 225,000 and likewise 100,000 oxytocic units from a total of 122,000 shown by the initial assay.

Examination of the above table shows that fractions 2, 3 and 4 are relatively weak. They consist chiefly of protein material which naturally carries along an appreciable amount of activity. However, a separation and concentration of the two activities is taking place as is shown by the fact that fraction four is three times as potent by pressor as by oxytocic test, and the large fraction, five, is more than four times as potent by pressor as by oxytocic test. The oxytocic activity is accumulating in the residual solution and it is therefore to be expected that the last solid fraction (No. 6) will be comparatively potent in oxytocic activity also, since the oxytocic principle is not very soluble in ether.

Refractionation and Further Concentration of the Pressor Principle

The more potent of the separated fractions may be further concentrated by a repetition of the process already described, applying the same to the individual fractions.

The following laboratory experiment illustrates the results obtained in actual practice.

Seven g. of material assaying 3125% by pressor test and 700% by oxytocic test (equivalent to Fraction 5, Table VII) were dissolved in 210 cc. of 98% acetic acid and refractionated with the following results.

TABLE VIII

FRACTIONATION OF THE PRESSOR PRINCIPLE

Fraction number	Amount and kind of precipitant added	Assay results. %	Weights of fraction, g.
1	210 cc. Acetone	1000 Pressor, 150 oxytocic	1.35
2	105 cc. Acetone	1625 Pressor, 400 oxytocic	0.95
3	75 cc. Ether	3000 Pressor, 500 oxytocic	1.15
4	300 cc. Ether	4000 Pressor, 750 oxytocic	2.40
5	600 cc. Ether	2500 Pressor, 2000 oxytocic	0.52
6	Filtrate	150 Pressor, 4000 oxytocic	0.25
		Total	6.62

Repeated fractionation of the 4000% pressor fraction yields a fraction testing 6250% but it is difficult to increase the potency beyond this figure by this method. The subsequent use of other solvents, such as the alcohols, has raised its potency only to 8000%. This product is now being subjected to various purification methods in the hope of obtaining it in a condition of maximum potency.

The distribution of the pressor hormone among the various fractions in this process is shown graphically in Fig. 1, which is based upon the refractionation of 46.5 g. of a partially separated product testing 750% by pressor and 375% by oxytocic tests. The dark areas represent the amount of pressor principle present in the respective fractions, assuming a potency of 7500%, a value which we already know is somewhat below the actual potency of the pure principle. The white areas represent inert material.

Results analogous to those illustrated in Series 2 have already been recorded in Table VII. The best Fraction, 2E, testing 3125%, was refractionated and yielded Fractions 3A, 3B, 3C, 3D and 3E, testing 1000, 1625, 3000, 4000 and 2500%, respectively. The latter results are recorded in Table VIII.

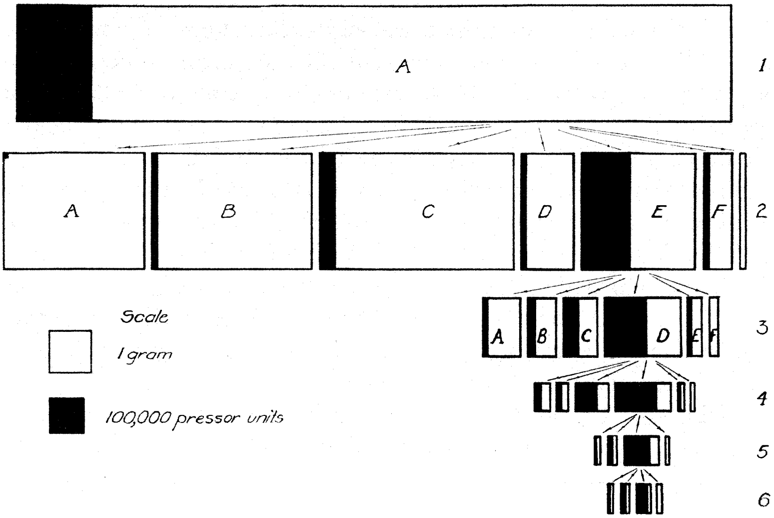

Fig. 1.—Separation of the pressor principle.

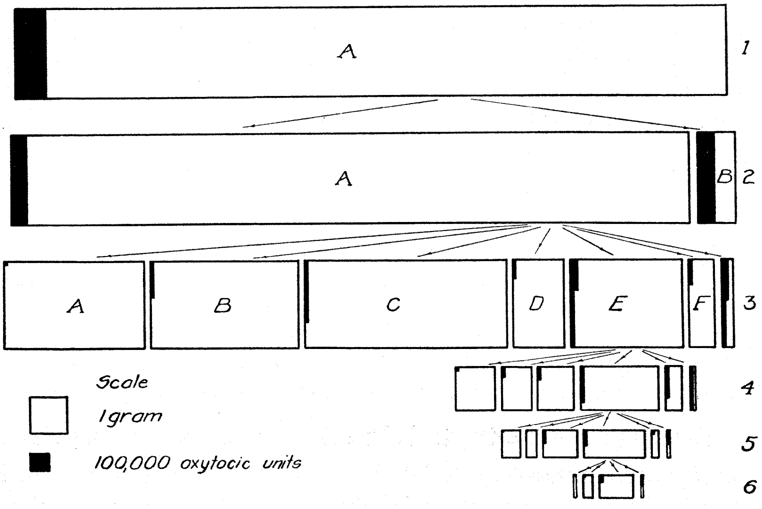

Fig. 2.—Separation of the oxytocic principle.

Fraction 3D, testing 4000%, was refractionated and yielded Fractions 4C and 4D, both testing 5000%. The latter fraction yielded a large

Fraction 5C, testing 5000%, and refractionation of this yielded the Fractions of the 6 series, the most potent of which tested 6250%.

The distribution of the oxytocic hormone among the various fractions in the process that has been described in detail is shown graphically in Fig. 2, which is partly based upon the oxytocic values recorded in Tables VII and VIII. The dark areas represent the amount of oxytocic principle present in the respective fractions, assuming a potency of 20,000% for the pure principle, an estimate which is, no doubt, considerably below the actual value. The white areas represent inert material.

The separation shown in Series 2, Fractions A and B, corresponds to the results obtainable by the procedure described above under the section headed "Partial Separation of the Two Active Principles." The fractions in Series 3 are identical with the fractions in Series 2 of Fig. 1; for example, Fraction 2E of Fig. 1 and 3E of Fig. 2 are based upon the same fraction, the former chart illustrating the proportion of pressor principle and the latter chart the amount of oxytocic principle in this sample.

It is to be noted that the oxytocic activity tends to accumulate in the end fractions shown at the right-hand end of the chart.

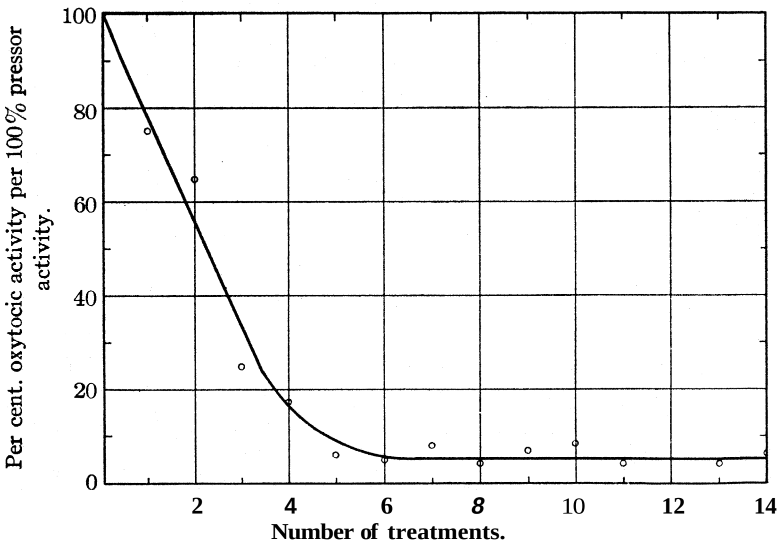

Fig. 3.—Separation of oxytocic principle from the pressor principle.

Limits of Separation of the Oxytocic Principle from the Pressor Principle

The most potent pressor material obtained by the acetic acid fractionation method, namely, a product testing 6250%, still contains approximately 10% of oxytocic activity per 100% pressor activity. It is difficult to reduce the oxytocic activity below 4% per 100% pressor. This is illustrated in Fig. 3, which represents fourteen treatments aiming at the removal of the oxytocic activity by the method already described, namely, solution in glacial acetic acid and precipitation with ether.

The curve illustrates the fact that the oxytocic activity is rapidly removed in connection with the first four treatments with acetic acid. After the sixth treatment the amount of oxytocic activity remains almost constant.

These results suggest that a small amount of oxytocic activity may be inherent in the pressor principle itself and we have in progress a new series of experiments aiming at a solution of this interesting problem. The fact that the pressor principle, as such, may possess a slight stimulating effect on smooth muscle would not be an unique case, since some relatively simple substances (as for example tyramine) also show both types of activity.

Purification of the Oxytocic Principle

The oxytocic principle resembles the pressor principle in every way except that it is appreciably soluble in organic solvents and particularly in a mixture of ether and acetic acid. A practical method of obtaining a potent solution of the oxytocic principle has already been described in the above experimental procedure under the heading "Partial Separation of the Two Active Principles."

The ether-acetic acid solution of the oxytocic fraction may be evaporated to dryness at a low temperature and the residue taken up in 0.25% acetic acid and filtered. This acid extract is then assayed for total solids and for oxytocic activity and usually tests 5000% of U. S. P. standard. Precipitation of the ether solution by the addition of petroleum ether according to the methods already described yields a product testing up to 12,000%, which is relatively low in pressor activity, and this method is preferable. The gummy precipitate is then merely dissolved in 0.25% acetic acid.

The aqueous solution containing the oxytocic fraction as the acetate may be evaporated at a low temperature. The residue is treated with alcoholic tartaric acid, which dissolves the active substance but may leave a crystalline residue of ammonium acid tartrate which is filtered off. From the alcoholic solution the oxytocic tartrate may be fractionally precipitated by the addition of ether. This process, however, has not raised its potency beyond 15,000–20,000%, and a more satisfactory method of purification is being sought.

Assay of such a fraction by the pressor method indicates that 98 to 99% of the pressor activity of the gland has been removed. Apparently there is little difficulty in removing the pressor from the oxytocic principle, and even for practical clinical work we have been able to supply a product which assays only 4% pressor for each 100% by oxytocic assay.

Adrenaline, which is an amine, may be precipitated from aqueous solutions of its salts, when present in sufficient concentration, by neutralization with ammonia. The pituitary hormones also appear to be amines but they are not precipitated from aqueous solutions of their salts upon neutralization, since the bases themselves are extremely soluble in water. Further work on the purification of these products will appear in subsequent articles.

Conclusive Evidence of the Presence of Two Principles

The evidence that we have presented in the quantitative results reported above should leave little doubt that at least two principles are present in pituitary extracts and that these two principles may be separated by practical methods. It seems advisable, however, to demonstrate that in our process none of the activity has been injured or one product converted into another. In other words, the sum of the parts should make a whole; and this should be demonstrated not merely by adding up the separate assay results but also by synthesis of the original by recombining the parts. This has been done in the following experiment.

A sample of a partially purified product was found to test **625%** by both the oxytocic and pressor methods (see Table VI, Expt. **1).** Ten g. of this material was then subjected to the acetic acid fractionation method with the following results.

TABLE IX

INITIAL FRACTION OF A PURIFIED PRODUCT CONTAINING ACTIVITIES IN ORIGINAL PROPORTIONS

Fraction	Wt., g.	Oxytocic assay, %	Pressor assay, %	Oxytocic units	Pressor units
1	3.8	175	125	13,300	9500
2	2.75	200	200	11,000	11,000
3	1.2	300	400	7200	9600
4	1.55	1875	2500	58,000	77,500
6	0.28	6000	500	33,600	2800
6	8 liters filtrate	..	...	2500	2500

Fractions **1** and **2** were obtained by acetone precipitation, Fractions **3** and **4** by ether precipitation and Fraction **5** with the aid of petroleum ether. Note that Fraction 1 contains more oxytocic than pressor activity, but in **3** and 4 the pressor activity is in excess, whereas in Fraction **5** the oxytocic activity is again in great excess. The large volume of filtrate contained only **2%** of the total activity.

The initial material used in this experiment contained **125.000** oxytocic units and **125,000** pressor units. The assays of the separate fractions total up to **125,600** oxytocic units and **113,100** pressor units.

The fractions were then recombined and the resultant mixture was submitted to assay as an unknown. The resultant pituitary product on the basis of the physiological tests was indistinguishable from the original product and assay demonstrated it to test **575%** by pressor test and **625%** by oxytocic test. This represents **110,400** pressor units and **120,000** oxytocic units, results which are within the limits of experimental error.

The above experiment has been repeated using known quantities of highly purified oxytocic and pressor fractions. Such solutions when combined in theoretical proportions were indistinguishable pharmacologically from plain pituitary extracts. Incidentally, these tests show that the oxytocic assay is not influenced seriously by the presence of the pressor principle and, *vice versa,* the pressor assay method is not adversely affected by the presence of moderate amounts of the oxytocic principle. The effect of the presence of excessive amounts of one principle upon the assay of the other requires further study.

The Diuretic-Antidiuretic Principle Appears to be Identical with the Pressor Principle

Extracts of the posterior lobe of the pituitary have a diuretic-antidiuretic action. Under some conditions injection of such extracts causes diminished excretion of urine but under different conditions the flow of urine is markedly increased.

We were interested in finding out which of the active principles, the oxytocic principle or the pressor principle, has the diuretic-antidiuretic action. In order to determine this question extracts containing the two activities were tested on rabbits.

The method of experiment was similar to that used by Magnus and Schafer,[45] Schäfer and Herrington,[46] and Houghton and Merrill[47] on dogs; and more recently on rabbits by Abel, Rouiller and Geiling,[2] Mackersie,[48] Smith and McClosky,[49] and others.

The rate of flow of urine was observed by counting the number of drops in five-minute intervals falling from a cannula tied into the urinary bladder. The rabbits were anesthetized with urethan (ethyl carbamate), *2* g. per kilogram of body weight, given by subcutaneous injection. The cannulas used were funnel-shaped at the end which was tied into the bladder and obliquely pointed at the other end. They were 1 cm. in diameter so as to prevent the possibility of capillary action interfering with the free flow of urine. In making a test the rabbit was laid on a board so that the cannula extended vertically downward through a hole in the board. Rabbit and cannula being in this position permitted the urine to drop as fast as it entered the bladder without the possibility of pocketing.

The solutions used for the diuresis experiments were Pituitrin which tested 100% pressor and 100% oxytocic, a solution of the pressor fraction which tested 100% pressor and 8% oxytocic; and a solution of the oxytocic fraction which tested 100% oxytocic and 4% pressor.

A typical experiment showing the effect of intravenous injections of Pituitrin, pressor fraction and oxytocic fraction is illustrated in Fig. *4.* These three substances were used in rotation so as to compare their effects on the same rabbit. The dosage of Pituitrin is stated in International Units, the dosage of the oxytocic fraction is stated in units equal to the International Units, and the dosage of the pressor fraction is stated in units of the pressor activity which we have defined above. The rabbit weighed 2.1 kilograms and had been fed on oats and green food with water always accessible.

It will be noted that Pituitrin and the pressor fraction caused a marked increase in the flow of urine while the oxytocic fraction caused only a slight increase in the flow. This difference is even more noticeable in some of

our other experiments. In only one experiment has there been any great flow of urine following the injection of the oxytocic fraction. It seems probable in that exceptional experiment some source of experimental error changed the apparent outcome. These diuresis experiments are still in progress and will be reported more in detail later by Dr. E. P. Bugbee.

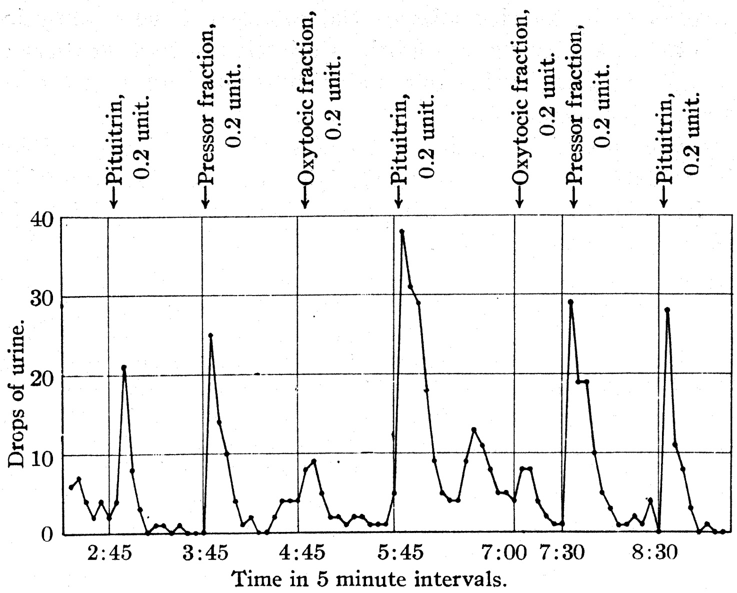

Fig. 4.—Showing the diuretic-antidiuretic effect of intravenous injections of pituitary extracts on a rabbit under urethan anesthesia.

The Pressor Effect of the Pressor Hormone

We have repeated the historical experiments of Howell[5] and of Schafer and Vincent[12] who have shown that when doses of pituitary extracts are administered intravenously in fairly rapid succession and in relatively large amounts a tolerance is quickly established so that after the second or third injection no further pressor effect is demonstrable.

When plain pituitary extracts are used the typical rise in pressure may actually be replaced by a depressor action due either to the presence of traces of histamine or to the acidity. Abel[50] has demonstrated this depressor action even with his purified fraction.

In repeating this early work we have used a purified pressor fraction and find that it acts exactly like an unmanipulated pituitary extract in respect to the development of tolerance, thus showing that the product has not been modified. However, the successive large doses fail to give

---

[50] **Abel,** Rouiller and Geiling, **J.** Pharmacol., 22,303 **(1923).**

any depressor action, thus attesting to the degree of purification of the product. The details of this work will appear in a separate publication by Mr. L. W. Rowe.

Therapeutic Indications

In an article presented from the standpoint of the chemist it is naturally inadvisable to discuss in any great detail the medical aspects of this problem. However, in view of the fact that many of our readers may be interested in the possible applications of these hormones, the subject of therapeutic indication will be commented upon briefly.

The oxytocic principle seems indicated in those obstetrical cases where the physician wishes to avoid elevating a blood pressure that is already too high. Incidentally there is a possibility that this principle will yield more satisfactory and uniform oxytocic results when administered by itself than when mixed with the pressor hormone.

There is a strong probability that the pressor principle is the active principle which is of value in the treatment of diabetes insipidus, and preliminary clinical reports seem to confirm this opinion.

Pituitary extracts have not proved successful for the relief of asthmatic conditions. It has been suggested that the beneficial effects produced by one principle are neutralized by the unfavorable actions of the other. Obviously such practical questions can now be studied in a more scientific manner since the shotgun is replaced by the rifle.

In view of the fact that the two separated principles are available for study it is now possible for the physiologist and the pharmacologist to analyze more correctly the physiological responses caused by the administration of pituitary extracts.

General Discussion

We have no doubt that most of the previous investigators in this field have actually been working with partial separations of the active principles.

The simple operation of desiccating fairly fresh pituitary glands with acetone results in yielding a very crude extract which contains 8% of the total oxytocic activity and only 2% of the pressor activity. Investigators who have made aqueous or saline extracts without using acid have dealt with material deficient in pressor activity, but in general this fact was not realized because the deficient extracts were used as standards of comparison.

Abel[50] was convinced that his methods yielded all the various activities in the identical proportions present in the original gland material but upon repeating his work we were surprised to obtain in the first step involving the mercuric chloride treatment a yield of only 30% of pressor activity. This experiment was checked three times with almost identical results. In the light of our present work we repeated such an experiment and found the yield of oxytocic activity to be 60% and that of pressor activity to be 30% of the total amount originally present. It is evident, therefore, that the very first step in Dr. Abel's process involves a partial separation of the two principles.

The products that we have obtained by the processes described in the experimental part of this paper, in sufficient detail so that the results may be readily duplicated, are certainly close approximations to the active principles themselves. Although we feel that additional purification may raise the potency values above those reported here and that ultimately we or others will be able to secure these two principles in crystalline form, such purification is not essential to the successful clinical application of these two new products.[51]

In contrast to all previous workers in this field we are able not merely to obtain fractions differing from each other when subjected to the two acceptable quantitative assay methods (which result might be due to partial injury of a single principle), but we have been able to secure the following results which we believe are new.

(1) Complete quantitative evidence has been obtained proving that a separation may be effected and by recombining the fractions in the original proportions a pituitary solution indistinguishable from the original is again obtained, thus proving that no injury of any active principle has taken place.

(2) By continuing our fractionation process we have effected a separation of the two principles which for all practical purposes may be considered as complete.

(3) Both principles have been obtained in the form of stable, highly potent, water-soluble powders.

(4) The separated principles have for the first time been made available to the medical profession for experimental clinical use and thousands of ampoules of the purified separated products have been distributed for this purpose.

Summary

1. The posterior lobe of the pituitary gland contains two important active principles: one which raises blood pressure and another which stimulates contraction of uterine muscle.

2. A substantially complete separation of these two active principles has been accomplished by the employment of salting-out methods and, subsequently, by the use of appropriate solvents and precipitants.

3. Solutions of these separated active principles have been recombined

---

[51] Note: This is analogous to the Insulin case. This product has proved to be a successful remedial agent and although recently it was obtained in somewhat more potent form and also in crystalline condition, it is not likely that the clinical use of Insulin will be greatly influenced.

to form a pituitary extract identical with the original from which they were prepared, thus proving that no decomposition **has** taken place.

4. The substantially pure pressor principle (β-hypophamine) has been obtained in the form of a white, stable, water-soluble powder 80 times as potent as the International Standard Powdered Pituitary.

5. The separated oxytocic principle (a-hypophamine) has been obtained in the form of a white, stable, water-soluble powder which is more than 150 times as potent as the International Standard Powdered Pituitary.

6. The pressor principle has been shown to be responsible for the diuretic-antidiuretic action of pituitary extracts.

7. The pressor principle when tested on animals for demonstration of pressor effects shows the development of tolerance which is characteristic of active pituitary extracts. It has been shown to possess no appreciable depressor action.

8. Both active principles are basic bodies, presumably amines.

9. Practical manufacturing methods have been developed for the separation of these two hormones and they have been made available to the medical profession for careful clinical trial.

10. As a result of this preliminary work the foundation is now laid for an investigation of the chemical nature of the separated hormones of the posterior lobe of the pituitary gland, together with a more exhaustive study of their pharmacological properties.

DETROIT, MICHIGAN

NEW BOOKS

General Chemistry. A Cultural Course Based upon the Texts of the Late Alexander Smith. By JAMES KENDALL, Professor of Chemistry, Washington Square College, New York University. The Century Company, 353 Fourth Avenue, New York City, 1927. xxix + 676 pp. 170 figs. and several plates. 13.5 × 20.5 cm. Price $3.50.

In this text Dr. Kendall has presented what he calls a cultural course in chemistry. It must be said, however, that if beginning students in chemistry master this book they will be entirely prepared to take advanced courses; hence it can be applied to any college or university freshman course with profit.

A number of additions to the usual content of the Smith texts have helped make the book interesting. The illustrations scattered liberally through it are very well chosen. This applies not only to those showing commercial processes but to the personal portraits of eminent chemists as well. The discussion of the personalities of these chemists is one of the ways in which human interest is aroused.

Familiar notes by Kendall add much to the ease of understanding of such topics as catalysis, ionization, etc. The citation of articles which may he assigned for reading is stimulating to the teacher at least. The new chapters on radium, atomic energy and atomic structure are also a distinct advance.

The writer feels sorry that Dr. Kendall has not seen fit to break away from the old idea of ionization and to give us a development based on the more modern ideas which he has included in the text. If the old ideas have been sadly shaken, and most chemists will agree that this is so, why wait for a perfect theory instead of stating logically the present accepted position? Such a revision would, of course, require a recasting of the methods for presenting the theory of ionization. That no one else has done this does not mean that it would not be acceptable. The book is in general up to the high standard of the Smith texts.

P. A. BOND

Leçons de Chimie Physique. (Textbook of Physical Chemistry.) By P. MAURICE VÈZES, Professor of Chemistry at the University of Bordeaux. Preface by G. Urbain. Librairie Vuibert, Boulevard Saint-Germain, 63, Paris, France, 1927. ix + 545 pp. 293 figs. 16.5 × 25.5 cm. Price (unbound) 50 fr.

The present work by a well-known authority on the platinum group of metals presents with clarity the principles of the classical physical chemistry. It is divided into four parts: the first consisting of four chapters treats Atoms and Molecules, their fundamental laws and the determination of atomic and molecular weights by the various methods. The second part is devoted to Electrochemistry with chapters on Electrolytes, Transport of Ions, Electromotive Force, Electrolysis and the Energy of Piles. The final chapter (IX) of Part Two introduces the atomic conception of electricity and modern atomic structure. (By a somewhat astonishing feat, the author was able to introduce and discuss many of the principles of *Radioactivity* without any mention of his distinguished countrymen whose names are universally associated with that subject.) Part III deals with Velocity of Reactions and Part IV with Chemical Equilibria.

The preface by Professor Urbain contains interesting comments on the teaching of Physical Chemistry, its relation to General Chemistry (between the two he makes a sharp distinction, rather from the didactic standpoint) and the value of Thermodynamics. The treatment of the latter is not segregated as in some texts, but distributed under various topics as occasion arises for its application.

VOL. 50 MARCH, 1928 No. 3

THIRTY-FOURTH ANNUAL REPORT OF THE COMMITTEE ON ATOMIC WEIGHTS. DETERMINATIONS PUBLISHED DURING 1927

BY GREGORY PAUL BAXTER

RECEIVED FEBRUARY 6, 1928 PUBLISHED MARCH 7, 1928

The Annual Report of the German Committee on Atomic Weights appeared as usual.[1] Nearly all the following investigations appeared during 1927.

Boron.—Briscoe, Robinson and Smith[2] by means of a standardized float have determined the densities of three specimens of boron trichloride obtained from different sources and have found an extreme variation in the atomic weight of boron of 0.023 unit. Fractionation of two of these samples showed them to be impure and halved the extreme difference. There is no proof that further purification would not have removed the discrepancy entirely.

Carbon.—Sameshima[3] has determined the density and compressibility of acetylene.

TABLE I

DENSITY OF ACETYLENE, 0°

Pressure	Volume	Density	PV ($(PV)_1 = 1$)
0.5341	143.422	0.6241	1.0053
.6279	143.424	.7348	1.0038
.9988	143.431	1.1739	0.9995
1.0007	143.431	1.1749	1.0005
1.5096	143.441	1.7845	0.9938

By interpolation the normal density is 1.1747 and by extrapolation the limiting density 1.1615. Then $C_2H_2 = 26.03$ and $C = 12.005$.

Stock and Ritter[4] have compared oxygen and ethylene in a gas displacement balance and find the weight of the normal liter of ethylene to be 1.26057 and the deviation from Boyle's Law 1.00790. Using 22.415 as the gram molecular volume, the molecular weight of ethylene is 28.034 and the atomic weight of carbon is 12.001.

Nitrogen.—Moles[5] discusses critically earlier work on the density and compressibility of ammonia and comes to the conclusion that 0.7715 and 1.01534 represent the most probable values of the density and compressibility, respectively. From these figures the atomic weight of nitrogen may be calculated to be 14.008.

Moles[6] reviews the evidence concerning the densities and compressibilities of oxygen and nitrogen and arrives at the following most probable values.

	Density	$(PV)_0/(PV)_1$	At. wt.	Gram molecular vol.
Oxygen	1.42892	1.00091	16.000	22.4148
Nitrogen	1 25046	1.00042	14.0082	.....

Moles and Clavera[7] have redetermined the density of nitrogen prepared by (1) decomposition of ammonium nitrite, (2) reduction of nitric oxide, (3) decomposition of urea by hypobromite, (4) decomposition of urea by sodium nitrite.

compressibility of neon which had been purified both chemically and by adsorption on chilled, dehydrated chabazite until spectroscopically free from helium and nitrogen.

The deviation from Boyle's Law is calculated in the conventional way from the densities at different pressures to be 0.99942 and the atomic weight of neon 20.182.

Chlorine.—E. Gleditsch and L. Gleditsch[9] have compared the densities of solutions of sodium chloride, saturated at 18°, prepared from salt occurring at different levels in the Alsatian deposits. Since no difference greater than the experimental error was found, the isotopic composition of the chlorine must be the same.

Source	Density of saturated solution
Ordinary (marine)	1,201066
Alsation, Level 1 (highest)	1.201063
Level 2	1.201076
Level 3	1.201070
Level 4 (lowest)	1.201058

Honigschmid, Chan and Birckenbach[10] purified chlorine by distillation and collected the product in exhausted glass bulbs which were ultimately sealed. These were weighed in air and in water, and were broken under a solution of ammonium arsenite. The glass fragments were collected and weighed. Comparison with silver followed and the silver choride was collected and weighed. The change in weight on fusion in chlorine and in air was applied as a correction. Ag = 107.880. Weights are in vacuum.

		Average	1.32867	35.457

after removing bromine and iodine. To prepare Sample Ib sodium chloride was crystallized and converted to hydrogen chloride. The solution of the latter was purified as above. Samples II and III were prepared from extreme fractions of carbon tetrachloride which had been repeatedly fractionally distilled with the object of separating the chlorine isotopes. Weights are in vacuum. Ag = 107.880.

The atomic weight of chlorine obtained as the result of these experiments is identical with that found by Richards and Wells.

Scandium.—Smith[11] purified scandium material (1) by solution of the fluoride in ammonium fluoride and (2) by purification of the double ammonium tartrate. The oxide was prepared through the oxalate and was converted to chloride in a current of nitrogen and carbon tetrachloride in an enclosed bottling apparatus. The chloride was then compared with silver. Weights are in vacuum. Cl = 35.457.

TABLE VI

ATOMIC WEIGHT OF SCANDIUM

Sample	Weight of $ScCl_3$	Weight of Ag	Ratio $ScCl_3:3Ag$	Atomic weight of Sc
1	0.593'11	1.26689	0.46815	45.142
1	1.13724	2.42790	.46838	45.225
1	2.14857	4.58924	.46817	45.149
1	1,10970	2.36945	.46832	45.202
		Average	.46825	45.179
2	1.02956	2.19934	.46811	45.132
2	1.50457	3.21486	.46801	45.094
2	0.90557	1.93409	.46822	45.161
2	1.79432	3.83257	.46817	45.151
2	1.71420	3.66083	.46826	45.174
		Average	.46815	45.142

These results confirm the higher value for scandium found by Hönigschmid, 45.10.

Potassium.—Honigschmid and Goubeau[12] have analyzed potassium chloride. The purified salt was dehydrated successively at 250 and 600° and was finally fused, all in a current of nitrogen. Solution and comparison with silver followed and the silver chloride was quantitatively collected. Samples Ia and Ib were prepared from the most and least volatile fractions of potassium metal which had been subjected to "ideal" distillation by v. Hevesy. Sample IV also was a "heavy" product from an incompleted similar distillation. Samples II, III and V were purified by crystallization as nitrate, chlorate and nitrate, respectively. All were finally crystallized as chloride. Weights are corrected to vacuum. Cl = 35.457.

Evidence of isotopic separation is so slight that Honigschmid and Goubeau have not separated Samples Ia, Ib and IV from the others in computing the average. The result is slightly lower than that found in the same way by Richards and Archibald, 39.106, and by Archibald, but higher than that found later by Richards and Stahler, 39.095, and by Richards and Mueller.

The ratio of silver to silver chloride computed from the above weights is 1.328670, a value identical with that found by Richards and Wells.

Argon.—Moles[13] discusses critically earlier work upon the density and compressibility of argon and arrives at the figures 1.7833 and 1.0009, respectively, as the most probable ones. The atomic weight of argon computed from these figures is 39.94.

Baxter and Starkweather[14] have redetermined the density and compressibility of argon which had been purified both chemically and by

The deviation from Boyle's Law is calculated in the conventional way from the densities at differentpressures to be 1.00080, and the atomic weight 39.943.

The densities of oxygen, nitrogen, neon and argon at different pressures as found by Baxter and Starkweather are then weighted according to their probable errors and combined in least squares solutions of the best straight line equations for the deviations from Boyle's Law. From these equations are calculated the following values, the limiting value of a molal volume being 22.4146 liters.

TABLE IX

CALCULATED VALUES

	Normal density, obs.	Normal density, calcd.	$\frac{(PV)_0}{(PV)_1}$	Atomic weight
Oxygen	1 42896 (5)	1.428965	1.00093	16 000
Nitrogen	1 25036	1 25037	1.00040	14 008
Neon	0.89990	0 89990	0 99941	20.183
Argon	1 78364	1 78304	1.00089	89 944

Yttrium.—Hönigschmid and H. Frh. Auer von Welsbach[15] have continued the work of Honigschmid and Meuwsen on yttrium (see Report for 1924) using the purest of the three specimens of material previously employed. This sample, which had been purified by Prandtl, originally gave the value 88.95. Further purification from a trace of erbium was effected by Prandtl by removing a ferrocyanide fraction. Conversion to chloride through the oxalate and oxide and gradual dehydration of the chloride in a current of nitrogen and hydrogen chloride was followed by comparing the chloride with silver and weighing the silver chloride. Weights are in vacuum. Cl = 33.457.

Silver.—Hönigschmid, Zintl and Thilo[16] carefully purified silver nitrate and prepared it for weighing by fusion in a current of pure, dry air. Then the salt was reduced to metal in a current of hydrogen, eventually at 800°. The silver nitrate and silver in most of the experiments were weighed in air and corrected to vacuum in the usual way. In a few experiments, after being weighed in air, both substances were weighed in an exhausted

weighing bottle. The latter procedure raised very slightly the weights of both substances but in the same proportion. N = 14.008.

The average ratio of silver nitrate to silver is identical with that previously found by Richards and Forbes.

Zintl and Goubeau[17] have converted potassium nitrate into potassium chloride by heating in a current of hydrogen chloride. The nitrate, after purification by crystallization, was cautiously fused in bulk and powdered preparatory to weighing. Weighings were first made in air of known density and corrected to vacuum, and then were repeated in an exhausted container. The latter were always smaller with potassium nitrate but usually larger with potassium chloride.

TABLE XII

THE ATOMIC WEIGHT OF SILVER

Air weight corrected to vacuum

Weight of KNO_3	Weight of KCl	Ratio $KNO_3:KCl$
6.88504	5.07669	1.35620

	Average	1 356111

With the ratios $KCl/Ag = 0.691149$ and $AgCl/Ag = 1.328668$, the following atomic weights are obtained:

$N = 14.008$

$KNO_3:KCl$	Ag	K	Cl
1.35617	107.872	39.102	35.454
1.356111	107.879	39.104	35.456

Brauner[18] suggests that in Baker and Riley's analyses of silver oxide (see Report for 1926) by reduction, silver might have been lost by volatilization. Baker and Riley[19] reply that owing to abundant opportunity for condensation loss of silver was unlikely, especially in view of the fact that ultimately the weight of the containing tube and silver remained constant on repeated fusion. Brauner[20] contends that a loss of silver by volatilization and condensation as smoke might readily have escaped visual detection, while the relatively small surface offered by fused silver might reduce the rate of volatilization after fusion. Baker and Riley[21] describe experiments to prove that silver, heated as in their experiments for reducing silver oxide in hydrogen, does not escape from the containing tube.

Antimony.—Krishnaswami[22] synthesized antimony tribromide from carefully purified metal which had been extracted from minerals occurring in India and Burma. The tribromide was purified by sublimation in a vacuum and collected in glass bulbs. The various fractions of tribromide, after being weighed, were dissolved in tartaric acid solution and the glass was collected and weighed. Precipitation and quantitative determination of the silver bromide was in two cases preceded by comparison with silver. Vacuum weights are given. Br = 79.920.

Dysprosium.—Hönigschmid and H. Frh. Auer von Welsbach[23] used as a starting point dysprosium sulfate which had been purified by C. Auer von Welsbach. This material was found by x-ray analysis to contain only 0.1% of holmium and a trace of terbium as impurities.

Conversion to chloride through the oxalate and oxide was followed by gradual dehydration in a stream of nitrogen and hydrogen chloride. The weighed, anhydrous chloride was compared with silver in the usual way, and the resulting silver chloride was collected and determined. Weights are in vacuum. Cl = 35.457.

The correction for holmium impurity is only —0.003 unit. The corrected value, 162.456, is somewhat lower than that found by Kremers, Hopkins and Engle, 162.52.

Moles[24] discusses gas density methods and results obtained in recent years. The best values for atomic weights determined in this way are found to be as follows: H = 1.0078; N = 14.008; F = 19.00; Cl = 35.458; Br = 79.918; Ag = 107.880; I = 126.92.

Zintl and Goubeau[25] find the weights of finely divided potassium nitrate and potassium chloride determined by weighing in air and correcting for the buoyant effect of the air in the usual way to be inconstant. Upon fusion the weight of potassium nitrate became constant but the weight was always less than that of the powdered material. Fused, powdered potassium nitrate when weighed in air and corrected to vacuum showed almost invariably a loss in weight (0.00–0.07 mg. per gram) when weighed in an exhausted container, and the weights determined by the latter method were more constant than those determined by the former. On the other hand potassium chloride sometimes weighed less but usually weighed more in a vacuum (0.00–0.05 mg. per gram). The conclusion by the authors is that the results may be explained by variable air adsorption on the surface of the finely divided material.

With the use of an improved mass spectrograph of greater resolving power and accuracy than earlier instruments Aston[26] has determined the deviations from integral values of the masses of the atoms of the following simple or complex elements.

H	1.00778	Cl^{37}	36.980

Hg	80	**200.61**	**202,200, 199, 198, 201,204, 196**
Pb	82	**207.22**	208, 207, 206, 209 (?), **203** (?), **204** (?)

Aston[27] was unable to distinguish between the mass spectra of ordinary mercury and that found in coal tar.

In the table of atomic weights on page 615, for which the author of this report solely is responsible, changes from the 1927 table are made in the cases of helium,[28] argon, dysprosium, neon and yttrium. The atomic weight of potassium seems to be in some doubt, but further evidence should be awaited before a change.

THEORIES OF UNIMOLECULAR GAS REACTIONS AT LOW PRESSURES. II

BY OSCAR KNEFLER RICE AND HERMAN C. RAMSPERGER

RECEIVED MAY 16, 1927 PUBLISHED MARCH 7, 1928

Certain gas reactions, termed by Hinshelwood quasi-unimolecular, are unimolecular at high pressures but fall off in rate below the unimolecular law at low pressures. In a recent paper[1] we have attempted, on the basis of collision hypotheses and classical statistical mechanics, to develop equations giving the relation between pressure and rate of reaction. We considered chiefly two theories which led to equations (5) and (19), respectively.

In the former article[1] we applied the theories to the decomposition of propionic aldehyde, which had been studied by Hinshelwood and Thomp-

---

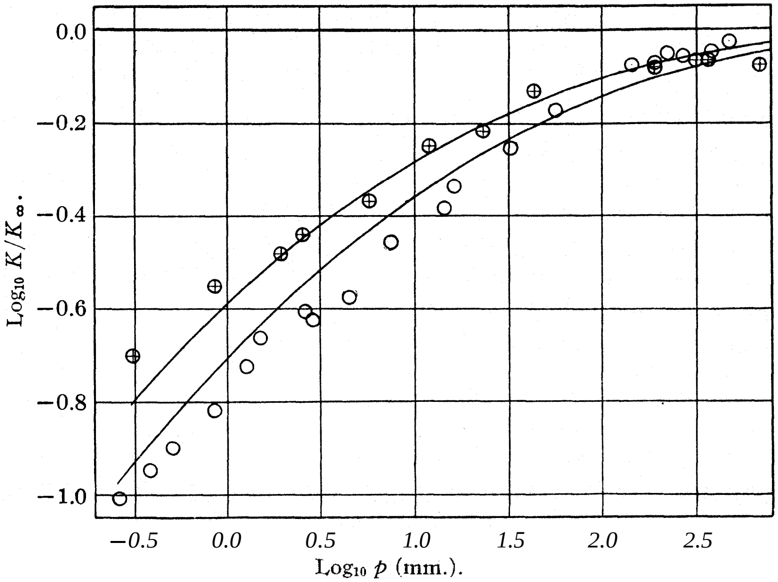
[27] Aston, Nature, 119,489 (1927).

[28] A recent unpublished determination of the compressibility of helium below one atmosphere by Mr. R. B. Ellestad and the author has yielded the value for $(PV)_0/(PV)_1$ of 0.9995. This value combined with the density found by Baxter and Starkweather, 0.17846, gives as the atomic weight of helium 4 002, a result identical with that found by Aston with the mass spectrograph.

[1] Rice and Ramsperger, THIS JOURNAL, 49, 1617 (1927).

son,[2] and found that we could not distinguish between the two theories. In this paper we shall apply our considerations to the decomposition of azomethane.[3]

In this case Theory I does not fit the data at all. If we make the curve fit the upper points it misses the lower ones by a factor of 10. The comparison of Theory II with the data is given in Fig. 1. In making the calculations we set[4] $n = 25$, which makes the rate fall off at about the right pressure, and $\epsilon_0 = 50{,}600$. s is given throughout the value of[5] 6×10^{-8}.



Upper curve, ⊕, 290°C ; lower curve, ○, 330°C.

Fig. I.

It must be remembered that ϵ_0, as given, is not the heat of activation as calculated from the original Arrhenius equation, but is related to it, as shown in our former article by equation (20) for Theory II. We have used the temperature coefficient originally found by Ramsperger.[6] We would now make a second approximation by using the temperature coefficient taken from the K_∞ values from the curves at the two temperatures, but the correction is negligible It may be well to remark that, although the values of many of the quantities involved are known to order of magnitude only, the temperature coefficients of all of them are known, and the relative positions of the curves at different temperatures, as well as their shapes, are fixed, in the plot used, once n is determined.

[2] Hinshelwood and Thompson, *Proc. Roy. Soc. (London)*,**113A**, *221 (1926).*

[3] Ramsperger, THIS JOURNAL, 49, *1495 (1927).*

[4] For the nomenclature and for the method of fitting curves to data see Rice and Ramsperger, ref. *1.*

[5] Though strictly the theory holds only for initial rate constants, average rates during a run were taken for azotnethane as they were practically the same.

[6] Ramsperger, THIS JOURNAL, 49, 912 *(1927).*

It is now necessary to use equation (24) of our previous article in order to test our assumption that deactivation, or at least sufficient loss of energy, occurs at every collision of an activated molecule. The curves used in the graphical integration of equation (19) for azomethane (which are similar to those of Fig. 1 of our previous paper) show that at the lowest pressure used at 330° approximately only 11.5% of the reaction was due to molecules having a greater energy than 62,600 calories per mole. The energy of an average molecule at this temperature, from our value of n, is about 15,000. Let us then take $\epsilon' = 77{,}600$ in equation (24); and let us take $\epsilon'' = 57{,}600$, since molecules of this energy lack equilibrium numbers by only 5%. (The number of molecules actually present is to the number present at equilibrium as the integrand in equation (19) is to the integrand at infinite pressure.) The value of (24) evaluated by a more accurate method than formerly used is less than 0.013, which is so small that Theory II needs no modification.

Correction to Previous **Article.**—The sentence below Fig. 1 should read: "At $\epsilon - \epsilon_0$ equal to 5000 the concentration lacks about 8% of the equilibrium value."

Note on Diethyl Ether

Hinshelwood has recently studied the decomposition of diethyl ether.[7] This fits Theory II a little better than Theory I. On Theory II it requires a value of n of 6.

Discussion

One of the most striking features of the results is the difference in the number of degrees of freedom[8] in the various cases. The number of degrees of freedom of azomethane fits well with the specific heats of similar compounds, C_p for acetone being about 24 calories per mole per degree in the range from 129 to 233°.[9] But the numbers of degrees of freedom of the propionic aldehyde and diethyl ether are surprisingly low; the specific heat of ether is about 44.5 calories per mole per degree at 350°. This might be due to some impedance to the transfer of energy in the molecule, only a few degrees of freedom being in communication in the proper place in the molecule, so the molecule acts like one with a smaller number of degrees of freedom.

One objection that might be brought against our interpretation of the results is the possible presence of some sort of a chain reaction, as the decomposition of azomethane is undoubtedly exothermic.[10] If this is

---

[7] Hinshelwood, Proc. Roy. *Soc.* (London), **114A,** 84 (1927).

[8] By the number of degrees of freedom we mean, as explained in our previous paper, the number of quadratic terms in the energy expression. C_v in calories is then approximately equal to the number of degrees of freedom.

[9] Landolt-Börnstein, "Tabellen," 1923, p. 1275.

[10] Azomethane explodes, presumably of course, with evolution of heat, when an electric discharge passes through it. The products are different from the products of thermal decomposition and contain a little over 20,000 calories more energy per mole of azomethane decomposed (estimated by us from heats of combustion). The heat of reaction must, therefore, be more than 20,000 calories per mole of azomethane [see Thiele, Ber., 42, 2575 (1909)].

the chief means of activation at low pressure, and unless the mechanism of transfer of energy is very specific, we would expect the reaction rate to fall off during the course of a run as the products of reaction accumulate but practically this is not the case, though the run falls off in most cases to a very small extent. What the effects of simple local-heating might be, and whether such an effect could be combined with our theory to give satisfactory results, we cannot at present decide.

Summary

Two theories based on collision hypotheses of quasi-unimolecular reactions, which we have previously developed, are applied to the decomposition of azomethane. It is possible to explain the falling off of the rate with pressure and to decide between the two theories. The efficiency of activation and deactivation at collision is considered, and the following are discussed: (1) the number of degrees of freedom involved in the various cases; (2) the effect of heat of reaction in the case of azomethane. The decomposition of diethyl ether is also considered briefly.

AN ATTEMPT TO PREPARE TRIATOMIC HYDROGEN[1]

BY HUGH M. SMALLWOOD[2] AND H. C. UREY

RECEIVED JUNE 9, 1927 PUBLISHED MARCH 7, 1928

Introduction

The preparation and properties of an active modification of hydrogen, supposed to be triatomic, have been described by a number of investigators[3]. According to their papers, whenever hydrogen is ionized or dissociated a small amount of active product is formed. The activating agents that have been used with success include a-particles, the Siemens ozonizer, the vacuum discharge and the corona discharge. It has also been stated that if oxygen is burned in an atmosphere of hydrogen, or if hydrogen-oxygen mixtures containing deficiency of oxygen are detonated, part of the hydrogen remaining after the combustion is activated. It has furthermore been reported that hydrogen is activated by passage over

heated metals such as platinum and palladium. Of these various methods of preparation the passage of hydrogen over heated metals or through the ozonizer is said to be the most readily performed.

This modification of hydrogen has been reported to have the property of reducing sulfur, arsenic, phosphorus, nitrogen, etc., at room temperature to form the corresponding hydrides, and it is this characteristic that has been used to test for the material. It is not completely destroyed upon passage through glass wool, as is monatomic hydrogen, and it is described as having a period of half-life of the order of several minutes. It retains its activity upon condensation at liquid air temperatures and subsequent evaporation. Wendt and Landauer[3b,c] state that it is catalytically decomposed by platinum, nickel, copper, lead, antimony and cadmium, but that it is not affected by silver, molybdenum, mercury, tin, bismuth, zinc or aluminum. They further observed that its preparation in a closed system is accompanied by a decrease in pressure. It is this observation that has led to the assumption of a triatomic molecule.

Recent workers, however, have been unable to duplicate these results. Bach,[4] Scanavy-Grigoriewa[5] and Paneth, Klever and Peters[6] were unable to obtain evidence of activation upon passing hydrogen over heated metals. The latter authors also report unsuccessful attempts with the ozonizer, bombardment with a-particles and detonation of hydrogen-oxygen mixtures. Curtius,[7] moreover, was unable to obtain activation with the ozonizer. On the other hand Elliott,[8] working with a similar apparatus, reports a large number of positive results including quantitative studies of the effects of the conditions of the various experiments upon the extent of activation.

There are therefore many contradictions in the past work on active hydrogen. The present paper describes a series of experiments attempting the preparation of this active hydrogen. The methods of the former workers have been repeated and, in some cases, extended. Throughout the work the results have been negative.

Experimental

1. Corona Discharge and Ozonizer.—The apparatus used in these experiments and those to be described was built of Pyrex glass throughout. The corona tube was similar to that employed by Wendt and Landauer in the previous work on this method. It consisted of a Liebig condenser about 1 m. long. The high tension electrode was a bare aluminum wire, 0.6 mm. in diameter, strung along the axis of the central tube of the condenser by means of tungsten hooks, the latter being sealed through the glass at each end of the central tube. A salt solution circulated through the cooling jacket

served as the ground electrode. The central tube, through which the hydrogen passed, was 1.2 cm. in diameter. The tube was operated at a potential of 11–12 kv. with 60 cycle alternating current. This gave a fairly uniform discharge from the central wire

The method used to determine the extent of activation was first developed by Wendt and Landauer.[3b,c] It is carried out as follows. After leaving the discharge the hydrogen is passed over glass wool (to remove atomic hydrogen) and is then mixed with nitrogen, the resulting mixture being scrubbed with 100 cc. of water. The presence of an active form of hydrogen results in the formation of ammonia, which is absorbed in the scrubbing water and determined by the usual Nessler test. The delicacy of this test was shown in the blank runs. These showed the absence of ammonia in the hydrogen and nitrogen used, but upon passing the hydrogen through the discharge without subsequent mixing with nitrogen, ammonia was found to be present to the extent of 0.0001% of the hydrogen passed. Presumably this was caused by the impurity of the original hydrogen. Both the hydrogen and the nitrogen were taken from cylinders, the nitrogen being bubbled through alkaline potassium pyrogallate and concentrated sulfuric acid.

Two thirty minute runs with this apparatus in which the pressure was maintained at one atmosphere and the temperature at room temperature, the rates of flow being 1400 and 180 cc. (0° and 760 mm.) of hydrogen per minute, respectively, failed to show an appreciable activation of the hydrogen in that the test for ammonia was no larger than that appearing in the blank run. The linear velocities of the gas flowing varied from 160 cm. to 1200 cm. per minute and the time spent in the ozonizer from 0.6 to 0.08 minute. This appears to be a sufficiently high velocity to insure removal from the activating zone and a sufficient time in the ozonizer to secure activation. Wendt and Landauer report only the volumes of hydrogen flowing per minute and not the dimensions of the apparatus, but from their description of their apparatus we believe that we have used both a wider range of linear velocities and times of activation than did these authors.

It was thought that this failure might be due to aluminum sputtered off the central electrode onto the glass walls. To remove this difficulty a Pyrex tube 4 mm. in diameter was inserted in place of the central electrode, being supported by a ring seal at each end. This tube was filled with salt solution and connected to the high tension terminal of a large spark coil. A uniform brush discharge throughout the tube was obtained with this set-up. Before commencing the actual runs the inside of the discharge tube was washed out with dilute hydrochloric acid and distilled water. Several half hour runs at atmospheric pressure and rates of flow of 400 to 800 cc. of hydrogen per minute gave no indication of the presence of an active form of hydrogen.

2. Combustion of Oxygen in Hydrogen.—The apparatus used was essentially the same as that employed by Venkataramaiah in the original work on this method. A large bulb was filled with hydrogen and the rate of flow of hydrogen through the bulb adjusted to a convenient value. Oxygen was then admitted through a platinum jet (8 mm. in diameter) and ignited by means of sparking points sealed through the wall of the bulb near the jet. The oxygen stream was regulated to give a flame about 3 cm. long. The products of combustion were passed through glass wool, over flowers of sulfur and finally directed against a piece of filter paper dipping into lead acetate solution. No formation of hydrogen sulfide could be detected with this apparatus.

3. Passage of Hydrogen over Hot Wires.—Hydrogen was passed over an electrically heated coil of nickel wire hung loosely from a horizontal porcelain tube. The temperature of the wire was varied from a dull red to the melting point of nickel. The rate of flow of hydrogen was varied through wide limits and in some experiments the gas was saturated with water by bubbling through water prior to entering the apparatus.

The hydrogen leaving the apparatus was led over flowers of sulfur and tested with lead acetate. No indications of the presence of an active modification of hydrogen were obtained although each new piece of nickel wire produced a very minute amount of hydrogen sulfide. In the light of the work of Bach and others (*loc. cit.*) these faint tests were interpreted as being due to some form of sulfur present in the original wire but which was soon exhausted.

Further experiments with platinum wires and the tungsten filament from a Mazda lamp gave no tests for hydrogen sulfide, although in some cases the wire was hot enough and the flow of hydrogen sufficiently great to melt the sulfur and even distil it into the lead acetate solution.

4. **Vacuum** Discharge.—The major part of the time spent on this research was devoted to an effort to determine whether or not an active modification of hydrogen capable of passing through a plug of glass wool is present in the gases drawn from a vacuum discharge.

Throughout this part of the work electrolytic hydrogen was used, the electrolyte being a 30% solution of potassium hydroxide. The hydrogen was passed through asbestos to remove as much as possible of the alkaline spray, and then passed over heated platinized asbestos to remove any trace of oxygen. In some experiments the hydrogen was dried with liquid air.

The first apparatus set up was, as nearly as possible, an exact replica of that used by Wendt and Landauer. This consisted of a discharge tube 10 cm. long from which the hydrogen was led over glass wool, then over flowers of sulfur and finally over a strip of filter paper dipping in lead acetate solution. No hydrogen sulfide was formed in this apparatus upon running it for as long as half an hour, although Wendt and Landauer report large tests at the end of three minutes. The pressure in the discharge was varied from 2 to 7 cm. of mercury and the rate of flow of hydrogen was varied through a wide range.

This method of detecting a small amount of hydrogen sulfide does not seem particularly delicate. To remedy this defect and to permit working at lower pressures another procedure was developed. The lead acetate bubbler was replaced with a trap filled with silica gel, which was activated by heating at 300–350° for one hour in a current of hydrogen at a pressure of 1–2 mm. The apparatus was then filled with hydrogen at atmospheric pressure and the gel heated for another fifteen minutes in a slow current of hydrogen which was led out of the apparatus and bubbled through a solution of lead acetate acidified with acetic acid. This was done to show that all of the sulfur had been removed from the gel. If this blank was satisfactory a run was made during which the gel was cooled with liquid air. At the conclusion of the run the apparatus was again filled with hydrogen and the heated gel swept out into the lead acetate solution as before. Although much more laborious than the methods used by previous workers, this procedure enabled the detection of exceedingly minute amounts of hydrogen sulfide.

On using this more delicate test it was found to be extremely difficult to obtain good blank tests. Commercial flowers of sulfur were found to contain fairly large amounts of volatile sulfides. To remedy this a very pure form of sulfur was prepared by acidifying a solution of sodium thiosulfate with hydrochloric acid and filtering off and distilling the precipitated sulfur. It was next found that in the course of a thirty-minute run enough sulfur could distil over into the gel to give fairly large amounts of lead sulfide, the elementary sulfur, of course, being reduced upon passing through the heated gel in the presence of hydrogen. This effect was eliminated by adjusting the Dewar flask holding the liquid air, in which the gel was immersed, in such a manner that the liquid air level stood 5–10 cm. above the top of the gel. The sulfur condensed to an opalescent film immediately upon reaching the cold tube. Upon removing the liquid air the hydrogen sulfide evaporated and could be swept out of the gel by heating without disturbing the sulfur condensed some distance away. Employing these precautions it was found possible to obtain perfect blank tests both upon running the discharge with no sulfur in the apparatus and upon passing the hydrogen over the sulfur in the absence of the discharge.

In the course of an actual experiment the hydrogen passed out of the discharge, through a plug of glass wool 10 cm. long and finally over the sulfur. At this point any of the active form present would react to form hydrogen sulfide, which would be adsorbed on the gel and would, at the end of the experiment, be made evident by the precipitation of lead sulfide. Such experiments frequently resulted in the formation of a small amount of precipitate but the tests so obtained were so minute and erratic that they could not be definitely ascribed to the presence of an active modification of hydrogen.

The conditions under which the various experiments were carried out were as follows. The pressure was varied in different runs from 1 to 80 mm. At the lower pressures rates of flow of 20–30 cc. per minute were used and at the higher pressures the rate was maintained at 200 cc. per minute, both volumes being measured under standard conditions. Throughout the low pressure work Wood[9] discharge tubes about 1 m. long were used. These were run with wet hydrogen, giving the red discharge due to atomic hydrogen, and with dry hydrogen, in which case the secondary spectrum was most prominent. The hydrogen to be tested was tapped off either in the middle of the tube or near one of the electrodes, since Smyth and Brasefield[10] have found that at that point in the discharge there are large amounts of H_3^+. The sulfur was inserted 15–30 cm. away from the discharge, connection being made with 7mm. glass tubing. In some of the experiments the discharge tube was cooled with tap water, with salt-ice mixture or with carbon dioxide snow and ether.

The experiments at higher pressures were carried out in smaller discharge tubes of the general type used by Wendt and Landauer. These were water cooled throughout. In some cases a condensed discharge was used, producing the atomic spectrum at a pressure of several centimeters.

During the whole series of experiments sporadic tests were obtained but these were so small that it was necessary to run for thirty minutes or more in order to produce a visible amount of lead sulfide. The size of the tests seemed to have no connection at all with the experimental conditions under which they were obtained. Efforts to show that the substance producing them was unstable enough to decay when led through a by-pass 4 m. long and 2 cm. in diameter before reaching the sulfur were not conclusive because of the strong fatigue effect observed in all the tubes. Attempts to rejuvenate a spent tube by washing with dilute hydrochloric acid, sodium hydroxide and distilled water were only partially successful. The great difficulty encountered in the whole work was that it was not possible to make a series of consistent runs in order to determine, for example, whether or not cooling the discharge had any effect on the size of the precipitate. No tube could be found that, when operated under identical experimental conditions, would give the same amount of lead sulfide three times in succession.

Wendt and Landauer have sought to obtain evidence for their assumption of a triatomic molecule by showing that the activation of hydrogen in a closed system is attended with a decrease in pressure. This experiment has been repeated and part of the original results confirmed. The apparatus used consists of a U-shaped discharge tube equipped with platinum electrodes and attached to a small closed arm manometer. If a discharge is passed at a hydrogen pressure of 9 cm. of mercury and at liquid air temperatures, there is a considerable pressure drop provided the electrodes are immersed

---

[9] Wood, *Proc. Roy. Soc. (London)*, *97*, 455 (1920).

[10] Smyth and Brasefield, *Proc. Nat. Acad. Sci.*, *12*, 443 (1926).

in the liquid air. If, however, the electrodes are not immersed in liquid air there is no effect. Wendt and Landauer report that the discharge has a yellow or greenish yellow color. In the repetition the discharge was the usual pale blue color throughout.

Discussion

The experiments just described indicate that, under the experimental conditions detailed, there is no appreciable activation of hydrogen. The failure of duplication of the results of the original workers may be accounted for in a number of ways. In the first 'place none of the papers announcing positive results report adequate blank experiments. All of the investigators were careful to ensure the absence of the particular hydride which was later to form the test from the hydrogen used in the work, but none report experiments designed to show that there was no source of sulfur or nitrogen, as the case might be, sufficiently near to the activating agent to cause the tests. Thus a little elementary sulfur blown back into a discharge can account for many of the results ascribed to H_3. On the other hand, the experiments described by Duane and Wendt and by Wendt and Landauer were so numerous and of such varied nature that it is difficult to account for them by assuming contamination of the apparatus. Although Elliott's results are detailed and self-consistent they are open to criticism on the ground that he did not sufficiently guard against the possibility of sulfur dust being blown back into the discharge. If his results were due to an active hydrogen, they fail to check those of previous workers in a number of instances. Thus he finds a much shorter period of half life than that reported by Duane and Wendt. This fact suggests a correlation between his work and that of Anderson[11] and of Mitchell and Marshall,[12] who found that the temperature at which copper oxide begins to react with hydrogen is decreased if platinum is placed in the hydrogen stream a short distance in front of the copper oxide. They showed that the effect was due to an unstable modification of hydrogen with an extremely short life. It is possible that some of these positive results may have been due to hydrogen molecules in metastable vibrational and rotational state. The question of blank tests, however, certainly deserves more attention than it has received. All of the papers, excepting the two last cited, in which the necessary controls are reported, record uniformly negative results.

An unknown catalytic effect might account for the uncertainty of the results. This could hardly be an anticatalytic effect since cylinder hydrogen has been used successfully. On the other hand, the hydrogen used in the greater part of the previous work could only have contained minute traces of water vapor, nitrogen or argon. The hydrogen used in the present work must have contained all of these gases as impurities

---

[11] Anderson, J. *Chem. Soc.*, 121, 1153 (1922).

[12] Mitchell and Marshall, *ibid.*, 123, 2448 (1923).

at one time or another. It seems unlikely that it is a question of the catalytic effect of the walls of the apparatus since, if this were the case, it should have been observed by the first workers in the field.

The pressure drop experiments fail to add any evidence since hydrogen is readily taken up by metallic electrodes and may be driven into the glass walls to an appreciable extent. In this connection it is interesting to note that in 1908 Fischer and Iliovici[13] subjected hydrogen at atmospheric pressure and liquid air temperatures to the silent discharge in a tube with *external* electrodes. They found a decrease in pressure of 0.5 mm. but, since this was less than their experimental error, they concluded that there is no new molecular species formed under these conditions. Wendt and Landauer's work would lead one to expect *a* large pressure drop in such an experiment. Furthermore, the pressure drop observed by them and duplicated by us was so large that, had it been due to the formation of H_3, it is extremely unlikely that the other experiments with the vacuum discharge would have been negative.

The only conclusion that can be drawn, therefore, is that the existence of triatomic hydrogen has not yet been established. Assuming that there is such a substance, however, it is more difficult to prepare than has been formerly supposed.

Summary

1. Unsuccessful attempts to prepare H_3 by means of the corona discharge, ozonizer, combustion of oxygen in hydrogen, passage of hydrogen over hot metals and the vacuum discharge are described.

2. The previous work on this subject is discussed with the conclusion that the existence of H_3 is not as certain as has been supposed.

THE SPECIFIC HEAT OF HYDROGEN GAS AT LOW TEMPERATURES FROM THE VELOCITY OF SOUND; AND A PRECISION METHOD OF MEASURING THE FREQUENCY OF AN OSCILLATING CIRCUIT

BY R. E. CORNISH AND E. D. EASTMAN

RECEIVED AUGUST 12, 1927 PUBLISHED MARCH 7, 1928

At room temperature the specific heat of hydrogen gas is but slightly less than the classical value for a diatomic gas without vibrational energy. This theoretical value is 5/2 R for specific heat at constant volume, where R is the gas constant expressed in the same units as the specific heat. It was found by Eucken,[1] who filled a calorimeter with hydrogen gas under pressure, that below room temperature the specific heat of hydrogen becomes less and approaches the value 3/2 R at a temperature a little below the boiling point of liquid air. A number of specific heat equations, based on quantum theory, have been proposed[2] and accordingly it seemed advisable to make, if possible, a more accurate experimental determination of the specific heat of hydrogen over this range of temperature. Since the moment of inertia of the unresonated hydrogen molecule is not known, it is an undertermined constant in the specific heat equations. However, apparently no theories fit our data. (See end of this paper.)

The experimental method chosen for the specific heat measurements was to determine the velocity of sound by Thiesen's[3] method of closed cylindrical resonators. This method was much improved by Grüneisen and Merkel,[4] who used oscillating circuits and a telephone in place of the siren used by Thiesen for the excitation of the sound in the gas. Grüneisen and Merkel worked at 0°, using both air and hydrogen. The most important further apparatus used by us was a means of obtaining the required constant low temperatures in a resonance tube 150 cm. long, and a means of measuring the frequency of an oscillating circuit (of constant frequency) with an accuracy of $^1/_{30,000}$. If the suitable number of comparison circuits (each with suitable frequency) are set up, the method can be used for measuring the frequency of *any* oscillating circuit which can be excited by radio tubes; the mean frequency over a period of fifteen minutes could (if desired) be measured with an accuracy of $^1/_{1,000,000}$, even

[4] (a) Grüneisen and Merkel, *Z. Physik*, 2, 277 (1920); (b) *Ann. Physik*, [4] 66, 344 (1921).

if the circuit oscillates only once per second. The only limitation of accuracy is due to the clock used to send the time signals, and to the constancy of the oscillating circuit.

Because of the low density of hydrogen gas, one must use resonance tubes of large diameter, to cut down damping. Because of the relatively long wave length of even the highest easily audible pitches (for example, 10,000 cycles per second) in a light gas, a longer resonance tube is required than with a heavier gas. An apparatus sufficient for determining the velocity of sound in hydrogen would give extremely accurate results with a heavier gas. In the latter case, however, the corrections for "imperfections" in the gas become larger, so that good data of state become necessary.

Calibration of Thermocouples.—For calculating specific heats from the velocity of sound, an error of 0.1°K. at 80°K. produces an error of 0.01 R in the specific heat. Accordingly, two separate thermocouples (C, Fig. 1) were used in all work, to detect any electrical defect appearing in the temperature element. For calibration, a hydrogen thermometer bulb was placed in the inner Dewar (D_2, Fig. 1) in place of the resonance tube. The pressure of the hydrogen was read to about 0.03 mm. by a Gaertner standard steel meter scale, using a cathetometer for interpolation. The bulb of the thermometer connected with the manometer by a capillary tube, and the dead space volume of hydrogen in the manometer was less than 3 cc. The hydrogen was made as for the velocity of sound work, taking special precautions to remove water vapor. Before filling, the thermometer bulb was evacuated for a week by a Cummings mercury vapor pump, using a McLeod gage. The gas pressure at the ice point was about 100.0 cm.

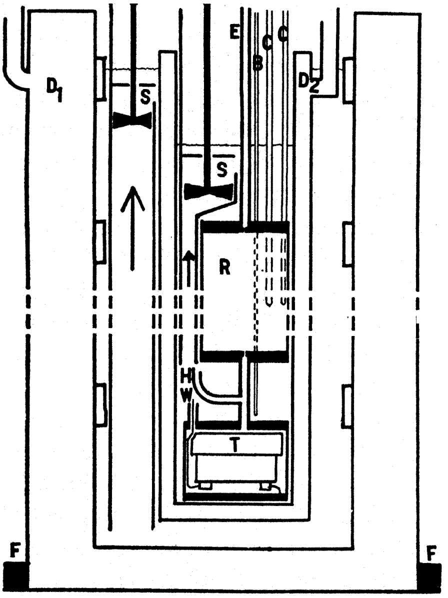

Fig. 1.—Resonator, showing temperature control.

The absolute temperature is not strictly proportional to the height of the mercury column; the necessary corrections are:

FIRST, the imperfections of the thermometer gas (see Equation 18).

SECOND, by combining the volume expansion of mercury with the linear expansion of steel for a 100cm. column at a temperature of 1° above the reference temperature (arbitrarily taken as 20°), a correction of 0.17 mm. in the mercury height (representing about 0.05" in temperature) is needed. The temperature of the mercury column was found by hanging calibrated mercury thermometers along it. The manometer was encased in a wooden box, and read through a plate-glass door.

THIRD, the pressure coefficient of the thermometer bulb was measured by filling with water, changing the pressure, and noting the rising and sinking of the water level in an end tube of known diameter. About two-thirds of the observed compression was accounted for by the known compressibility of water. The calculated correction is of course 0.000" at 273°K., and below that point the Charles' law temperature must be decreased by 0.001" at 250°K., and by 0.002° at 200°K. or any lower temperature down to 50°K.

FOURTH, the dead space and gradient space. To make these corrections small a large bulb (2410 cc.) of hydrogen was used. Volumes were measured by weighing mercury (water for the bulb). The gradient length of capillary was very short, but three thermocouples were firmly mounted on it, and their readings were considered. A thread of black glass was sealed into the top of the dead space of the manometer, and the volume of the dead space measured to the lower tip of the thread. During runs the top of the lower meniscus could be adjusted to *below* the tip of the black glass thread, since the diameter of the manometer tube was accurately known.

FIFTH, .variations in capillary depression of mercury menisci. This affects both the observed pressure and the dead space volume; the latter variation is negligible in our apparatus. The diameters of the manometer columns were 1.65 cm. From a rough extrapolation of a table given by Guyot[5] with the help of some measurements by Palacios,[6] one finds that a change of 0.4 mm. in the height of a meniscus affects the pressure reading by 0.01 mm.

SIXTH, the thermal contraction of the Pyrex thermometer bulb gives a considerable correction, which has been calculated by Dr. R. M. Buffington from the measurements of Buffington and Latimer.[7] We copy Buffington's table as Table I; from a plot the correction at any temperature can be read.

During measurements a vacuum of 0.0001 mm. or better was maintained over the upper meniscus.

In some of the work one thermocouple read as much as 2 microvolts different from the other. This is not serious, since our four-junction

couple gives from 180 to 75 microvolts per degree over the range used in this work. The true e.m.f. was taken as the mean of the readings of the two couples; it was assumed that the temperature was 273.1°K. when this mean reading was zero.

From the equations given by Eastman and Rodebush[8] for the e.m.f. of a certain four-junction copper-constantan thermocouple, the e.m.f. was calculated for the various temperatures at which we used the hydrogen thermometer. These values were larger than our measured values and the ratios were calculated. The results are in Table II, in the order taken. All points represent from 3 to 6 determinations, any one of these series of 3 to 6 determinations being taken at one time, over a period of about half an hour. During this time the temperature of the apparatus drifted from 0.05 to 0.5°, but the results were calculated for the mean temperature by using d (e.m.f.)/d T. In all but two determinations the temperature difference between the top and bottom of the apparatus was 0.02° or less. In the series at 158.61° the difference became 0.05'' and in the one at 134.87° the difference became 0.25°. This temperature difference was noted by differential thermocouple "B" (Pig. 1), and was due to heat leak at the top of the inner Dewar, since the inner bath was warming up although the outer bath was several degrees colder. At 135°K. the viscosity of the petroleum ether becomes large enough so that the stirring propellor cannot effectively equalize the temperature. This effect was avoided in the next measurement at 135°K. by filling the outer Dewar with liquid air. There is very little radiation at these temperatures and the cold air boiling off from the outer bath keeps the top of the inner Dewar cold. Even so, it was necessary to stir for three hours to obtain a uniformity of 0.02° at 133°K.

The lower temperatures for the velocity of sound measurements were calculated from the Eastman and Rodebush equations, applying the factors given in Table II.

For temperatures above 0° the boiling point of water was checked against our thermocouples a number of times. The e.m.f. was 1.01360 times

that calculated from the table of L. H. Adams.[9] All our temperatures above 0° were calculated from Adams' table, using this same factor. This sort of procedure has been used before in this Laboratory for temperatures not below the boiling point of liquid air.[7]

We have four checks on our scale. The freezing point of mercury was measured as 234.24°K. while the accepted value is 234.22°. The transition point of sodium sulfate was measured as 305.51°, instead of 305.5°K. Finally, we placed together, in a liquid air-bath, the old Laboratory standard of Eastman and Rodebush,[8] our thermocouples and thermocouple "No. 17" of Giauque, Buffington and Schulze.[10] The three temperatures obtained are, respectively, 81.75, 81.77 and 81.92°K. The same comparison a year earlier of ours with the Eastman and Rodebush couple gave a difference of 0.00°.

The Resonator Tubes for the Gas (see Fig. 1).—Four different resonance tubes, 168 cm. or less in length, were used. They were made from brass tubing, the ends being closed with brass plates. The plates were soldered in place, after measuring the thicknesses and drilling central 1mm. holes. These holes were each 1 mm. long, and led into $^{3}/_{16}$-inch thin walled brass tubing. The tubing was fastened with silver solder and served to carry the sound in and out of the various resonators. Larger sized tubing was not used in order to damp out or broaden resonance maxima due to vibrating gas in these end fittings. Smaller tubing ($^{1}/_{8}$-inch diameter) was tried, but did not transmit sound well enough when filled with hydrogen, although it was satisfactory for air.

The lengths of the resonators were determined by comparison with a Gaertner steel meter scale, using a cathetometer as intermediate. Temperature corrections were made, assuming the steel scale to be exactly 1 meter long at 20° as stated by the makers and using expansion coefficients of 0.18×10^{-4} per degree for brass and 0.11×10^{-4} per degree for steel. The end thicknesses were subtracted from the lengths as determined by the cathetometer (Table III).

TABLE III

DIMENSIONS OF RESONATORS AT 0° (NO. 168 AT 20°)

[10] Giauque, Buffington and Schulze, THIS JOURNAL, 49, 2343 (1927).

The accuracy of the lengths is 0.01 cm. or better. As the end surfaces of the resonators were not exactly perpendicular to the long axes, determinations 90 degrees apart were made of each length, and the average was taken. As much as 0.04 cm. difference in the length as measured along two opposite sides was found in one resonator (No. 150 A).

Sound in the resonators was heard through the $^3/_{16}$-inch tubing E, 30 cm. or more in length, with the ear pieces from a stethoscope fastened to the free end of the $^3/_{16}$-inch tube by a short piece of rubber tubing. During measurements, hydrogen gas was flowing out through the stethoscope into the ear of the observer. The stethoscope was most sensitive when not clamped tightly in the observer's ear, but held loosely. This effect was later avoided by by-passing the escaping hydrogen so it did not build up a pressure in the observer's ear. The only setting made while listening is a variable condenser, which is adjusted to give a maximum of sound (see below).

A too rapid flow of hydrogen through the apparatus produced uncertainty. The noise of vacuum pumps or talking was troublesome; these distractions were eliminated during all the velocity measurements. Stirring motors were shut off during actual setting of the resonant frequency.

At one time while working at low temperatures, a very baffling difficulty was found to be due to atmospheric air being drawn into the apparatus through tube "W," due to gravitation; this was later prevented by proper precautions.

As the resonators were mounted vertically in a thermostat, the telephone "T" was encased in a copper can, fastened at the bottom of the resonator (Fig. 1). The telephone was activated by an amplifier, the lead wire W (broken off in Fig. 1) being insulated by a small-sized rubber tube, encased in a steel tube. Tests showed a large fraction of the energy from the amplifier to be lost, due to the capacity between the lead wire and the encasing tube, for the return from telephone to amplifier was made by grounding to the apparatus. This loss was worst with frequencies of 10,000 per second or higher. The hydrogen was led into the short tube connecting the telephone and resonator by means of a copper tube H running from top to bottom of the thermostat. A very slow stream of the gas flowed around the telephone, and out through the steel current conduit so that gas in the telephone could not flow through the resonator. The main quantity of hydrogen flowed out through the stethoscope.

The "Impure" Hydrogen (for Tables VIII and X).—The hydrogen was made by the 500-ampere electrolytic generator which is used in this Laboratory for preparing hydrogen for the liquefaction cycle. According to Latimer, Buffington and Hoenshel,[11] the hydrogen contains about 1% by volume of oxygen as it comes from the generator, but this oxygen changed to steam by passage through the nickel catalyst of those authors. Using their method, analyses were run for oxygen both before this research was begun, and after it was finished. In both cases about 0.01% by volume of oxygen was found, and part might well be due to imperfect removal of dissolved air from the solutions necessary. The hydrogen was passed through 100 cm. of glass tubing cooled with liquid air and through a plug of glass wool also kept at liquid air temperature. From this the hydrogen was kept flowing continuously through the resonance tube during measurements, and in fact for at least six hours before beginning them. When

---

[11] Latimer, Buffington and Hoenshel, THIS JOURNAL, 47, 1571 (1925)

soldering had been done on the resonance apparatus, this was evacuated for at least twelve hours to evaporate the water from the soldering flux. It sometimes required six hours to pump out even most of this water, as indicated by a small manometer. Whatever parts of the system must be immersed in a liquid were carefully tested for leaks, using air presstire and immersing in water.

The "Pure" Hydrogen (for Table XI).—The purity of the above hydrogen cannot be guaranteed to better than 0.01% by volume. Because of the form of the relation between specific heat and velocity of sound, and because of the low density of hydrogen relative to air, an impurity of 0.01% by volume of oxygen or nitrogen amounts to 0.5% error in the specific heat, or to 0.0125 R. Accordingly, it was decided to repeat the measurements with hydrogen purified by passing through a glass spiral which was immersed in liquid hydrogen (using also the other glass spiral in liquid air as a preliminary). This new spiral contained a glass wool plug to collect air or other dust. The spiral was mounted in a hydrogen liquefier designed by Dr. W. F. Giauque of this Laboratory. The liquefier holds about 2 liters of liquid hydrogen, which permits measurements to be safely made for twelve hours. Some liquid is present even after twenty hours. The hydrogen used in the resonator was presumably never liquefied, but was certainly cooled to the condensing point since in the trap it was under slightly greater pressure than the liquid hydrogen in the surrounding container. As shown in Fig. 3, the specific heat results obtained below room temperature are only very slightly lower than those with hydrogen direct from the generator. In this new series the resonator was carefully evacuated for several days at a temperature higher than that used in the next run, using a Cummings mercury diffusion pump. In this way a few small leaks (otherwise practically undetectable) in the telephone chamber were detected and repaired from time to time, as they appeared, these being detected by the McLeod gage on removing the liquid from the thermostat. As previously explained, gas from the telephone cannot get into the resonator during specific heat runs; but it was found that, especially when the resonator was heated, a considerable amount of adsorbed gas (probably water) was given off, enough to account for the high results obtained above room temperature with "impure" hydrogen. We then check the statement of Latimer, Buffington and Hoenshel[11] that their nickel catalyst gives hydrogen better than 99.99% pure by volume. In this second series the resonator was never filled with hydrogen until measurements with the McLeod gage showed a rate of de-adsorption of gas which would not contaminate the hydrogen to as much as 0.001% by volume (taking into account the rate of flow of the hydrogen through the apparatus); at 100° this required several days of pumping.

The Air (for Table XII).—Runs were made with air at room temperature, to verify the Kirchhoff-Helmholtztube correction. To avoid variation from day to day, *all* the air to be used was pumped into a gas cylinder by our liquid air plant compressor, first blowing out the compressor for some time to avoid fractionation due to the air liquefier. As used, the air was bubbled through several towers of concentrated potassium hydroxide solution, through towers of concentrated sulfuric acid and finally through a 100cm. glass spiral cooled with solid carbon dioxide. Several feet of glass wool were installed in appropriate places in the line, and especially more than enough to eliminate the smell of sulfuric acid spray.

Air cannot be purified safely by passing through a liquid air trap. Fresh liquid air contains about 20% oxygen, but the gas evaporating from it contains about 5% oxygen.[12] Obviously if ordinary air is passed very slowly through a trap cooled by fresh

---

[12] Dodge and Dunbar, THIS JOURNAL, 49,607 (1927).

liquid air, the gas emerging will contain 5% oxygen. This explains the supposedly surprising statement of Stock and Ritter[13] that the density of dried air varies from day to day over a range of 0.13%. Some measurements of ours (not given in this paper) on the velocity of sound in air purified by a liquid air trap indicated an even greater concentration of nitrogen than was found by Stock and Ritter. Moreover, Dr. M. Tamele of this Laboratory has found that carbon dioxide is not completely removed by passing air through a liquid air trap containing copper gauze unless at least some of the air is condensed, presumably thus wetting the carbon dioxide dust enough to allow it to stick to the gauze.

Oscillating Circuits.—The sound was produced by exciting the telephone ("T," Fig. 1) by radio apparatus. The telephone diaphragm must be tightly clamped to work at high frequencies without enormous distortion. In this telephone the hard rubber clamp was replaced by one of brass, as the rubber one becomes loose with large temperature changes. Presumably, using diaphragms of smaller diameter than ours of 1.75 inches, results could be obtained with frequencies higher than 12,000 cycles per second. This was not advisable, because the ear is not very sensitive to frequencies above 15,000 cycles, especially in recognizing changes in intensity. Also the ear shows a very great fatigue effect at such frequencies after listening for a few seconds.[14]

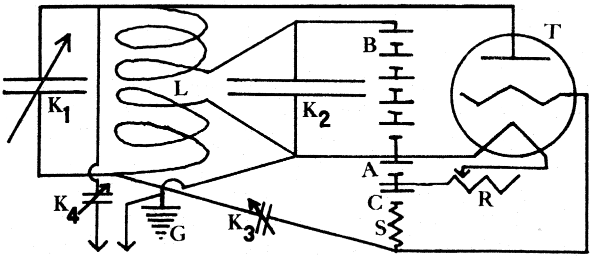

Fig. 2.—Oscillating circuit.

Two independent oscillating circuits are used, as should always be done when a constant frequency is desired; if the frequency of the circuit should begin to vary erratically, that is most easily noted by setting up beats between the two circuits.

The double inductances used in the two circuits for most of the measurements (L in Fig. 2) were of about 0.025 and 0 10 henries, respectively. Inductances were made from No. 21 wire, or wire larger in diameter, giving a low damping coefficient. Each inductance was in two approximately equal sections, for the "Hartley Circuit."

Small 3-electrode radio tubes were used for excitation. For constancy of frequency tungsten filaments were preferable to oxide filaments for the oscillator (not necessarily for the amplifier); the real requirement is probably a good vacuum in the tubes. A filament voltage of 2 to 5 volts heated the filament, battery "A" with rheostat " R being used. The grid was coupled through a small 3-plate variable condenser "K_3." Its capacity, and the filament voltage, should be somewhat, but not a great deal, larger than the minimum necessary; the plate voltage should not be excessive. Below 1000 cycles "K_3" was short-circuited by a switch. The negative grid "bias" was maintained by battery "C" and resistance "S" (500,000 ohms).

Except for occasional replacing of inductances, the frequency was controlled by capacity "K_1," which could be varied continuously from 3 to almost 0 μF.

---

[13] Stock and Ritter, *Z. angew. Chem.*, 39,1463 (1926).

[14] See, however, a method by which the velocity of sound was measured at frequencies as high as 1,500,000 cycles per second, Pierce, ***Proc. Am. Acad. Arts Sci., 60,*** 271 (1924–1925).

K_2 was a 15 μF by-pass condenser for the B battery. K_2 was often disconnected altogether, as usually it did not affect the constancy or ease of production of osciliations.

The output energy was very small, passing through a 3-plate condenser K_4 similar to K_3. This lead, together with the battery ground, excited the amplifiers.

It is important that all electrical connections be tight. Switches were avoided except for filament rheostats. Trouble was often produced by screws in the 3-plate condensers or in the tube supports working loose. Also the spring clips in the tube supports must sometimes be sandpapered.

With precautions noted above, the "instantaneous" frequency of the circuits did not usually change by more than 1 part in 30,000 in half an hour, as shown by heat measurements. This was sometimes true even only an hour after charging the batteries, and applies to the range 200 to 12,000 cycles per second. Frequencies below 300 were sensitive to changes in battery voltage.

Except for Murdock variable air condensers for the fine adjustment, of total range 0.001 or 0.0005 μF each (sometimes filled with oil to double the range), the condensers K_1 have mica for dielectric. Some are ordinary radio condensers, each of capacity 0.005 μF or less, connected in parallel by binding posts. The layers of the radio condensers were tightly clamped with nuts and bolts. After clamping it was necessary to measure the capacities of the small radio condensers, using a Wheatstone Bridge. For each inductance a plot of frequency against capacity was made to hasten the adjusting of capacities. By using logarithmic plotting paper a straight line is obtained.

Measurement of the Frequency.—The frequency of the oscillating circuits was measured by comparison with a siren, using a beat method. It is not necessary for the siren to run at constant speed, as long as the beats do not come too fast to be counted. The siren disk had 80 or 20 holes in the rim. Through these air was blown by a jet operated at a pressure of 50 lb. per sq. inch or less. The disk was mounted on a motor with a maximum speed of 50 revolutions per second It was hard to make comparisons with the siren at frequencies higher than 6000 cycles, due to the preponderance of the noise of the driving motor over the high frequency. Accordingly, the main oscillating circuit is compared with the auxiliary one, whose frequency is almost $^1/_2$, $^1/_3$ or $^1/_4$ as great, by a beat method described below. Later the auxiliary circuit was kept at about the resonant frequency of the hydrogen (or at about twice the resonant frequency), which enormously speeded up the measurements, as only a few measurements on the siren were needed at each temperature, even when a large number of overtones was measured. The auxiliary oscillator operates a telephone near the siren, a radio tube providing amplification. This telephone was in a tight glass compartment from which a short glass tube led to an open end within 2 inches of the siren jet. The open end may be stuffed with cotton waste, the siren motor also being supported on rubber stoppers to drown out the noise of the motor. The siren note may be heard, for a cotton plug transmits more sound than can enter through the entire wall of the glass tubing.

Sound within the short glass tube is heard through a T-connection, using the ear pieces from a stethoscope. Thus any beats are easily heard and counted.

Besides the siren disk a 10-lb. flywheel is mounted on the motor. This shunt-wound, 0.5 horsepower D. C. motor was operated by a storage battery. After starting the motor, all resistance was cut out of the armature circuit. To obtain changes in speed, the armature voltage could be varied at will from 20 to 105 volts, in approximately 2-volt steps, by adding storage cells. The field was excited by the entire 105-volt battery, and fine adjustments of speed were obtained by a rheostat in series with the field coil. These precautions were necessary to obtain the required constancy and reliability in speed.

A second shaft is direct-connected to that of the motor by a short piece of rubber tubing, the rubber being prevented from slipping by wires through holes in the shafts. Thus, using a worm and gear, a disk is driven at a rate $^1/_{192}$ as fast as the siren disk.

For recording time on the two disks, we had two short, pointed No. 12 copper wires, one held near each disk. Either of the pointed wires could be connected at will to the secondary of an induction coil. The two disks are smoked by holding them in the flame of burning camphor, so that a spark mark made while the disks are moving may be located as a pinhole in the soot.[15]

A telegraph relay was actuated once a second by means of a chronometer in the Department of Astronomy. Tests showed the relay, together with our sparking system, to give two-second intervals to $^1/_{1000}$ second. The platinum contacts of the relay were in the primary circuit of the induction coil, which circuit could be finally completed by a knife switch so that sparks are not necessarily made whenever the relay moves. The relay had a set of contacts on each side of the moving arm, the second set operating a machine for counting seconds.

An actual comparison is made as follows:

Listening with the stethoscope, and with the proper armature voltage, the operator adjusts the field rheostat until the frequency of the siren is slightly above (or below) that of the telephone. This is noted by the slow beating between the two pitches of sound. The beats are then counted for a 120-second interval, there being between 200 and 600 beats during that time. At the start of the 120-second interval, that is, on the zero second, a spark mark is allowed to be made by the chronometer on the high speed siren disk. The sparking point near the disk is then shifted by means of a small electromagnet, and another spark mark is allowed to be made on the 120th second. On the No. 2 and No. 122 seconds, spark marks are made on the slow-moving disk. Here again an electromagnet allows the two spark marks to fall on circles of different radius, so that they may be distinguished from each other. The machine is stopped, and the spark positions measured. From the four positions, from the number of beats counted and from the whole number of revolutions of the slow-moving disk in 120 seconds (determined separately, usually between 5 and 25), the frequency of the telephone is calculated. If everything is working properly, a second comparison checks this to 0.10 cycle per second for frequencies around 3000 cycles per second. Frequencies less than 500 are checked to 0.01 cycle per second. The comparison must be made twice, because of the many chances for mistakes. The beats were occasionally double or triple, but measurements with the siren first above and then below the frequency of the auxiliary circuit eliminate any such uncertainty.

The "clock-fork" invented by Koenig many years ago gives frequencies *as* accurately as our siren; Miller[16] claims a possible accuracy of 1/650,000 for the frequency of his 60 to 70 cycle per second clock fork. However, for our purposes the siren has certain advantages of variability of pitch, ruggedness and quick operation.

Amplifiers.—Three amplifiers are used. The first is the radio tube which operates the telephone for comparison of the auxiliary oscillating circuit with the siren. The second amplifier was excited by the main oscillating circuit and consisted of two 7.5-watt stages, with two transformers. The output energy was regulated by the filament voltages. The output of this amplifier operates the telephone at the end of the hydrogen chamber, by which means stationary sound waves are set up in the hydrogen gas. A resistance repeating amplifier with 800 volts on plate[17] was tried in place of the transformer repeater but it did not increase the range of possible measurements to more than 14,000 cycles per second, while 12,000 cycles per second could be used with the trans-

---

[17] Morecroft, "Principles of Radio Communication," John Wiley and Sons, Inc., **1921.**

former repeater. Because of the erratic character of the 3 determinations of velocity made using the resistance repeater (3 highest frequencies with tube No. 100A at 0°, see Table VIII), further work with it was abandoned.

The third amplifier was used for comparing the main and auxiliary oscillating circuits with each other. Three radio tubes were used. One was excited by the auxiliary circuit, one by the main circuit (through the output of the second amplifier) and both of these tubes induce into the third tube by means of a transformer. (Where the frequency of the main circuit is many times that of the comparison circuit, this third tube must be replaced by a 3-tube amplifier.) The last tube operates a pair of headphones, so that any beats may be heard. The auxiliary oscillator had approximately $^1/_2$ or $^1/_3$, etc. (the numerator of the fraction being 1 or occasionally 2), the frequency of the main oscillator. Calling this fraction x/n (where x/n is reduced to its lowest terms), the auxiliary frequency v and the main frequency $nv/x \pm d$, xd beats per second are usually heard in the headphones of the third amplifier, due to "distortion."[4a] A suitably small, variable condenser formed part of K_1 in the auxiliary oscillator and, by moving this, it could be found whether d was positive or negative. This condenser was fitted with a stop so that it could be brought to either end of its range but have a reproducible capacity at those two positions. From the measured difference of capacity between the ends of this range, together with the approximate frequencies of the two oscillating circuits and the value of K_1 in the auxiliary circuit, we may calculate the change in d when the small variable condenser is moved from one end of its range to the other. If now we measured the difference in the number of beats per second in the headphones for the two positions of this condenser, this was found almost always to agree with the calculated value. In a *very* few cases, however, this number of beats was exactly half (not twice) the calculated number; also, both types of beats were sometimes heard at once.

When the *difference* in the numbers of beats was a *multiple* of the calculated difference, or if the *total* number of beats was very large, a spurious maximum was being used. Obviously these tests are most reliable if the auxiliary circuit is kept at the resonant frequency of the hydrogen.

Accordingly, the auxiliary and main circuits were compared by counting the number of beats produced by the third amplifier in a definite time (25 sec.), with the above condenser at one end of its range, and by determining the sign of this beat difference, from the effect of moving the condenser.

Maintenance of Temperatures (see Fig. 1).—The resonator and its telephone were immersed in a stirred liquid-bath contained in a 180 cm. long Dewar tube (D_2). The stirrer propellor was so efficient that when this Dewar was filled with water and a 5cm. layer of crushed ice was maintained at the top, the temperature difference between top and bottom dropped to 0.003° in about thirty minutes; but the behavior of this thermostat was discussed in the section on "calibration of thermocouples." For work at lower or higher temperatures than that of the room, a liquid bath was maintained in a larger Dewar (D_1) outside the first one.

The larger Dewar was made from a steel tube 9 inches in diameter and 220 cm. long, and an inner tube of sheet Monel Metal 6 inches in diameter. The space between the walls and between the bottoms was filled with silk floss and a vacuum of about 0.003 mm. or better maintained by continuous pumping with a Cummings mercury vapor pump and a liquid air trap. A leak prevented a better vacuum. (This was later remedied by replacing the Monel Metal tube by a brass tube.) The pressure sometimes rose to between 0.01 mm. and 0.02 mm., due to various causes, and this increased the heat leak into the outer bath by a factor of 3 or 4. The 6 inch sheet Monel tube was made by folding and riveting a flat sheet of the metal and soldering. Considerable trouble was found due to vacuum leaks around the soldered rivets. Dr. W. F. Giauque of this Laboratory found that this trouble could be avoided by using Monel Metal rivets in place of rivets of galvanized iron. At the lower temperatures the outer bath warmed about 2° per hour.

The lower end of the outer tube was threaded so that an ordinary 9-inch pipe cap could be screwed on (see "F" in figure). Gas leakage past the threads was prevented by de Khotinsky cement.

The smaller Dewar was made from brass tubing. For about 20 cm. from the top, the inner piece of brass tubing was replaced by a German silver tube (thickness 0.01 inch) for reducing heat leak. The diameters of the walls were 3.5 and 2.75 inches. A vacuum of 10^{-5} mm., or better, was maintained by continuous pumping, using a liquid air trap as well.

At first a 180cm. silvered Pyrex glass Dewar was used in place of the brass one, many of the measurements being made with it. However, two such Dewars were lost by breakage, due in at least one case to the giving way of strains and not to mechanical shock. The metal Dewar gave a somewhat greater heat leak at the top than the glass one but the vacuum in the metal Dewar could always be read.

For all work where water or liquid air or oil (heated electrically) were not used for the baths, petroleum ether was used. This was cooled by immersing in it large test tubes (with a 2-liter baffle at the top), to hold liquid air.

Thermal Expansion of Brass.—In velocity of sound determinations other than at room temperature, it is necessary to know the thermal expansion of the apparatus. Buffington and Latimer[7] measured the coefficients of expansion of copper and aluminum over the required temperature range and, accordingly, the coefficient of expansion of the brass sound tube No. 150A was measured relative to both copper and aluminum. For this purpose, three aluminum rods 0.25 inch in diameter barely projected out of the smaller Dewar, which was nearly filled with an appropriate stirred liquid bath, with a thermocouple for measuring the temperature. A scratch was made on each of the three aluminum rods and the heights of these scratches measured at various temperatures, by means of a cathetorneter, after scraping off the atmospheric ice. One of the aluminum rods was short and was soldered to the top of the brass resonance tube. Another much longer aluminum rod was soldered near the bottom of the brass tube. The third aluminum rod was short and was soldered to a long copper rod, the other end of the copper rod being soldered to the bottom of the brass tube. The relative motion of the scratches gave the relative thermal expansions of brass, copper and aluminum, for bending of the rods was prevented. In Table IV are given the results; either series is probably accurate to 0.1 mm. A graph was used for the velocity of sound calculations. The uncertainties which are evident are due to us and not to Buffington and Latimer.

TABLE IV

LENGTH OF A 100CM. BRASS TUBE RELATIVE TO ITS LENGTH AT 273.1°K

Abs. *temp., °K.*	From *copper data, mm.*	From aluminum *data, mm.*	Average
273.1	0.00	0.00	0.00
254.1	− .32	− .39	− .36
236.3	− .57	− .68	− .63
218.3	− .93	− .95	− .94
196.3	−1.31	−1.35	−1.33
174.4	−1.67	−1.71	−1.69
157.2	−1.93	−1.97	−1.95
151.6	−2.00	−2.06	−2.03
81.7	−3.05	−2.92	−2.98

For work above 0°, the coefficient of expansion of brass was obtained from tables.[18]

Calculation of Specific Heat from Velocity of Sound at a Given Temperature

In this section all quantities except pressure are taken in absolute, C. G. S. units.

R = Gas constant (ergs per degree per mole).
P = Pressure (dynes per sq. cm.).
p = Pressure (atmospheres).
V = Volume of 1 mole of substance (cc.).
M = Molecular weight of substance and number of grams in 1 mole.
T = Absolute temperature.
C_p = Specific heat at constant pressure (ergs per degree per mole).
C_v = Specific heat at constant volume (ergs per degree per mole).
W = Velocity of sound (cm. per sec.).
S = Entropy of substance (ergs per degree per mole).

Other quantities are defined as needed.

Many years ago Sir Isaac Newton showed that

$$W = \sqrt{-\frac{V^2}{M}\cdot\frac{\partial P}{\partial V}} \qquad (1)$$

for a gas or liquid or for longitudinal waves in a solid. Assuming the process to be reversible and adiabatic, the entropy of any part of the gas is constant, or

$$W = \sqrt{-\frac{V^2}{M}\left(\frac{\partial P}{\partial V}\right)_S} \qquad (2)$$

As[19]

$$C_p = T\left(\frac{\partial S}{\partial T}\right)_P \text{ and } C_v = T\left(\frac{\partial S}{\partial T}\right)_V$$

$$W = \sqrt{-\frac{V^2}{M}\left(\frac{\partial P}{\partial V}\right)_T\frac{C_p}{C_v}} \qquad (3)$$

Also[20]

$$C_p - C_v = -T\left(\frac{\partial V}{\partial T}\right)_P^2\left(\frac{\partial P}{\partial V}\right)_T \qquad (4)$$

As the equation of state of hydrogen at low pressure, we will take

$$PV = RT + \frac{a}{V} \qquad (5)$$

where a is a function of T, but not of P or V. This equation, or one equivalent to it, was used by Kamerlingh Onnes and his staff for calculating the relation between the hydrogen and thermodynamic temperature scales.[21]

Solving (5) for P, and differentiating

$$\left(\frac{\partial P}{\partial V}\right)_T = -\frac{1}{V^2}\left[RT + \frac{2a}{V}\right] \qquad (6)$$

---

[19] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 132.

[20] Ref. 19, p. 136.

[21] See, for example, Onnes and Braak, *Comm. Phys. Lab. Univ. Leiden*, No. 97b, p. 34, where it is shown that the form of this equation of state introduces an error not larger than 0.0003° in the hydrogen scale at as low a temperature as 56°K., although his total correction to change to the thermodynamic scale amounts to 0.076° at this temperature.

Also, dividing (5) by P, and differentiating

$$\left(\frac{\partial V}{\partial T}\right)_P = \frac{1}{P}\left[R + \frac{1}{V}\frac{\mathrm{d}a}{\mathrm{d}T} - \frac{a}{V^2}\left(\frac{\partial V}{\partial T}\right)_P\right]$$

Solving this for $\left(\frac{\partial V}{\partial T}\right)_P$, and substituting for P its value from (5)

$$\left(\frac{\partial V}{\partial T}\right)_P = V\frac{R + \frac{1}{V}\frac{\mathrm{d}a}{\mathrm{d}T}}{RT + \frac{2a}{V}} \tag{7}$$

If, now, we eliminate C_p between (3) and (4), solving for C_v, and substitute for the partial derivatives their values given by (6) and (7)

$$C_v = T\frac{\left[R + \frac{1}{V}\frac{\mathrm{d}a}{\mathrm{d}T}\right]^2}{MW^2 - \left[RT + \frac{2a}{V}\right]} \tag{8}$$

This equation gives C_v at p atmospheres if the velocity of sound is measured at that pressure. Supposing the experiment to be carried out at a pressure of p atmospheres and writing C_{v_0} for the specific heat of the substance at zero pressure, we have first[22]

$$\left(\frac{\partial C_v}{\partial V}\right)_T = T\left(\frac{\partial^2 P}{\partial T^2}\right)_V \tag{9}$$

Now by dividing (5) by V and then differentiating twice, we have

$$\left(\frac{\partial^2 P}{\partial T^2}\right)_V = \frac{1}{V^2}\frac{\mathrm{d}^2a}{\mathrm{d}T^2}$$

Substituting this value for the second derivative in (9), we may integrate

$$C_v - C_{v_0} = \int_{P=0}^{P=p\text{ atm.}} \frac{T}{V^2}\frac{\mathrm{d}^2a}{\mathrm{d}T^2}(\partial V)_T = T\frac{\mathrm{d}^2a}{\mathrm{d}T^2}\int_{P=0}^{P=p\text{ atm.}} \frac{(\partial V)_T}{V^2} = \frac{-T}{V}\frac{\mathrm{d}^2a}{\mathrm{d}T^2} \tag{10}$$

Now the terms involving a in (8) and (10) are so small that we may write $1/V = P/RT$ in them without appreciable error for pressures of 1 atmosphere or less. We also expand the square in the numerator of (8) and neglect the second order term involving $(1/V)^2$. Then, if (8) and (10) are combined, eliminating C_v, and solving for C_{v_0} we obtain finally

$$\frac{C_{v_0}}{R} = \frac{R\left[T + \frac{2P}{R^2}\frac{\mathrm{d}a}{\mathrm{d}T}\right]}{MW^2 - R\left[T + \frac{2aP}{R^2T}\right]} + \frac{P}{R^2}\frac{\mathrm{d}^2a}{\mathrm{d}T^2} \tag{11}$$

We may remark that the R on the left-hand side of equation (11) may be taken in any units in which we wish to have C_v expressed; the R's on the right side of the equation must be in absolute c.g.s. units.

The data of state for hydrogen gas at pressures of 1 atmosphere or less are expressed by Onnes and Braak as values of B'_T at various temperatures.[23]

---

[22] Ref. 19, p. 141.

[23] Onnes and Braak, *Comm. Phys. Lab. Univ. Leiden*, No. 101b, p. 16; *Verslag. Akad. Wetenschappen Amsterdam, 1907,* p. 427.

B'_T is defined by the equation[24]

$$pv = A_T\left[1 + \frac{B'_T}{v}\right]$$

Here p is the pressure in atmospheres and we will write $P = bp$, b being the number of dynes per sq. cm. in 1 atmosphere. A_T is defined as $T/273.10$ and v is the volume divided by the "theoretical normal volume." As the latter volume is, for 1 mole, $273.1\ R/b$ cc., we have $v = bV/273.1\ R$. The Leiden equation of state may then be written in c.g.s. units as

$$PV = RT + \frac{273.1\ B'_T\ R^2T}{bV} \tag{12}$$

Comparing this with equation (5), we see that

$$a = \frac{273.1\ R^2T\ B'_T}{b} \tag{13}$$

Considering again equation (11), we see that it involves three correction terms, each involving P to the first power. Expressing now the pressure in atmospheres, (11) may be written

$$\frac{C_{v_0}}{R} = \frac{R(T + Yp)}{MW^2 - R(T + Xp)} + Zp \tag{14}$$

and it follows that

$$\begin{aligned} X &= \frac{2ab}{R^2T} = 546.2\ B'_T \\ Y &= \frac{2b}{R^2}\frac{da}{dT} = 546.2\ \frac{d(T\ B'_T)}{dT} \\ Z &= \frac{b}{R^2}\frac{d^2a}{dT^2} = 273.1\ \frac{d^2(T\ B'_T)}{dT^2} \end{aligned} \tag{15}$$

Merely for convenience, we define a new quantity Δ such that

$$B'_T\ 10^3 = 1 - \frac{110}{T} + \Delta \tag{16}$$

In Table V are given values of Δ at the temperatures of the measurements of Onnes and Braak,[23,24] as well as their values of B'_T.

TABLE V

HYDROGEN DATA OF STATE

Abs. temp.. °K.	$1 - \frac{110}{T}$	$B'_T\ 10^3$	$\Delta \cdot 10^3$
373.10	+0.705	+0.6321	−0.073
293.10	+ .625	+ .622	− .003
273.10	+ .597	+ .5807	− .016
169.55	+ .351	+ .394	+ .043
133.25	+ .174	+ .229	+ .055
109.00	− .009	+ .018	+ .027
90.34	− .218	− .241	− .023
77.89	− .412	− .432	− .020
68.47	− .606	− .692	− .086

55.77	− .972	−1.203	− .231

---

[24] Onnes and Braak, *Comm. Phys. Lab. Univ. Leiden*, No. 97b, p. 33; *Verslag.* Akad. *Wetenschappen* Amsterdam, 1907, p. 668.

Equations (15) may now be written in the form

$$\begin{aligned} X &= 0.5462\left(1 - \frac{110}{T} + \mathrm{A}\right) \\ Y &= 0.5462\left(1 + \frac{\mathrm{d}(T\Delta)}{\mathrm{d}T}\right) \\ Z &= 0.2731\left(\frac{\mathrm{d}^2(T\Delta)}{\mathrm{d}T^2}\right) \end{aligned} \qquad (17)$$

We have plotted A from Table V, drawing the best curve. From this curve values of A and hence of X may be obtained at 10° intervals, from which Y could be obtained. Similarly, by again differentiating these slopes, we may obtain Z. The slopes found were smoothed out by plotting them directly against T (see Table VI).

For comparison we give Table VII, calculated from Berthelot's equation of state, using a critical pressure of 12.8 atmospheres and a critical temperature of **33.1°K.** Use of the actual critical volume in this equation gives poorer agreement with Table VI.

TABLE VI

VALUES OF CORRECTION TERMS IN EQUATIONS (14), (18) AND (21), FOR HYDROGEN, FROM DATA OF ONNES AND BRAAK

300	.327	.391
200	.304	.424
100	.125	.603
70	− .123	.851
60	− .289	1.017

An equation of state of Keyes[25] requires that $Z = 0$, and hence that C_v is independent of pressure. But Table V shows that A has a second derivative different from zero; in any case, the Z term is less than the experimental errors of this research.

In Table VI we give $t°$, the correction for giving the temperature scale

---

[25] **Keyes, Townshend and Young, J.** *Math. Phys.,* Mass. *Inst.* Tech., 1,251 (1922).

in terms of the absolute scale. In the constant volume hydrogen thermometer, if T be any temperature, J the corresponding pressure of the hydrogen in atmospheres and J_0 the pressure when $T = 273.1$°K., we define t° as follows

$$T = 273.10\,\frac{J}{J_0} + t^\circ J_0 \tag{18}$$

We may calculate t° from equation (12). In the correction term of that equation we may write

$$V = \frac{Pv_0}{273.1\ R} = \frac{b\ J_0}{273.1\ R}$$

which gives for the equation of state of the thermometer gas

$$PV = RT\,(1 - B'_T\,J_0)$$

Equating the hydrogen volume at T with that at 273.1°, we obtain, neglecting second order corrections

$$T = 273.1\,\frac{J_0}{J} + T(B'_{273.1} - B'_T)\,J_0$$

that is

$$t^\circ = T\,(0.5807\cdot10^{-3} - B'_T) \tag{19}$$

We may put Keyes' hydrogen scale correction in the form[26]

$$t^\circ = 0.055^\circ\left(1 - \frac{T}{273.1}\right) \tag{20}$$

This agrees with Table VI at 273.1°K. Also, at 373.1°K., Equations (20) and (19) differ by only 0.001°, for Keyes, Townshend and Young picked the 0.055° with that very purpose in mind. However, (20) requires that t° should not become greater than 0.055" at low temperatures, but the values of t° in Table VI become considerably greater.

Referring to Equation (14) for our measurements we take p = 1 atmosphere, not bothering to read the barometer at any time. We have also R = 8.316 × 10^7 ergs per degree,[27] and for the molecular weight of hydrogen M = 2.01554 g. per mole.[28] Our final equation for the calculation of the specific heats of hydrogen is, then, from (14)

$$\frac{C_{v_0}}{R} = \frac{T + Y}{2.42369 \times 10^{-8}W^2 - T - X} + Z \tag{21}$$

T being the absolute temperature of the measurement and W being in cm. per mean solar second.

Effect of the Tube on the Velocity of Sound

When hydrogen is confined in a tube, the velocity of sound is less than in the free gas. This decrease in velocity is almost entirely due to the walls of the tube, rather than the ends, if the tube is very long. The effect of the walls is given by the formula of Kirchhoff and Helmholtz[29]

---

[29] Kirchhoff, *Pogg. Ann.*, **134**, 177 (1868).

(Equation 22). Many observers have said that this formula gives too small a correction,[30] but their work involves tubes containing a large amount of dust. The correction affects our specific heats by about 2%, but in some work of Partington and Shilling[31] an incorrect application of this correction makes their gas specific heats at high temperatures too low by about 13%. This is because they use a tube correction 9 times too great. These observers claim an accuracy of 1%. The only plausible explanation of their high results seems to be that they did not carefully measure their frequency, for they used a "standard wave meter." Making that explanation, a recalculation of Partington and Shilling's data for air at 1073°K. gives C_p as 7.87 cal. per mole per degree, while Lewis and Randall[32] estimate 7.57, and Partington and Shilling give **7.222.** Assuming Partington and Shilling to have the correct frequency, we obtain 8.17. These calculations were only made roughly.

The holes in the ends of our resonators were 1 mm. in diameter as with Grüneisen and Merkel; however, ours were 1 mm. long as well. The careful work of Grüneisen and Merkel[4b] indicated that with air at 0°, the end openings have very little effect. With hydrogen, the end openings might be much greater, because of the ability of hydrogen to be easily blown through small openings. In the case of regular, viscous flow, we find that since the viscosity of hydrogen is about half that of air,[33] only twice as much energy will be lost through the end openings with hydrogen as with air. If then the flow is not at all turbulent, the end correction amounts to about twice the percentage of the velocity of sound with hydrogen as with air (for the same frequency); accordingly we ignore any end correction. The purpose of using tubes of different lengths was to measure the end correction, but it was found, as also noted by Grüneisen and Merkel, that with hydrogen the end correction is less than the error of experiment.

Because of the importance of the wall correction, a large number of measurements (Table VIII) were made at 0° (although with "impure" hydrogen), so that a more or less reliable estimate of that correction could be made. Each value of Table VIII represents the mean of six determinations. The Kirchhoff-Helmholtz relation requires that the tube correction be inversely proportional to the square root of the frequency, but the range of frequency over which the velocity of sound can be measured accurately in hydrogen is not sufficient to test that (see Equation 22). Moreover, our source of sound was probably not a pure sine vibration.

Mean	1256.95	1255.0	1257.8	**(Certain values not considered)**

Grüneisen and Merkel found, by taking average results of the 8th to the 16th or 17th overtones, a velocity of sound of 1258.9 m. per sec. for a 5cm. diameter tube, and 1256.5 m. per sec. for one of 2.6 cm. diameter. Assuming an inverse diameter law, this gives a correction of about 2.6 m. per second for the 5cm. tube, and a corrected velocity of 1261.5 m. per sec. Their wider tube was about 95 cm. long and the narrower one about 79 cm. The range of frequency is from about 5000 cycles per sec. to 12,000. For our own data, this same method of calculation was tried; from our 150cm. tubes (Table VIII) we obtain 1258.9 meters per sec. (Later results with "pure" hydrogen give 1260.75 m. per sec.) Grüneisen and Merkel believe their best value to be 1260.2, but their method of calculation consists in making a rather doubtful comparison with the tube correction for air.

In Table VIII it was not considered necessary to give the frequencies, these being converted into velocity by dividing by the number of the overtone and multiplying by twice the inside length of the tube in question. The three highest frequencies used for tube 100A were amplified with the resistance repeater and not considered in the average. The overtones below No. 11 in the longer tubes, or below No. 8 in the shorter tube, were not sharp or well defined. The dashes in the table are overtones which could not be measured accurately because some other maximum, due to the brass apparatus or perhaps to hydrogen in the telephone chamber, was close to the overtone wanted. In some cases disturbing maxima could be eliminated by using a lower intensity of sound in the telephone. If an unnecessarily large current was fed into the telephone, disturbing maxima appeared, or the true maximum became less well defined.

We need the tube correction for a 4.8cm. diameter tube at **all** temperatures used. From Table VIII we obtain **1256.95–1255.0,** or **1.95** meters per second for 0°. Combining with the **2.5** m. per sec. of Griineisen and Merkel for 0°, an average of **2.2** meters per second is to be used for 0°. If we write W for the velocity of sound, S for the density of the gas, n for the coefficient of viscosity, j for the heat conductivity, v for the frequency and D for the diameter of the tube, then the Kirchhoff-Helmholtz value for the tube correction *AW* is, using absolute c.g.s. units (except that any consistent energy unit may be used for C_p, C_v and j),[29]

$$\frac{\Delta W}{W} = \frac{1}{D\sqrt{\pi v S}}\left\{\sqrt{n} + \left[\sqrt{\frac{C_p}{C_v}} - \sqrt{\frac{C_v}{C_p}}\right]\frac{j}{C_v}\right\} \tag{22}$$

For $0°$, we take D = 4.8 cm., v as 7000 cycles per second as a rough mean value of the frequencies used, and obtain from equation **(22)** $\Delta W/W = $ **0.00185.** About three-fourths of the correction is due to viscosity and the other one-fourth to heat interchange between the walls and the gas. The experimental value of the correction, quoted above, gives $\Delta W/W = 2.2/1259.3 =$ **0.00175.** The agreement is close, and it **was** decided to use theoretical values for the Kirchhoff-Helmholtz correction.

TABLE: IX

KIRCHHOFF-HELMHOLTZ CORRECTION FOR HYDROGEN IN A TUBE OF 4.8 CM. DIAMETER

Observed velocity of sound is too low by percentage in table, at frequency of 10,000 cycles per second.

Abs. temp., °K.	Correction, %	Abs temp., °K.	Correction, %
373.1	0.191	100	0.075
273.1	.155	50	.063
250	.144	SAME FOR AIR	
200	.122	298	0.0476
150	.0995		

In Table IX are given the values of $\Delta W/W$ for various temperatures. The values of heat conductivity, viscosity and C_v were taken from Landolt-Börnstein.[33] A curve was plotted to make interpolation easy.

The values are for 10,000 cycles per second but the correction varies inversely as the square root of the frequency.

To settle finally the correctness of the Kirchhoff-Helmholtz correction, a wide tube 9.87 cm. in diameter was made (No. 168, Table III). Measurements at room temperature (Table XI, at 294.27°K.) were made with "pure" hydrogen and the specific heat was calculated. As seen in Fig. **3,** this point falls nearly on the curve. The effect of the correction is to lower the specific heat by about 0.017R while results in Tube 150A at about the same temperature are lowered by about 0.035R, a difference of 0.018R; but Fig. **3** shows a deviation of much less than 0.018R. This is more obvious if the specific heats of Table XI near room temperature are plotted on a larger scale. The total evidence for the correctness of Kirchhoff and Helmholtz is overwhelming.

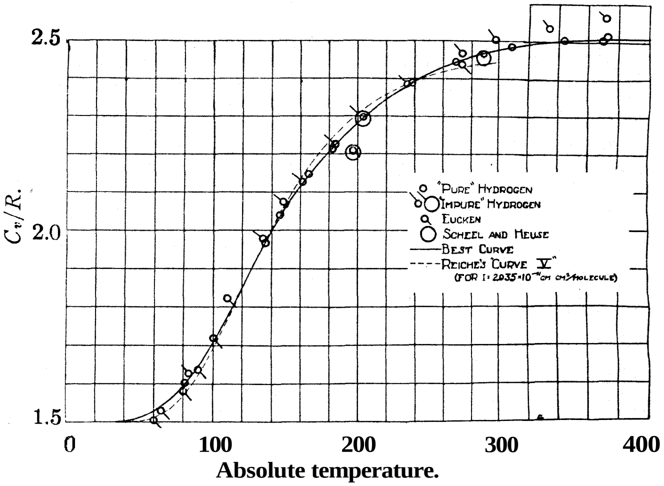

Fig. 3.—Specific heat of hydrogen.

Griineisen and Merkel concluded from their own data that the Kirchhoff-Helmholtz formula holds for air, but we also made runs with air at room temperature (purified as already stated). The difference between the tube corrections is not much more than the experimental error, and the results of Table XII check the Kirchhoff-Helmholtz formula to a fortuitous degree, although the three runs of the table each represent the mean of about 50 determinations. For reducing the air results to the same temperature, it was assumed that the velocity of sound is proportional to $\sqrt{T}$ over the small temperature range in question. For 24°, we obtain 34,566 cm. per sec. as the velocity of sound in free air.

Determination of Velocity of Sound and Specific Heat

For the Griineisen and Merkel data at 0°, it is best to ignore their narrow tubes. Applying the theoretical tube correction to the data from their largest tube, we obtain 126,115 cm. per sec. while our best curve (Fig. 3) gives 126,075. Either of these values is preferable to the value 126,020 cm. per sec. which Grüneisen and Merkel estimate from their own data. A mean of 126,090 cm. per sec. is probably the best value.

The measurements of velocity of sound at each temperature other than 0° consisted, both with "impure" and with "pure" hydrogen, of five or more different overtones, each overtone being measured at a slightly different temperature due to temperature drift of the thermostat. For each overtone the variable condenser of the main oscillating circuit was set at the maximum of sound about 6 times successively. The frequency was noted each time by beat comparison (for 25 seconds) with the very constant auxiliary oscillating circuit. Accordingly, for every temperature in the tables, from 30 to 60 independent measurements are averaged together.

The data are fairly consistent. For each of the temperatures used the values of the fundamental resonant frequency are usually the same, as given by the various overtones, within 0.1% or less. Moreover, the various measurements of a given overtone usually agreed among themselves to 0.1% or less. With air the agreement was to about 0.03% or less. For brevity the actual data are omitted. To take account of temperature drift during the various series, a single plot of e.m.f. of thermocouple against frequency was made and the slopes were read off the curve for each temperature in question. We thus may obtain the several values for the fundamental, reduced to the same mean temperature. While this method of calculation obviously gives the same result as a simple average (even if the wrong slope is read from the curve), yet it makes possible the elimination of a few slightly displaced maxima. These displacements and their cause are discussed above.

[a] Tube 168 used.

In Tables X and XI are given the velocity of sound and the specific heat. The velocity was found by multiplying the fundamental frequency by twice the length of the tube, applying the corrections for thermal expansion (Table IV) and the Kirchhoff-Helmholtz correction (Table IX). The specific heat was then calculated from Equation (21), using Table VI.

The results of Table XI for the velocity of sound and for the specific heat are believed to be correct to about 0.1 and 0.5%, respectively, but an extra decimal place is added. The result of Table XII for the velocity of sound in air at room temperature is believed to be good to 0.01%. All values are for 1 atmosphere pressure, but the specific heats at zero pressure may be found by merely adding algebraically the Z of Table VI; this effect is never more than 0.001.

TABLE XII

VELOCITY OF SOUND IN DRY CARBON DIOXIDE-FREE AIR AT ROOM TEMPERATURE

Series	Tube	Overtones	Abs. temp., °K.	Velocity (in tube), m./sec.	Velocity at 296.324°K., m./sec.
1	150A	No. 37 to 44	298.60	346.276	344.959
2	150A	45 to 56	296.324	345.009	345.009
3	168	30 to 40	296.237	345.019	345.070

Series	Mean Kirch. Helm. corr., m./sec.	Velocity of sound in free air, m./sec.
1	0.242	345.201
2	.216	345.225
3	.137	345.207
		Av., 345.21

Velocity at 24° in dry, carbon dioxide-free air = 345.66 meters per sec.

For the purpose of comparison, the results of some other observers are plotted in Fig. 3, as well as our own results. Also, Reiche's[2b] "curve V" is given, assuming a moment of inertia 2.035×10^{-41} gm. cm.^{2} per molecule.

Relation of Results to Quantum Theory

All quantum theories of rotational specific heat assume various states in which the number of molecules is proportional to $Pe^{-E/RT}$, where P is the "probability" of the state, e the base of the natural system of logarithms, E the energy of the state and RT the gas constant times the absolute temperature.

G. N. Lewis suggests the following graphical method of attacking the data. At low temperatures only the first two states have appreciable weight. Hence, writing now E for the energy difference between these two states, we have for the rotational heat content, H_r

$$H_r = PEe^{-E/RT}$$

as the limiting law for low temperatures. Differentiating, and writing $dH_r/dT = C_r$, we may easily show (using common logarithms)

$$\log (T^2C_r/R) = \log (PE^2/R^2) - E/2.303\,RT \tag{23}$$

Accordingly, by plotting log (T^2C_r/R) against $1/T$, the equation of the limiting straight line for low temperatures gives us both E and P. This was done, and from the "impure" hydrogen we obtain $E = 1003$ cal./mole and $P = 1.48$. The "pure" hydrogen gives $E = 1035$ cal./mole and $P = 1.51$ (see below, however).

These values for P are less than 2. Most theoretical equations proposed previously make P 2 or more. One of the best of such equations is curve V of Reiche, which gives $E = 1160$ cal./mole and $P = 2$, and which is shown for comparison in Fig. **3** (assuming moment of inertia 2.035×10^{-41} gm.cm.^{2}/molecule). E independently of P determines the moment of inertia; we obtain for the moment of inertia 0.742×10^{-41} $(n_2^2 - n_1^2)$ gm.cm.^{2}/molecule, assuming quantum numbers n_1 and n_2 for the first two states, and E as 1060. cal./mole. We may remark that all theoretical equations *must* lead to about the same value for the first energy jump; differing moments of inertia are due to use of different quantum numbers.

A recent specific heat equation due to Dennison[34] fits our data extremely closely below 250°K. It gives lower values than ours above 250°K., as might be expected if stretching of the molecule at high rotational speeds is ignored. He assumes a moment of inertia, 4.64×10^{-41}, but the fit is better with 4.75×10^{-41}. At this moment of inertia we find $n_2^2 - n_1^2 = 4.75/0.742 = 6.4$. To get such a large value theoretically Dennison could assume a large quantum number for the zero state, but he rather assumes two independent series of quantum numbers $^1/_2$, $^5/_2$, $^9/_2$, $^{13}/_2$, ... and $^3/_2$, $^7/_2$, $^{11}/_2$, $^{15}/_2$, etc., three-fourths of the molecules

---

[34] Dennison, *Proc. Roy. Soc. (London),* **115A,** *483 (1927).*

being in the latter series. For the first series (the only one effective at the lowest temperatures) $n_2^2 - n_1^2 = {}^{25}/_4 - {}^1/_4 = 6$. The second series gives ${}^{49}/_4 - {}^9/_4$ or 10. It would seem that under certain conditions Dennison's mixture would evolve up to 100 cal. per mole when passed over a palladium catalyst. Although the first energy jump is a part of the specific heat curve that must be fitted, we do not imply that it is the only requirement; any theory whatever can be made to give this energy jump by adjusting the moment of inertia.

At 145°K. the rotational heat content is estimated from Fig. 3 to be around 35 cal./mole (by graphical integration), and this is small compared to 1035 cal. Accordingly, since also the amount of gas in the 2nd resonated state is here around 0.01%, Lewis' assumptions are nearly justified at temperatures as high as 150°K. Making allowance for about $3^1/_2$% of the gas not in the lowest state at 145°K. we find an increase in the value of E of 25 cal., so that finally $E = 1060$ cal. and $P = 1.69$. It is possible that these values for E and P may be found a little high (that is, they should be closer to the values 1035 and 1.51, respectively) when allowance is made for the molecules in the second activated state. This will be considered in a subsequent paper.

As this work was made possible by the loan of valuable clocks and condensers by the Departments of Physics and Astronomy, we take this opportunity of expressing hearty appreciation, especially to Professors L. B. Loeb and R. T. Crawford of those Departments. We must acknowledge our indebtedness to Dr. R. M. Buffington for suggestions in connection with calibrating the thermocouples, and to Dr. W. F. Giauque for many of the points in our quantum theory discussion

Summary

A rapid precision method, capable of an accuracy of ${}^1/_{1,000,000}$, is described for measuring the frequency of any regularly oscillating circuit, and the properties of certain "audio-frequency" oscillators are discussed. Details are given of rigorous calculation of the specific heats of hydrogen from the velocity of sound. The thermal expansion of a sample of brass at low temperatures is measured and the hydrogen thermometer is briefly discussed. Details are given of the construction and operation of a thermostat 180 cm. long for low or moderately high temperatures. The claim by Stock and Ritter of large variations in the composition of atmospheric air is shown to be baseless. Measurements of the velocity of sound in hydrogen gas, and the corresponding calculated specific heats, are given for the range 80 to 373°K. The energy difference between the first two rotational states of the hydrogen molecule is shown, by a method of calculation due to G. N. Lewis, to be 1060 cal. per mole, and the relative "probabilities" of the first two states are found to be 1:1.69 (Reiche's best

equation giving 1160 and 1:2, respectively). The effect of a confining tube on the velocity of sound in a gas is found to be accurately given by the formula of Kirchhoff and Helmholtz. Neglect of that fact caused errors of over 10% in the sound velocity specific heat measurements of Partington and Shilling, making their work worthless unless recalculated. The velocity of sound in unconfined, dry, carbon dioxide-free air at 24° is found to be 345.66 meters per second and the velocity of sound in free hydrogen at 0° is found to be 1260.9 meters per second.

DISPLACEMENT OF METALS FROM SOLUTIONS OF THEIR SALTS BY LESS ELECTROPOSITIVE ELEMENTS

IV. POTASSIUM AMMONO BERYLLATE AND SODIUM AMMONO BERYLLATE

BY F. W. BERGSTROM

RECEIVED SEPTEMBER 12, 1927 PUBLISHED MARCH 7, 1928

In attempting to prepare aluminum amide by the action of ammonium bromide—an acid in liquid ammonia—upon a solution of sodium ammono aluminate in accordance with the equation, $Al(NH_2)_2NHNa + NH_4Br = NaBr + NH_3 + Al(NH_2)_3$,[1] the author obtained precipitates which varied in composition approximately between the limits of $Al(NH)NH_2$ and $Al_2(NH)_3$. In explanation of this behavior it is suggested that these precipitates be regarded as indefinite compounds resembling the hydrous oxides in constitution, and therefore appropriately called ammonous aluminum nitrides, $AlN + xNH_3$. In view of the chemical similarity between aluminum and beryllium one might expect that beryllium amide would likewise prove to be an ammonous beryllium nitride. The present investigation was then undertaken primarily for the purpose of preparing beryllium amide or an ammonous beryllium nitride. As the potassium ammono beryllate required in the expected reaction, $Be(NHK)_2 + 2NH_4Br = Be(NH_2)_2 + 2NH_3 + 2KBr$, is unknown, the first experiments were directed toward the preparation of this compound.

Potassium Ammono Beryllate.—Since potassium hydroxide dissolves metallic beryllium to form potassium aquo beryllate, we should expect the analogous base of the ammonia system, potassium amide, to dissolve beryllium to form a potassium ammono beryllate. N. C. Jones and P. F. Frohring, at Western Reserve University in the summer of 1926, found that beryllium dissolves in solutions of sodium and potassium amides in liquid ammonia to form extremely soluble ammono beryllates

---

[1] Bergstrom, *J. Phys. Chem.*, March, 1928. This reaction resembles the precipitation of aluminum hydroxide by the addition of an acid to a solution of an aquo aluminate in water.

which they were unable to analyze in the time at their disposal. It was for the added purpose of bringing to completion the preliminary work of Jones and Frohring that this portion of the present investigation was undertaken.

Beryllium reacts with potassium amide dissolved in liquid ammonia to form an opaque blue solution, which was shown to contain metallic potassium,[2] the reaction probably proceeding in accordance with the equation, $Be + 2KNH_2$ $Be(NH_2)_2 + 2K$. The apparent anomaly of beryllium replacing the more electropositive element potassium can readily be understood if one recalls the fact that dilute solutions of the alkali metals in liquid ammonia are salt-like in character.[3] The (+) ions in such solutions are the normal ions of the alkali metal, while the (−) ion is the solvated negative electron, e^-. Now beryllium does not dissolve in liquid ammonia to form a solution sufficiently concentrated to exhibit a blue color such as characterizes solutions of the alkali and alkaline earth metals in this solvent. Nevertheless, one may ascribe an extremely slight solubility to beryllium in view of the fact that all of the very electropositive metals, including magnesium, dissolve, at least to some extent, in ammonia. One may assume, by analogy with the alkali metals, that beryllium dissolves to a slight degree in ammonia to form Be^{++} ions together with an equivalent number of solvated negative electrons. Since potassium amide forms K^+ and NH_2^- ions, the reaction of this base with beryllium will simply involve interaction between the ions Be^{++}, NH_2^-, K^+ and e^-. $Be(NH_2)_2$ is very slightly soluble in ammonia and so will form to some extent as a precipitate, leaving in solution equivalent quantities of K^+ and e^- ions, which constitute a solution of metallic potassium. Since $Be(NH_2)_2$ is not entirely insoluble in ammonia it is necessary to consider the above reaction as an equilibrium.

Potassium, formed in the reaction of the preceding paragraph, reacts with the solvent, in the presence of a catalyst such as beryllium, to form potassium amide and hydrogen, while the potassium amide thus formed dissolves the amphoteric base beryllium amide to form potassium ammono beryllate, in the sense of the equation, $Be(NH_2)_2 + KNH_2 = Be(NH_2)\text{-}NHK{\cdot}NH_3$. Aluminum has previously been found to react with potassium amide in an entirely analogous manner.[4]

Potassium ammono beryllate is, however, most conveniently prepared by the action of a solution of metallic potassium in liquid ammonia upon an excess of beryllium. The metallic beryllium, acting as a catalyst, first converts the potassium to potassium amide, which in turn reacts with the beryllium in accordance with the equations of the preceding paragraph.

---

[2] Bergstrom, This Journal, 45, 2789 (1923), has described the test used.

[3] Kraus, *ibid.*, 44, 1224 (1922).

[4] Bergstrom, ref. 2, p. 2788; 46, 1548 (1924).

For the purpose, then, of preparing potassium ammono beryllate, a small tube containing about **0.35** g. of potassium is placed in one leg of a reaction tube[5] together with about two atomic equivalents of metallic **beryllium.**[6] Within a day or two after ammonia is distilled into the reaction tube the potassium is completely converted into a colorless solution of potassium ammono beryllate, which is then decanted into the other leg of the reaction tube to effect a separation from the residue of unused beryllium. Attempts to obtain crystals from a concentrated solution of potassium ammono beryllate at −40° having failed, analyses were made of the colorless solid remaining after evaporation of solvent ammonia from the reaction tube.

Potassium ammono beryllate is vigorously hydrolyzed by water to potassium hydroxide, ammonia and beryllium hydroxide, the latter remaining partly in solution as potassium aquo beryllate. In preparation for analysis the products of the hydrolysis were dissolved in dilute sulfuric or hydrochloric acid. Beryllium was determined on an aliquot portion of this solution as oxide, according to the method of Bleyer and Boshart.[7] Potassium was recovered as sulfate or chloride from the filtrate of the beryllium hydroxide. Nitrogen in a second aliquot portion was estimated volumetrically as ammonia.

Preparation 1, dried in a vacuum at 20°, weighed **0.8776** g. At 185° in a vacuum it lost **0.1071** g. of ammonia of crystallization. (The ammonia was not all pumped off.) One-fourth of the preparation gave **0.0736** g. of nitrogen. Another fourth gave **0.0582** g. of BeO and **0.1696** g. of KCl.

Preparation 2, dried in a vacuum at 20°, weighed **0.8478** g. Heated in a vacuum at 160° it lost **0.1388** g. of ammonia. One-fourth gave **0.0623** g. of nitrogen. A second fourth gave **0.0560** g. of BeO and **0.1674** g. of KCl.

Preparation 3, dried in a vacuum at −40°, weighed **0.8244** g. In a vacuum at 25° it lost **0.0067** g. and at 215° a further **0.1382** g. of ammonia. One-half gave 0.1080 g. of BeO. One-quarter gave **0.1584** g. of KCl. One-quarter gave **0.0603** g. of nitrogen.

Analyses.—Calcd. for $Be(NH_2)NHK{\cdot}NH_3$: Be, **9.4;** N, **43.7; K, 40.7.** Found, dried in a vacuum at room temperature: Be, **9.6, 9.5, 9.5; N, 43.6, 42.9, 43.4; K, 40.6, 41.4, 40.7.** This salt, when converted into $Be(NH_2)NHK$, should lose **17.7% of** ammonia. Specimens No. **2** and **3** lost, respectively, **16.4** and **17.6%** of ammonia when heated in a vacuum above **160°.**

Potassium ammono beryllate may be represented as a salt of the ammonia system, $Be(NH_2)NHK{\cdot}NH_3$, as a double compound of beryllium amide and potassium amide, $Be(NH_2)_2{\cdot}KNH_2$, or, following Werner, as the coordination compound, $K[Be(NH_2)_3]$. In accordance with the

---

[5] A description of the manipulations concerned in the preparation of compounds in liquid ammonia may be found in the following articles by Franklin and his students: THIS JOURNAL, 27, **832 (1905);** 29, **1694 (1907);** 35, **1460 (1913);** J. Phys. *Chem.,* 15, **510 (1911);** 16, 694 **(1912).**

[6] The beryllium, which was in the form of small chips, was found to **be** practically free from other metals.

[7] Bleyer and Boshart, *Z.* anal. *Chem.,* **51, 754 (1912).**

fact that beryllium resembles aluminum more closely in properties than it does magnesium, potassium ammono beryllate was found to resemble potassium ammono aluminate, $Al(NH_2)_3 \cdot KNH_2$, more closely in constitution and properties than it does potassium ammono magnesiate, $Mg(NH_2)_2 \cdot 2KNH_2$.[8] Both potassium ammono aluminate and potassium ammono beryllate are readily soluble in liquid ammonia and both melt in their ammonia of crystallization upon heating, each losing one molecule of ammonia. Potassium ammono magnesiate, on the other hand, is very slightly soluble in ammonia and does not readily lose ammonia when heated.

Sodium **Ammono** Beryllate.—This salt is best prepared in the same manner as potassium ammono beryllate, that is, by the action of a liquid ammonia solution of sodium upon an excess of metallic beryllium.

Preparation 1, dried in a vacuum at 20°, weighed 1.2017 g. One-quarter gave 0.0950 g. of BeO and 0.2743 g. of Na_2SO_4. One-quarter gave 0.1537 g. of nitrogen.

Preparation 2, dried in a vacuum at 20°, weighed 1.0378 g. One-half gave 0 2696 g. of nitrogen. The other half gave 0.1646 g. of BeO and 0.3847 g. of NaCl.

Preparation 3, dried in a vacuum at −40°, weighed 0.8035 g. When heated in a vacuum at room temperature, 0.0038 g. of ammonia of crystallization was lost. One-quarter gave 0.1032 g. of nitrogen. Another quarter gave 0.0633 g. of BeO and 0.1497 g. of NaCl.

Analyses.—Calculated for $Be(NH_2)NHNa \cdot NH_3$: Be, 11.2; N, 52.5; Na, 28.8. Found, dried in a vacuum at room temperature: Be, 11.4, 11.4, 11.4; N, 51.2, 52.0, 51.6; Na, 29.6, 29.2, 29.5. These analyses indicate that sodium ammono beryllate has lost a little of its ammonia of crystallization in a vacuum at room temperature. When heated in a vacuum between 150 and 200°, sodium ammono beryllate melts and loses approximately one molecule of ammonia.

Sodium ammono beryllate resembles the corresponding potassium salt closely in physical and chemical properties.

Beryllium Amide.—It was hoped that beryllium amide would be formed, in accordance with the equation, $BeI_2 + 2KNH_2 = 2KI + Be(NH_2)_2$, when potassium amide is added to a solution of a salt of beryllium in liquid ammonia. Unfortunately, potassium amide precipitates ammonobasic mixtures from solutions of both beryllium iodide and thiocyanate.

When a solution of ammonium bromide is slowly poured into a solution of sodium ammono beryllate, a flocculent, white precipitate containing much sodium is thrown down instead of the expected beryllium amide.

Magnesium amide may be formed by the action of a liquid ammonia solution of sodium chloride or iodide upon magnesium.[9] An attempt to prepare beryllium amide by the analogous action of a solution of sodium chloride on beryllium failed.[10]

[8] Franklin, THIS JOURNAL, 35,1463 (1913).

[9] Bergstrom, *ibid.*, 48,2849 (1926).

[10] Since beryllium chloride is very soluble in liquid ammonia at room temperature, there is no tendency for the reaction $Be + 2NaCl \qquad BeCl_2 + 2Na$ to take place.

Notes.—Since a solution of sodium ammono magnesiate attacks magnesium to form magnesium amide,[9] it was expected that a solution of sodium ammono beryllate would likewise react with magnesium to form magnesium amide. The anticipated reaction does not take place. Magnesium amalgam, however, reacts with a solution of sodium ammono beryllate to form a very impure magnesium amide and sodium amalgam.

Addition of a solution of sodium ammono beryllate to a solution of magnesium thiocyanate throws down a flocculent precipitate of the composition $Mg(NH_2)_2 \cdot Be(NH_2)_2$, which may be a mixture of beryllium and magnesium amides and not a definite compound.

A solution of sulfur in liquid ammonia reacts slowly with beryllium to form a yellow precipitate of an ammonated beryllium mono- or polysulfide. This precipitate slowly dissolves in an excess of sulfur solution to form soluble polysulfides of beryllium.

Beryllium, the surface of which has been cleansed by the action of a liquid ammonia solution of ammonium chloride,[11] does not dissolve in pure liquid ammonia to form a visibly colored solution. Under similar conditions it will be remembered that magnesium dissolves to form a light blue solution.[12]

In conclusion, the author wishes to express his thanks to Dr. E. C. Franklin for his interest in this work and for reading the manuscript prior to publication.

Summary

(1) Potassium and sodium ammono beryllates of the general formulas $Be(NH_2)NHK \cdot NH_3$ and $Be(NH_2)NHK$ have been prepared by the action of solutions of the corresponding alkali metal or alkali metal amide upon metallic beryllium.

(2) Attempts to prepare beryllium amide, $Be(NH_2)_2$, have failed.

THE ACTION OF LIQUID AMMONIA SOLUTIONS OF AMMONIUM SALTS ON METALLIC BERYLLIUM. AMMONATED BERYLLIUM HALIDES AND AMMONOBASIC BERYLLIUM SALTS

BY F. W. BERGSTROM

RECEIVED SEPTEMBER 12, 1927 PUBLISHED MARCH 7, 1928

Franklin and Kraus[1] have pointed out that many substances, among which are the hydrogen halides, are acids in liquid ammonia solution as well as in water. It has indeed been shown that solutions of these acids in liquid ammonia, in the form of course of their ammonium salts, react with most elements more electropositive than nickel.[2] One should then expect the electropositive element beryllium to react readily with solutions of ammonium salts in liquid ammonia. Since aqueous solutions of the normal salts of beryllium dissolve this metal to form very soluble aquo basic salts, it should be possible to prepare a series of ammonobasic beryllium salts by the action of solutions of the normal salts in liquid ammonia upon an excess of beryllium. Bearing in mind the difficulties encountered in crystallizing basic beryllium salts from water,[3] it became of added interest to attempt their preparation in liquid ammonia in the hope of obtaining crystallizable compounds. As a secondary purpose of this investigation it was hoped to prepare beryllium amide by the action of potassium amide upon a soluble beryllium salt, in the sense of the equation $BeI_2 + 2KNH_2 = Be(NH_2)_2 + 2KI$.

Newton C. Jones,[4] working under Dr. Franklin at Western Reserve University in the summer of 1926, found that beryllium dissolves readily in liquid ammonia solutions of an excess of ammonium chloride, ammonium ammono nitrate (ammonium azide), ammonium thiocyanate, ammonium iodide and ammonium cyanide with the evolution of hydrogen. From the solutions so prepared Jones was in most cases able to crystallize the corresponding normal salts of beryllium with ammonia of crystallization, but he was unable definitely to determine their composition in the limited time at his disposal.

Beryllium Chloride Diammonate and Tetrammonate, $BeCl_2 \cdot 2NH_3$ and $BeCl_2 \cdot 4NH_3$.—Normal beryllium chloride may readily be prepared by dissolving beryllium in a solution of more than two equivalents of ammonium chloride in liquid ammonia. From this solution, cooled to $-40°$,

[4] Unpublished work.

there separates an abundant crop of well formed, colorless crystals which, after drying in a vacuum at $-40°$ or at room temperature, correspond in composition to the formula $BeCl_2 \cdot 4NH_3$. When heated in a vacuum at 210–255°, two molecules of ammonia of crystallization are lost and $BeCl_2 \cdot 2NH_3$ is formed.

Unlike most metallic chlorides, beryllium chloride is readily soluble in liquid ammonia at room temperature. Solutions of beryllium chloride of proper concentrations separate into two liquid phases which have a lower consolute temperature between 0 and $-40°$. Other compounds have been found which exhibit a similar behavior in liquid ammonia.[5]

A description of a typical preparation of beryllium chloride will serve to illustrate the general method by which all of the normal and ammonobasic halides of beryllium were made.

In one leg of a two-legged liquid ammonia reaction tube[6] was placed 0.10 g. of metallic beryllium[7] together with 0.63 g. or 2.5 equivalents of ammonium chloride. Ammonia was distilled into the tube to dissolve the ammonium chloride, after which the apparatus was set aside for a few hours until all of the beryllium had gone into solution. To effect separation from a small quantity of insoluble material, the clear solution of beryllium chloride was decanted into the other leg of the ,reaction tube. By cooling this solution in a bath of liquid ammonia there was obtained a good crop of colorless crystals. After one recrystallization, the salt was dried in a vacuum at 20 and 210°, hydrolyzed by water and dissolved in dilute sulfuric acid. Beryllium in an aliquot portion of this solution was determined as oxide after a previous precipitation as hydroxide according to the method of Bleyer and Boshart.[8] On other aliquot portions, chlorine was determined as silver chloride and nitrogen was estimated volumetrically as ammonia.

Anal. Calcd. for $BeCl_2 \cdot 4NH_3$: Be, 6.1; N, 37.8; Cl, 47.9. Found, dried in a vacuum at 20°: Be, 6.2, 6.5; N, 37.9, 37.8; Cl, 47.8, 47.7. When these specimens were heated in a vacuum at 210 and 255°, they lost, respectively, 22.0 and 23.0% of ammonia; calculated for the loss of two molecules of ammonia from the tetrammonate, 23.0%. Beryllium chloride retains only four molecules of ammonia in a vacuum at $-40°$.

Beryllium Bromide Tetrammonate, $BeBr_2 \cdot 4NH_3$.—Beryllium bromide is readily obtained by dissolving beryllium in an excess of a liquid ammonia solution of ammonium bromide. Following the preliminary work

of Jones,[4] it was expected that an ammonated beryllium bromide would crystallize from solutions at low temperature, but for some reason protracted cooling of a concentrated solution of this specimen at −40° failed to cause the formation of crystals. The reaction tube was then set aside for a week to allow a gradual concentration of the solution by leakage of ammonia past a defective stopcock. The well formed crystals of beryllium bromide thus obtained were washed with a small quantity of solvent, dried in a vacuum at 20° and analyzed.

Anal. Calcd. for $BeBr_2 \cdot 4NH_3$: Be, 3.8; N, 23.6; Br, 67.4. Found: Be, 3.7; N, 24.2; Br. 67.4.

Biltz and Messerknecht[9] have prepared beryllium chloride with 2, 4, 6 and 12 molecules, and beryllium bromide with 4, 6 and 10 molecules, of ammonia of crystallization.

Ammonobasic Beryllium Chloride.—A solution of ammonium chloride in liquid ammonia dissolves metallic beryllium to form normal beryllium chloride, and this in turn reacts with an excess of the metal to form a colorless, very slightly soluble ammonobasic beryllium chloride. One preparation was found on analysis to be a little more basic than indicated by the formula, $BeCl_2 \cdot Be(NH_2)_2 \cdot xNH_3$. However, one of Dr. E. C. Franklin's students at Western Reserve University reports a number of preliminary analyses agreeing more closely with this formula. Perhaps this is not a definite compound, for the basic halides of the composition $Be(NH_2)_2 \cdot BeBr_2$ and $Be(NH_2)_2 \cdot BeI_2$ have not been obtained.

Ammonobasic Beryllium Bromides: $2BeBr_2 \cdot Be(NH_2)_2 \cdot 8NH_3$, $3Be(NH_2)_2 \cdot BeBr_2 \cdot 4NH_3$ and $3Be(NH_2)_2 \cdot BeBr_2 \cdot 8NH_3$. Experiment 1.—A liquid ammonia solution of 0.69 g. of ammonium bromide was poured upon 0.06 g., or one atomic proportion, of beryllium in one leg of a reaction tube. There resulted a rather brisk evolution of hydrogen. Upon examining the reaction tube the next morning, it was found that the beryllium had disappeared, being in part replaced by a number of small white crystals of an ammonobasic beryllium bromide. The solution in equilibrium with this precipitate consisted of two liquid phases which had a lower consolute temperature between 10 and 15°. The crystals were washed to free them from material soluble in liquid ammonia. After evaporation of solvent from the reaction tube, the two legs were separated before the blast lamp and their respective contents submitted to analysis.[10]

Excepting that larger quantities of ammonium bromide and beryllium were used, the subsequent experiments were essentially duplicates of the first. In Experiment 3 the sparingly soluble crystals alone were analyzed.

---

[9] Biltz and Messerknecht, *Z. anorg. Chem.*, 148,157 (1925).

[10] The crystals were sealed off in the leg of the reaction tube to which the stopcock was attached. The leg containing the washings of the crystals was drawn down in the blast flame and a small stopcock tied on with rubber tubing.

TABLE I

ANALYSES OF THE SPARINGLY SOLUBLE AMMONOBASIC BROMIDE

	Calcd. for $3Be(NH_2)_2 \cdot BeBr_2 \cdot 4NH_3$	Found, dried in a vacuum at 20° 1	2	3	4
Be	10.0	10.5	10.4	10.4	10.3
N	38.9	38.8	38.8	38.7	38.6
Br	44.4	45.2	44.4	44.5	44.3

When dried in a vacuum at −40°, specimen No. 3 corresponded in composition to $3Be(NH_2)_2 \cdot BeBr_2 \cdot 8NH_3$. Calcd.: Be, 8.4; N, 45.8; Br, 37.4. Found: Be, 8.8; N, 45.3; Rr, *37.7*.

TABLE II

ANALYSES OF THE SOLUBLE AMMONOBASIC BROMIDE

	Calcd. for $2BeBr_2 \cdot Be(NH_2)_2 \cdot 8NH_3$	Found, dried in *a* vacuum at 20° 1	2	4
Be	5.2	5.3	5.4	5.2
N	27.2	27.8	27.4	27.6
Br	62.0	61.2	61.8	61.5

The low bromine and high nitrogen analyses are due in part to the presence in solution of a small quantity of the salt, $3Be(NH_2)_2 \cdot BeBr_2 \cdot 4NH_3$. There is perhaps some doubt as to the chemical individuality of a substance which could not even be crystallized from solution at −78°, and therefore was analyzed without purification. In support of the view that this salt is a definite compound, it was found that the composition of the soluble material in equilibrium with the crystals of $3Be(NH_2)_2 \cdot BeBr_2 \cdot 4NH_3$ did not change over a period of two weeks. Thus, in the three experiments 1, 2 and 4 the solution was in contact with the crystals of the sparingly soluble basic bromide for 3, 8 and 12 days, respectively.

Ammonobasic Beryllium Iodides (1), $3Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$.—A solution of ammonium iodide in liquid ammonia reacts rapidly with an excess of beryllium to form the normal iodide and then very soluble ammonobasic iodides. One of these, $3Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$, can easily be separated in definite crystalline form by cooling a solution of one to two atomic proportions of beryllium in one molecular proportion of ammonium iodide to −40° in a bath of liquid ammonia.

The two preparations, analyses of which are given below, were crystallized in good yield from solutions prepared by the action of ammonium iodide upon one atomic proportion of beryllium.[11] The salt which separated from solution on cooling was again crystallized, dried in a vacuum at 20°, dissolved in dilute sulfuric acid and analyzed. Found: Be, 8.2, 8.1; N, 30.7, 30.6; I, 55.4, 55.8. Calcd. for $3Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$; Be, 7.9; N, 30.8; I, 55.9. This salt lost very little ammonia when heated in a vacuum at 130°, but lost approximately one molecule when heated to 205°.

(2), $5Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$.—If a liquid ammonia solution of $3Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$ is brought in contact with metallic beryllium, the

---

[11] In view of this it seems very doubtful whether a salt of the formula $Be(NH_2)_2 \cdot BeI_2 \cdot xNH_3$ exists.

latter slowly dissolves and within the course of a few weeks a point is reached at which an amorphous, white precipitate begins to form. The liquid ammonia solution, separated at this stage by decantation from the unused beryllium and the white precipitate, can be concentrated to an almost unpourable sirup at 20° without crystallization. An analysis of the crude, white solid remaining after evaporation of the solvent ammonia from the reaction tube gave 9.8% Be, 35.4% N and 48.9% I, corresponding roughly to a compound of the formula $5Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$, which requires 10.1% Be, 36.6% N and 47.3% I.

In an attempt to prepare this compound in a purer condition, the foregoing experiment was repeated. When a moderately concentrated solution of the salt was cooled for some time in an ether-carbon dioxide snow mixture, an abundant crop of small, colorless crystals was obtained. These were freed from mother liquor, dried in a vacuum at 20°, hydrolyzed with water,[12] dissolved in dilute sulfuric acid and analyzed. There was found 10.3% Be, 37.2% N and 47.1% I, in better concordance with the calculated composition of $5Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$ given in the preceding paragraph.

Potassium amide throws down from a solution of the basic salt, $3Be(NH_2)_2 \cdot BeI_2 \cdot 4NH_3$, a flocculent, white precipitate, which was shown by analysis to be an ammonobasic mixture containing approximately ten atoms of beryllium per atom of iodine. In one experiment the solution in equilibrium with this precipitate was found to contain three atoms of beryllium for each atom of iodine,[13] indicating the dissolved substance to be $5Be(NH_2)_2 \cdot BeI_2 \cdot xNH_3$.

Ammonobasic Beryllium Cyanide.—A solution of mercuric cyanide in liquid ammonia reacts with beryllium, as it does with aluminum,[14] to form a double beryllium-mercuric cyanide, and then a very soluble normal beryllium cyanide, which was not isolated in a state of purity because of the ready formation of soluble ammonobasic cyanides by further reaction with beryllium.

Discussion

It is well known that solutions of the normal beryllium salts in water can dissolve large quantities of beryllium hydroxide, extending in the case of the acetate to six equivalents, while the chloride can hold four and the sulfate three.[3,15] On diluting these solutions with water, precipitates of

---

[12] This salt is hydrolyzed by water with evolution of heat to form ammonia, ammonium iodide, beryllium hydroxide and possibly aquo basic salts of beryllium.

[13] That is, per atom of iodine not present in the solution as potassium iodide. The latter salt is also a product of the reaction, as the following equation shows: $3[3Be(NH_2)_2 \cdot BeI_2] + 2KNH_2 = 2[5Be(NH_2)_2 \cdot BeI_2] + 2KI$.

[14] Bergstrom, THIS JOURNAL, 46, 1559 (1924).

[15] Sidgwick and Lewis, *J. Chem. Soc.*, 129, 1287–1302 (1926).

a highly basic nature are thrown down, while on evaporation gummy, non-crystalline masses are obtained. Perhaps the only basic beryllium compounds which have been prepared in a state of purity are the salts of the type of basic beryllium acetate, $3Be(CH_3COO)_2{\cdot}BeO$ or $Be_4O(CH_3COO)_6$.[16] In contrast with the difficulty of obtaining aquo basic salts of beryllium in a state of purity from water is the relative ease with which many crystalline ammonobasic halides of beryllium can be prepared in liquid ammonia. It is noteworthy though unexpected fact that the very basic compound, $5Be(NH_2)_2{\cdot}BeI_2$, is much more soluble in liquid ammonia at $-40°$ than the less basic $3Be(NH_2)_2{\cdot}BeI_2$.

In conclusion, the author wishes to thank Dr. E. C. Franklin for his interest in this work and for looking over the manuscript prior to publication.

Summary

I. Beryllium dissolves in liquid ammonia solutions of an excess of ammonium chloride and bromide to form normal beryllium halides with ammonia of crystallization. The salts, $BeCl_2{\cdot}4NH_3$, $BeCl_2{\cdot}2NH_3$ and $BeBr_2{\cdot}4NH_3$ have been prepared.

2. Solutions of the normal halides of beryllium in liquid ammonia readily react with metallic beryllium to form ammonobasic halides; $3Be(NH_2)_2{\cdot}BeBr_2{\cdot}4NH_3$, $3Be(NH_2)_2{\cdot}BeBr_2{\cdot}8NH_3$, $3Be(NH_2)_2{\cdot}BeI_2{\cdot}4NH_3$ and $5Be(NH_2)_2{\cdot}BeI_2{\cdot}4NH_3$ have been prepared in crystalline form. There is good evidence for the existence of $2BeBr_2{\cdot}Be(NH_2)_2{\cdot}8NH_3$, although it has not been obtained in crystalline form.

THE SOLUBILITY OF SILVER IN MERCURY[1]

BY ARTHUR A. SUNIER AND C. B. HESS

RECEIVED OCTOBER 3, 1927 PUBLISHED MARCH 7, 1928

In connection with work on solutions in this Laboratory, attention was directed to the lack of conclusive data on the solubility of silver in mercury. Many determinations have been made at isolated temperatures[2] but, to our knowledge, Joyner[3] has made the only systematic attempt to investigate this system over a range of temperatures. Yet his work,

dealing mainly with the ternary system tin-silver–mercury is not accompanied by sufficient control work to weight his results properly on silver and mercury alone.

The present paper is a report of solubility determinations of silver in mercury up to 200°.

Materials

The mercury used was first washed by dropping it five times through a five foot Meyer column containing mercurous nitrate. The dried mercury was then distilled three times from an all-glass apparatus according to the method of Hulett and Minchin.[4] Samples of the purified product yielded no residue when carefully distilled in *vacuo*.

Two samples of silver were used. The first, employed in what are later to be described as Series A, B, C determinations, was U. S. Mint bar of the "999" fineness. Filings of this were obtained with a clean, hard file. Because traces of iron were appearing in the final analyses, a second sample was used in our final (Series D) determinations. This was 1000 fine foil, very kindly supplied us by the Philadelphia Mint. Thin strips of this were used in charging the solubility tubes. Below (Table I) are given the results of analysis of both samples by the authors.

Table I

Analysis of Silver Used

					Av.
Ag filings, % Ag	99.76	99.72	99.71	99.73	99.73
Ag foil, % Ag .	99.97	99.96	99.96	99.96	99.96

Apparatus

The solubility tube (Fig. 1) was made of Pyrex glass. It consists essentially of a sample tube B with projections C for suspending it in the balance case, a capillary filter finely constricted at D, a glass-wool filter E and a lower tube F in which the amalgams were prepared.

For stirring the amalgams a long, vertical rod pivoted at its center was used. The lower end of this rod had two projecting posts so spaced that the two eyes of the tubes could be slipped over them. The upper end of the rod was slotted and attached to the arm of an automobile windshield cleaner. When in operation a pendulum-like motion was imparted to the solubility tubes on the lower end of the rod of such an amplitude as to completely transfer the amalgams from one end of the tubes to the other.

The thermostat, a ten-gallon copper tank heavily lagged, contained cylinder oil which had a flash point of 275°. After three months' use this oil did not smoke appreciably at 180° and showed no evidences of carbonization or lowering of the flash point. Four double paddle stirrers

---

[4] **Hulett** and Minchin, *Phys. Rev.*, **21, 388 (1905).**

(1000 r.p.m.) kept the oil in violent agitation. Heat was supplied by four 500-watt immersion heaters. Thermal balance at any temperature was obtained by the use of two circular nichrome heating elements of variable resistance immersed in the bath near the top and bottom. The mercury thermo-regulator operated a 40-watt elongated bulb. Beckmann thermometers permanently placed in the bath showed a deviation of much less than 0.1° over a period of eight hours.

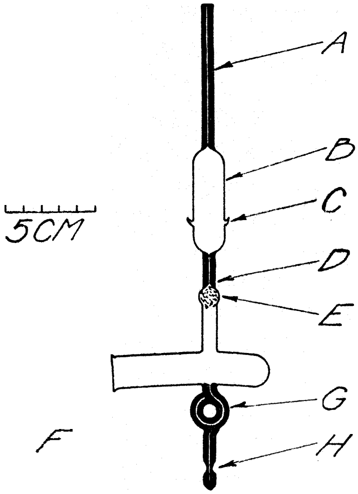

Fig. 1.

Temperatures were read from a mercury thermometer especially standardized for this investigation by the Physical Laboratory of the Taylor Instrument Companies. At the conclusion of the solubility work, this thermometer was compared against one recently standardized for us by the Bureau of Standards.

The amalgam samples were vacuum distilled from an all-glass apparatus previous to analysis. A Cenco pump produced a vacuum of 0.003 mm. Pressures were read from a McLeod gage capable of being read to 0.001 mm.

Experimental Procedure

About 7 cc. of pure mercury and excess silver were put into the Tube F (Fig. 1), which was then sealed off. Capillary A was connected to a Cenco pump and the amalgam boiled out, when the tube was sealed off from the pump and A bent into an eye. A fine wire was attached at G and the constricted capillary H file marked, The eyes on the tubes enabled them to be slipped onto the stirrer posts, the whole device then being firmly clamped in the thermostat.

For a determination of the solubility at a certain temperature, saturation in every case was attained from the low and then from the high temperature side. In the former case the shaker with four tubes was started and the bath raised to the desired temperature, which usually required about an hour. After thermal balance was established at this temperature, the tubes were shaken for an additional period of three hours and then sampled.

For the corresponding high side determination, four tubes were inserted in the hot-bath, the temperature was raised about 20°, held there for an hour or more and then allowed to drop back to the determination temperature. This preheating, occupying from three to five hours, was succeeded by the usual three hour shaking at constant temperature and sampling.

The remarkable agreement between these two measurements at every temperature was sufficient evidence that equilibrium was being attained.

When the amalgams were ready to be sampled, the shaker was stopped and a tube slipped off, keeping it at all times below the oil surface. The counterweighted eye A was then released and the wire on G firmly held, when the tube inverted under the oil Carefully drawing up the wire until the tip H just protruded (Fig. 2), the exposed capillary was wiped dry and broken under clean rubber tubing. Atmospheric pressure forced the amalgam through the glass wool filter E into the lower tube. After filtration the tubes were removed from the bath, dried and cooled. Sample tube B was cut off, suspended in the balance case and weighed. The amalgam samples were then transferred to the distillation tubes and boiled out prior to distillation. All glassware with which the cooled amalgam came in contact was treated later in the analysis with nitric acid.

The tubes containing the amalgams were sealed to the distillation apparatus and the system was evacuated. The temperature was gradually raised to about 200°, distillation requiring about two hours. The residues were then flamed in the vacuum to the softening point of Pyrex. Separate control distillations established the fact that these residues consisted approximately of 1 atom of mercury to 50 of silver.

Tubes and contents were then transferred to beakers and treated with 10 cc. of concentrated nitric acid. After boiling, the solutions were diluted, the tubes removed and the silver was precipitated with dilute hydrochloric acid. Digestion until the volumes were well below 50 cc. was followed by filtration, re-solution of the silver chloride with ammonia, and a second precipitation and digestion to small volume. Porcelain crucibles with unglazed porous bottoms were used in the weighing.

Before adopting the above method of analysis, much control work was done on the methods available. The first investigated was that of Joyner,[3] devised to provide for the appreciable solubility of silver chloride in mercuric nitrate solutions.[5] The standard blowpipe method was also studied, using cupels of dental investment compound. In Table II are given results using each method for the analysis of 400 mg. of silver dissolved in 5 cc. of mercury. In Joyner's method the amalgam is dissolved directly in nitric acid; in the other two, distillation was first carried out.

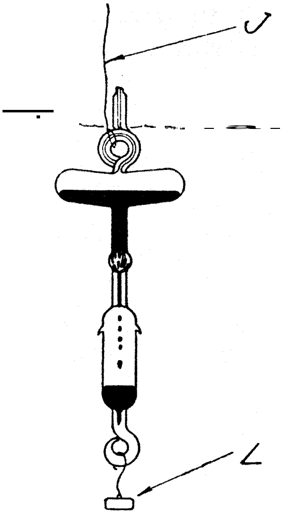

Fig. 2.

TABLE II

COMPARISON OF ANALYTICAL METHODS

Method	Joyner	Blowpipe	Present paper
% Ag recovered	99.38	98.8	99.78
	99.03	99.4	99.66
	98.45	99.9	99.78
	98.94	..	99.69
Av.	98.95	99.0	99.73

To test the whole experimental arrangement, four tubes were made up containing weighed amounts of silver and mercury and carried through the entire procedure outlined above, including shaking in the bath for three hours and sampling; in Table III are given the results.

TABLE III

[5] Buttle and Hewitt, *J. Chem. Soc.*, 93,1405 (1908).

Results

In all four series of determinations were made. The first two (**A** and B) were distinctly preliminary and included much of the control work given above. The results were of the same order of magnitude as our final values, except that in the measurements from the high temperature side the method of stirring then in use was not producing equilibrium. The shaking device above described was then installed.

34–40 D	198.9	1.746[a]	5.2

[a] At these higher temperatures it was feared that the large precipitate of AgCl obtained in the analysis might have contained mother liquor or salt in the precipitation from the small volumes necessary in working at the lower temperatures. Mr. G. H. Reed, working in this Laboratory, repeated the measurements above 180" using greater care in the washing and drying of the AgCl. His results were about 0.03 atomic per cent. lower than ours. They are

Temp., °C.	181.8	193.3	212.7
Solubility, atomic %	1.365	1.573	1.953

TABLE VI

SOLUBILITY OF SILVER IN MERCURY AT ROUNDED TEMPERATURES

(From Log N vs. $1/T$ Plot)

Temp, °C.	100 N (from curve)	100 N (calcd.)	Error, p.p.t.
80.0	0.288	0.286	7
100.0	.419	.419	0
120.0	587	.587	0
140.0	.797	.797	0

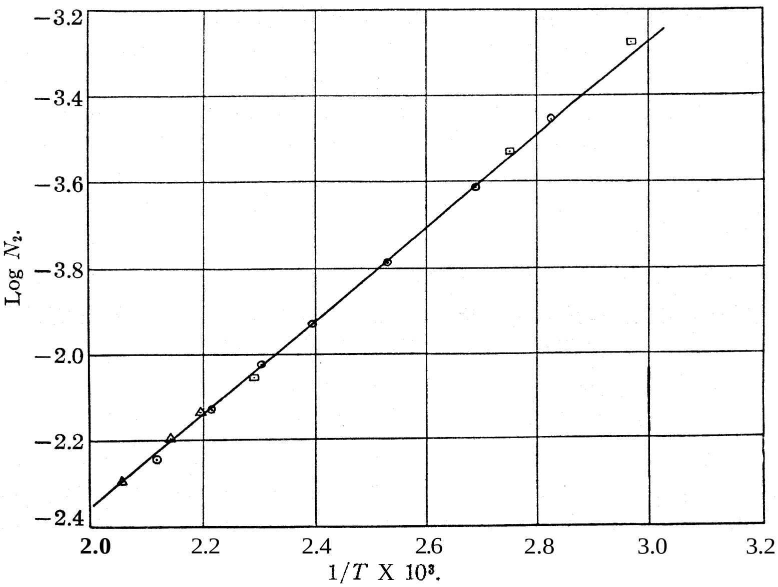
180.0	1 356	1.350	4
200.0	1 708	1 700	4

Of the 56 final determinations only eight have been omitted. Of these six were due to poor filtering, oil in tubes, or bumping in distillation. Two determinations only were rejected because their deviation from the mean was more than 4 times the average deviation for that temperature.

All solubilities are given in atomic per cent. (atoms of silver per 100 total atoms).



□, Joyner; △, Reed, ⊙, Authors.

Fig. 3.—Solubility of silver in mercury.

Discussion of Results

In Fig. 3 the results are plotted as log N vs. $1/T$. The values of Joyner and Reed have been distinguished from those of the present authors. Very satisfactory agreement is found in the various results.

This agreement is particularly of interest since Joyner used thermostatting periods of a fortnight in the preparation of his amalgams. He also used a pipet for sampling, an instrument which in the hands of others has often led to fictitious solubility data.

Joyner's data show, in some cases, an experimental error of 200 p.p.t. Much of this is undoubtedly due to his method of sampling.

A large scale plot was carefully constructed and used in determining the equation for the straight line which results. The equation which has been found to hold satisfactorily is $\log_{10} N = -1074.2(1/T) + 0.501$. The rounded solubility values in Table VI were obtained from this large plot. The calculated values in Table VI are those obtained using the above equation; the agreement is seen to be quite satisfactory.

In the analysis of the amalgams, it was found that distillation at 0.1 mm. and 200° yielded a residue of the approximate composition Ag_3Hg_4. As has been mentioned above, increasing the vacuum to 0.003 mm. and using flame temperatures, a residue composed of about 1 atom of Hg to 50 of Ag was obtained. There is every reason to believe that with a further decrease in pressure in distillation, results found by weighing the residues as silver would be fully as accurate as most wet methods for the determination of silver in the presence of mercury.

The authors wish to thank Professor Willard R. Line of the University of Rochester for his help in the analytical phase of the work.

Summary

1. A method of preparing and analyzing silver amalgams has been described which yields results uniformly only 2 p.p.t. low.

2. A tube has been developed of general applicability to solubility work, which permits of sampling without removal of the equilibrium mixture from the thermostat or the introduction of sampling devices.

3. This tube has been used to determine the solubility of silver in mercury up to 200°, over fifty determinations having been made.

THE ADSORPTION OF ORGANIC COMPOUNDS ON HYDROUS OXIDES AND FULLER'S EARTH

BY DONALD P. GRETTIE WITH ROGER J. WILLIAMS

RECEIVED OCTOBER 13, 1927 PUBLISHED MARCH 7, 1928

Adsorbents have not infrequently been used in the separation of materials of biological importance from extracts of tissues containing them. They have been used in this Laboratory for work of this nature where attempts are being made to isolate a "bios" from yeast extracts. The desire to use adsorbents as intelligently as possible made it desirable to have data on the adsorption of various organic compounds by different adsorbents under comparable conditions. The particular question which appeared most interesting to us was whether the adsorption of various compounds would take place in accordance with the acidic and basic properties of the adsorbent and adsorbate, and to what extent one might expect the adsorption to be specific and unpredictable.

Because data of this sort were not available the work here reported was done. This consisted in a study of the adsorption from solution of a series of pure organic compounds on the hydrous oxides of silicon, iron and aluminum and (because of its previous use as an adsorbent for organic bases) fuller's earth.

Preparation of **Adsorbents.**—The behavior of the hydrous oxides as adsorbents depends largely on the method of their preparation. Impurities on the adsorbents and the heat treatment of the adsorbents affect greatly the extent of adsorption on them. The adsorbents used in the work here reported were prepared according to methods previously used by other workers.

The silica was prepared by precipitating silicic acid and ferric hydroxide together by adding a solution of ferric chloride to a diluted solution of water glass After the precipitate was dried the ferric hydroxide was dissolved out by treatment with 6 *N* hydrochloric acid. The remaining hydrated silica was then washed by decantation with water until the water in which the silica had soaked for several hours gave no precipitate with silver nitrate. When this silica was dried and heated to 120° for several hours a very superior adsorbent resulted. Before use it was ground fine enough to pass through a 200-mesh sieve. This method of preparation was devised by Holmes and Anderson.[1]

The alumina was prepared according to the method described by Willstätter[2] for the preparation of his type B. A solution of aluminum sulfate was added slowly to a strong (20%) solution of ammonium hydroxide. The precipitate was washed four times by decantation with water and was then treated with ammonium hydroxide again, after which it was washed by decantation and then by filtration until free of sulfate ions. The product was dried at 120° for an hour and then ground and passed through a 200-mesh sieve.

The hydrous ferric oxide was prepared in a manner analogous to that used for the preparation of the alumina except that ferric chloride was used instead of aluminum sulfate.

The fuller's earth used was similar in appearance and general behavior as an adsorbent to the English earth marketed by Eimer and Amend, but its exact history is unknown.

Choice of Compounds for Adsorption.—An attempt was made to select a group of organic compounds of widely different chemical properties, both as to acidic and basic strengths and also as to molecular structure and complexity. The choice of compounds for this study was limited to those which are sufficiently soluble and to those which were available in pure form. Eighteen organic compounds, listed in the table, varying in acidic and basic strengths from aspartic acid, having a dissociation constant of $k_a = 1.4 \times 10^{-4}$, to piperidine, having a dissociation constant of $k_b = 1.2 \times 10^{-3}$, were finally chosen. Most of these substances are of biological importance. All except glucose contain nitrogen.

Carrying Out of Adsorption and Analysis.—Solutions of eighteen organic compounds in 0.01 M concentration were prepared and 25cc. samples of these solutions were shaken in a mechanical shaker for five minutes

---

[1] Holmes and Anderson, *Ind. Eng. Chem.*, 17, 280 (1925).

[2] Willstatter, *Ber.*, 56, 149 (1923).

with 0.5 g. of the dried adsorbent which had been ground and passed through a 200-mesh sieve. The solution was then filtered from the adsorbent through filter paper in a Gooch crucible and analyzed for the amount of the compound left in the solution. The methods of analysis were different for the different types of compounds studied. Those compounds which were not volatile at 100°, the temperature of the drying oven, were analyzed simply by evaporating 10 cc. of the filtrate *to* dryness in a weighed crucible and weighing the non-volatile material. Any of the adsorbent that might have come through the filter was taken account of by igniting the material and weighing the crucible plus the non-combustible residue. Those compounds which are distinctly acidic or basic could be titrated and this method was used wherever possible. Some of the nearly neutral compounds were volatile at the temperature of the oven and the solutions of these compounds could not be analyzed by either of the two above methods. Since all of these compounds contained nitrogen the filtrates were analyzed as to their nitrogen content by means of the micro-Kjeldahl method as modified by Koch and McMeeken[3] in which hydrogen peroxide is used as an oxidizing agent.

Whenever results were doubtful or unexpected they were checked at least approximately by using more than one method of analysis. Control experiments showed that adsorption by the small filter used was too small to affect the results detectably, and evaporation during the filtration was shown to be too small to change the results appreciably. Bacterial contamination of the solutions was avoided by using only fresh solutions in case of compounds which might be attacked by micro-organisms. The adsorbents were kept in stoppered containers and the parallel adsorption experiments were all carried out within a short time so that the adsorbents would be uniform for the different tests.

Results and Discussion.—In Table I are given the results obtained in these experiments. The PH values listed were determined directly in the case of the more nearly neutral compounds and were calculated from the ionization constants in the case of the stronger acids and bases. The values apply to the 0.01 M solutions of the pure substances used in the experiments. The following facts should be noted from a consideration of the results: (1) the adsorption by silica seems to be roughly proportional to the basic strength of the compound adsorbed. This is in keeping with the acidic character of silica. The negative adsorption noted in several cases was due to the selective adsorption of water and the consequent increase in concentration of the solution. (2) Adsorption by alumina is most marked in the case of the acidic compounds, though the most basic substance, piperidine, is also adsorbed very appreciably. These results are not unexpected in view of the well-known amphoteric charac-

---

[3] Koch *and* McMeeken, THIS JOURNAL, **46,** 2066–2069 (1924).

ter of alumina. (3) Although the hydrous iron oxide used was apparently an excellent absorbent, the adsorption was very irregular, being strongest in the case of acid substances, as might be expected, but also taking place markedly in the case of certain of the neutral and basic compounds. (4) The adsorption by fuller's earth parallels very roughly the adsorption by silica. One striking exception appears in the case of caffeine. Approximately eight times as much of this substance is adsorbed by fuller's earth as by silica. (5) All of the adsorbents chosen have, rather surprisingly, adsorbent properties of about the same order, in spite of their different characters and sources.

TABLE I

RESULTS OF ADSORPTIONS

Substance	P_H	By silica, %	By alumina, %	By iron oxide, %	By fuller's earth
Piperidine	11.46	94.5	5.7	25.2	73.8
Nicotine	10.6	87.3	1.5	2 2	43.7
Arginine	9.5	72.5	1.2	34.2	31
Quinoline	8.6	47	2	1	71.2
Adenine	8.4	10.6	2	00	21.2
Caffeine	7.8	11.2	0.5	0.0	87
Creatine	7.2	4.7	1.3	3	7.42
Betaine	7.5	5.5	0	0 0	5.08
Acetanilid	7.2	2.37	1.8	12 3	3.05
Urea	7.1	1.9	2.94	0.3	5
Acetamide	7.1	1.1	3.7	1	5.4
Glucose	7.1	0.7	1.0	11.0	0.0
Succinimide	6.0	.7	0.5	0.0	.5
Glycine	6.1	.7	3.0	15 85	.0
Vicine	6.0	.7	13.85	20.25	2.86
Asparagine	5.4	.7	10.95	44.77	.0
Glutamic acid	3.2	.6	74.3	81.6	.0
Aspartic acid	3.1	.0	84.5	87.5	.0

In order to throw some light on the irregularity of adsorption by hydrous iron oxide, another sample was prepared, using an entirely different method. Ferric chloride, which is not obtainable in very pure form, was used for the preparation of the sample used above. For a second iron oxide preparation, pure electrolytic iron was oxidized by ozone in the presence of water, using a piece of platinum foil as a catalyst. The oxidation proceeded slowly but eventually a sample of hydrous iron oxide was obtained. This was heated and screened as in the former cases and tested on several solutions similar to those used above.

The results indicated in Table II show that the second sample of hydrous oxide was not, in general, as good an adsorbent as the precipitated hydrous oxide. This result is not surprising, but it is surprising to note that there is no parallelism in the behavior of the two samples toward the compounds tested. The large differences obtained emphasize the difficulty and irregularities which are liable to be encountered because of the variation in the quality of the adsorbent.

TABLE II

RESULTS WITH SECOND IRON OXIDE SAMPLE

Compound adsorbed	Adsorbed by Sample No. 1. %	Adsorbed by Sample No. 2, %
Piperidine	25.2	19.6
Nicotine	0.2	2.7
Arginine	34.2	15
Quinoline	1	22.9
Glutamic acid	81.6	15.53
Aspartic acid	87.5	14.9

Further experimentation on the effects of different factors on adsorption of organic compounds is contemplated for the future.

Summary

The extent to which eighteen pure organic compounds are adsorbed from 0.01 M solutions on the hydrous oxides of silicon, aluminum and iron and on fuller's earth has been determined. It is found that the extent of adsorption on silica of the compounds used is roughly proportional to their basic strengths, and roughly proportional to their acidic strengths in the case of adsorption on alumina. Adsorption by hydrous iron oxide was very irregular, possibly due to impurities on the adsorbent. The extent of adsorption by fuller's earth was somewhat similar to the adsorption by silica, but in a few cases there was no parallel.

THE INTERNAL PRESSURE OF LIQUID CARBON DIOXIDE FROM SOLUBILITY MEASUREMENTS

BY ELTON L. QUINN[1]

RECEIVED OCTOBER 28, 1927 PUBLISHED MARCH 7, 1928

In a previous paper[2] on the surface tension of liquid carbon dioxide it was found that carbon dioxide had an internal pressure much the same as carbon tetrachloride, toluene and chloroform. This was determined by comparing the total energy of surface formation with the values found for these compounds, according to the method of Hildebrand.[3] It seemed desirable to check these results with the solubility data of liquid carbon dioxide but it was found that the few determinations[4,5] of a quantitative

nature available did not lend themselves readily to a calculation of this kind. It was thought best, therefore, to make a series of determinations using naphthalene and iodine as solutes and if possible to apply the method of Hildebrand[6] in calculating the relative internal pressure of the solvent.

Experimental Procedure

Fig. 1 is a drawing of the reaction tube in which the solubility determinations were made. It will be noted that this type of reaction tube is essentially the same as that ordinarily used for liquid ammonia, the slight modifications being made to increase the strength and to facilitate handling in the thermostat. These tubes were made of soft glass tubing having an internal diameter of about 8 mm. and a 2mm. wall. The connecting tube between the measuring and reaction tubes had an internal diameter of about 4 mm. It was found that a smaller tube at this point did not work satisfactorily as it prevented the free passage of the liquid from one tube to the other. The tube was carefully cleaned with a boiling solution of sulfuric and nitric acids, then washed and dried. A plug of glass wool was placed in the end of the leg designed for the solute and the proper quantity of solute introduced. Both legs were then sealed, great care being taken to keep the flame away from the open ends. The measuring tube was then graduated, the graduation marks being etched into the glass with a solution of hydrofluoric acid.

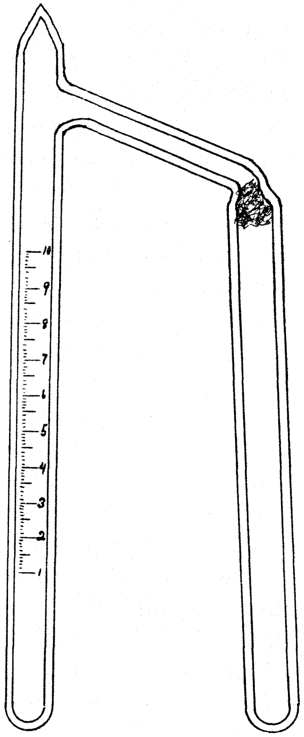

Fig. 1.

The method of introducing the liquid carbon dioxide into the tubes was essentially the same as that described in connection with the surface tension measurements.[2] In this case, however, the calcium chloride drying tower was made from an iron pipe 6.4 cm. in diameter by 56 cm. high. A safety valve fitted to the top of the tower made it possible to admit the gas to the reaction tube under any pressure up to the saturation pressure of liquid carbon dioxide.

Equilibrium between the solution and the solute was obtained by pouring the liquid carbon dioxide into the reaction tube and causing it to flow backwards and forwards over the solute for six to eight hours while it was kept at constant temperature in a thermostat. The thermostat was provided with a mechanical arrangement which kept the contents

---

[6] Nildebrand, *Proc. Nat. Acad. Sci.*, *13*, *No.* 5,267 (1927).

of the tubes agitated during the time required to reach equilibrium. It was found in preliminary tests that tubes agitated one, two or three hours gave practically the same solubility; it was therefore assumed that a run of six or seven hours would be sufficient to reach equilibrium in all cases.

The naphthalene solution was, of course, colorless but the iodine solution was of a beautiful violet color. This latter fact is of some importance as it indicates the absence of solvation in the iodine solutions and places carbon dioxide in the class with "regular" solvents.

A few minutes before the end of each run the solubility tube, which had been hanging with the reaction leg below, was turned over so that the measuring leg came underneath and the agitation was continued until all of the solution had run into this part of the apparatus. Rubber gloves were worn whenever any of the tubes were handled in order to protect the hands in case one exploded and also to prevent any temperature change in the solutions. When the tube was removed from the thermostat the height of the liquid was quickly read and it was then placed in a freezing mixture and allowed to remain until the solution had frozen to a solid mass. A small hole was then melted in the top of the measuring tube and it was allowed to remain in the freezing mixture until the whole system had reached room temperature, which usually took from twenty-four to thirty-six hours depending upon the amount of solid carbon dioxide in the freezing mixture. When the tube was removed from the ether-bath the solute was found in beautiful crystals in the bottom of the measuring leg. The measuring tube was then sealed off from the rest of the apparatus and preserved until a convenient time for analysis.

The amount of naphthalene in each solution was determined by weighing the solid left after the solvent had evaporated. The iodine was determined by washing it out of the measuring tube with a strong solution of potassium iodide and titrating with a standard solution of sodium thiosulfate. The solution volume was found by filling the tube with water to the mark reached by the solution and weighing. From the weight of water the volume of the solution was calculated.

The operations described above gave the weight of solute and the volume of the solution. This was, of course, not sufficient to calculate the solubility of these substances in terms of their mole fractions. The densities of the solutions were determined by means of the special type of pycnometer shown in Fig. 2. In this tube was placed a definite quantity of the solute just sufficient to saturate the solution and leave a slight excess at the highest temperature at which readings were to be made. Liquid carbon dioxide was then admitted and the amount carefully adjusted so that it would nearly fill the tube at the highest temperature of the laboratory. It was very important that the liquid did not completely fill the tube as this condition always resulted in an explosion. After weighing the pycnometer and its contents, it was placed in a thermostat and the height of the meniscus determined at several temperatures. The solution was then frozen and the tube opened by melting a very small hole in the tip. After the solvent had evaporated at a low temperature, the tube was weighed. The difference between this weight and the weight of the tube plus contents gave the weight of the carbon dioxide in the liquid and gaseous state. The solute was then washed cut and the tube again weighed after drying. The difference between this and the previous weight gave the weight of the solute. The tube was then calibrated to the marks reached at the various temperatures. Subtracting from the total weight of carbon dioxide the weight of the vapor, which was calculated by means of Amagat's[7] values, and correcting for the small amount of undissolved solute, the weight of the solution was obtained. In this manner it was possible to determine the density of the solution over a range of about eight degrees. It was not possible to make these determinations much below the temperature of the laboratory on account of the difficulty of keeping the temperature of the tube below the danger point during the weighing operation.

The question arose as to whether the density tubes had the same volume when filled with liquid carbon dioxide, exerting a pressure of 50 to 60 atmospheres on the inside, that they had after the carbon dioxide had been removed. In order to test this point a side tube was sealed onto a test-tube and then bent into a shape something like the letter S. This was filled with distilled water until it overflowed through the side tube. The pycnometer filled with carbon dioxide was then carefully lowered to the bottom of the test-tube and the water overflowing through the side tube was collected in a weighing bottle and weighed. This was repeated several times and the carbon dioxide was then discharged and several more readings were taken sometimes several days apart in order to give the glass time to regain its former condition. In no case could a difference greater than the experimental error be detected, and as the volume of the tube could be determined within less than 0.1% the change in the tube, if any, must be smaller than this and could, of course, be neglected in this work.

Fig. 2.

The densities of the solutions at lower temperatures were determined in the following manner. First, the solubility curve was constructed by plotting the weight of solute obtained from a definite volume of solution against the temperature and extrapolating to zero concentration. This gave the point where the density of the solution became the same as the

---

[7] Amagat, Ann. *chim.* phys., [6] **29,** [68] (1893).

pure solvent. Then on large scale cross section paper the density curve of the pure solvent was constructed using the density values of Behn[8] and Jenkin.[9] The experimental densities of the solutions were plotted beside this curve for the pure solvent and curves constructed which cut this solvent curve at the temperature where the concentration of the solute became zero. These solution curves came so close to the curve of the pure solvent that no great accuracy was necessary at the junction point. The values read from these curves are shown in Table I.

TABLE I

VALUES READ PROM THE CURVES

Purification of Material

The carbon dioxide used in these determinations was obtained from commercial cylinders of the liquefied gas manufactured by the Pure Carbonic Company of Berkeley, California The analysis of the gas showed a purity of 99.85% of carbon dioxide with a trace of water vapor when the sample was taken from the top of the cylinder. Although oil was found when the gas was taken from an inverted tank, no evidence of it was ever found when the sample was taken from the top of the cylinder.

The naphthalene used was Baker's Analyzed, Lot No. 4425, with a melting point of 79". This was fractionally distilled several times, the middle fraction only being collected from each distillation. This was crystallized from redistilled alcohol twice and dried in a desiccator for several weeks. The freezing point of the purified naphthalene was then determined by taking the cooling curve of a large sample in a test-tube. Several determinations gave values between 79.9 and 80.2" with an average of 80°. The iodine used was also Baker's Analyzed. This was resublimed once in the presence of potassium iodide before it was used.

The results obtained from these solubility determinations are shown in Tables II and III.

[a] This is the second set of iodine determinations made. The agreement between the averages in the two sets was quite satisfactory but the agreement between the individual measurements in the first set was not.

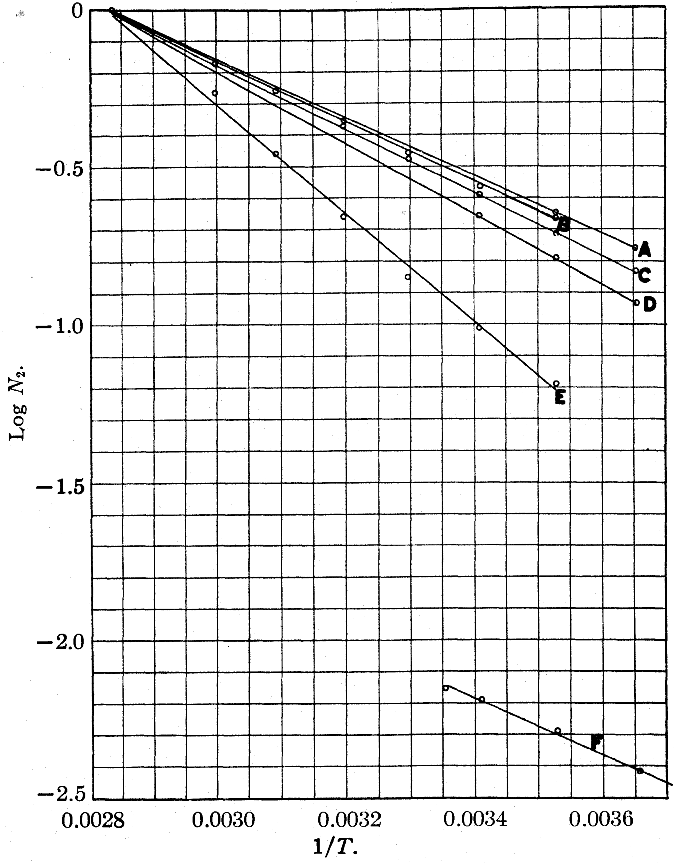
Discussion of Results

The relation between the internal pressure of a solvent and the deviation of its solutions from Raoult's law has been discussed in detail by Hildebrand.[10] He points out that one of the most important methods of estimating internal pressure differences between various solvents is to plot their solubility curves for the same solute (log N_2 against $1/T$) with the curve of the ideal solvent. The displacement of these curves from

---

[10] **Ref. 3,** p. 115.

that of the ideal solution is a measure of their internal pressure differences and from such a plot it is possible to arrange the solvents in an internal pressure series. This method has the disadvantage of requiring the plotting of the curves before the position of any solvent in the series can be assured and in addition lacks quantitative significance. Recently Hildebrand[6] developed an equation by means of which this deviation can be calculated quantitatively for what he calls regular solvents and which has the added advantage that the approximate internal pressure factor can be calculated from a single solubility measurement.

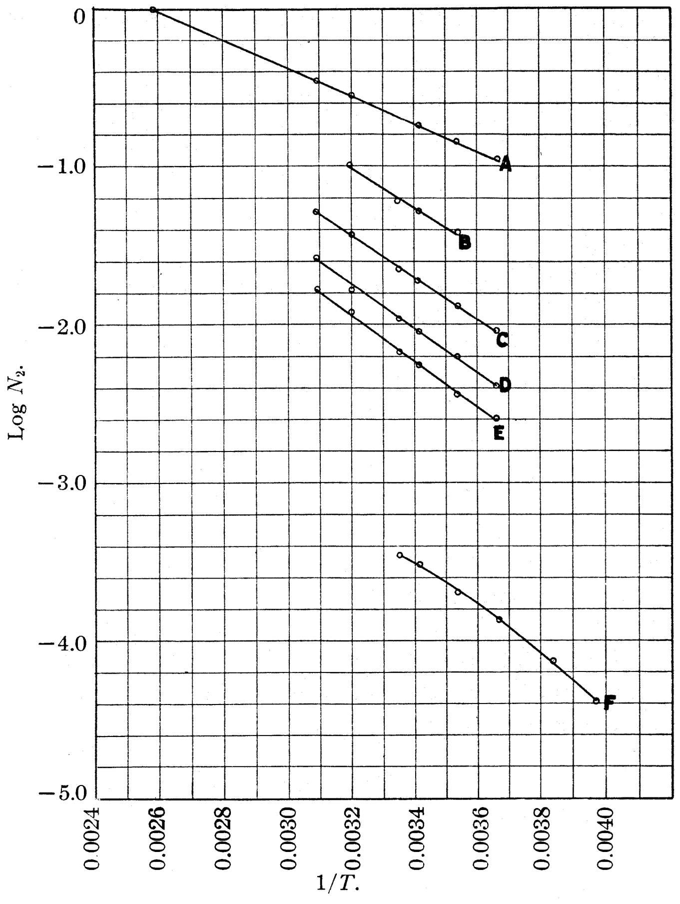


A, ideal; B, C_6H_5Cl; C, C_6H_6; D, CCl_4; E, C_6H_{14}; F, CO_2.

Fig. 3.—Solubilities of naphthalene.

The Hildebrand equation may be written in the following form, $\ln N_2^R/N_2 = bN_1^2/RT$, in which N_2^R and N_2 are mole fractions of the ideal and experimental solubilities of a solute, respectively, at the absolute temperature T, while N_1 is the mole fraction of the solvent, b is a constant which is related to the difference in internal pressure for the two components and R the usual gas constant or 1.99. The ideal solubility of N_2^R can be calculated from the heat of fusion and melting point of the solute.

Ward[11] has made solubility determinations of naphthalene in a number of solvents and Fig. 3 shows a few curves plotted from his data together with the curve for the solubility of naphthalene in carbon dioxide. This gives a clear idea of the relation of carbon dioxide as a solvent to the more common solvents and indicates that the internal pressure of liquid carbon dioxide is very low. Fig. 4 plotted in the same manner from data given by Hildebrand shows the solubility of iodine in various solvents. This also indicates that carbon dioxide has a very low internal pressure.



A, ideal; B, $CHBr_3$; C, $CHCl_3$; D, CCl_4; E, C_7H_{16}; F, CO_2.

Fig. 4.—Solubilities of iodine.

---

[11] Ward, *J.* Phys. Chem., 30, 1327 (1926).

If we write the Hildebrand equation as $(T \log N_2/N_2^R)/N_1^2 = k$ and calculate the value of k for the solutions of naphthalene and iodine in liquid carbon dioxide at different temperatures, we obtain the results indicated in Tables IV and V.

			Average	469

TABLE V

DATA FOR IODINE

$\log N_2^R$	Lon N_2	N_2	T	k
−0.673	−3.442	0.000361	298	827
− .723	−3.515	.000305	293	820
− .829	−3.683	.000207	283	807
− .942	−3 864	.000136	273	800
−1 075	−4.123	.0000753	262	800
−1.200	−4 392	.0000405	252	805
			Average	810

In order to show the relation of these values of k to the average value obtained for other solvents, Table VI has been arranged, in which the solvents have been placed in the increasing order of their internal pressures. The data from which these values of k were calculated were taken from the determinations made by Ward and the tables published by Hildebrand. In the series of solvents of naphthalene the value of k was calculated at five degree intervals over a range of temperature from 0 to 25°, while the series of solvents for iodine were calculated at ten degree intervals from 0 to 50°.

TABLE VI

INTERNAL PRESSURE SERIES

Naphthalene as solute		Iodine as solute	
Solvent	**k**	**Solvent**	**k**
Carbon dioxide	469	Carbon dioxide	810
Carbon tetrachloride	57	Heptane	450
Toluene	30	Carbon tetrachloride	393
Benzene	26	Chloroform	302
Chlorobenzene	8	Bromoform	178
Nitrobenzene	23		
Acetone	74		
Aniline	122		

Internal Pressure from Surface Tension Measurements

When an attempt was made to evaluate the internal pressure of carbon dioxide from the surface tension measurements there was much doubt as to the best way to accomplish this. The total energy of surface formation was calculated by means of the Thomson equation and a value of 62 was obtained. This indicated that carbon dioxide had an internal pressure much the same as carbon tetrachloride, toluene and chloroform. In the light of these solubility determinations it is readily seen that this comparison is very misleading, as carbon dioxide has a very much lower internal pressure than any of these compounds. It is now clear that some other unit of comparison should have been used and if we calculate the value of $\gamma/V^{1/3}$ at 20° we obtain a value of 0.35, which places carbon dioxide in the internal pressure series in a position more nearly in accord with that obtained from solubility determinations. A more exact comparison at this time is not feasible.

Summary

1. A method has been described for determining the solubility of solids in liquefied gases, which can be applied to liquids having very high vapor pressures.
2. The solubility of naphthalene and iodine in liquid carbon dioxide has been determined over a range of temperature from 25 to —21°.
3. The position of liquid carbon dioxide in the internal pressure series has been determined. This indicated that this compound has an internal pressure much less than those liquids commonly used as solvents.

THE STANDARDIZATION OF SILVER NITRATE SOLUTIONS USED IN CHEMICAL STUDIES OF SEA WATERS[1]

BY THOMAS G. THOMPSON

RECEIVED NOVEMBER 1, 1927 PUBLISHED MARCH 7, 1928

The advantages of the use of standard sea water prepared by the Hydrographic Laboratories of Copenhagen have been pointed out by Knudsen.[2] This standard water has been used for over a quarter of a century for the evaluation of silver nitrate solutions employed in oceanographic investigations and is obtainable only from the Hydrographic Laboratories. However, Bertrand, Freundler and Ménager,[3] Ménager[4] and Giral[5] have recently criticized this standard and the two latter authors have recommended the use of sodium chloride.

---

[1] Presented before the Division of Water, Sewage and Sanitation at the 74th meeting of the American Chemical Society, Detroit, Michigan.

[2] Knudsen, *Publications de circonstance*, No. 2 (1903); No. 87 (1925).

[3] Bertrand, Freundler and Ménager, *Compt. rend.*, 174, 1251–1253 (1922).

[4] Ménager, *ibid.*, 179, 195–198 (1924).

[5] Giral, *Publications de circonstance*, No. 90 (1926).

To properly carry out the determination for the halide ions, as recommended by the International Council for the Study of the Sea, standard sea water is necessary and the titer tables[6] are essential, while the special pipets and burets provided by the Hydrographic Laboratories are recommended. The chlorides[7] are calculated as grams of chlorine per kilo ($^0/_{00}$) and by the use of the Hydrographical Table the salinity[8] may be readily ascertained.

The use of standard sea water and the special apparatus produces unnecessary inconveniences because of the time required for procurement. The substitution of common volumetric apparatus, made to meet the specifications of the United States Bureau of Standards, and of pure sodium chloride solutions gives results that are just as accurate.

Experimental

Standardization of Silver Nitrate Solution.—The Mohr method, using potassium chromate solution as an indicator for the determination of chlorine, is generally accepted as the standard method in oceanographic and thalassographic chemistry. A comparison of this method with that of Volhard's and the usual gravimetric procedure has recently been made by Smith and Thompson[9] in which the general agreement of the three methods as applied to sea water was demonstrated.

Two methods for standardizing the silver nitrate solution were used, (1) pure sodium chloride and (2) standard sea water from the Hydrographic Laboratories.

1. The sodium chloride was prepared by treating a filtered saturated solution made from Merck's blue label salt with hydrogen chloride. The precipitated crystals were dried, a saturated solution was made and from this the salt was precipitated with alcohol. The crystals were finally dried at 150°. Liter solutions of sodium chloride were then prepared equivalent to (a) 17.409 g. and (b) 19.411 g. of chlorine for silver nitrate solution No. 1 and (c) 19.409 g. of chlorine for silver nitrate solution No. 2. Twenty-five cc. of these solutions were pipetted into casseroles and titrated with the silver nitrate solution. Titration in a yellow light facilitated the observance of the end-point.

---

[6] "Hydrographical Tables," edited by Martin Knudsen, Copenhagen, 1901.

[7] The amount of chlorine in sea water is universally defined as the grams of chlorine contained in one kilogram of water, assuming the small quantities of bromine and iodine to be replaced by chlorine.

[8] The salinity has been correlated with chlorine by Knudsen, Sørensen and others and is expressible in the formula, $S = 0.03 + 1.805\ \mathrm{Cl}$. It is defined as the weight in grams of all the salts dissolved in a kilogram of sea water, after the carbonates have been converted to oxides, the bromine and iodine have been replaced by chlorine and the organic matter has been completelv oxidized.

[9] Smith and Thompson, *University of Washington Eng. Expt. Sta. Bull., No. 41,* 38–41 **(1927).**

2. Two tubes of standard sea water at 20° were opened and 25cc. portions immediately pipetted and titrated. The samples, according to the analysis of the Hydrographic Laboratories, contained 19.386 and 19.379 g. of chlorine per kilo, respectively, and the calculated densities at 20° were 1.021280 and 1.02478. The standard sea water thus contained 19.867 and 19.859 g. of chlorine per liter at 20°.

Ordinary pipets and burets calibrated by the United States Bureau of Standards for 20° were used. A temperature of 20° for titration has been found by the author to be more desirable than that of 15° both for work in the laboratory and on board ship.

The results of the standardization of two silver nitrate solutions are shown in Table I.

TABLE I

STANDARDIZATION OF SILVER NITRATE SOLUTION AT 20°

	1 cc. of $AgNO_3$ equiv. in mg of Cl	
	No. 1	No. 2
Sodium chloride (a)	10.067	....
Sodium chloride (b)	10.070	. .
Standard sea water	10.072	....
Sodium chloride (*c*)	....	0.9855
Standard sea water	....	.9853

The above results show that the standardization of the silver nitrate solution may be accomplished with the same result using either standard sea water or pure sodium chloride and that the salts other than chlorides present in the sea water have no effect upon the titration. The latter statement confirms the work of Giral[5] with synthetic sea waters. Thus pure sodium chloride, which is readily obtainable, may be used as a standard. It is suggested that liter solutions of sodium chloride approximating the concentration of chlorine in the sea waters under investigation be utilized and that in all cases 25cc. samples at 20° be taken for titration. The grams of chlorine per liter at 20° of water are thus calculated from the data given by the titration.

In order to arrive at the relation between the chlorine per liter at 20° and the chlorine per kilo, the data in Table II were calculated from the

TABLE II

DATA FROM WHICH EMPIRICAL FORMULA WAS CALCULATED

Grams of chlorine per liter at 20°, Cl_v	Grams of chlorine per kilogram, Cl_w	Cl_v − 14 244	Cl_w − 14.000	$\frac{Cl_w - 14\ 000}{Cl_v - 14.244}$
14.244	14.000	0	0	0
15.282	15.000	1038	1000	.96340
16.322	16.000	2078	2000	.96246
17.366	17.000	3122	3000	.96092
18.412	18.000	4168	4000	.95969
19.461	19.000	5217	5000	.95844
20.513	20.000	6269	6000	.95709

Hydrographical Tables and the following empirical formula was derived, where Cl_v represents the grams of chlorine per liter at 20° and Cl_w the grams of chlorine per kilogram of sea water.

$$Cl_w = 0.008 + 0.99980\,Cl_v - 0.001228\,Cl_v^2$$

The difference, $Cl_v - Cl_w$ shows the marked error introduced should a liter of sea water be assumed to weigh a kilogram, an assumption sometimes found in the literature.

From the above formula a table has been calculated whereby, knowing the grams of chlorine per liter at 20° of sea water, one can readily calculate the grams of chlorine per *mille*, or vice versa, and thus have a means of arriving at the desired densities.

Table III shows the corrections for reducing grams of chlorine per liter at 20° to grams per kilo at any temperature.

TABLE III

CORRECTIONS FOR REDUCING GRAMS OF CHLORINE PER LITER AT 20° TO GRAMS PER KILO AT ANY TEMPERATURE

Chlorine, g./l. at 20°	Correction	Chlorine, g./l. at 20°	Correction	Chlorine g./l. at 2do	Correction	Chlorine, g./l. at 20°	Correction
5	−0.02	9	−0.09	13	−0.20	17	−0.35
6	− .04	10	− .12	14	− .23	18	− .39
7	− .05	11	− .14	15	− .27	19	− .44
8	− .07	12	− .17	16	− .31	20	− .49

In order to test the validity of the formula, samples of water collected from various sources were analyzed both by volume and by weight. The results are given in Table IV. The samples were secured from the North Pacific off the Alaskan Coast, the Puget Sound Biological Station in the San Juan Islands, several points in Puget Sound and one sample is that of standard sea water obtained from the Hydrographic Laboratories of Copenhagen and evidently collected from the Atlantic Ocean.

TABLE IV

ANALYSES OF VARIOUS SEA WATERS SHOWING AGREEMENT WITH CALCULATED VALUES

Determined		Calcd.	
G. of Cl per liter at 20° Cl_v	G. of Cl per kilo,[a] Cl_w	G. of Cl per kilo, Cl_w	Diff.
15.66	15.38	15.37	+0.01
16.36	16.03	16.03	.00
17.40	17.03	17.03	.00
17.96	17.56	17.57	− .01
17.26	16.90	16.90	.00
19.87	19.39	19.39	.00
15.84	15.54	15.54	.00
16.54	16.20	16.21	− .01
15.72	15.49	15.42	+ .07

[a] Weighed in air.

Five of the samples were analyzed by Miss Margery Walker and Mr. Ronald Benson. Particular attention is called to the last sample in the table, as it represents the sea water taken near the mouth of a pipe discharging bleach waste from a paper pulp mill into Puget Sound. In this case by determining the grams of chlorine per liter and per kilo of sea water and converting the former with the aid of the conversion table to grams per kilo, an indication of the extent of pollution may be ascertained from the difference between the calculated and determined values for Cl_w.

The excellent agreement of the calculated results and those obtained by analyses demonstrates not only the accuracy of the tables but also of the method of analysis. The relatively high degree of precision of the analytical method is also cited by Helland-Hansen[10] and others. The suggestion of Giral[6] for increasing the permissible error recommended by the International Council for the Exploration of the sea is unwarranted.

Conclusion

1. Sodium chloride may be substituted for standard water for standardizing silver nitrate solutions to be used for oceanographic studies. Both standards give practically identical results.

2. An empirical formula has been derived and corrections have **been** calculated therefrom permitting the conversion of grams of chlorine per liter at 20° of sea water to grams of chlorine per *mille* or *vice versa.*

INFRA-RED ABSORPTION BY THE N-H BOND
II. IN ARYL, ALKYL AND ARYL-ALKYL AMINES

BY JOSEPH W. ELLIS

RECEIVED NOVEMBER 23, 1927 PUBLISHED MARCH 7, 1928

This paper represents a continuation of a study of the near infra-red absorption in primary, secondary and tertiary amines, Part I[1] of which was limited to an examination of aniline, five mono- and five dialkyl anilines. The present paper presents the absorption **curves** to about 2.5μ of the following compounds, all of which were bought from the Eastman Kodak Company: mono-, di- and tri-*n*-propyl-, n-butyl- and iso-amylamine; mono- (aniline), di- and triphenylamine; mono-, di- and tribenzylamine; a-, methyl-a-, dimethyl-a-, ethyl-a- and diethyl-α-naphthylamine; and *p*-, methyl-p- and dimethyl-*p*-toluidine. The primary purpose of the investigation is to test further the hypothesis advanced in

---

[10] "Internat. Rev. Hydrobiol. und Hydrograph.," Hydrograph. suppl., Series I, part 2, 1912, p. 39.

[1] Ellis, THIS JOURNAL, 49, 347 (1927).

Part I that certain definite absorption bands below 3μ are associated with the N-H bond.

Two cell thicknesses, 2 mm. and 40 mm., were used with each of the liquid members of this group of compounds. The 2mm. cells were microscope depression slides with thin cover glasses. It was found that these slides, even in a vertical position, retained the liquid indefinitely without any sealing. The 40mm. cell was of glass with quartz ends of 2 mm. thickness held on by pressure exerted by threaded brass collars.

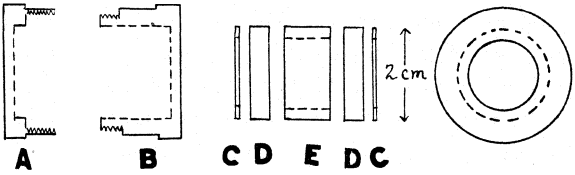

Fig. 1.—A demountable absorption cell.

The four members which are solids at room temperature, namely, di- and triphenylamine, α-naphthylamine and p-toluidine, were maintained in a molten state at temperatures just above their respective melting points. A demountable cell, 10 mm. in length, sketched in Fig. 1, was constructed for this purpose A and B are two parts of a brass housing, threaded to screw together. D, D are 4mm. quartz end-plates which fit snugly against the ground faces of the Pyrex glass cell E. C, C are steel spring washers designed to allow for the unequal expansions of brass, quartz and glass. The cell was packed with the compound which was to be examined and fitted into a well in an asbestos block, 10 X 10 X 3.5 cm., which could be raised to the desired temperature. Heat was produced in the block by maintaining a controlled current in a high resistance wire which threaded it. If the cell was not sufficiently filled after melting took place, it was cooled and more of the substance added.

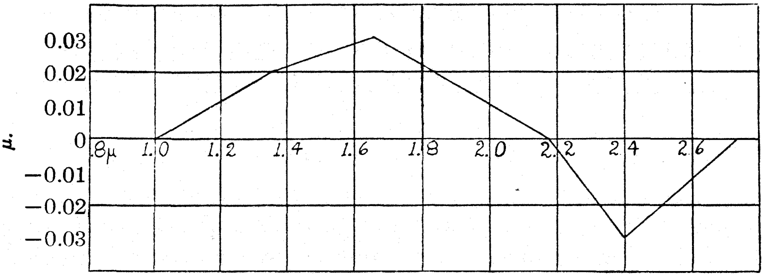

Fig. 2.—Wave length corrections to previous values.

In Figs. 3–18 are given the absorption records of the above-mentioned amines as traced by the recording spectrograph which has been used throughout this and other investigations. During another study[2] it was discovered that, because of inaccurate calibration, slight corrections must be made to many of the wave length values previously published by the author in several papers. These corrections apply to some of the values given for absorption bands in aniline and the alkyl anilines of Part I of this paper. In Fig. 2 a correction curve is given which should be used with all values previously published. Throughout this article only corrected values will be stated when quoting previous work.

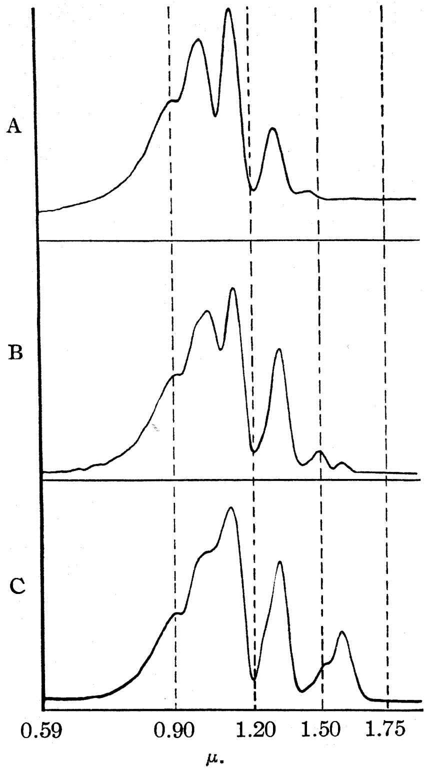

Fig. 3.—A, n-propylamine, 40 mm.; B, di-n-propylamine,40 mm.; C, tri-n-propylamine, 40 mm.

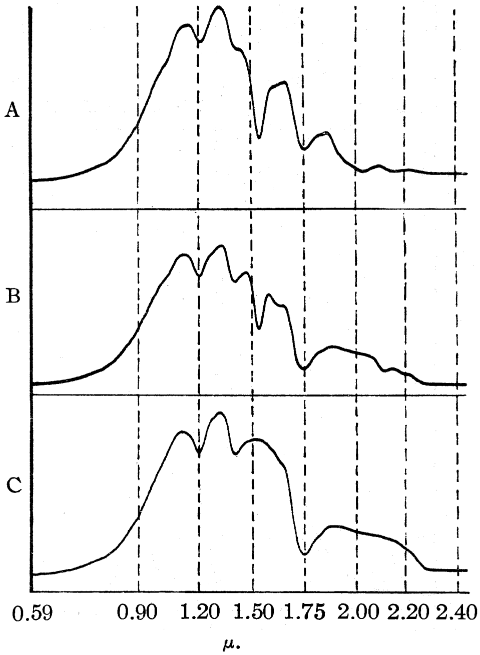

Fig. 4.—A, n-propylamine, 2 mm.; B, di-n-propylamine, 2 mm.; C, tri-*n*-propylamine (purified), 2 mm.

Absorption maxima at 1.49μ and 1.03μ[3] have been discovered in the spectra of aniline and five mono-alkyl anilines which, when taken with a strong isolated maximum discovered by Bell[4] at 2.8μ, form a parabolic series when expressed in wave numbers. The disappearance of these three bands

---

[2] Ellis, *Proc. Nat. Acad. Sci.*, 13,202 (1927).

[3] *A* careful recheck of this value gives 1.03μ instead of the 1.04μ value previously given.

[4] Bell, THIS JOURNAL, 47,2192 (1925).

in the spectra of the corresponding dialkyl anilines lent support to the hypothesis advanced by the writer that these maxima represent characteristic frequencies associated with natural oscillations of the N-H pair of atoms.

Bell[5] has continued his study with four additional papers in which he has found absorption bands for numerous primary and secondary alkyl, aryl and aryl-alkyl amines analogous to the 2.8μ band in aniline and mono-alkyl anilines, varying in position from 2.9μ to 3.05μ. These are considerably diminished in the secondary amines and disappear, or practically disappear, in the tertiary amines.

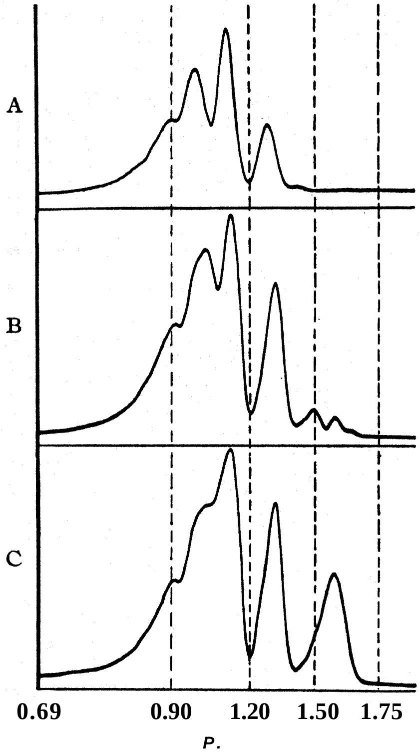

Fig. 5.—A, n-butylamine, 40 mm.; B, di-n-butylamine, 40 mm.; C, tri-*n*-butylamine, 40 mm.

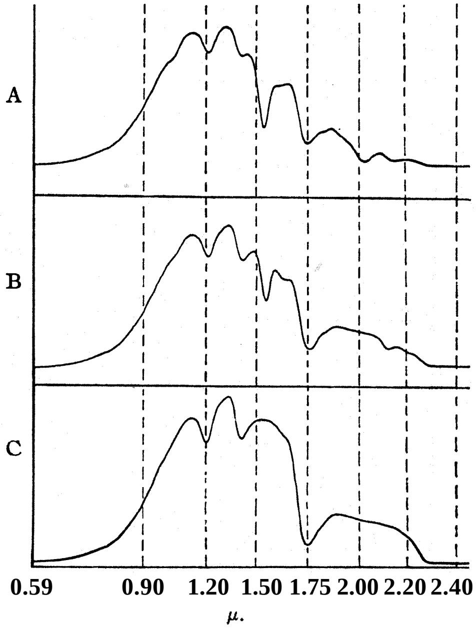

Fig. 6.—A, n-butylamine, 2 mm.; B, di-n-butylamine, 2 mm.; C, tri-*n*-butylamine, 2 mm.

In the records of the primary and secondary amines, Figs. 3–18, it is seen that there are two bands varying respectively from 1.49μ to 1.55μ and 1.03μ to 1.06~. These are analogous to the 1.49μ and 1.03μ bands of the anilines. In general it is noticed that a shift toward longer wave lengths of the band near 3μ is accompanied by a corresponding shift in the two

---

[5] (a) Bell, This Journal, 47,3039 (1925); (b) 48,813 (1926); (c) 48, 818 (1926); (d) 49, 1837 (1927).

shorter wave length bands. Furthermore, these latter absorption maxima disappear in most of the tertiary amines. In the cases where they remain as traces in the original samples of the tertiary compounds they have been proved to be due to impurities, as will be pointed out later.

The records for the alkyl amines are shown in Figs. **3–8.** The bands ascribed to the N-H linkage are found at **1.54–1.55**μ and 1.06μ. These may well be interpreted as the second and third members of series analogous to that found for the anilines or, in terms of the older phraseology, as the first and second harmonics (or overtones) of the value found by Bell at 3.00–3.05μ. A trace of the 1.55μ absorption remains in the record of tri-*n*-propylamine, Fig. 3C. A portion of the original sample of this material was treated by Dr. G. R. Robertson of the Chemistry Department with the aim of removing any possible primary or secondary amines. The process adopted was similar to that used in the purification of methylethylaniline (Part I).[6] That the trace of a band present in Fig. *3C* is

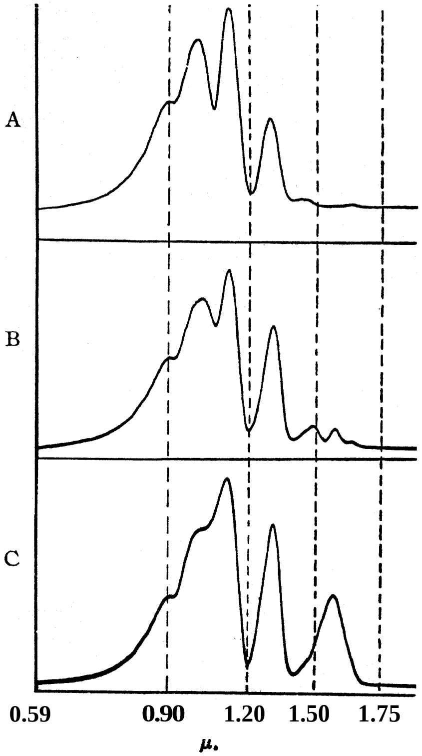

Fig. 7.—A, iso-amylamine, 40 mm.; B, di-*iso*-amylamine, 40 mm.; C, tri-*iso*-amylamine, 40 mm.

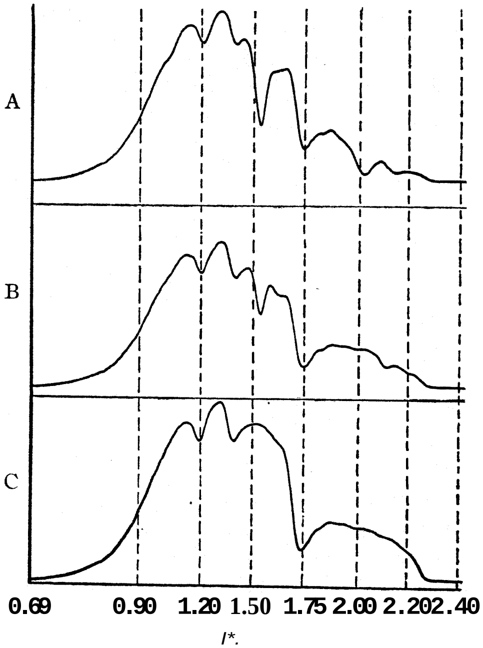

Fig. 8.—A, *iso*-amylamine, 2 mm.; B, di-iso-amylamine, 2 mm.; C, tri-*iso*-amylamine, 2 mm.

---

[6] Ref. 1, p. 352.

not due to tri-*n*-propylamine is proved by its absence in the records of the treated substance, Figs. 18A and 4C.

The maxima at 1.75, 1.40, 1.20, 1.02 and 0.92μ are the established C-H bands characteristic of alkyl groups.

The 1.49μ and 1.03μ bands of aniline are found diminished in the record of diphenylamine, Fig. 9, while they are essentially lacking in the record of triphenylamine. The 1.68, 1.41 and 1.15μ maxima are C-H bands characteristic of the phenyl group.

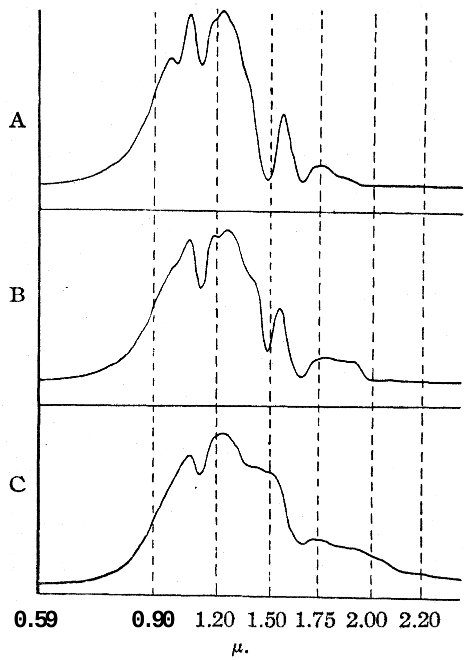

Fig. 9. —A, aniline, 10 mm.; B, diphenylamine, 10 mm.; C, triphenylamine, 10 mm.

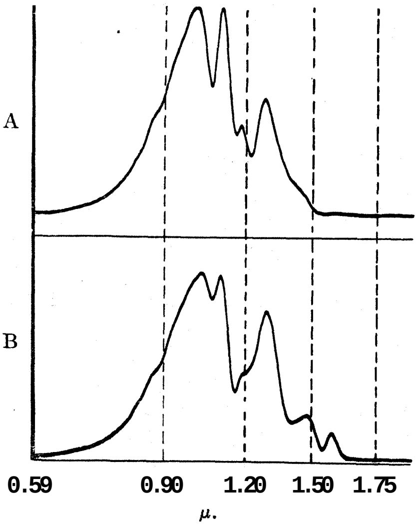

Fig. 10. —A, benzylamine, 40 mm.; B. dibenzylamine, 40 mm.

The shift toward shorter wave lengths of the absorption maxima associated with carbon-hydrogen linkages in the case of aryl compounds is doubtless to be associated with the lack of saturation in the molecules. It appears that this unsaturation also affects an amino group attached to an aryl group. Thus we have low wave length values for the N-H bands in aniline as compared with the corresponding values in the alkyl amines. In mono- and dibenzylamine, Figs. 10 and 11, where the amino group is attached to an alkyl rather than to the phenyl group, the N-H bands have the high wave length values 1.55μ and 1.06μ. The contributions of both the phenyl and alkyl C-H pairs are seen in the [1.68, 1.75μ], and possibly the [1.15, 1.20μ] regions.

In the spectra of a-, methyl-a- and ethyl-a-naphthylamine, *p*-, methyl-p- and ethyl-*p*-toluidine, Figs. 12–17, the N-H bands have the anticipated low values of 1.49–1.51 μ and 1.03 μ There are traces of the 1.49 μ band in the records of dimethyl-a- and diethyl-a-naphthylamine and dimethyl-p-toluidine. That these disappear when treated for the removal of probable primary or secondary amines is shown in the case of the last two substances in the records of Fig. 18. No attempt was made to purify dimethyl-a-naphthylamine. It is of interest to note that the tertiary amines which retain traces of the 3 μ band in Bell's records are included among the compounds which have here been shown to contain impurities.

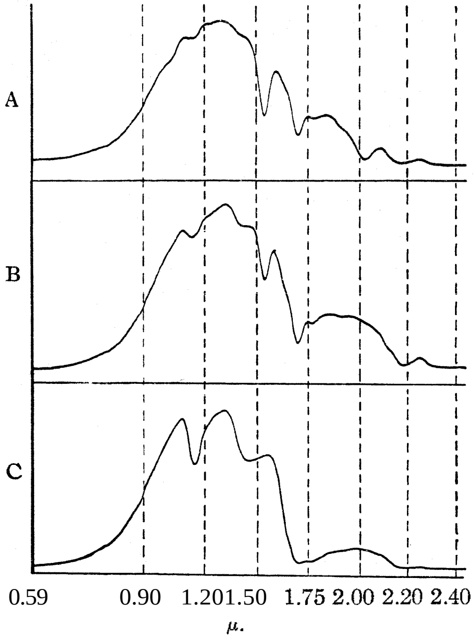

Fig. 11.—A, benzylamine, 2 mm.; B, dibenzylamine, 2 mm.; C, tri-benzylamine, 10 mm.

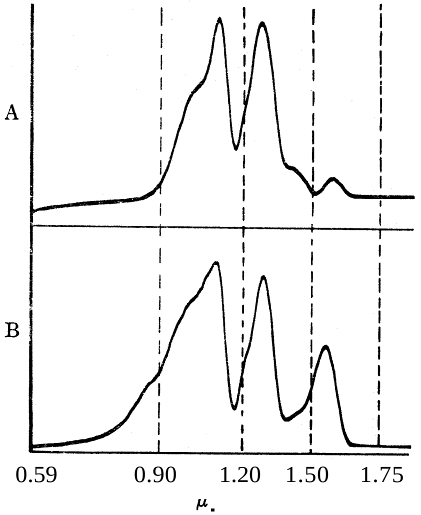

Fig. 12.—A, methyl-α-naphthylamine, 40 mm.; B, di-methyl-a-naphthylamine, 40 mm.

Bell[5d] has found a very pronounced absorption band at 6.25 μ in mono-alkyl amines, which practically disappears in the di- and trialkyl amines. He points out that his spectra of primary aryl and aryl-alkyl amines show evidence of absorption by the amino group in this region, although a band characteristic of benzene, naphthalene and their derivatives tends to make interpretation difficult.

Salant[7] has examined the spectra of certain secondary and tertiary amines in the 6.2 μ region with the definite purpose of testing his previous assumption[8] that a fundamental band characteristic of the N-H bond

---

[7] Salant, *Nature*, 119, 926 (1927).

[8] Salant, *Proc. Nat. Acad. Sci.*, *12*, 74 (1926).

occurs there. He concludes that such a fundamental does not exist. The strength of the 6.25μ band, however, found by Bell in the mono-alkyl amines suggests this as a fundamental.

This band is of interest in connection with a maximum at 2.01–2.03μ observed in the spectra of primary amines in the present paper. It might be regarded as the second harmonic of the 6.25μ band, while those at 1.49–1.51μ and 1.03–1.06μ might be regarded as the third and fifth harmonics respectively. There are two arguments, however, against this interpretation: (1) the deviation from integral multiple relationship among these bands is of the wrong sense; that is, a harmonic should have a slightly longer rather than a shorter wave length than one-half, one-third, etc., of the value of its fundamental; (2) whereas the 1.49–1.55μ and 1.03–1.06μ maxima retain their positions with diminished intensities in passing to the secondary amines, the 2.01–2.03μ maximum either shifts to a longer wave length value or disappears.

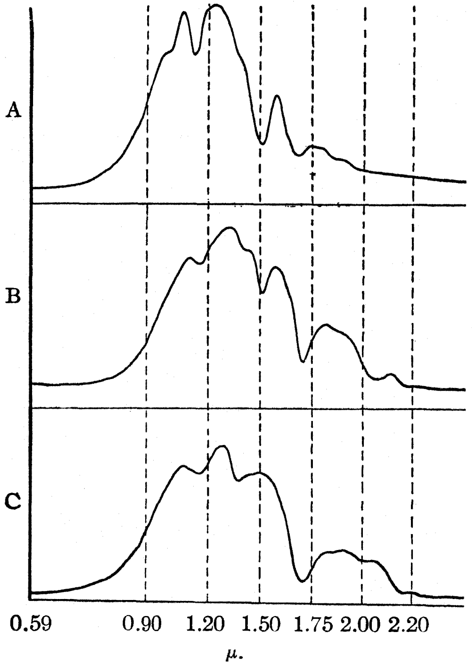

Fig. 13.—A, a-naphthylamine, 10 mm.; B, methyl-a-naphthylamine, 2 mm.; C, dimethyl-a-naphthylamine, 2 mm.

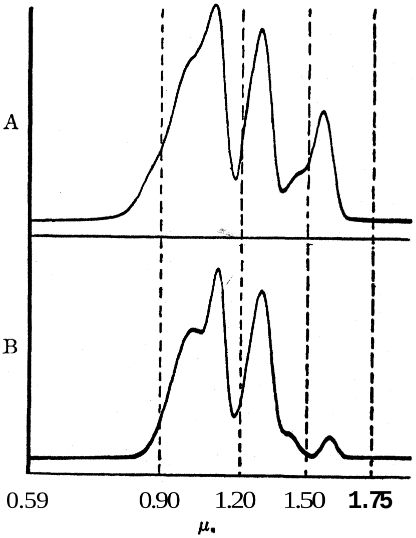

Fig. 14.—A, ethyl-a-naphthylamine, 40 mm.; B, diethyl-a-naphthylamine, 40 mm.

The writer is inclined to interpret the N-H bands in a manner analogous to his modified interpretation of the C-H bands.[2] The 6.9μ and 3.45μ bands, and the 6.75μ and 3.25μ bands, characteristic of alkyl and aryl groups, respectively. are assumed to be associated with two fundamental modes of vibration of the C-H pair. The longer wave length fundamental seems to have no harmonics, while the [1.75 (alkyl), 1.68μ (aryl)], [1.20μ, 1.15μ] and [0.92μ, 0.88μ] bands are regarded as the first three harmonics of the 3.45μ (3.25μ) fundamental. The maxima in the regions of 2.30μ (2.18μ), 1.40μ, 1.02μ and 0.83μ are interpreted as "combinations" of the 6.9μ (6.75μ) band with the 3.45μ (3.25μ) fundamental and its overtones, respectively. A combination band is one whose frequency is determined by the addition of two other frequencies.

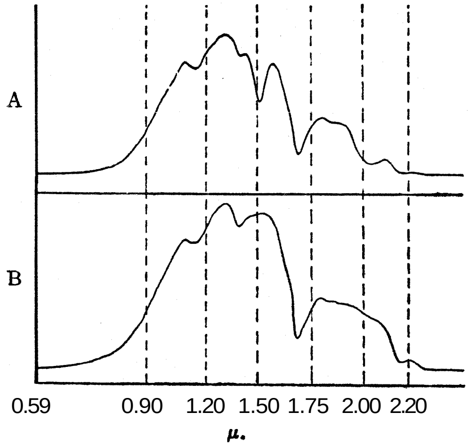

Fig. 15.—A, ethyl-α-naphthylamine, 2 mm.; B, diethyl-α-naphthylamine (purified), 2 mm.

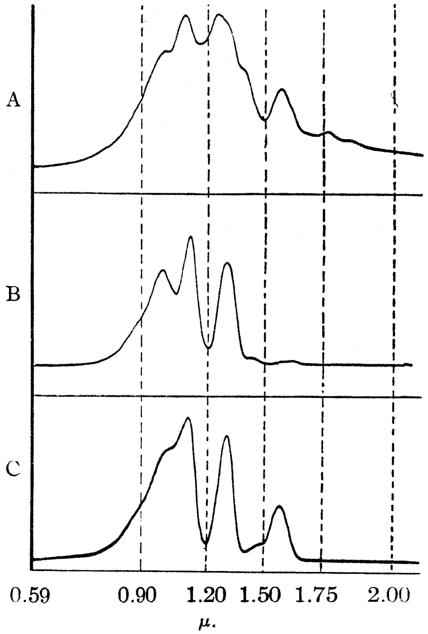

Fig. 16.—A, *p*-toluidine, 10 mm B, methyl-p-toluidine, 40 mm.; C, dimethyl-*p*-toluidine, 40 mm.

The 6.25μ N-H band may be regarded as analogous to the one at 6.9μ (6.75μ) due to C-H, while the 3.05–2.80μ, 1.55–1.49μ, 1.06–1.03μ series may parallel the 3.45μ (3.25μ) fundamental and its overtones. A combination of the 6.25μ and 3.00–3.05μ frequencies yields a wave length value of 2.03–2.05μ in good agreement with the 2.02μ value observed for the primary alkyl amines and benzylamine. This is illustrated by the following addition of the frequencies of the 6.25μ and 3.00μ values expressed in mm.$^{-1}$: 160 + 333 = 493 mm.$^{-1}$. The wave number of the observed 2.02μ band is 495 mm.$^{-1}$. The agreement is less satisfactory in the case of aniline, however, with a calculated value of 1.93μ as compared to an observed value of 2.01μ. (It will be observed that the interpretation of this band in aniline differs from that given in Part I of this paper.)

In the spectra of methyl-α- and ethyl-α-naphthylamine and methyl-p-toluidine this band occurs at 2.03μ, while in the dialkyl amines and dibenzylamine it has apparently shifted to 2.10μ.

In the region 1.21–1.23μ there seems to be evidence of a contribution to absorption by the amino group. This is shown by the records for aniline and diphenylamine in Fig. 9 and for benzyl- and dibenzylamine in Fig. 10. These values are in good agreement with the 1.20–1.24μ combination band calculated from the 6.25μ and 1.49–1.55μ maxima. There is also evidence of the existence of this band in the records for the primary and secondary alkyl amines, but the occurrence of C-H absorption at 1.20μ practically obscures it.

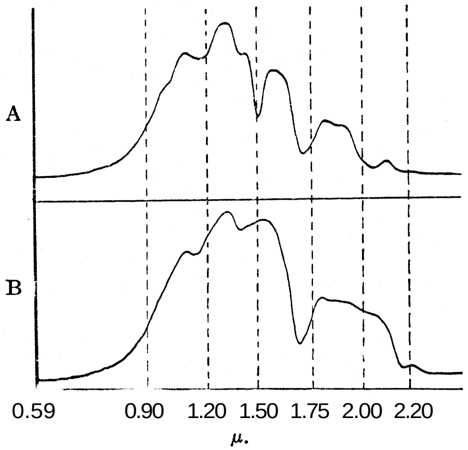

Fig. 17.—A, methyl-*p*-toluidine, 2 mm.; B, dimethyl-*p*-toluidine (purified), 2 mm.

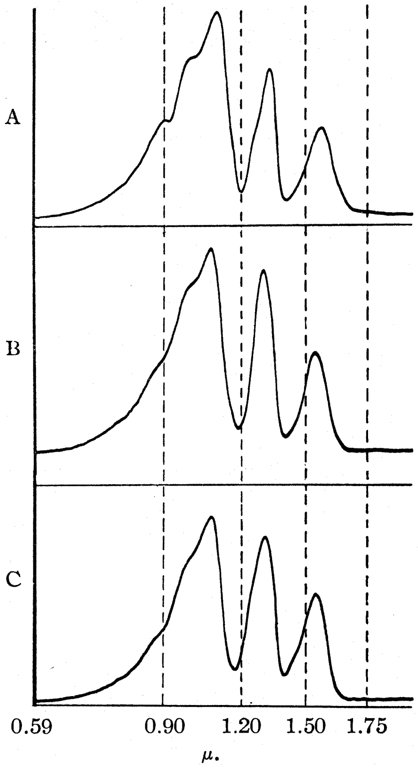

Fig. 18.—A, tri-*n*-propylamine (purified), 40 mm.; B, dimethyl-*p*-toluidine (purified), 40 mm.; C, diethyl-α-naphthylamine (purified), 40 mm.

In Table I is given a summary of the values attributed to the nitrogen-hydrogen linkage, including the measurements on mono-alkyl anilines recorded in the first portion of this paper. The values found by Bell and by Salant for the band near 3μ are included.

TABLE I

BANDS CHARACTERISTIC OF THE N H BOND

n-Propylamine	3.05,	1 . 5	1.06μ	2.02μ
Di-n-propylamine	3.05; 3.04 S[a]	1.55	1.06	2.10
n-Butylamine	3.00	1.55	1.06	2.02
Di-*n*-butylamine	3.05; 3.01 S	1.55	1.06	2.10
iso-Amylamine	3 00	1.55	1.06	2.02
Di-iso-amylamine	3.05; 3.07 S	1.54	1.06	2.10
Aniline	2.80	1.49	1.03	2.01
Diphenylamine	2.90; 2.89 S	149	1.03	[b]
Methylaniline	2 80	149	1.03	2.06
Ethylaniline	2 90	149	1.03	2.06
n-Propylaniline	2.80	1.49	1.03	[b]
n-Butylaniline	2.80	1.49	1.03	[b]
iso-Amylaniline	2.70	1.49	1.03	[b]
Benzylamine	3.00	1.55	1.06	2.02
Dibenzylamine	3.00; 3.00 S	1.55	1.06	2.10
α-Naphthylamine	2.90	1.51	1.03	[b]
Methyl-a-naphthylamine	2.90	1.51	1.03	2.03
Ethyl-a-naphthylamine	2.90	1.51	1.03	2.03
p-Toluidine	...	1.49	1.03	[b]
Methyl-p-toluidine	...	1.51	1.03	2.03

[a] All of the 3μ values are from Bell's papers, with the exception of those marked S, which are due to Salant.

[b] Records do not permit of measurement in this region.

The writer is grateful to Dr. G. R. Robertson, who purified certain of the compounds used and to Mr. W. A. Munson for assistance in obtaining the spectra recorded.

Summary

1. Using a registering spectrograph, the infra-red absorption spectra below 2.5μ have been obtained for mono-, di- and tri-n-propyl, n-butyl and iso-amylamine; mono- (aniline), di- and triphenylamine; mono-, di- and tribenzylamine; a-, methyl-a-, dimethyl-a-, ethyl-a- and diethyl-a-naphthylamine; and p-, methyl-p- and dimethyl-*p*-toluidine.

2. Bands which occur at 1.49–1.55μ and 1.03–1.06μ for the primary amines and with diminished intensities for the secondary amines but which disappear for the tertiary amines, thus apparently originating in the nitrogen-hydrogen linkages, form an "harmonic" series with a band found by Bell at 2.80–3.05μ.

3. Absorption maxima at 2.01–2.03μ and 1.21–1.23μ, apparently also characteristic of the amino group, are suggested as "combination" bands arising from the 2.80–3.05μ and 1.49–1.55μ values taken with a band found by Bell at 6.25μ.

THE DISSOCIATION CONSTANT OF ACETIC ACID AND THE ACTIVITY COEFFICIENTS OF THE IONS IN CERTAIN ACETATE SOLUTIONS[1]

BY EDWIN J. COHN, FRANCIS F. HEYROTH[2] AND MIRIAM F MENKIN

RECEIVED NOVEMBER 29, 1927 PUBLISHED MARCH 7, 1928

The characterization of weak and of strong electrolytes has involved quite different conceptions and methods. The concept of partial dissociation and the method of conductivity yielded the Ostwald dilution law, and accurate constants in terms of which the dissociation of weak acids could be defined. The dissociation constant of acetic acid has been very accurately determined by this method to be 1.85×10^{-5} by Kendall.[3] Recently MacInnes[4] has shown that a slightly lower value for this constant is obtained "provided (a) that the degrees of ionization are computed in a manner which allows for inter-ionic attraction, and (b) that the resulting ion concentrations are multiplied by the appropriate activity coefficients." His values for the dissociation constant of acetic acid vary from 1.743 to 1.784×10^{-5}.

The partial neutralization of a weak acid by a strong base may also be described by the mass law. The salt of the weak acid formed by the neutralization must be considered a strong electrolyte leading to inter-ionic forces. None the less the mass law must hold provided the quantities involved are expressed as activities. When the neutralization is followed by electromotive force measurements with the hydrogen electrode the activity of the hydrogen ion is determined. The activity of the acid anion may be expressed by multiplying its stoichiometric concentration by its activity coefficient. If the activity coefficient of the acetate ion is defined by the Debye-Hückel equation, a general expression is obtained[5] which may be written in the following logarithmic form for acetic acid

$$P_{H^+} - \log\,[(CH_3COO^-)/(CH_3COOH)] = P_K - 0.5\sqrt{\mu}/(1 + \kappa b) + Ks\mu = P_{K'} \quad (1)$$

In this equation P_{H^+} and P_K are the negative logarithms respectively of the hydrogen ion activity and of the dissociation constant of the acid; μ is the ionic strength; and b and Ks and κ are the usual terms in the Debye-Hückel equation, the latter having the value of $0.33 \times 10^8\sqrt{\mu}$. The assumption made by MacInnes that the activity coefficient of the undissociated acetic acid is equal to unity has been tentatively adopted. As

a result K_S is attributed entirely to the acetate anion, although it includes the effect on acetic acid. This simplification influences neither the value of the apparent nor of the true dissociation constant of acetic acid.

The Dissociation Constant of Acetic Acid

The left side of Equation (1) yields the negative logarithm of the apparent dissociation constant of the acid, sometimes expressed by the symbol $P_{K'}$. At low values of the ionic strength the activity coefficient of the acetate ion approaches one and $P_{K'}$ approaches the negative logarithm of the true dissociation constant, P_K. If $P_{K'}$ is plotted as ordinate, and the square root of the ionic strength as abscissa, a graphical method of determining the true dissociation constant of the acid is obtained, for at low values of ionic strength the terms containing b and Ks become vanishingly small and linear extrapolation possible.

In the study of buffer solutions,[6,7] the useful approximation has generally been made that the concentration of the acid anion, (CH_3COO^-), could be put equal to the concentration of sodium acetate. This approximation breaks down in precisely those solutions with which we are concerned here, namely, those that are both very dilute and appreciably acid. Under these circumstances the assumption is no longer justified that the amount of the anion derived from the dissociation of the acid is negligible in comparison with that derived from the dissociation of the salt. The amount derived from the salt may be put equal to the concentration of sodium ions, and that derived from the acid to the stoichiometric concentration of hydrogen ions. The sum of these concentrations yields the concentration of the anion

$$(Na^+) + (H^+) = (CH_3COO^-) \tag{2}$$

Electromotive force measurements do not yield the stoichiometric concentration but the activity of the hydrogen ion, a_{H^+}. This quantity divided by the activity coefficient of the hydrogen ion, γ_{H^+}, yields the concentration of hydrogen ions and may be substituted in the above equation. Lewis and Randall,[8] Scatchard,[9] and Sherrill and Noyes[10] have estimated the activity coefficient of the hydrogen ion. Their results over the range employed do not differ by more than one per cent. The values employed in these calculations have been taken from a curve drawn through their values relating the activity coefficient of the hydrogen ion to the ionic strength of the solution. Taking into account the acetate

anion derived from the dissociation of acetic acid, the complete equation for the apparent dissociation constant, $P_{K'}$, in mixtures of acetic acid and sodium acetate becomes

$$P_{H^+} - \log \frac{(Na^+) + (a_{H^+}/\gamma_{H^+})}{(CH_3COOH)} = P_K - 0.5\sqrt{\mu}/(1 + \kappa b) + K_s\mu = P_{K'} \qquad (3)$$

The concentration of acetic acid, (CH_3COOH), has been substituted for its activity and has been estimated by subtracting the concentration of the anion from the total acetate in the system.

Accurate electromotive force measurements upon dilute equimolecular mixtures of acetic acid and sodium acetate were made by Walpole[11] in 1914, and Brönsted[12] attempted certain calculations with these data in 1921. Walpole's result at very low molecular concentrations do not fall upon a straight line, probably because of the difficulty of making measurements in such dilute solutions. No attempt has been made to make measurements at these low concentrations, but from 0.02 to 0.2 M it has been possible to confirm the general trend of Walpole's data.

The determination of P_K by extrapolation becomes more accurate the lower the ionic strength of the solution. On the other hand, the usual experimental errors are encountered in measurements upon solutions of low molecular concentration. In the case of buffer mixtures this difficulty has been overcome by studying mixtures containing relatively large amounts of the weak acid but small amounts of the salt. Under these

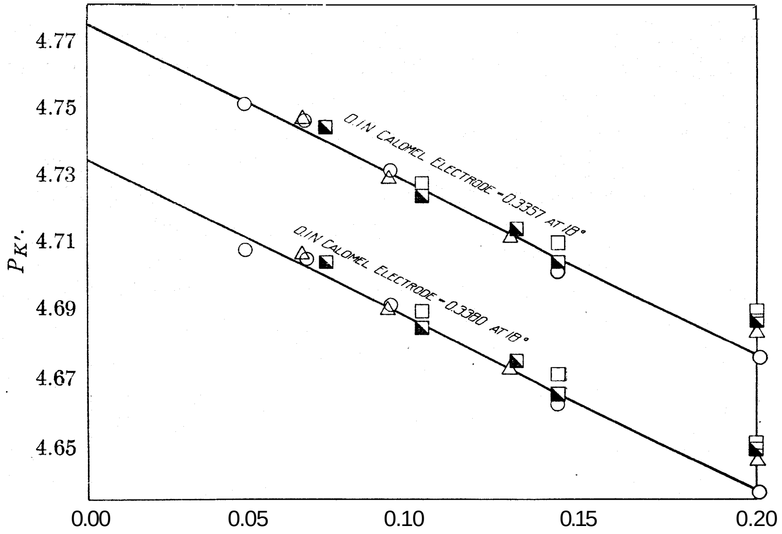
circumstances the molecular concentration may be retained at a relatively high level and the ionic strength allowed to reach a much lower value. Measurements have now been made upon solutions containing four and nine times as much acetic acid as sodium acetate. A 0.02 molecular solution of acetic acid of which only 0.1 has been transformed into sodium acetate has an ionic strength of 0.00217. None the less this solution is well buffered and readily studied by means of the hydrogen electrode. Measurements upon such solutions are recorded in Table I and, together with Walpole's measurements, graphically represented in Fig. 1.



Square root of ionic strength.

Fig. 1.

Measurements upon dilute acetic acid solutions have been reported by Loomis and Acree[13] and Walpole. Their results are not in entire agreement, and the empirical dilution law deduced by Walpole from his data is at variance with the theoretical equation under consideration. These data upon dilute solutions of acetic acid, like those upon extremely dilute buffer solutions, show an apparent change in $P_{K'}$ upon dilution far greater than should be expected. For the present it seemed desirable to restrict the investigation to buffered solutions whose concentrations were not lower than 0.01 molar.

The electromotive force measurements that have been made have been calculated as hydrogen potentials by means of Sørensen's[14] value for the 0.1 N calomel electrode in order to render them comparable to Walpole's

measurements upon standard acetate solutions. Walpole states that his measurements were constant and reproducible to 0.1 millivolt. He attempted to correct for diffusion potentials by the Bjerrum extrapolation method but reported no diffusion potential as great as 0.1 millivolt for the solutions considered in Table I. He noted the extremely small diffusion potentials of all of the acetate solutions that he studied. In our measurements the saturated potassium chloride salt bridge was employed and no correction for diffusion potentials attempted.

The mean values of the hydrogen potentials recorded in Table I have been employed in Table II for the calculation of the apparent dissociation constant of acetic acid by means of Equation (3). The measurements upon equimolecular mixtures of acetic acid and sodium acetate of Walpole and of Michaelis and his collaborators[15] are included in Table II. Our results and those of Walpole upon solutions with ionic strengths less than 0.05 (excepting those of Walpole upon the most dilute solutions, which are given in parentheses) are graphically represented in Fig. 1, in which $P_{K'}$ is the ordinate and the square root of the ionic strength the abscissa.

In dilute solutions, which alone are considered in Fig. 1, the change in $P_{K'}$ is nearly proportional to the square root of the ionic strength. Under these circumstances the values of the apparent dissociation constant, calculated in Table II, may be employed in estimating the true dissociation constant of acetic acid. This was attempted by the graphical extrapolation in Fig. 1. A straight line originating at P_K 4.733 (where $\sqrt{\mu} = 0$) has been drawn with the theoretical slope of 0.5 demanded by the Debye equation. This line passes between the lower set of experimental points, but the specific ion effects, which are known to occur from the study of more concentrated solutions, and are evident in the figure when $\sqrt{\mu}$ is greater than 0.1, exert a slight influence even in more dilute solution. Were these effects considered, a slightly lower value of P_K would have to be adopted, approximately equal to 4.73. The value of P_K, 4.733, equal to $Ka = 1.85 \times 10^{-5}$, is identical with Kendall's estimate of the dissociation constant of acetic acid derived from conductivity measurements. The uncertainty in obtaining a value of P_K from the extrapolation of the electromotive force measurements in Fig. 1 is not greater than $\doteq$ 0.005. The results of Kendall's conductivity measurements and these electromotive force measurements are thus entirely consistent with each other, provided Sørensen's value of the 0.1 normal calomel electrode is employed.

The Value of the 0.1 N Calomel Electrode

The value of the 0.1 N calomel electrode has long been in doubt by over 2 millivolts. As a result the entire scale upon which so much chemical and

---

[16] Dr. Michaelis has made the following personal communication to me regarding the **PH** of standard acetate as calculated by Michaelis and Kakinuma: "The activity coefficients of HCl had been calculated by Lewis and Randall from the mean activity of HCl. In order to obtain the activity coefficient of the hydrogen ion one had to apply the hypothesis that $\gamma_{H^+} = \gamma_{Cl^-} = \sqrt{\gamma_{HCl}}$. Such an assumption, **which** is certainly justified for molecules such as KCl, is not true for HCl. It seemed to me better to take γ_{H^+} in $N/500$ HCl = 1. Upon this assumption the value P_H 4.607 was obtained. In the meantime, γ_{H^+} has been determined more carefully by Scatchard, and we should take γ_{H^+} for 0 002 HCl = 0.956. In this case the value 4.607 must be changed to 4.627, **which** is in agreement with Walpole's original value, my own earlier values, and Cohn's new measurements."

biochemical work depends is in doubt. Sørensen's value for the 0.1 *N* calomel electrode at 18° was 0.3380, and Clark[17] has calculated a value for this half cell of 0.3360 from Lewis, Brighton and Sebastian's[18] measurements upon the normal calomel electrode at 25°. Although he has pointed out this discrepancy, Clark has suggested that the Sørensen value for the 0.1 N calomel electrode be retained, since so much work already published depends upon it.

In certain incidental measurements of the activity coefficients of the hydrogen ion in dilute hydrochloric acid solutions, we were forced to the use of the Lewis, Brighton and Sebastian value for the 0.1 N calomel electrode.[19] The Sørensen value rendered the accumulated data uninterpretable. Sørensen's measurements were made in 1909, and his value depended upon estimates of dissociation derived from conductivity data. He has recently pointed out, in collaboration with Linderstrøm-Lang,[20] that the value 0.3357 is obtained provided the activity of the hydrogen ion is referred to. They have suggested retaining both the old and the new value, the one referring to the concentration, the other to the activity of hydrogen ions. Scatchard[8] has also recalculated Sørensen's old value "using 0.0801 instead of 0.0917 for the mean activity of the ions of 0.1 M hydrochloric acid." "Taking 0.0762 for the activity of the chloride ion in 0.1 M potassium chloride" Scatchard obtains 0.3353 for the half cell at 25°. The same temperature coefficient as has been previously employed renders Scatchard's estimate identical with Sørensen's own revision of this electrode potential, 0.3357 at 18°. Lewis and Randall in recalculating the result of Lewis, Brighton and Sebastian estimate "the activity of chloride ion in 0.1 M KCl . . . . to be 0.0794, whence for the deci-normal electrode . . . . E = –0.3351" at 25°. Their value for the half cell thus becomes 0.3355 at 18°.

These various estimates of the 0.1 N calomel electrode based upon the activity of hydrogen ions in 0.1 N solution thus vary from 0.3355 to 0.3360 at 18°. If the electromotive force measurements reported are calculated by means of these values of the 0.1 N calomel electrode, the value of P_K becomes greater than that estimated by means of Sørensen's original value. The upper set of points in Fig. 1 has been calculated on the basis of the value 0.3357 for the 0.1 N calomel electrode at 18°. Besides increasing all the values of $P_{K'}$ by approximately 0.04, this effects a relatively greater change in $P_{K'}$ the more acid the reaction. For this reason measurements made upon mixtures containing but a small proportion of sodium acetate are raised in $P_{K'}$ more than are equimolecular mixtures by the assumption

of a lower value for the calomel electrode. The points representing the measurements upon the most dilute acid solutions appear to fall more nearly on a straight line when calculated by means of the lower value for the calomel electrode.

A far greater uncertainty is introduced in the interpretation of these measurements by the value ascribed to the calomel electrode than by the measurements themselves. The uncertainty regarding the calomel electrode depends upon the activity coefficient of the hydrogen ion in cells containing strong electrolytes in concentrations as great as 0.1 molal. The inter-ionic forces in such solutions are appreciable. Electromotive force measurements by means of the hydrogen electrode can, however, be carried on upon mixtures of a weak acid and its salt in solutions of relatively high molecular concentration, but of such low ionic strength that specific ion effects can practically be neglected. It is therefore suggested that electromotive force measurements upon mixtures of a weak acid and its salt might be used in the standardization of calomel electrodes (see also the papers of Michaelis and his collaborators[15]) since the dissociation constants obtained by the extrapolation of such data may be compared with the very accurate constants of the weak acids yielded by means of the Ostwald dilution law and conductivity measurements.

In the recalculation of the dissociation constants of weak acids recently reported by MacInnes, "the only case in which there is a definite trend in the value of the constant K is that of acetic acid in which there is a change of 2.2% from 0.07 to 0.002 *N*. This is probably due to the fact that the conductance data for the acid and its sodium salt were obtained by different workers." This is unfortunate and renders it desirable either that new conductance work be done on acetates, or that electromotive force measurements be made upon the other weak acids studied by MacInnes and by Sherrill and Noyes. The values calculated by MacInnes range in P_K from 4.749 to 4.759. The difference of 0.01 in P_K or P_{H^+} is greater than the probable error in the measurements reported, but only one-fourth as large as the difference introduced by the use of the new and the old values of the 0.1 N calomel electrode. If MacInnes' calculations are assumed to yield the correct value of P_K, the value of the 0.1 N calomel electrode should lie between 0.3364 and 0.3370.

It is not possible, at this time to do more than indicate the interdependence of estimates of the dissociation constant of a weak acid derived from conductivity measurements, with those derived from electromotive force measurements and with the value of the calomel electrode. A redetermination of any of these quantities will yield more accurate values of all the others. The values of the negative logarithm of the dissociation constant of acetic acid, P_K, derived from the reported electromotive force measurements upon acetate solutions, and the various values of the 0.1 N calomel electrode are reported in Table III, and compared with the values of P_K derived from conductivity measurements by Kendall and MacInnes.

TABLE III

THE RELATION BETWEEN THE VALUES OF THE DISSOCIATION CONSTANT OF ACETIC ACID AND OR THE 0.1 N CALOMEL ELECTRODE

	Values of the 0.1 *N* calomel electrode at 18°	Values of P_K denved from elertromotive force measurements	Values of P_K derived from conductivity measurements	
Sørensen[14]	0.3380	4.730	Kendall[3]	4.733
Clark[17] from Lewis, Brighton and Sebastian's measurements	.3360	4.765		...
Sørensen and Linderstrøm-Lang[20]	.3357	4.770	MacInnes[4]	4.749 to 4.759
Scatchard[9] from Sørensen's measurements	.3357	4.770		
Lewis and Randall[8]	.3355	4.773		...

The Activity Coefficients of the Ions in Certain Acetate Solutions

The activity coefficients of the acetate anion that may be derived from electromotive force measurements are independent of the value ascribed to the calomel electrode. The difference between $P_{K'}$ in any given solution and P_K yields the negative logarithm of the activity coefficient of the anion in that solution, provided both are calculated by means of the same value for the reference electrode. In Fig. 1 values of $P_{K'}$, derived from hydrogen electrode measurements upon dilute mixtures of acetic acid and sodium acetate, were plotted against $\sqrt{\mu}$, and graphical extrapolation yielded a value of P_K equal to 4.733, with an uncertainty not greater than 0.005. A slightly lower value of P_K, perhaps 4.730, would have resulted had not linear extrapolation been entirely relied upon, for the effect of the size of the ions, which becomes so significant a factor in more concentrated solutions, cannot be entirely neglected in these dilute solutions.

Taking the round value 4.73 for P_K the values of the constants in Equation (3) have been estimated from measurements of the PH of systems containing known amounts of acetic acid and sodium acetate, and therefore having known ionic strengths. The ionic strength per liter of solution rather than per thousand *g.* of water is always given. Measurements of the PH of the same mixture of acetic acid and sodium acetate, at various dilutions, may be employed, and values of b and *Ks* deduced from them by means of Equation (3). If, on the other hand, values of b and Ks, derived from such calculations, be assumed, the equations can be solved for P_K. In this way the experimental results can be considered from the point of view of the additional information that they yield regarding the dissociation constant of acetic acid.

The stock solutions employed in preparing the acetate mixtures consisted of 4 *M* sodium hydroxide and of 4 *M* and 8 *M* acetic acid. The acetic acid solutions were regularly standardized against the sodium hydroxide and these in turn were standardized against 0.1 *M* oxalic acid. The stock solutions were always diluted approximately to 0.1 *M* for standardization.

The solutions to be measured were prepared by placing a given amount of acetate as acetic acid in a volumetric flask and transforming the desired amount into sodium acetate by the addition of sodium hydroxide. Boiled distilled water was then added to bring the solution to volume. At least two, and sometimes three, mixtures of each mole fraction, at each concentration, were measured by means of three different electrodes. The electromotive force measurements upon dilute acid solutions are reported in Table I and have already been considered with respect to certain of the implications to be derived from them. These solutions varied in molecular

concentration from 0.02 to 0.2, and in ionic strength from 0.00216 to 0.1. This range is extended by the data in Table IV, in which are reported measurements upon solutions more concentrated than those studied by Walpole. The concentrations varied from 0.2 to 4.0 molecular, and the mole fraction of total acetate as CH_3COONa from 0.1 to 0.9. The ionic strengths in Table IV thus vary from 0.02016 to 1.80. If all of the measurements be considered they range in ionic strength from 0.00216 to 1.80.

The averages are taken in Table IV of the different electromotive force measurements made upon these different acetate solutions. With a few exceptions each solution was prepared several times, from different stock solutions, and studied by more than one of us. In Table V, $P_{K'}$ has been calculated from the average PH measurements by means of Equation (3). In the accompanying figure $-\log \gamma$ has been plotted as ordinate and the square root of the ionic strength as abscissa. The straight line which represents the limiting slope for a univalent ion originates at $P_K = 4.73$, and the values of $-\log \gamma$, given as ordinates, are calculated on this basis. The curves which pass through the experimental points have been constructed on the basis of the values of b given in Table V. The term Ks has been retained constant at 0.16 throughout these preliminary calculations. It is probable that certain of the measurements could have been more accurately represented by varying not only b but Ks as well. This was certainly the case with the most alkaline series studied. However, it was not believed that this was warranted by the experimental accuracy that has been achieved, and the simplification in calculation that results renders it desirable to consider Ks constant.

The description of these measurements upon diverse mixtures by means of a constant value for the salting-out constant is noteworthy. In the study of the activity coefficients of the ions in certain phosphate solutions, it was found possible to describe the data on the basis of a constant value for b, but a variable value for Ks. It was pointed out that this approximation could be justified only in so far as the Debye-Hückel equation was being employed as an empirical interpolation formula. Though the same reservation must be made in connection with the present investigation, it should be pointed out that in this case we are not dealing with the univalent and bivalent salts of a weak acid but with the weak acid itself and its univalent salt. Under these circumstances not only is the change of the activity coefficient with concentration very much less—the limiting slope being 0.5 instead of 1.5—but in all save the most dilute acid solutions the ionic strength is proportional to the sodium ion. Whether or not this simple proportionality results in the apparent constancy of Ks must await further experimentation. It may well be a real rather than an apparent phenomenon, to be expected in other comparable mixtures of weak univalent acids and their salts.

Another method of considering these data is presented in Table V. The values of b and *Ks* employed in the construction of the curves in Fig. 2 have been used in the calculation of the values of $-\log \gamma$ given in the table. These values of the negative logarithm of the activity coefficient of the acetate anion, added to the negative logarithm of the apparent dissociation constant $P_{K'}$, yield in the last column calculated estimates of the negative logarithm of the true dissociation constant, P_K. Errors either in the theoretical calculation of the activity coefficient or in the experimental determination of the PH appear as deviations from the theoretical value of this constant. The method of calculation has the further advantage that these deviations are proportional to their value as errors in PH. It will be noted that in all of the calculated values of P_K, made from measurements of the PH of solutions varying in mole fraction of sodium acetate from 0.1 to 0.9 and in ionic strength from 0.00217 to 1.80, none is higher than 4.741 and none lower than 4.721. Within the range that has been considered, no error in estimating the PH of a solution greater than 0.02

					Average	4.720

[a] Calculated on the basis of the value 0.3380 for the 0.1 N calomel electrode at 18°. The values at 0.2 M are the averages of those obtained by Walpole and by us.

[b] The values of $-\log\gamma$ have been calculated by means of the equation

$$\left(\frac{0.5\sqrt{\mu}}{1+\kappa b}-0.16\mu\right)$$

The following values of 0.33×10^8 b were employed for the mole fractions of total acetate as the sodium salt from 0.1 to 0.9: 0.3, 0.7, 1.0, 1.2, 1.5.

should therefore be expected in employing the values for b and K_S that have been deduced from these data.

Moreover, the average of all of these calculated values of P_K is 4.729, which is in excellent agreement with the value obtained by graphical extrapolation in Fig. 1. In so far as the Sørensen value is accepted for the 0.1 N calomel electrode, it therefore appears that 4.73 may be employed as the negative logarithm of the dissociation constant of acetic acid; Ka = 1.86×10^{-5}. This result, as we have seen, is in excellent agreement with Kendall's value of 1.85×10^{-5}, an estimate based upon conductivity data uncorrected for inter-ionic forces. Recalculation of the data in Table V by means of the value 0.3357 for the 0.1 N calomel electrode yields a value of P_K higher by approximately 0.04. The activity coefficients of the acetate anion that have been estimated appear to be calculable, regardless of any assumption regarding the calomel electrode, by means of the Debye-Hückel equation and the appropriate constants.

The acetate solutions that have generally been used as standard buffers are those studied by Walpole and by Michaelis and his collaborators. Their measurements were, for the most part, upon solutions whose total acetate concentration was 0.2 M. These solutions are sufficiently dilute and all but the most acid are of so nearly the same ionic strength that the apparent dissociation constants calculated from the PH measurements only vary from 4.615 to 4.689. This constancy unquestionably demonstrates why it was possible to apply the mass law to the titration of univalent weak acids by strong bases without considering the activity coefficients of the anions.[6,15,17] Indeed, in the most diverse solutions that have now been studied $P_{K'}$ varies only from 4.52 to 4.79. As a first approximation there can be no doubt, therefore, that the dilution of acetate buffer solutions does not greatly affect their acidity.

The electromotive force measurements made by Walpole upon the titration of 0.2 M acetic acid by means of sodium hydroxide have been employed in Table VI in the calculation of $P_{K'}$ on the basis of both the old and the new values of the 0.1 N calomel electrode. The former have been subtracted from 4.73, and the latter from 4.77 to yield estimates of $-\log \gamma$, given in the fourth and fifth columns.

The complete Debye-Hückel equation that has been employed in the more concentrated acetate mixtures that have now been studied is not necessary for the characterization of the dilute acetate mixtures studied by Walpole and previous investigators. As has previously been pointed out,[1] the changes in the apparent dissociation constant of such solutions can be satisfactorily calculated by omitting the salting-out term in the Debye-Hückel equation and employing instead so high a value for b as 5.4×10^{-8} cm. Values of $-\log \gamma$, calculated by this approximation, are compared with those previously deduced for concentrated solutions in the

[a] Walpole's results were calculated by means of the value 0.0577 for RT/F at 18°. We have recalculated his results with the same value though the other measurements in this paper have been calculated with the value 0.05772

final columns of Table VI. Until 0.8 of the acetic acid has been transformed into the sodium salt, the two equations yield results which agree within 0.01 PH. In more alkaline solutions the approximation equation yields too high results since the salting-out phenomenon is encountered there. The agreement with the values of the activity coefficients calculated from Walpole's data by means of the old value of the 0.1 N calomel electrode, and the value 4.73 for P_K, is adequately represented by either of the interpolation equations from mole fraction 0.1 to 0.9. These successive approximations render it possible to estimate the activity coefficients and therefore the ***PH*** of these solutions with an error not greater than 0.01 in ***PH***. The general relations that have been deduced thus include and are capable of characterizing the solutions studied by Walpole.

In the more acid solutions studied by Walpole the values of $-\log \gamma$ calculated by means of the value 0.3380 for the 0.1 *N* calomel electrode diverge widely from what should be expected from the Debye equation. Indeed the values of $-\log \gamma$ calculated in Table VI show no significant drift from acetic acid to the mixture containing 0.1 mole fraction sodium acetate, although $\sqrt{\mu}$ varies from 0.046 to 0.142 and the calculated values of $-\log \gamma$ from 0.021 to 0.057. If, however, the value 0.3357 is employed for the 0.1 *N* calomel electrode and 4.77 for the negative logarithm of the dissociation constant of

acetic acid this discrepancy is largely removed. Walpole's results and those that are now reported are rendered more consistent by the use of what must now be considered, upon other grounds, a more probable value for the 0.1 N calomel electrode.

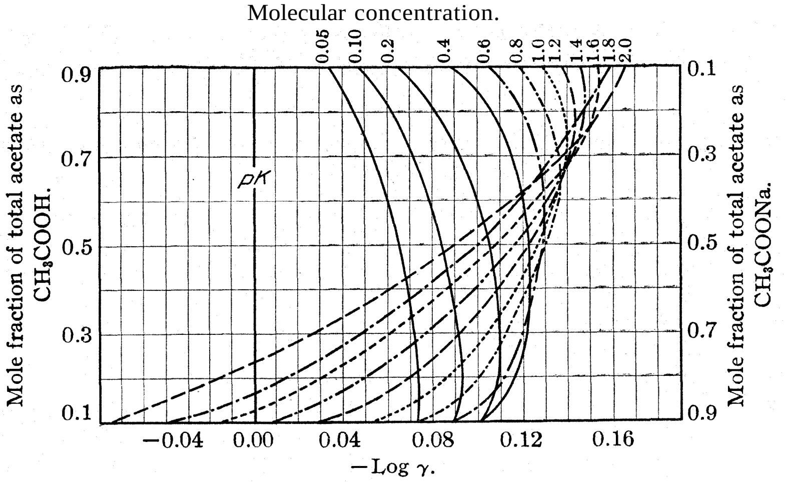

Fig. 3.

It has become a matter of convenience in a great deal of chemical and biochemical work to prepare solutions of known P_H and ionic

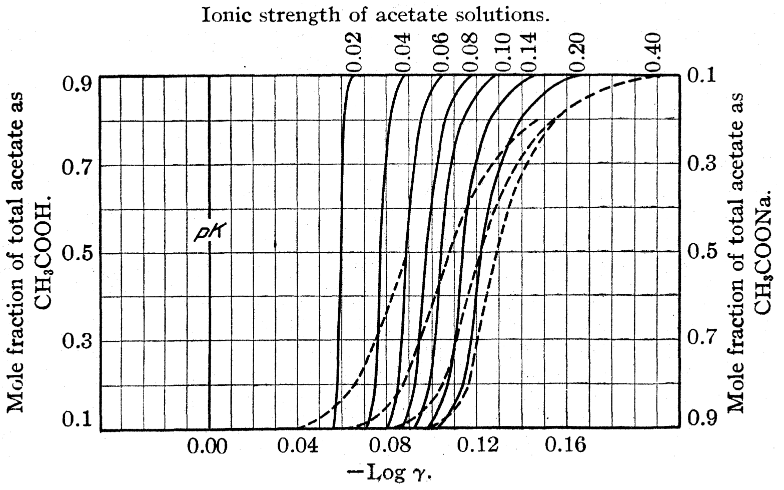

Fig. 4.

strength, and the present paper is a contribution to this end. It therefore seemed desirable to construct interpolation tables so as to facilitate the preparation of any desired solution of known P_H and ionic strength.

This has been done by calculating values of $-\log \gamma$ for different mixtures of acetic acid and sodium acetate for even values of the total acetate concentration (Table VII), and for even values of the ionic strength (Table VIII). These interpolated values are graphically represented in Figures III and IV, in which $-\log \gamma$ is given as abscissa and the mole fraction of total acetate as the sodium salt as ordinate. In the one chart the contour lines represent the molecular concentration, in the other the ionic strength of the acetate solution whose P_H is to be calculated.

Summary

1. The dissociation of acetic acid has been studied in the presence of its sodium salt. Inter-ionic forces have been considered by combining the mass law expression for the dissociation of a weak acid with the Debye-Hückel equation for the activity coefficient of an ion. This yields for acetic acid

$$P_{H^+} - \log [(CH_3COO^-)/(CH_3COOH)] = P_K - 0.5\sqrt{\mu}/(1 + \kappa b) + Ks\mu = P_{K'}$$

2. Precise measurements can be made with the hydrogen electrode upon buffer solutions of relatively high molecular concentration but such low ionic strength that specific ion effects are nearly eliminated. Under such circumstances the dissociation constant of the acid can be accurately determined by extrapolation.

3. If 0.3380 is taken as the value of the 0.1 N calomel electrode, these data yield for acetic acid $P_K = 4.73$; Ka = 1.86×10^{-5}. The dissociation constant of acetic acid derived from electromotive force measurements, and this value for the 0.1 N calomel electrode, thus agree with Kendall's estimate from conductivity measurements of 1.85×10^{-5}.

4. The electromotive force measurements that have been made determine the dissociation constant of acetic acid with an error of less than 0.6 millivolts. The value assumed for the 0.1 N calomel electrode thus becomes the controlling factor in determining the dissociation constant of acetic acid by this method.

5. If 0.3357 is taken as the value of the 0.1 N calomel electrode, these data yield $P_K = 4.77$; Ka = 1.7×10^{-5}. Certain of the results are more consistent when calculated by means of this value of the 0.1 N calomel electrode.

6. It is urged that the accumulating data render it desirable both from theoretical and practical considerations to employ a value for the 0.1 N calomel electrode other than 0.3380, and therefore to increase the entire P_H scale. It is suggested that the comparison of electromotive force measurements of the kind here presented, with conductivity measurements upon the same weak acid and its salt, corrected for inter-ionic forces, could form the basis for standardization.

7. The activity coefficients estimated for the acetate anion are inde-

pendent of any assumption regarding the 0.1 N calomel electrode. Values of the salting-out constant, Ks, and of b, have been estimated for solutions varying in molecular concentration from 0.02 to 4 M, and in the mole fraction as CH_3COONa from 0.1 to 0.9.

8. Interpolation tables and graphs are given to facilitate the preparation of buffer solutions of the same ionic strength and varying P_H, or of the same P_H and varying ionic strength.

9. These measurements upon acetate mixtures together with those already published upon phosphate mixtures render it possible to prepare buffer solutions of known ionic strength at any reaction between P_H **3.6** and 7.6.

THE DECOMPOSITION OF AZO-ISOPROPANE. A HOMOGENEOUS UNIMOLECULAR REACTION

BY HERMAN C. RAMSPERGER[1]

RECEIVED NOVEMBER 29, 1927 PUBLISHED MARCH 7, 1928

The decomposition of azomethane was found to be first order at high pressures[2] but at lower pressures a reduction in the rate constant was found.[3] This result has been accounted for on one of the theories (Theory II)[4] of unimolecular gas reactions developed by Rice and Ramsperger.[5] It was to be expected that other azo compounds would also decompose in unimolecular manner and that the higher, more complex azo compounds would maintain the same rate constant to lower pressures than does azomethane. In this research the rate of reaction of azo-isopropane has been determined at initial pressures from 4.60 cm. to 0.025 cm. and at temperatures from 250 to 290°.

Reaction Products

Azomethane reacted principally according to the equation $CH_3NNCH_3 = N_2 + C_2H_6$. A small amount of side reaction could be attributed to either of the following reactions.

$$2CH_3NNCH_3 = 2N_2 + C_2H_4 + 2CH_4$$
$$CH_3NNCH_3 = N_2 + C_2H_4 + H_2$$

The final pressure was 2.04 times the initial pressure instead of exactly 2 times, due to one or both of these side reactions. The complete decomposition of azo-isopropane at constant temperature and constant

---

[5] Rice and Ramsperger, *ibid.,* 50, 617 (1928).

volume gave an average final pressure of 2.15 times the initial pressure. The main reaction and side reactions analogous to azomethane are

$$C_3H_7NNC_3H_7 = N_2 + C_6H_{14} \quad (1)$$
$$C_3H_7NNC_3H_7 = N_2 + C_3H_6 + C_3H_8 \quad (2)$$
$$C_3H_7NNC_3H_7 = N_2 + C_6H_{12} + H_2 \quad (3)$$

One can distinguish between Side Reactions (2) and (3) by freezing out all of the hydrocarbons with liquid air. From the final pressure value given above and assuming Equation (2), 53.5% of the gas should be condensable, and assuming equation (3) 46.5% should be condensable. Two results of 53.0 and 53.8% show that the final pressure can be accounted for if 85% reacts according to Equation (1) and 15% according to Equation (2).

The Preparation of Azo-isopropane

Azo-isopropane was prepared by the method of Lochte, Noyes and Bailey.[6] Symmetrical di-isopropylhydrazine hydrochloride was prepared by the method of Lochte, Bailey and Noyes.[7] It was recrystallized twice from absolute alcohol. An alkaline solution of the compound was treated with an excess of copper acetate and the azo-isopropane distilled. It was dried with calcium chloride, redistilled and finally was very slowly distilled at 0° through soda lime and calcium chloride in a vacuum line. It was freed from air in the same manner as was azomethane.[2] The supply of gas for some of the decomposition experiments was contained in a 700-cc. bulb which was painted black to prevent possible decomposition by light. For some of the lower pressure experiments a 250-cc. bulb was used with a capillary tube between the bulb and the reaction cell. For the lowest pressure experiments the desired amount of gas was allowed to flow through the capillary into the tubing leading to the cell but was prevented from flowing into the cell by a mercury U-trap. By lowering the mercury in this trap, the gas could be let into the cell and a pressure measurement usually made within ten seconds. The decomposition during this period would be negligible at the lower temperatures but a small correction of at most several per cent. was made at high temperatures, the amount of the correction being usually determined by the final pressure obtained. One sample of azo-isopropane was used for Expts. 1 to 18, inclusive. The bulb was filled from the same liquid four times. The first filling was for Expt. 1, the second for Expts. 2 and 3, the third for Expts. 4 to 8, inclusive, and the fourth from 9 to 18, inclusive. Examination of the results shows that the constants did not vary with the fraction of the sample used. However, a new sample of liquid made from a different sample of di-isopropylhydrazine hydrochloride gave somewhat lower and irreproducible constants at the same pressure range as Expts. 13 to 18. Another

sample was made more carefully and gave the results of Expts. 19 to 2G. These experiments were made to test the effect of increased surface and were sufficiently reproducible for this purpose, but are all somewhat lower and were not used to determine the heat of activation.

Pressure Measurements

The reaction cell and thermostat were the same that were used in the experiments with azomethane.[2] The Pyrex reaction cell is ring-sealed into an outer chamber in which mercury is boiled under a known pressure. The rate of the reaction was determined by pressure measurements with a McLeod gage in much the same way as with azomethane.[3] In this case, however, the McLeod gage and mercury trap were surrounded by an air-bath at a temperature of 80° for Expts. 1 to 18 and 50" for Expts. 19 to 26. This was necessary to prevent condensation of the gas in the capillary of the McLeod gage. The calculation of the partial pressure of azo-isopropane in the reaction cell at the beginning and end of each time interval was the same as in the previous paper.[3] This calculation was made as follows.

Let P be the pressure read on the gage. Let the pressures in the reaction cell be designated as follows: P', the pressure before the reading was made; P^W, the pressure after the reading was made; P'_A, the partial pressure of azo-isopropane before each reading; P''_A, the partial pressure of azo-isopropane after each reading. Let V be the volume of the reaction chamber, V_1 the volume of the trap and V_2 the total volume of the McLeod gage. Let T_1 be the temperature of the trap and gage and T_2 the temperature of the reaction cell. Let N_1 be the number of moles of gas in the trap and N_2 the number of moles in the reaction cell. We can calculate P'' in terms of P and the temperature and volume constants as follows. $PV_1 = N_1RT_1$, $PV = N_2RT_2$, $P^WV = (N_1 + N_2)RT_2$. Blirninating N_1 and N_2 we find $P'' = P(V_1T_2/VT_1 + 1)$. P' may be calculated as follows. Let N_3 be the number of moles passing into the gage only, when the mercury is lowered for a reading. Let A P be the increase in pressure read on the gage in two successive readings. Then $\Delta PV_2 = N_3RT_1$ and $P_1'V = (N_1 + N_2 + N_3)RT_2$; $P' = P^W + \Delta PV_2T_2/VT_1$. Now the increase in pressure in the reaction cell, after one reading was made at time t and before the next reading at time t', is $P'_{t'} - P''_t$. If this increase be divided by 1.15, we get the change in azo-isopropane pressure. Therefore we have the relation $P'_{At'} = P''_{At} - (P'_{t'} - P''_t)/1.15$; also, $P''_{At} = P'_{At}\ P''_t/P'_t$. The first order rate constants were then calculated from the relation $K = \log_{10} P''_{At}/P'_{At'}$ X $2.303/(t' - t)$, where t and t' are given in seconds.

Experimental Results

A summary of all of the experiments except Expts. 10 and 15, in which some gross error was made, is given in Table I and the complete data of three typical experiments are given in Table II.

The $\log_{10}$ of the average constant at each temperature is plotted against the reciprocal of the absolute temperature in Fig. 1. The slope of the straight line multiplied by 2.303 R is the "heat of activation," Q, as given by the Arrhenius expression for the temperature coefficient of reaction rate which is $(d \ln K/d)1/T = Q/R$. The intercepts of the straight line

are for $1/T$ = 0.00177 $\log_{10}$ K = —2.06 and for $1/T$ = 0.00192 $\log_{10}$ K = —3.40. Q is found to be 40,900 cal. per mole. The rate constant $K = 5.6 \times 10^{13} \times e^{-\frac{40900}{RT}}$.

Expts. 24, 25 and 26 were made with enough small Pyrex tubing in the cell to make the surface six times as great. They are to be compared to five other experiments at that temperature and from the same sample, namely, 19, 20, 21, 22 and 23. The average rate constant of these five is 1.86×10^{-3} and of the three with tubing 1.85×10^{-3}. It is apparent that the reaction rate is not influenced by increase of wall surface and that the reaction is therefore homogeneous. It is also evident from the two experiments at the lowest, pressures, that is, Expts. 20 and 26, that within experimental error there is no change in the rate constant at this low pressure.

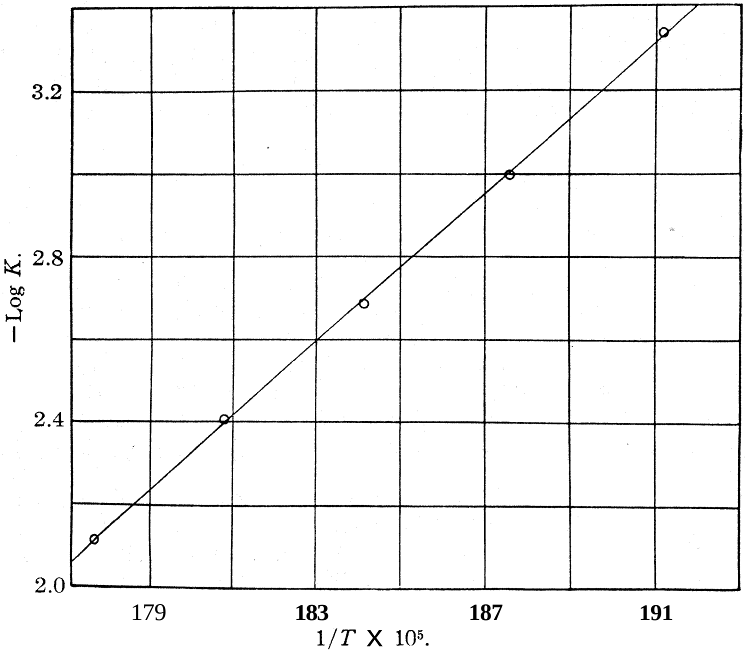

Fig. 1.

Theoretical

The results indicate that the more complex azo-isopropane maintains a constant value of the rate constant to low pressures where azomethane deviates greatly from the high pressure rate. In the case of azomethane the rate constant was appreciably below the high pressure rate constant at 4 cm. initial pressure and became steadily lower as the initial pressure was decreased until at 0.025 cm. the rate had dropped to 22% of the high pressure value when the temperature was 290° and to 10% for 330°.[3] It has been found that Theory II of Rice and Ramsperger[4] explains all of the rate constants of azomethane over the 3000-fold pressure range if 25 internal degrees of freedom are used.[5] Theory I by the same authors does not fit the data Twenty-five degrees of freedom is a reasonable value for this molecule. The specific heat (C_v) of the gas would then be expected to be about 28 cal. per mole at a temperature of 300°, since each degree of freedom is equivalent to $^1/_2R$ cal. per mole and the three translational degrees of freedom are to be added. The specific heat of azomethane is not known but acetone might be expected to have a similar specific heat. Its specific heat (C_v) at 26 to 110° is 18.1 cal. and at 129 to 233° it is 21.9 cal. per mole, so that the twenty-five degrees of freedom required to fit the data is a reasonable value. If we apply either Theory I or Theory II to azo-isopropane, we find that 45 to 50 degrees of freedom will be required if the same rate constant is to be maintained to 0.0257 cm. initial pressure. The very large specific heat which is required is not impossible for such a large molecule. hzomethane has 10 atoms and 10 chemical bonds while azo-isopropane has 22 atoms and 22 chemical bonds, so that we might expect a specific heat about twice as great for azo-isopropane. Theory I is an extension of the theory of Hinshelwood and Lindemann[8] so that their theory likewise requires this large number of degrees of freedom. The theory of Fowler and Rideal was used by Bernard Lewis[10] to explain the decomposition of azomethane before the data on azomethane at low pressures were published. This theory has not been developed so far as to show the manner in which the rate will change at low pressures. It requires fewer degrees of freedom but has the disadvantages pointed out by Tolman, Yost and Dickinson.[11]

Other possible explanations of the rate of unimolecular reactions are the chain mechanism and the radiation hypothesis. A reaction chain mechanism has been shown to be impossible in the case of most unimolecular reactions[12] and it was shown by the author[13] that in the photochemical decomposition of azomethane with a light photon of much higher energy than the heat of activation, only two molecules were decomposed per photon absorbed. The radiation theory of chemical reaction has been definitely disproved in at least one instance by Lewis and Mayer.[14]

The theories which are still capable of explaining all of the first order gas phase reactions are all collision theories which in most instances depend upon rather large internal energies. It is noteworthy that these theories differ in the assumptions concerning energy transfer between molecules at collision and energy transfer within the molecule. Three cases may be mentioned.

[8] Hinshelwood and Lindemann, *Proc. Roy. Soc. (London)*, **113A,** 230 (1926).

[9] Fowler and Rideal, *ibid.*, **113A,** 570 (1927).

[10] Lewis, *Proc. Nat. Acad. Sci.*, 13, 546 (1927).

[11] Tolman, Yost and Dickinson, *ibid.*, 13, 188 (1927); Lewis, *Science*, 66,331 (1927), has corrected an error in this paper.

[12] Lewis and Smith, THIS JOURNAL, 47, 1508 (1925); Tolman, *ibid.*, 47, 1524 (1925).

[13] Ramsperger, *ibid.*, 50, 123 (1928).

[14] Lewis and Mayer, *Proc. Nat. Acad. Sci.*, 13,623 (1927).

First, the theories of Hinshelwood and Lindemann,[8] and Theory I of Rice and Ramsperger, in which the *total energy* of the molecule should equal or exceed a minimum energy in order that the molecule be activated. Some of them react, but the chance of reaction is independent of the amount of energy in excess of this minimum. It is assumed that the rate of activation is equal to what the rate of deactivation would be under equilibrium conditions. The rate of deactivation is calculated on the assumption that *every collision of an activated molecule results in deactivation and the ordinary kinetic theory radius is used in this calculation.*

Second, the theory of Fowler and Rideal,[9] which requires that *if the sum of the energies of two colliding molecules is equal to or exceeds a certain minimum of energy, all of this energy is transferred to one molecule which is then activated.* Lewis[11] shows that in the case of N_2O_5 this leads to *a deactivation radius of* 6.07×10^{-6} *cm.*

Third, Theory II of Rice and Ramsperger,[4] in which the rate of deactivation and of activation is calculated as in Theory I. *In addition it requires that a particular degree of freedom get a minimum of energy after which reaction occurs immediately. It must be possible for energy to be redistributed among the various degrees of freedom within the molecule between collisions.*[15]

It seems likely that the conditions of energy transfer differ widely in different molecules and that as a consequence there may be reactions which will fit each theory and some reactions that are intermediate in type and cannot be fitted exactly by any of the above theories. Two evidences of variation in energy transfer may be cited.

First, the experiments of Stuart,[16] which show that the quenching of the resonance fluorescence of mercury differs very widely for different gases, being greatest for H_2 and least for He. Second, the experiments of Hinshelwood show that of a number of inert gases only hydrogen can maintain the high pressure rate constant of a "quasi" unimolecular reaction at low pressures. It may be expected that the fewer quantum states of simpler molecules will introduce special restrictions of energy transfer which would be far less likely to occur in the complex molecules which decompose in unimolecular manner.

Summary

The thermal decomposition of azo-isopropane has been studied at temperatures from 250 to 290°, at initial pressures from 4.60 cm. to

---

[15] A fourth type which is not quite comparable with the three cases listed above is the theory of J. J. Thomsen [*Phil.* Mag. [7] 3, *241* (1927)], in which energy may be transferred from the fields of neighboring molecules. The energy of a given molecule "waxes and wanes" and thus at some instant may get sufficient excess energy from the field to cause reaction.

[16] Stuart, *Z. Physik,* 32, *262 (1925).*

0.025 cm. and with increased wall surface. The reaction was found to be homogeneous and unimolecular at all pressures.

The heat of activation as given by the Arrhenius expression for the temperature coefficient of reaction rate is 40,900 cal. per mole. The rate constant is given by the expression $K = 5.6 \times 10^{13} \times e^{\frac{-40{,}900}{RT}}$.

A discussion of these results in relation to various theories of reaction rate is given. Theory II of Rice and Ramsperger would require that the rate constant of the reaction become smaller at pressures below 0.025 cm. if the azo-isopropane molecule had 45 to 50 degrees of freedom, It is thought likely that the specific heat of azo-isopropane would be large enough to permit this number of degrees of freedom.

THE REDUCTION POTENTIAL OF SELENIUM AND THE FREE ENERGY OF AQUEOUS SELENOUS ACID

BY HERMAN F. SCHOTT, ERNEST H. SWIFT AND DON M. YOST

RECEIVED DECEMBER 5, 1927 PUBLISHED MARCH 7, 1928

Introduction

The fact that selenous acid, H_2SeO_3, is reduced to elementary selenium by iodides in acid solutions is well known and is made use of in analytical methods for the determination of selenium.[1] The reduction, however, is quantitative only in moderately strong acid solutions. It was found, as a result of a number of preliminary experiments, that in more dilute acid solutions the substances taking part in the reaction are present in measurable amounts when equilibrium is attained.

In this paper are described equilibrium measurements at 25° for the following reaction, together with the thermodynamic quantities calculated from them, $Se(s) + 2I_2(s) + 3H_2O(l) = H_2SeO_3(aq) + 4H^+ + 4I^-$.

We wish to express here our appreciation of the many useful suggestions made by Professor A. A. Noyes. The investigation was aided on the financial side by funds granted to him by the Carnegie Institution of Washington.

Outline of the Investigation

The reaction mixtures were prepared by mixing standard solutions of selenous acid, potassium iodide, perchloric acid and water in 250cc. volumetric flasks and transferring the contents to glass-stoppered bottles

---

[1] Muthman and Schäfer, *Ber.*. 26, 1008 (1893); Gooch and Reynolds, *Z. anorg. Chem.*, 10,248 (1895).

containing solid iodine and black selenium[2] Some precautions were taken to exclude atmospheric oxygen, but it was never entirely eliminated, as will appear below. The bottles were rotated in a thermostat at 25° for at least one week, the preliminary experiments having shown that equilibrium is attained within this time.

Preparation of the Materials

Selenium.—Pure, sublimed selenium dioxide was dissolved in a slight excess of dilute sodium hydroxide solution, and the resulting mixture was treated with sodium thiosulfate and heated to boiling for several hours. The precipitate of elementary selenium which formed was filtered off, washed with water and alcohol, and finally dried in a current of air. This procedure yields the black selenium, which is stable at ordinary temperatures[3]

Selenous Acid.—Commercial black powdered selenium was dissolved in nitric acid, evaporated to dryness and heated until the yellow color disappeared. The residue was then dissolved in water, the solution filtered, evaporated to dryness and the residue sublimed.[4] The stock solution of selenous acid was prepared by dissolving the fine, needle-like crystals in water.

Hypochlorous Acid.—This was prepared by passing chlorine through a mixture of water and solid mercuric oxide for about one hour and distilling in a current of air the resulting solution, after removing the excess of mercuric oxide.[5] The distillate containing the hypochlorous acid was absorbed in ice-cold water.

Other Materials.—The iodine, potassium iodide and perchloric acid used were the purest trade preparations.

Analysis of the Equilibrium Mixtures

Samples of the liquid phase, free from any solid, were removed from the bottles by forcing the solutions into a 50cc. pipet equipped with an asbestos filter, compressed air being used which had been passed over solid iodine.

Two samples were required for a complete analysis of each equilibrium mixture. One of them was used for the determination of the iodine and selenous acid, the other for the determination of the acid. The standard solutions were all about 0.1 N. The two methods of analysis used were as follows.

Determination of Iodine and Selenous Acid.—A 50cc. sample, immediately after its removal from the reaction mixture, was run into a glass-stoppered flask containing 10–30 cc. of standard hydrazine sulfate solution and 13–16 millimoles of Na_2HPO_4. The excess of iodine remaining

---

[2] Beckmann and Grünthal, Z. *anorg. chem.*, *84*, **97** (1913), have shown that selenium and iodine form no compounds, mixed crystals or solid solutions.

[3] See Abegg-Auerbach-Kappel, "Handbuch der anorganischen Chemie," Band IV, 1 Abt., 1 Hälfte, S. Hirzel, Leipzig, 1927. The product used here was a fine black powder.

[5] Bray and Cuy, THIS JOURNAL, 46,858 (1924).

was then titrated with more of the standard hydrazine solution.[6] In this mixture, which is practically neutral, the iodine is reduced quantitatively to iodide by the hydrazine, while selenous acid is not appreciably affected by either the iodide or hydrazine during the time required for the analysis.

To the sample after the hydrazine titration, there was added 4–4.5 cc. of 6 N sulfuric acid and an excess (35–60 cc.) of the standard hydrazine, and the resulting mixture was kept at about 100° for three to four hours.[7] After cooling and filtering the solution it was made neutral with 4-6 cc. of 4 N sodium hydroxide, and excess (10–25 cc.) of standard hypochlorous acid added and after five minutes the liberated iodine was titrated with the standard hydrazine. In this process selenous acid is reduced to elementary selenium by the hydrazine and iodide in the hot acid solution. The hypochlorous acid added to the neutral solution quantitatively oxidizes the excess of hydrazine and also liberates iodine, the latter then being determined with the standard hydrazine.

Determination of the Strong Acid.—To determine in the equilibrium mixtures the "strong acid" present (that is, the acid in other forms than selenous acid) a 50cc. sample of the equilibrium mixture was introduced into a flask containing 10–25 cc. of standard thiosulfate and an excess (25–55 cc.) of standard hydrocarbonate solution. The rest of the iodine present was then just decolorized by titrating it with more of the standard thiosulfate. The resulting solution was titrated with standard hydrochloric acid, using a mixture of methyl red and methylene blue as indicator. A blank containing only selenous acid in the same amount that was present in the sample was treated with an excess of standard hydrocarbonate and the excess determined with standard hydrochloric acid.

It was necessary to decolorize the iodine in order to see the color changes of the indicator. The reaction between iodine and thiosulfate in hydrocarbonate solution produces not only tetrathionate, but also some sulfuric acid according to the reaction[8]

$$2S_2O_3^{=} + I_2 = S_4O_6^{=} + 2I^-, \text{ and}$$
$$S_2O_3^{=} + 4I_2 + 5H_2O = 2SO_4^{=} + 10H^+ + 8I^-$$

It was possible to make a correction for the acid formed by the second reaction, since the total amount of iodine present was known from the results of the hydrazine titration, namely, since for each equivalent of iodine that reacts in the second way there would be a decrease of $^7/_8$ mole in the thiosulfate consumed, and since this reaction produces $^{10}/_8$ equivalent of hydrogen ion for each equivalent of iodine, the acid produced is $^{10}/_7$ times the difference between the equivalents of iodine present and the mole of thiosulfate used. Making this correction and also that resulting from

the blank analyses of the selenous acid alone, the concentration of the strong acid in the equilibrium mixture was calculated. Duplicate analyses always agreed within 1%.

Density Measurements.—In order that the volume concentrations might be converted into weight concentrations, a definite volume of each equilibrium mixture (free from solid) was weighed.

Calculation of the Equilibrium Concentrations

The concentration of strong acid and the total concentration of selenous acid were calculated directly from the analytical data. To obtain the concentration of hydrogen ion due to both the free acid and the dissociated selenous acid it was necessary to employ the first ionization constant of 56-60 selenous acid. This has been determined by Blanc[9] to be 2.7×10^{-3}. The second ionization constant (5×10^{-8}, according to Blanc) is small enough to be neglected at this point. The concentration of undissociated selenous acid was obtained as follows. If a is the concentration of strong acid, b the total concentration of selenous acid and x that of the dissociated selenous acid, then $a + x$ is the concentration of H^+ in the solution, x that of $HSeO_3^-$, and $b - x$ that of the undissociated selenous acid, H_2SeO_3. Substituting these quantities in the expression $(H^+)(HSeO_3^-) = 2.7 \times 10^{-3} (H_2SeO_3)$, the value of (H_2SeO_3) is obtained.

The concentration of iodide ion was obtained by first subtracting from the total iodine concentration as determined by analysis the solubility of iodine in water and then multiplying the difference, which is the concentration of tri-iodide ion, I_3^-, by the known value of the iodide-tri-iodide ratio for a solution saturated with respect to iodine and having the same total iodide (iodide plus tri-iodide) concentration as the equilibrium mixture. The value of the ratio for each mixture was interpolated from the results given by Bray and MacKay,[10] which are in part as follows.

Total iodide $(I^-) + (I_3^-)$	0.1000	0.020	0.010
Ratio $(I^-):(I_3^-)$	0.99	1.04	1.06

Their value for the solubility of iodine in water (1.33 millimolal) was also used.

The activity of the undissociated selenous acid was taken equal to its concentration. The activity coefficient of the hydriodic acid was found by interpolating the activity coefficient corresponding to the ionic strength of each equilibrium mixture from the table given by Pearce and Fortsch,[11] some of whose results are as follows.

Molality of HI	0.050	0.100	0.200
Activity coefficient, γ	0.868	0.846	0.834

---

[9] Blanc, *J. chim. phys.*, 18, 28 (1920).

[10] Bray and MacKay, THIS JOURNAL, 32, 914 (1910).

[11] Pearce and Fortsch, *ibid.*, 45, 2852 (1923).

The ionic strengths of the equilibrium mixtures were taken as the total molality of the cations since all ions present at appreciable concentrations were univalent.

Composition of the Equilibrium Mixtures

The initial compositions of the mixtures, expressed in millimoles per liter, are given in Table I. Solid iodine and solid black selenium were always present initially and when equilibirum was attained.

TABLE I

INITIAL CONCENTRATIONS OF THE MIXTURES

Expt.	1	2	3	4	5
KI	4.15	87.88	0.00	0.00	58.88
$HClO_4$	50.15	39.67	.00	9.87	26.50
H_2SeO_3	0.00	10.00	.00	14.00	25.00

In Table II are given the concentrations of the various constituents present when equilibrium was attained. The auxiliary data necessary to calculate the equilibrium constant are also included. All concentrations are expressed in millimoles per liter. The values for the equilibrium constant, K, were calculated by the expression

$$K = (H_2SeO_3)(H^+)^4(I^-)^4\gamma^8/w^9$$

In this expression (H_2SeO_3) is the concentration of undissociated selenous acid, γ the activity coefficient of hydriodic acid and w the weight of water per liter of solution. This last factor served to change the values of the equilibrium concentrations given in the table from millimoles per liter of solution to moles per kilogram of water.[12]

TABLE II

FINAL CONCENTRATIONS OF THE EQUILIBRIUM MIXTURES AT 25°

Expt.	1	2	3	4	5

					Mean 1.46

---

[12] Owing to the fact that oxygen was always present initially and this caused the liberation of some iodine in the acid-iodide mixtures, the final acid concentrations cannot be estimated from the changes in the concentrations of selenous acid. In all cases the true equilibrium concentrations were taken to be those determined by analysis.

The Equilibrium Constant

The agreement among the values for the equilibrium constant is very satisfactory, especially when it is considered that the large exponents occurring in the mass action expression cause small errors (always less than 1%) in the analytical results to be greatly magnified in the values for the equilibrium constant.

As the best value of the equilibrium constant $K = (H_2SeO_3)(H^+)^4(I^-)^4$ the mean value 1.46×10^{-14} may be adopted. In this value the concentrations are expressed in moles per 1000 g. of water, and activities of H^+ and I^- are used in place of their concentrations.

Free Energies and Reduction Potential

From the equilibrium constant of the reaction the free energy decrease accompanying it was calculated by the well-known expression $-\Delta F^\circ = RT$ In K. The result is expressed by the equation

$$Se(s) + 2I_2(s) + 3H_2O(l) = H_2SeO_3 + 4H^+ + 4I^- - 18{,}880 \text{ cal.} \qquad (1)$$

Now, according to Lewis and Randall,[13] at 25°

$$2I_2(s) + 2H_2(g) = 4H^+ + 41 + 49{,}440 \text{ cal.} \qquad (2)$$

Subtracting we get

$$Se(s) + 3H_2O(l) = H_2SeO_3 + 2H_2(g) - 68{,}320 \text{ cal.} \qquad (3)$$

This is, however, the reaction that occurs in the cell $Se(s), H_2SeO_3 || H^+, H_2(g)$. Its free energy decrease therefore corresponds to the reduction potential of $Se(s) + 3H_2O(l) = H_2SeO_3 + 4H^+ + 4E-$. Multiplying the free energy value by 4.185 (to change it to joules) and dividing by 4 X 96,500 coulombs, we get for this reduction potential the value –0.740 volt.

We may find also the free energy of 1 M H_2SeO_3 (un-ionized) by adding to Equation (3) the following[13]

$$3H_2(g) + 3/2\ O_2(g) = 3H_2O(l) + 169{,}680 \text{ cal.}$$

Hence

$$Se(s) + 3/2\ O_2(g) + H_2(g) = H_2SeO_3 + 101{,}360 \text{ cal.} \qquad (4)$$

That is, ΔF°_{298} for H_2SeO_3 (un-ionized) is –101,360 cal.

From the first and second ionization constants of selenous acid, which are 2.7×10^{-3} and 5×10^{-8} according to Blanc,[9] we get

$$H_2SeO_3 = H^+ + HSeO_3^- - 3{,}510 \text{ cal.}$$
$$H_2SeO_3 = 2H^+ + SeO_3^= - 13{,}470 \text{ cal.}$$

Adding separately each of these equations to Equation (4) gives

$$Se(s) + 3/2\ O_2(g) + H_2(g) = H^+ + HSeO_3^- + 97{,}850 \text{ cal.}$$
$$Se(s) + 3/2\ O_2(g) + H_2(g) = 2H^+ + SeO_3^= + 87{,}890 \text{ cal.}$$

That is, ΔF°_{298} is –97,850 cal. for $HSeO_3^-$, and –87,890 cal. for $SeO_3^=$

[13] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 607.

Summary

In this paper are described determinations of the equilibrium of the reaction $Se(black) + 2I_2(s) + 3H_2O = H_2SeO_3 + 4H^+ + 4I^-$ at 25". The equilibrium constant $K = (H_2SeO_3)(H^+)^4(I^-)^4$ was found to be 1.46×10^{-14}, expressing the concentrations in moles per 1000 *g.* of water and using the activities of H^+ and I^- in place of their concentrations.

From this constant and existing thermodynamic data the reduction potential of $Se(black) + 3H_2O(l) = H_2SeO_3 + 4H^+ + 4E^-$ was calculated to be −0.740 volt, showing that the reducing power of selenium (at 1 *M* H^+ concentration) is about the same as that of Fe^{++}, Fe^{+++} (−0.747), and intermediate between those of I^-, $I_2(s)$ (−0.536) and Ag, Ag^+ (−0.800).

The corresponding free energies (AF^{o}) at 25° of H_2SeO_3, $HSeO_3^-$, and $SeO_3^=$ at 1 *M* were found to be −101,360, −97,850 and −87,890 calories, respectively.

TRANSITION CELLS OF THE SIXTH CLASS

BY ERNST COHEN AND ERNEST J. JOSS

RECEIVED DECEMBER 5, 1927 PUBLISHED MARCH 7, 1928

A transition cell may be defined broadly as any reversible galvanic element containing a solid substance which may exist in a number of modifications.

While five different classes of such elements have been treated theoretically as well as experimentally by Ernst Cohen and his co-workers,[1] transition cells of the sixth class have not, as yet, been experimentally realized. Such an element is to contain a depolarizer which possesses a transition point. This paper deals with a transition cell of this type, the depolarizer being silver iodide.

Experimental

It was thought best to use a cell with a standard electrode, rather than two electrodes of silver iodide, one stable and the other metastable. With the former type of cell the temperature-e.m.f. curve may be run over a wide range of temperatures, the transition temperature being indicated by a sudden change in the temperature coefficient of e.m.f. The choice of an electrolyte afforded some difficulty. The use of aqueous solutions was impractical, since the temperatures to be used were as high as 175". The solvent finally chosen was fused calcium chloride hexahydrate. The boiling point of this substance was within the temperature range over

---

[1] Ernst Cohen, "Physico-chemical Metamorphosis and Some Problems in Piezochemistry," McGraw-Hill Book Co., New York, 1926, p. 151 ff.

which the experiments were to be run, so a closed apparatus was necessary. The melting point was 29.9" which was well below all experimental temperatures.

The cells were made up according to the following scheme:

$$\mathrm{Ag_{(s)} - AgI_{(s)}} \left| \begin{array}{c} \mathrm{CaCl_2.6H_2O_{(l)}} \\ \mathrm{AgI_{(c_1)}} \\ \mathrm{PbI_{2(c_2)}} \end{array} \right| \mathrm{Pb_{(s)}}$$

The design of the cell is shown in Fig. 1.

A, the positive pole, is a silver iodide electrode made after the method of Jones and Hartmann.[2] B is the standard electrode, made of pure lead. The two electrodes were joined to the H-cell by means of inner seals. A side tube was provided for introducing the electrolyte. The whole cell, made of heavy Pyrex glass, was quite small and compact.

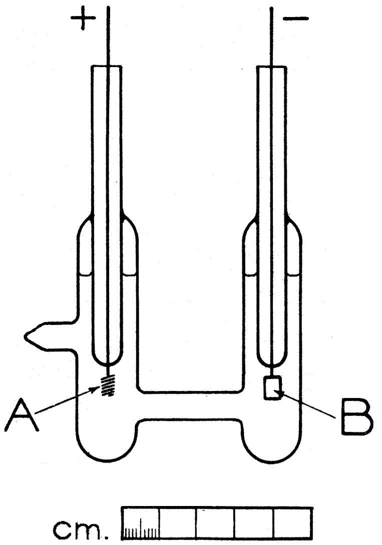

Fig. 1.

The electrolyte was molten calcium chloride hexahydrate saturated with both silver iodide and lead iodide at 40°. This solution was introduced into the cell through the side tube, which was subsequently sealed off at a constriction provided for this purpose. It is probable that little if any silver iodide was in solution around the lead electrode, due to interaction with the metallic lead.

The cell was completely immersed in a bath of Crisco, a hydrogenated cooking fat. This bath was placed in an air thermostat for temperature control. The air thermostat was built from an ordinary 50 X 45 X 30 cm. gas oven. This was covered on all sides with a 2 cm. layer of sheet asbestos. Air circulation was maintained within the oven by means of a 20cm. four bladed fan. The shaft driving this fan ran in a bearing fastened in a board across the top of the oven. The fan was driven at about 1400 r.p.m. by a small electric motor. A separate motor ran a stirrer for the oil-bath. The stirrer passed through the top of the oven and was connected directly to the motor. The speed of this motor was approximately 200 revolutions per minute.

The temperature of the oven was controlled by means of a spiralled, mercury in glass, thermal regulator. The capillary tube at the top of the regulator was passed through the top of the oven and protruded eight centimeters up into the outside air. This precluded the dangers of mercury at high temperatures. The temperature was measured by means of a thermometer immersed in the oil-bath, so that the mercury bulb was very close to the transition element. The thermometers used were very long so that the scale was visible above the oven. These thermometers were graduated with 0.1° divisions and calibrated against standard thermometers calibrated by the Physikalisch-Technische Reichsanstalt at Charlottenburg-Berlin.

The oven was fitted with a main electrical heating unit, consisting of a number of coils of nichrome wire wound on Pyrex glass tubes, and an auxiliary heating unit made by winding a single coil of nichrome wire on asbestos board. One end of the main

---

[2] Jones and Hartmann, THIS JOURNAL, 37, 755 (1915).

heating coil was attached to one end of the auxiliary coil, from which junction a common lead was run to the source of current (110 A.C.). The other end of the main heating coil was connected, in series with a variable rheostat (Ward-Leonard, Type RLR 156) and an ammeter (Weston, 10-ampere range, with 1.5 multiplier), to the source of current. The other end of the auxiliary coil was connected, in series with a fixed resistance and a relay, to the source of current. Both circuits were equipped with knife switches so that they might be operated independently. The relay in the auxiliary circuit was governed by the mercury thermo-regulator and a four-volt source of current. The resistances were fixed so as to cause the main heating coil alone to raise the temperature to about five degrees below the desired temperature; while the auxiliary coil, if the circuit were kept closed, would further raise the temperature to about five degrees above that desired.

The leads from the transition cell were carried out through small glass tubes passing through the side of the oven.

The vibration of the stirrers increased the sensitivity of the thermo-regulator markedly.

With the thermostat described above, temperatures constant to within 0.1° for long periods of time were obtainable.

The electromotive force of the cell was measured by means of the Poggendorff compensation method. A Leeds and Northrup student potentiometer was used in connection with a quite sensitive galvanometer. The standard of electromotive force was a Weston cell.

The method used was to start measurements at the lower end of the temperature range and so regulate the current through the main heating element as to have the temperature rise approximately one degree centigrade every five minutes. The electromotive force was measured for every half degree rise in temperature, the potentiometer being balanced against the standard cell every few readings. When the temperature had risen as high as was desired, the current was so adjusted as to allow cooling at the same rate as the heating. Measurements were again made in the same manner as with rising temperature.

The cell came to equilibrium very rapidly under the conditions of the experiment. This was proved by the fact that the electromotive forces measured with rising temperature checked those with falling temperature within experimental error.

Each of the two runs shown in the following tables was completed without interruption. A different cell was used in each run.

Table I gives the data for the first cell, which we shall designate as Cell I. In this table t refers to the actual temperature in centigrade degrees and E to the electromotive force of the cell in volts. The points indicated by asterisks are those arbitrarily chosen for calculations.

These data when plotted give the graph shown in Fig. 2. The ordinates are electromotive forces in volts and the abscissas are temperatures in centigrade degrees.

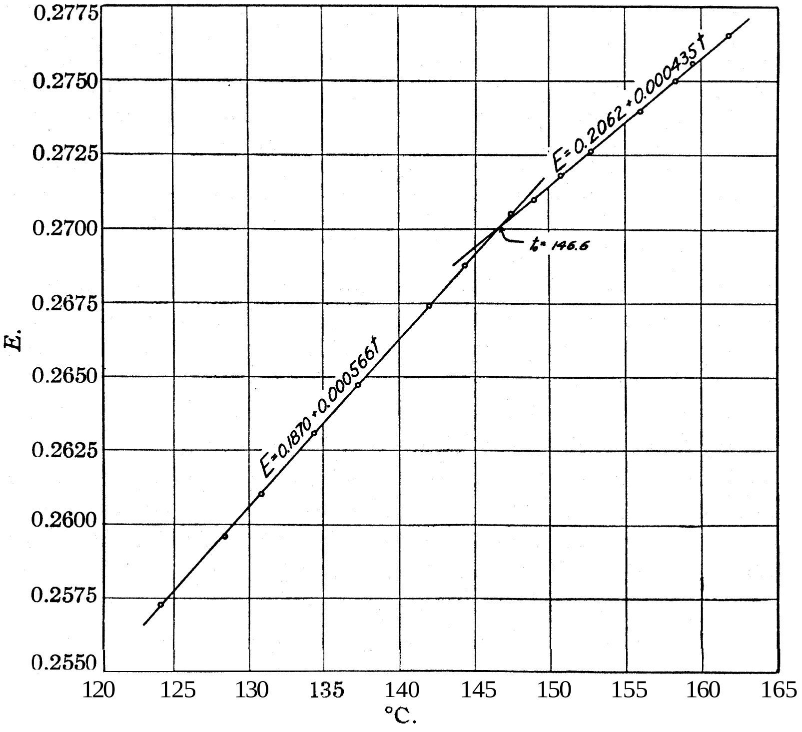

Fig. 2.

It may be seen that the temperature coefficient of e.m.f. is constant over two distinct ranges of temperature. The intersection of the two curves gives the transition temperature. To find this temperature accurately it was necessary to calculate the equation for each of the two curves, using the method of least squares, and to solve for the point of intersection. The equation of the lower curve, which we shall call the a-curve, since the a-form of silver iodide is stable in this range, is

$$E_1 = 0.1870 + 0.000566\,t \qquad (1)$$

The equation of the upper curve, which we shall designate as the P-curve, is

$$E_2 = 0.2062 + 0.000435\,t \qquad (2)$$

The intersection of these curves is found to be at 146.6°. This is the transition temperature of a- and β-silver iodide.

Table II shows the results obtained with Cell II. The asterisks indicate the points upon which calculations were based.

The equation of the a-curve, the one along which a-silver iodide is stable, is

$$E_1 = 0.1775 + 0.0005026\,t \qquad (3)$$

The equation of the β-curve is

$$E_2 = 0.1968 + 0.000371\,t \qquad (4)$$

The intersection of the two curves is found to be at 146.7°.

The transition temperature of silver iodide will be treated by us in a special paper. Suffice it to say here that the values mentioned in the earlier literature vary from 138 to 147°. This is a consequence of the strong retardations which may occur in this transition. In our case evidently there occurred no retardation, the electrolyte acting as an accelerator.

It is of interest to know the heat of transition of silver iodide. If we write this reaction, assumed to be occurring in the cell below the transition temperature, we have:

$$\mathrm{AgI}_\alpha + {}^1/_2\mathrm{Pb} = \mathrm{Ag} + {}^1/_2\mathrm{PbI_2} \qquad (5)$$

The reaction assumed to be occurring above the transition temperature is:

$${}^1/_2\mathrm{PbI_2} + \mathrm{Ag} = \mathrm{AgI}_\beta + {}^1/_2\mathrm{Pb} \qquad (6)$$

The summation of the two reactions gives

$$\mathrm{AgI}_\alpha = \mathrm{AgI}_\beta \qquad (7)$$

At the transition temperature, the two forms of silver iodide are in equilibrium, hence the free energy increases of the two reactions are equal, that is

$$\Delta F_5 = \Delta F_6 \qquad (8)$$

where the subnumerals refer to the marginal numbers of the equations. The increase in heat content for the transition as expressed by Equation (7) is given by the following equation

$$\Delta H_7 = TNf\left[\frac{dE_5}{dT} + \frac{dE_6}{dT}\right], \qquad (9)$$

where T is the temperature of transition on the absolute scale, N is the valence change, f is Faraday's constant and E is the electromotive force of the cell.

Let us now apply this equation to the data of Cell I. From (1) and (2)

$$\Delta H_7 = 419.6 \times 1 \times 96{,}500\ (0.000566 - 0.000435)$$
$$\Delta H_7 = 5304 \text{ joules} = 1267 \text{ cal. per gram mole}$$

The same calculation for Cell II (from 3 and 4) gives

$$\Delta H_7 = 419.7 \times 1 \times 96{,}500\ (0.0005026 - 0.000371)$$
$$\Delta H_7 = 5330 \text{ joules} = 1274 \text{ cal. per gram mole}$$

The average of these two values is 1270 cal., that is

$$\mathrm{AgI}_\alpha = \mathrm{AgI}_\beta - 1270 \text{ cal.}$$

Previous determinations by various investigators vary from 1355 to 1597 cal.

Summary

1. A type of transition cell pointed out by one of us many years ago, but hitherto never experimentally realized, has been constructed.

2. This transition cell of the sixth class, in which the depolarizer undergoes a polymorphic transformation, is experimentally realized in the case of silver iodide.

3. Temperature-e.m.f. measurements show the transition temperature to be 146.6°.

4. The heat absorbed during transition of one mole of AgI_α to one mole of AgI_β, calculated from the slopes of the e.m.f.-temperature curves, is 1270 cal.

DECOMPOSITION OF DIACETONE ALCOHOL BY WEAKER BASES

BY GÖSTA ÅKERLÖF

RECEIVED DECEMBER 6, 1927 PUBLISHED MARCH 7, 1928

Introduction

In two preceding papers[1] have been given the results of the measurements of the decomposition velocity of diacetone alcohol in alkali hydroxide-alkali salt solutions. In this paper will be presented some measurements with weaker bases, such as ammonia, used as catalysts. Similar measurements for hydrogen ion catalysis with weaker acids present have been carried out by Harned and Hawkins[1c] for the hydrolysis of ethyl formate and ethyl acetate.

Previously it has been shown by Arrhenius,[2] Brönsted,[3] Harned[1] and others,[4] that when a neutral salt, which in itself is a strong electrolyte, is added to a solution of a weak electrolyte, the dissociation of this increases. For water as a weak electrolyte this increase has been measured by Harned[4a,b] Harned and Swindells,[5] Åkerlöf,[6] and Harned and James[7] for a number of different salt solutions. At low salt concentrations the curves obtained for the decomposition velocity of diacetone alcohol in neutral salt solutions of the weaker bases seemed to be of the same type as the curves obtained for the concentration of water as an electrolyte in the same salt solutions. In other words, the concentration of the weak bases as electrolytes was changed by the addition of neutral salts in the same manner as for water.

The method proposed by **Harned** and **Hawkins** was used to calculate the concentration of the catalyzing ion and then from the mass action law the activity coefficients of the weak bases as electrolytes in their salt solutions. In agreement with the fundamental assumption made it was found that the curves for the activity coefficients came quite near each other. In many cases they seemed to superimpose well within the experimental uncertainties.

Experimental Methods and Materials

The weaker bases except ammonia were all obtained from the Eastman Kodak Company. Ammonia was redistilled from an alkali hydroxide solution with the usual precautions, but all the others were used without any attempt at further purification, due to well-known difficulties with small scale operations. An inquiry relative to the purity of the aliphatic amines used seemed to indicate that their purity was quite high. To judge from the methods used for their synthesis the amount of free ammonia present must in all cases have been very small. The bases were tested for the presence of carbonic acid and non-volatile matter. In a few cases slight traces were indicated but were considered as negligible. The method of measurement was the same as described in the preceding papers. In Table I are given some measurements for 0.2 N ammonia in sodium sulfate solutions.

It might be thought that the high volatility of the pure amines would cause errors due to their evaporation during the filling of the reaction tubes. The partial vapor pressure in 0.2 *N* pure aqueous solutions of some of the amines used may be estimated from a few measurements of Doyer[8] at 60° and those of Perman[9] for aqueous ammonia at varying temperature. Assuming proportionality in all cases, the following values

---

[8] Doyer, *Z. physik. Chem.*, *6*, 486 (1890).

[9] Perman, *J. Chem. Soc.*, *[2]*83, 1168 (1903); Landolt-Börnstein, "Tabellen," 4th ed., p. 429.

in mm. of mercury are obtained: ammonia, 2.2; methylamine, 1.6; dimethylamine, 1.6; ethylamine, 2.6; diethylamine, 9.2. At least the order of magnitude is certain. When a salt is added the vapor pressure of water decreases and therefore that of the amine may increase. Let us assume that the partial vapor pressure of the latter has increased to 30 mm. of mercury and that the back pressure from the vacuum pump is 5 mm. The time used for filling the reaction tubes was about five minutes. The diameter of the capillary was around 0.08 cm. and the total length 90 cm. Applying the formula of Poiseuille for the flow of liquids through a capillary, we find that even under ideal conditions an almost negligible quantity (approximately 3%) of the amine as gas may pass through the capillary. However, the partial vapor pressure of the amine must rapidly decrease during the filling of the reaction tube because the evaporating surface decreases at about the same rate as the gas bubbles disappear. Therefore the amount of the amine actually lost must be far less than calculated for continuous equilibrium conditions. Differentiation of the mass action formula shows that a small error for the stoichiometrical concentration gives a very much smaller error for the hydroxyl ion concentration. In agreement herewith the velocity measurements appeared always to be very consistent.

[a] All K-values are to be multiplied by 10^{-5}.

[b] Due to unknown impurities in the ethylamine used, the velocity values found are probably all a little too small.

[c] The amine is partially salted out at higher salt concentrations.

[d] Tetramethylammonium hydroxide was used in 0.05 N solution.

[e] The values for K/K_0 with 0.1 N NaOH in NaCl solutions.

Experimental Results

The velocity measurements were carried out at 25° with the amines in sodium chloride or sulfate solutions. A summary of the results obtained is given in Table II. A few measurements with 0.05 N tetramethyl-

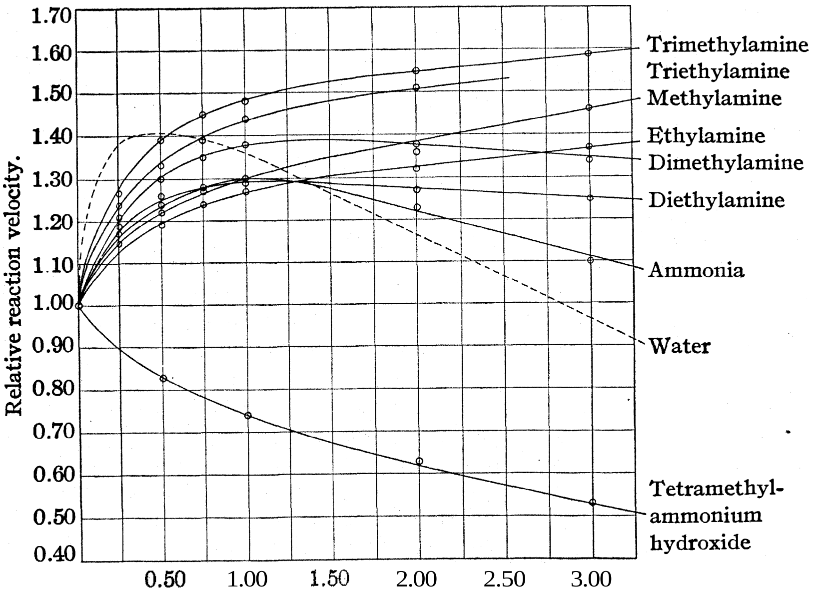

Fig. 1.—Curves for the relative decomposition velocity of diacetone alcohol in sodium chloride solutions of 0.2 N weaker bases.

ammonium hydroxide are also included. All salt concentrations m_s are given in weight normality. The amount of diacetone alcohol used was about 2% of the total volume of the solution. The velocity constants are given with the minute as unit of time. A graphical representation of the results is given in Fig. 1 for the amines in sodium chloride, in Fig. 2 in sodium sulfate solutions.

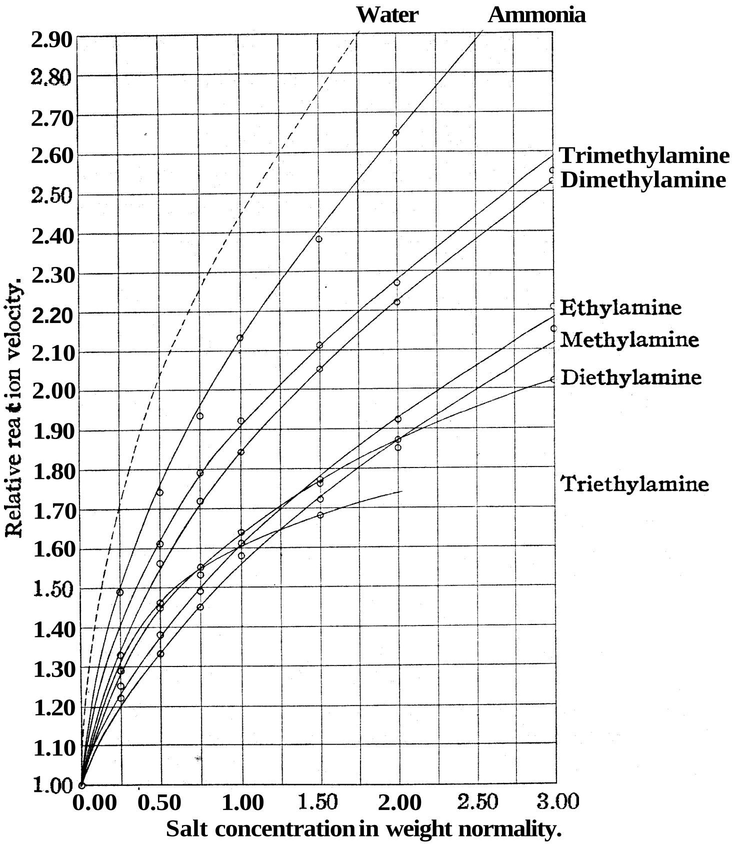

Fig. 2.—Curves for the relative decomposition velocity of diacetone alcohol in sodium sulfate solutions of 0.2 N weaker bases.

The Equilibrium Constants of the Weak Bases Used

The equilibrium constant k for the weak bases may be given by the following equation

$$k_{\mathrm{BOH}} = \frac{a_{\mathrm{B}} \cdot a_{\mathrm{OH}}}{a_{\mathrm{BOH}}} = \frac{\gamma_{\mathrm{B}} \cdot c_{\mathrm{B}} \cdot \gamma_{\mathrm{OH}} \cdot c_{\mathrm{OH}}}{\varphi_{\mathrm{BOH}} \cdot c_{\mathrm{BOH}}} = \frac{\gamma_{\mathrm{BOH}} \cdot c_{\mathrm{OH}}}{c_{\mathrm{BOH}}} \qquad (1)$$

where a denotes activities, γ ionic activity coefficients, c concentration and φ_{BOH} the activity coefficient of the non-electrolyte. The changes of φ_{BOH} may be relatively small. Therefore it may be assumed always to equal unity in pure aqueous solutions of the weaker **bases.** The equilibrium constants given in the literature are calculated without any reference to the changes of γ_{BOH}. At constant stoichiometrical concentration c we then obtain for the ratios between the equilibrium constants

$$k_1/k_2/k_3 \ldots = c_{OH(1)}/c_{OH(2)}/c_{OH(3)} \ldots \qquad (2)$$

The correction of c for c_{OH} is neglected because it is always comparatively small and the values of the equilibrium constants themselves seem many times to have appreciable errors. With the assumption of proportionality between hydroxyl ion concentration and reaction velocity, the following equation is obtained

$$\sqrt{k_1}/\sqrt{k_2}/\sqrt{k_3} \ldots = K_1/K_2/K_3 \ldots \qquad (3)$$

For ammonia the equilibrium constant seems to be known more accurately than for any other weak base. All the measurements were carried out by a conductivity method.[10] The curve for the changes of this constant for ammonia with varying temperature is shown in Fig. **3.** Interpolation gives for 25° the value $k = 1.85 \times 10^{-5}$. Table III summarizes

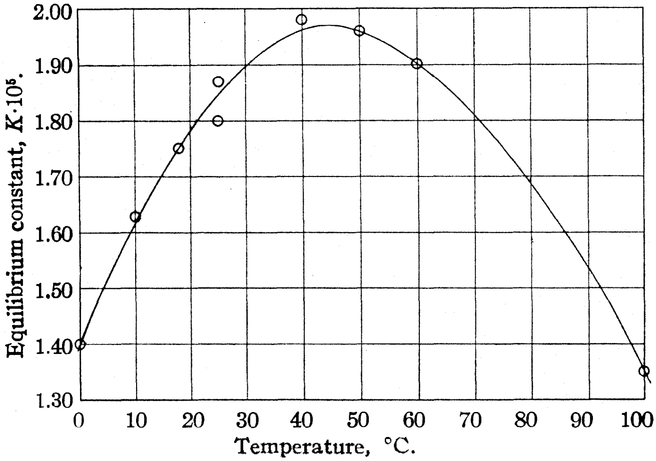

Fig. 3.—The equilibrium constant for ammonia at varying temperatures as obtained from conductivity measurements.

[10] (a) Lunden, J. *chim. phys.*, *5*, *574* (1907); (b) Kanolt, THIS JOURNAL, 29, 1408 (1907); (c) Noyes, Kato and Sosman, *Z. physik. Chem.*, *73*, 1 (1910); (d) Landolt-Börnstein, "Tabellen," 4th ed., p. 1133.

the calculations of the value of this constant as obtained from the velocity measurements. The equilibrium constants used were measured by Bredig.[11] The mean value is only a little lower than the one obtained from the conductivity measurements but the agreement may seem to be rather accidental. It might seem to be possible to test the value for the equilibrium constant in another way. Assume that the proportionality factor between reaction velocity and mean activity of the base used is the same for a weak one as for a strong one. For 0.1 *N* sodium hydroxide the activity coefficient is $\gamma_{NaOH} = 0.767$ and the reaction velocity for the decomposition of diacetone alcohol $K = 0.0208$. With the equilibrium constant for ammonia $k = 1.85 \times 10^{-5}$ and the activity of the hydroxyl ion corrected according to the limiting function of Debye and Hiickel, the calculation gives for 0.2 N solution $K = 49.2 \times 10^{-5}$ as against the measured value $K = 33.2 \times 10^{-5}$. At least the order of magnitude is the same for both values. The discrepancy seemed, however, to be too large and therefore the velocity value for the pure ammonia solution was remeasured with the greatest care. A slightly higher value was found but the difference from the previous value was so small that a correction was considered unnecessary.

For 0.2 N ammonia we may therefore accept the equilibrium constant $k = 1.85 \times 10^{-5}$ and the reaction velocity for the decomposition of diacetone alcohol $K = 33.2 \times 10^{-5}$. A summary of the calculations of the equilibrium constants for the other weak bases used from the velocity measurements with these reference values is given in Table IV.

TABLE IV

EQUILIBRIUM CONSTANTS CALCULATED FROM THE VELOCITY MEASUREMENTS

Base	$K \times 10^5$	k	k (Bredig)
Methylamine	458	3.5×10^{-3}	5.0×10^{-4}
Dimethylamine	240	9.7×10^{-4}	7.4×10^{-4}
Trimethylamine	62.5	6.5×10^{-5}	7.4×10^{-5}
Ethylamine	283	1.3×10^{-3}	5.6×10^{-4}
Diethylamine	278	1.3×10^{-3}	1.3×10^{-3}
Triethylamine	194	6.3×10^{-4}	6.4×10^{-4}
Ammonia	33.2[a]	1.85×10^{-5}[a]	.....

[a] Reference values.

The k-values obtained for the weakest bases agree fairly well with the values measured by Bredig. The strongest bases are gases at ordinary temperatures and far more difficult to purify than the weaker ones. Since any impurity like free ammonia apparently must lower their k-values, it is believed, that our values are nearer the true ones than those previously given in the literature. The reaction velocity and k-value for ethplamine are probably a little too small.

---

Activity Coefficients of the Weak Bases as Electrolytes in Sodium Chloride and Sulfate Solutions

In the preceding paper it was shown that the decomposition velocity for diacetone alcohol in pure aqueous solutions of the alkali hydroxides was proportional to their mean activity

$$K_{\mathrm{MeOH}} = R\cdot\gamma_{\mathrm{MeOH}}\cdot m_{\mathrm{MeOH}} \qquad (4)$$

where R is the proportionality factor. For alkali hydroxide-salt solutions this simple formula cannot be applied but the reaction velocity may be expressed by the following equation

$$K_{\mathrm{MeOH(S)}} = R\cdot m_{\mathrm{MeOH}}\cdot F(x) \qquad (5)$$

where (S) indicates an hydroxide-salt solution and $F(x)$ is a complex unknown factor. If we exchange the alkali hydroxide in the salt solutions against a weak base, the activity coefficient of the hydroxyl ion must remain nearly constant, because it is given by the nature of the environment, which remains nearly constant. The reaction velocity in the weak base-salt solution may then be expressed by a formula similar to (5)

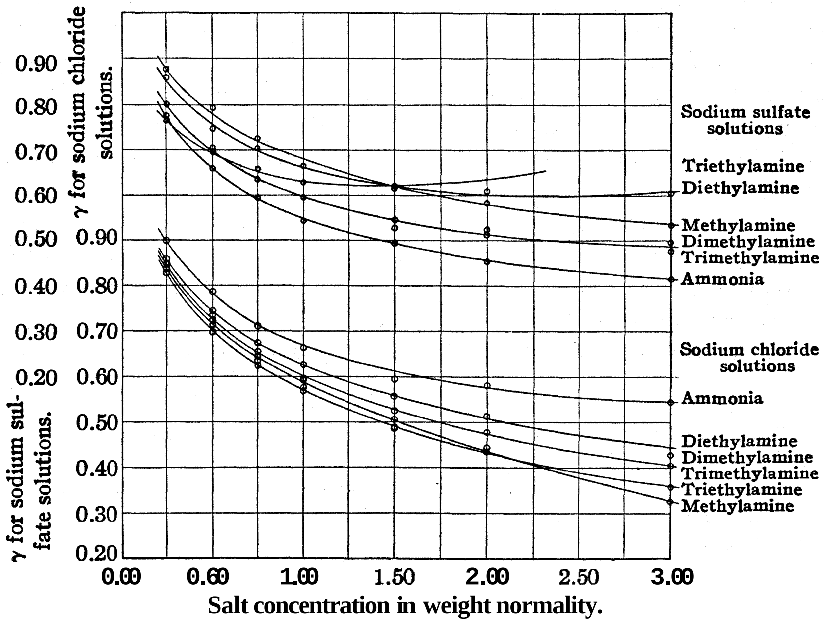

Fig. 4.—Curves for the mean activity coefficients of the weaker bases as electrolytes in sodium chloride and sulfate solutions calculated with the velocity measurements for 0.1 N sodium hydroxide in the same salt solutions.

$$K_{\mathrm{BOH(S)}} = R\cdot m_{\mathrm{OH(BOH)}}\cdot F(x) \qquad (6)$$

Assuming complete dissociation of the hydroxide, division of (5) by (6) gives

$$K_{\mathrm{MeOH(S)}}/K_{\mathrm{BOH(S)}} = m_{\mathrm{MeOH}}/m_{\mathrm{OH(BOH)}} \qquad (7)$$

From this equation we may calculate $m_{\mathrm{OH(BOH)}}$, when all other variables are known. Harned and Hawkins used the same method for calculating the hydrogen-ion concentration in weak acid-salt solutions. With the knowledge of $m_{OH(BOH)}$ we may use the mass action law to obtain γ_{BOH} on the assumption that φ_{BOH} (Equation 1) always equals unity. The magnitude of φ_{BOH} is connected with the salting out effect on the amines. At present we will disregard the influence of this factor in order to see whether we get reasonable values for the ionic activity coefficients of the weak bases without it. In Table V is given a summary of the calculated mean activity coefficients of the weak bases as electrolytes in sodium chloride and sulfate solutions. The curves for the mean activity coefficients are given in Fig. 4.

A–F, values for sodium chloride; G M, values for sodium sulfate solutions. All reaction velocities to be multiplied by 10^{-4}.

Discussion of the Results

The values for the mean activity coefficients of the weaker bases as electrolytes given in Table V were calculated without any consideration that the values used for the reaction velocities did not refer to solutions of the same total ionic strength. Due to the approximate nature of the calculations, a correction seems to be unnecessary. It would cause only very slight changes for the values of the mean activity coefficients.

The curves for these activity coefficients in Fig. 4 show that for a given salt concentration values of the same magnitude were obtained for all the weaker bases used. Several curves superimpose on other curves in their entire length. For some of them where this is not the case, it seems as if they were superimposable within the experimental errors. In accordance with the assumption made for the method of calculation used this could be expected.

So far the results seem to be reasonable. However, at small salt concentrations the slope of the curves seems to be too small. In other words, the values obtained may be too high. There are no other electrolytes found with such high values for the mean activity coefficients in dilute solutions. On the contrary, we would expect these amines to have quite small activity coefficients in salt solutions on account of the complexity of their ions. In this case the addition of a small amount of salt would have caused a very sharp decrease for their activity coefficients.

It seems to be out of the question that the measurements themselves could have such large errors that they gave a distorted view of the calculations. The assumption of incomplete dissociation of the alkali hydroxide in hydroxide-salt solutions would give an increase for the activity coefficients and therefore cannot be considered. The salting out effect on the amines increases the value of φ_{BOH} and as we calculated the hydroxyl ion concentration without any assumption regarding this effect we have instead multiplied the activity coefficients with the increase in this factor. The increase must, however, be small even in fairly concentrated salt solutions, as might be concluded from the measurements with triethylamine.

It was shown above that the value for the decomposition velocity of diacetone alcohol in 0.2 N ammonia as calculated from the equilibrium constant and the velocity in 0.1 N sodium hydroxide ($49.2 \cdot 10^{-5}$) did not agree with the measured one ($33.2 \cdot 10^{-5}$). The proportionality factor for reaction velocity and ionic activity must have changed from the strong base to the weak one in the ratio of these two values. Harned and Hawkins found that the same proportionality factor could be used for strong as well as weak acids. A reason for the difference might be found in the difference in behavior the reactions used show towards the properties of the catalysts. Harned and Pfanstiel[12] have found it probable that the velocity of hydrolysis of ethyl acetate in solutions of hydrochloric acid is proportional to the activity of the hydrogen ion. For the decom-

---

[12] Harned and Pfanstiel, THIS JOURNAL, 44, 2193 (1922).

position of diacetone alcohol in alkali hydroxide solutions the measurements seem to indicate that the velocity is proportional to the mean activity of the hydroxides. If then the cation present is exchanged against another one of different character it might be reasonable to expect a change also for the proportionality factor.

In Table VI are given some values for the mean activity coefficients of the weaker bases corrected for the change in proportionality factor from the alkali hydroxides to the weaker bases. There is also given a comparison between these corrected values and those derived from the measurements with tetramethylammonium hydroxide in sodium chloride solutions. The cation of this base must stand far nearer the cations of the weak bases than the alkali metal ions. In Fig. 5 are shown curves for the corrected and uncorrected values, a curve for values calculated from the measurements with tetramethylammonium hydroxide and the corresponding curves obtained by Harned and Hawkins for weak acids in sodium chloride solutions. Tetramethylammonium hydroxide apparently belongs to the strong bases, but it is considerably weaker than any one of the alkali hydroxides. The mean activity coefficients of the weaker bases obtained with the measurements for solutions of this hydroxide come between the corrected and uncorrected values given in Table VI.

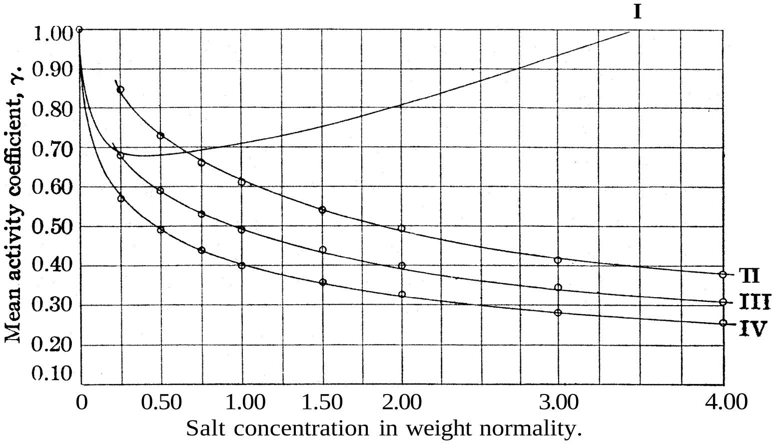

Fig. 5.—Comparison of the curves for the mean activity coefficients of the weaker bases as electrolytes in sodium chloride and sulfate solutions calculated:

I, with velocity measurements for 0.1 N sodium hydroxide (Curve II for dimethyl- or diethylamine in NaCl solutions); II, with velocity measurements for 0.05 N tetramethylammonium hydroxide (Curve III for dimethyl- and diethylamine in NaCl solutions); III, with corrected proportionality factor (Curve IV for dimethyl- and diethylamine in NaCl solutions); Curve I gives the activity coefficient for mono- or dichloro-acetic acid in sodium chloride solutions.

The corrected values seem to be of a reasonable magnitude with regard to the measurements of Harned and Hawkins. As was expected, quite small mean activity coefficients are obtained at high salt concentrations.

[a] Uncorrected values given in Table V for sodium chloride solutions.

[b] Values calculated from measurements with 0.05 N tetramethylammonium hydroxide in sodium chloride solutions.

[c] Values calculated with corrected proportionality factor.

[d] The letters D, E, F, etc., refer to those for the amines in Table V. All values are corrected.

Summary

Measurements of the decomposition velocity of diacetone alcohol in sodium chloride and sulfate solutions of weak bases are presented. A discussion of the equilibrium constants of the weak bases used has been given. The values found for the strongest bases are probably more accurate than values previously given in the literature.

The activity coefficients of the weaker bases as electrolytes in salt solutions cannot be calculated on the assumption that a weak base has the same proportionality factor between activity of the base and reaction velocity as a strong one. A correction factor for the activity coefficients was calculated from the reaction velocities measured in pure aqueous solutions of 0.1 N sodium hydroxide and one of the amines.

The corrected mean activity coefficients seem to have reasonable values. The decrease in dilute salt solutions is of the same magnitude as found by Harned and Hawkins for weak acids in the same salt solutions.

THE SYNTHESIS OF AMMONIA BY ALPHA RAYS[1]

BY S. C. LIND AND D. C. BARDWELL

RECEIVED DECEMBER 14, 1927 PUBLISHED MARCH 7, 1928

Owing to the general interest in active nitrogen and the various efforts to learn something of its nature by means of its reactivity towards hydrogen and other reagents, the writers decided to reëxamine the behavior of a mixture of hydrogen and nitrogen under a radiation of radon.

Earlier experiments were made in a stagnant system by Cameron and Ramsay[2] who mixed hydrogen, nitrogen and radon in a volume of 2.3 cc. and judged the rate of ammonia synthesis from the resulting fall in pressure. From their results Lind[3] calculated the ion yield to be $+M_{NH_3}/-N_{(N_2 + H_2)} = 0.12$ or about 8 ion pairs for 1 molecule of ammonia formed. Later, Usher[4] repeated the experiments of Cameron and Ramsay with refinements. While he confirmed a reduction in pressure, he could find no very certain amounts of ammonia (less than 1% of that required by the pressure change) and attributed the decrease of pressure largely to a loss of hydrogen in the glass wall, which he in fact recovered by heating, together with a much smaller amount of nitrogen.

In the present experiments the writers employ the method of streaming a mixture of hydrogen and nitrogen past a thin a-ray bulb containing radon and later titrate the ammonia after direct absorption in water or in acid. Thus we avoid the disadvantages of a system of small volume.

Fortunately the stoichiometric mixture of highly purified hydrogen and nitrogen used in the Fixed Nitrogen Research Laboratory for catalytic synthesis of ammonia was at our disposal. This was passed at the rate of 50 cc. per minute under ordinary pressure through a glass sphere (625 cc. volume; 10.6 cm. diameter) at the center of which was mounted a thin a-ray bulb (1.4 mm. diameter; about 5μ wall thickness). The system is essentially that originally used for ozone synthesis[5] with some modification, as in later work,[6] of the method of sealing in the a-ray bulb and of retaining the radon in it.

Preliminary qualitative tests with Nessler reagent proved the production of ammonia. The quantitative titrating agents were 0.01 N sulfuric acid and 0.01 N potassium hydroxide solutions. Sodium alizarin sulfate

[c] 1.0 cc. of 0.01 N H_2SO_4 in about 75 cc. of water.

Discussion of Results

From Table I (next to last column) one sees that there is a distinct synthesis of ammonia in an a-ray flow system. The yield is much higher than found by Usher[4] and nearly twice as high as reported by Cameron and Ramsay[2]—both in small volumes of stagnant gas.

As long as water was used as absorbent liquid, the yield recovered per ion pair fell steadily as the concentration of ammonia in the total gas diminished due to the decay of the radon. This suggests incomplete absorption. Although absorption in water is the standard method used in testing ammonia catalysts, our concentration is of much lower order, one part in 10^5 to 10^6 as against parts per 10^2 in catalysis. In the last two experiments some initial acid (not a final excess) was added to the water to obtain better retention of ammonia. The recovered yield was

---

[7] Cohn, "Indicators and Test Papers," John Wiley and Sons, Inc., New York, 1902, p. 25.

increased and remained constant at 0.205, which is, however, considerably below the initial 0.276 in water, so that some doubt must remain as to the exact yield, which could only be settled by more elaborate experiments on absorption at low concentration. The yield appears to lie between 0.2 and 0.3 molecule of ammonia per ion pair.

From such a low ionic efficiency, relative to most other reactions that have been examined under α-radiation,[8] it is difficult to judge whether the ions of either reactant are directly responsible for the reaction. In a mixture of $3H_2:1N_2$ about 60% of the ionization produced by a-rays falls on the N_2 and 40% on the H_2, so that referring all the reaction to either set of ions would not raise the yield to a value that would aid in the decision. Furthermore, such reasoning loses its point if we accept the recent evidence of Harnwell[9] and others that positive ions capture electrons from molecules of lower ionization potential so that all of the ionization is transferred to one species of molecules. If it means that both components must be ionized (or activated) it is an interesting analogy with the recent result of Lewis[10] that it is necessary to activate bath nitrogen (Strutt's method) and hydrogen (Wood's method) in order to synthesize ammonia by such means.

Equilibrium under a-Radiation

Although it is not the purpose of this paper to discuss the equilibrium of the reaction, one or two simple deductions will be made.

According to Wourtzel[11] the rate of decomposition of NH_3 by a-rays at 25° is approximately $-M_{NH_3}/N_{NH_3} = 1$, which has been confirmed by Lind and Bardwell.[12] If we take the rate of synthesis as $+M_{NH_3}/N_{(H_2 + N_2)} = 0.2$, then equilibrium as predicted on simplest assumptions from the two opposed rates should be realized in a mixture when 5 times as much ionization falls on the $3H_2 + N_2$ molecules as on the NH_3 molecules. Taking the specific molecular ionization of $3H_2 + N_2$ as 0.41 and that of NH_3 as 0.82, equilibrium should occur when 83.3% of initial NH_3 has been decomposed, that is, in 10 volumes of stoichiometric mixture to 1 volume of ammonia, or a mixture containing 9.09% of NH_3 by volume. No direct test of this prediction has been made. Since Usher found very little synthesis in a static system he concluded that equilibrium would lie almost entirely on the decomposition side. This conclusion is not supported by the present results on synthesis and is also at variance with the indications of the kinetic course of the decomposition. Application

[12] Unpublished results.

of the general equation to Usher's data for decomposition[13] to 57%, showed that the velocity constant falls steadily as the reaction proceeds, as if due to reverse reaction. The results of Lind and Bardwell,[12] in which decomposition proceeded to 73%, show a similar and more far-reaching drop with some indication that the yield in synthesis is somewhat nearer 0.3 than 0.2 molecule per ion pair.

Summary

Using a method of flowing a stoichiometric mixture of hydrogen and nitrogen past an a-ray bulb, the rate of ammonia synthesis found by chemical titration is estimated to be 0.2 to 0.3 molecule per ion pair produced in the mixture, a yield higher than previously found in stagnant gases for this reaction but low in comparison with the majority of gas reactions under a-radiation. This yield in synthesis is in general accord with the observed fall of velocity constant in decomposition of ammonia by a-rays as a function of the ammonia concentration.

AN INVESTIGATION OF THE REACTION OF SODIUM ALIZARIN MONO-SULFONATE WITH ALUMINUM UNDER DIFFERENT EXPERIMENTAL CONDITIONS WITH REFERENCE TO ITS USE IN COLORIMETRY

BY JOHN H. YOE AND WILLIAM L. HILL

RECEIVED DECEMBER 19, 1927 PUBLISHED MARCH 7, 1928

A method for the colorimetric determination of aluminum has been reported by Atack,[1] in which the principal reagent is sodium alizarin mono-sulfonate (Alizarin Red S). With aluminum in alkaline solution this dye forms a red lake which is fairly stable in the presence of a considerable excess of acetic acid.

> "The original solution (5 to 20 cc.) is acidified with hydrochloric acid or sulfuric acid, as acetic acid would form the highly dissociated aluminum acetate, and this has been found to give a somewhat more intense coloration than the inorganic salts; nitric acid in considerable amounts leads to the partial destruction of the coloration. Ten cc. of glycerine and 5 cc. of a 1% solution of Alizarin S are added, the solution made up to about 40 cc. with water, and then rendered slightly ammoniacal. After standing for five minutes it is acidified with dilute acetic acid, the Alizarin S acting as an indicator, acetic acid being added until no further change in the coloration occurs. The liquid is then made up to 50 cc. and compared with a standard."

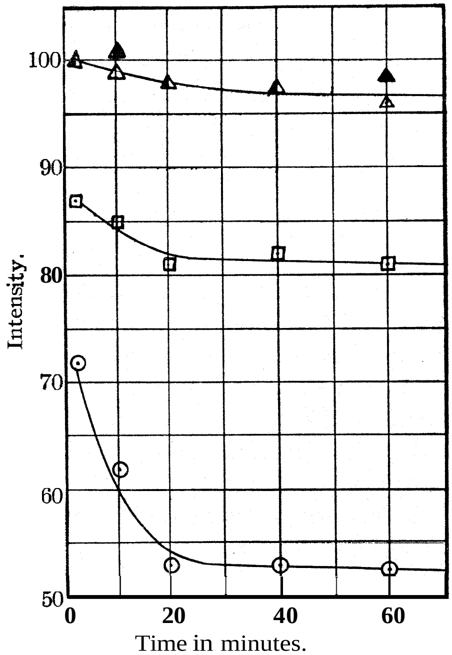
Commenting upon this procedure, Atack states in substance:

[13] Lind, *J. Phys. Chem.*, 16, 595 (1912).

[1] Atack, *J. Soc. Chem. Ind.*, 34, 936 (1915).

(1) A very large excess of the dye is necessary, but its original color in acid solution is not of sufficient intensity to interfere with the test. **(2)** Moderate amounts of calcium, magnesium or zinc salts do not affect the final color intensity. **(3)** Large quantities of iron and chromium salts and of phosphates interfere with the test. (4) The interference of iron and chromium may be prevented by the addition of a citrate before adding the ammonium hydroxide. Thus, the coloration given by **0.015** mg. of aluminum was not affected by **10** mg. of iron. (5) Since acetic acid slowly attacks the aluminum lake, especially in the presence of phosphates, the comparisons must be made within a short time. (6) The temperature at which the lake is formed does not affect the final color, if the acetic acid is added in the cold. (7) The glycerine prevents precipitation, which takes place readily in the presence of salts of other metals. (8) One part of aluminum in 10 million parts of water can be detected readily; suitable amounts for estimation are **0.005** to **0.05** mg.

The purpose of this paper is to present some specific data on the effects of varying the several factors in the procedure outlined above. The apparatus, method of attack and general procedure have been described in detail in a recent paper by Yoe and Hill.[2]



△, **0.1%** of dye, **5** cc. of HAc in light; ▲, 0.1% of dye, 5 cc. of HAc in dark; ⊡, 0.1% of dye, 5 cc. of HAc and 10 cc. of glycerine; O, 0.1% of dye, **10** cc. of HAc.

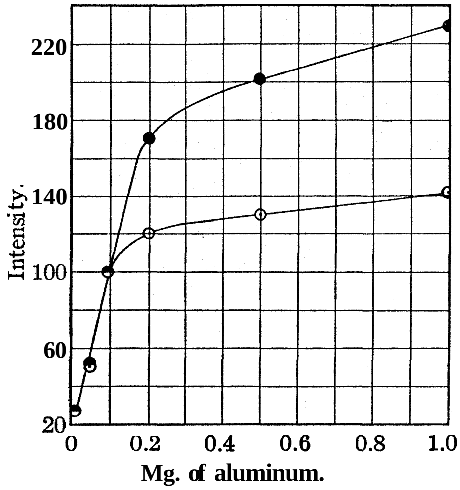
Experimental

Reagents.—1. Acetic acid, 5 N. 2. Hydrochloric acid, 1 N. **3.** Ammonium hydroxide, 5 *N*. 4. Ammonium citrate, 5 N. 5. Standard aluminum chloride solution; 1 cc. contained 0.10 mg. of aluminum. For method of preparation and standardization, see ref. 2. 6. Solutions of the several salts used in the study of the effects of ions were prepared so that 1 cc. would contain 10 mg. of the desired ion if the salt were completely dissociated. In the study of positive ions chlorides were used, in all other cases sodium salts were employed. 7. Alizarin S solution. Four grams of Alizarin Red S, Schultz No. 780, National Aniline and Chemical Co., Inc., New York, N. Y., was dissolved in distilled water, filtered from the small amount of sediment and made up to a volume of 400 cc. This 1% stock solution was diluted to 0.1% and 0.2% solutions as needed. 8. Glycerine, clear white.

---

[2] Yoe and Hill, THIS JOURNAL, 49,2395 (1927).

Procedure.—The order of addition of the reagents, as well as the quantities added, unless otherwise stated, was as follows. To 1 mg. of aluminum in a Nessler tube were added 5 cc. of 1 N hydrochloric acid, 5 cc. of a 0.1% Alizarin S solution and sufficient distilled water to bring the volume to 30 cc. Then 2 cc. of 5 N ammonium hydroxide was added with gentle stirring and after standing for five minutes 5 cc. of 5 N acetic acid was put in and mixed thoroughly. The solution was then diluted to 50 cc., thoroughly mixed and allowed to stand in the Nessler tube until time for comparison. In all instances where glycerine was employed it was added just after the hydrochloric acid and thoroughly mixed. Unless otherwise stated the temperature was 23°.



⊙, with 0.1% of dye; ■, with 0.2% of dye.

Fig. 2.—Concentration of aluminum.

"Aging."—In Fig. 1 the curves show the decrease in color intensity with time after the addition of acetic acid, both in the light and in the dark, for different concentrations of acetic acid, and also when 10 cc. of glycerine was added. The intensities for each curve have been expressed in terms of the two minute intensity with 5 cc. of acetic acid and "aged" in the light.

Effects of Varying the Quantities of the Reagents.—The quantities of the reagents were varied one at a time, all other conditions being kept constant. All solutions were "aged" for twenty-five minutes and the intensities are expressed in terms of the intensity of the standard at the end of twenty-five minutes. The results are shown in Figs. 2, 3 and 4, and in Table I.

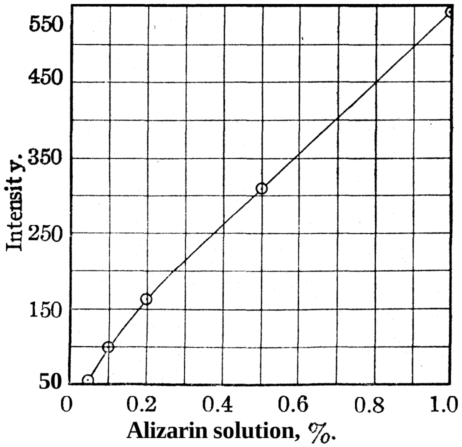


Fig. 3.—Concentration of Alizarin S.

Conditions During Lake Formation.—In Figs. 5 and 6 are shown the curves for the three variable conditions: namely, (1) time allowed for the lake to form, (2) the temperature at which the lake was formed and (3)

TABLE I

VARIATIONS IN QUANTITIES OF REAGENTS

Hydrochloric Acid		Ammonium Hydroxide	
Reagent, cc.	Intensity, %	Reagent, cc.	Intensity, %
0	102	1.5	52
3	105	2.0	100
5	100	2.5	130
8	97		

the volume of the solution when the lake was formed. For (1) and (2) measurements were made at the end of twenty-five minutes and sixty minutes, respectively.

Presence **of Other** Ions.—The intensity of solutions containing 15 mg. of chloride, nitrite, normal phosphate, orthophosphate, sulfate or sulfite ions or of silica was sensibly the same as that of the standard containing only aluminum. Furthermore, the presence of these ions caused no appreciable decrease in intensity at the end of one hour. The final color was not altered by 45 mg. of the orthophosphate ion.

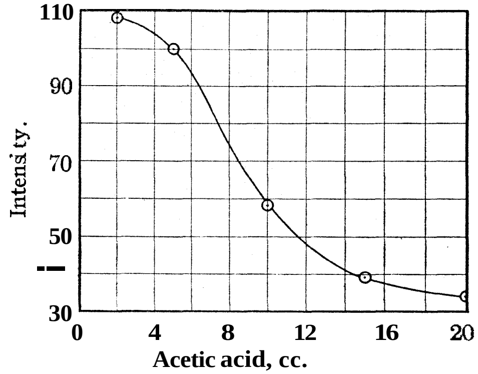

Fig. 4.—Concentration of acetic acid.

With 5 mg. of nitrate ion the intensity was 99% and had not decreased at the end of one hour; with 15 mg. the intensity was 96%, and with 30 mg. it was 39%. With 1 mg. of sulfur as sulfide the intensity was 100%, decreasing to 97% at the end of one hour. Greater quantities yielded a turbid solution.

Solutions containing 15 mg. of chromium as chromate, zinc, calcium or magnesium gave readings in accord with that of the standard. The effects of some other positive ions are summarized in Table II.

An effort was made to prevent iron from interfering by adding ammonium citrate before the ammonium hydroxide, Some representative results are given n the following table:

Citrate, cc.	0	10	10	20	20	20
Aluminum, mg.	0.1	0.0	0.1	0.1	0.1	0.1
Iron, mg.	.0	.0	.0	.0	1.0	5.0
Intensity, %	100	128	131	320	314	388

Limits of the Test for **Colorimetric** Work.—The data for the sensitivity curve, Fig. 7, are shown in Table III.

At the left is shown the volume of solution in liters containing one gram atomic weight of aluminum; *B* is mg. of aluminum in 50 cc. of the

1,355,000	.001	.0005	2000	.0015	.733	.500	291	11.12
3,387,500	.0004	barely distinguishable from "blank"						
With 10 cc. of glycerine								
13,550	.100	.015	66.7	.115	.870	.150	29.0	2.04
With 0.2% dye								
13,550	.100	.016	62.5	.116	.862	.137	29.0	1.98

solution; A is the increment in mg. of aluminum necessary to produce a perceptible difference in the color intensity of 50 cc. of solution, $S = 1/\Delta$ = Sensitivity, and $B' = B + A$. For convenience in plotting, one-fourth of the square root of the volume and the sensitivity has been taken.

With 1 mg. of aluminum present the lake had coagulated and settled 1 cm. at the end of two hours; with 5 mg. the precipitate began to settle before the addition of acetic acid, was dispersed by the acid and after two hours had settled, leaving a clear yellow liquid.

For purposes of comparison the aluminum content of three solutions, as determined by Alizarin S and by "Aluminon" are given in Table IV.

TABLE IV

DETERMINATION OF ALUMINUM IN SOLUTION

Solution	Al, mg.	Found by Alizarin S.	by "Aluminon"[a]
I	0.10	0.08	0.12
II	.05	.05	.06
III	.03	.03	.03

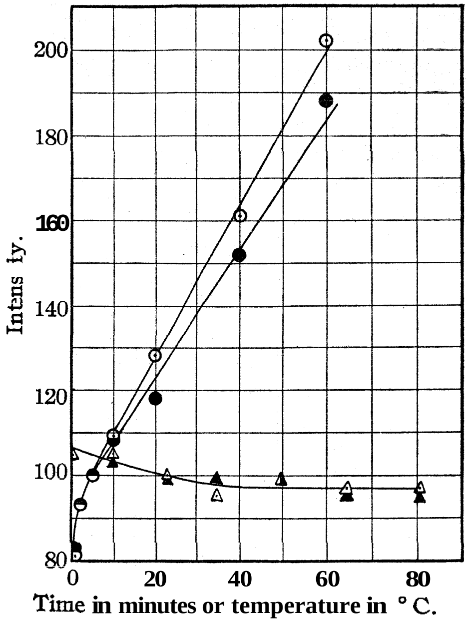
[a] The ammonium salt of aurintricarboxylic acid.

Discussion

The "aging" effects in the light and in the dark are about the same. An increase in the excess of acetic acid increases the rate of change in the color intensity during the first twenty minutes; however, after this time interval all the curves run almost parallel with the axis of time.

Fig. 2 indicates that the intensity is directly proportional to the aluminum content, provided that an excess of the dye is present. With 0.1% of dye the curve breaks at 0.1 mg. of aluminum, and with 0.2% of dye it breaks in the vicinity of 0.2 mg. of aluminum, supporting Atack's opinion[1] that a definite chemical compound is formed, or more likely simply representing an equilibrium condition.

Atack[1] recommends a 1% alizarin solution, but we have found, working with a liquid volume of 50 cc. in Nessler tubes, or in a colorimeter of the Kennicott-Campbell-Hurley type, that it is impossible to use the dye solution stronger than 0.4% on account of the very intense color. Weaker solutions yielded more satisfactory results. Fig. 3 shows a curve for the variation in the amount of dye used.



⊙, Time, "aged" 25 min.; ●, time, "aged" 1 hour; △ temperature, "aged" 25 min.; ▲, temperature, "aged" 1 hour.

Fig. 5.—Conditions at lake formation.

Variations of less than 1 cc. in the quantity of hydrochloric acid produce a negligible effect on the results; however, the final intensity is very sensitive to slight variations in the concentration of ammonium hydroxide. This is probably due to the alteration of the excess acetic acid by the ammonia.

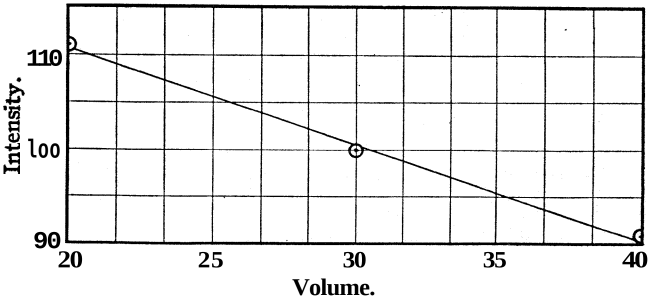


Fig. 6.—Volume at lake formation.

The temperature effect (Fig. 5) is very slight, while the intensity increases quite rapidly with the time given for the lake to form. The volume effect (Fig. 6) is practically the same as in the case of "Aluminon."

One mg. of sulfur as sulfide, or 10 mg. of nitrate ion may be present in 50 cc. of solution without the results being impaired. One mg. of stannic tin is allowable, but the copper content must be considerably less than 1 mg. Ten mg. of nickel is permissible; iron, chromium, cobalt and manganese must be removed if present in more than a trace. The use of a citrate to prevent the interference by iron and chromium was not successful. Fifteen mg. of the other positive ions studied do not interfere with the determination.

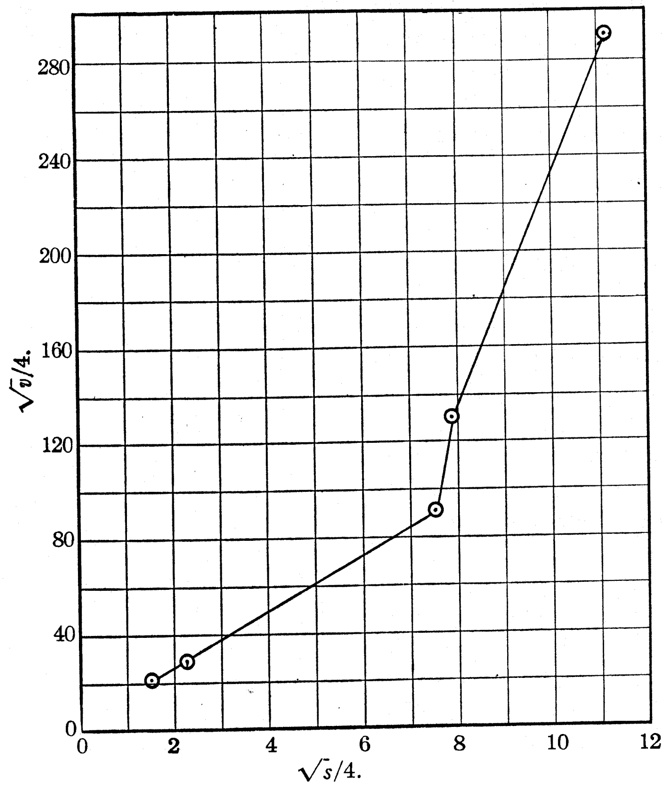

Fig. 7.—Sensitivity curve.

With 50cc. Nessler tubes the range of the test is from 0.0004 to 0.2 mg. of aluminum; with a volume of 50 cc. in the Kennicott-Campbell-Hurley colorimeter 0.005 to 5 mg. may be determined. The lake produced by 10 mg. of aluminum remains in suspension long enough for a reading to be taken, but a smaller volume of the liquid must be employed. By using glycerine greater quantities may be kept in suspension.

According to the method of Horn,[3] the sensitivity curve (Fig. 7) shows that with 50cc. Nessler tubes the best range of the test is from 0.01 to 0.2 mg. When glycerine or a stronger solution of the dye is employed, the sensitiveness is decreased considerably.

Summary

An experimental study of the reaction of Alizarin Red S with aluminum under various conditions has been made, and quantitative measurements on the following effects were obtained: (1) time, (2) temperature, (3) volume, (4) concentration of reagents and (5) the presence of other ions. The range and the sensitiveness of the test have been determined.

APPLICATIONS OF CERIC SULFATE IN VOLUMETRIC ANALYSIS. I. THE PREPARATION AND STABILITY OF SOLUTIONS OF CERIC SULFATE (CONTAINING FREE SULFURIC ACID). II. POTENTIOMETRIC STUDY OF THE REACTIONS BETWEEN CERIC AND FERROUS OR OXALATE ION. APPLICATION TO THE STANDARDIZATION OF CERIC SOLUTIONS. III. THE POTENTIOMETRIC DETERMINATION OF CERIUM

BY N. HOWELL FURMAN

RECEIVED DECEMBER 19, 1927 PUBLISHED MARCH 7, 1928

Introduction

Barbieri[1] was apparently the first to propose the use of a solution of ceric sulfate in volumetric analysis. He described the direct titration of nitrite with ceric sulfate. The end-point was determined by the disappearance of the yellow color of the ceric ion (the nitrite solution was placed in the buret). He found that more exact results could be obtained by adding an excess of ceric solution. The excess of ceric salt was then determined iodimetrically. It was stated that the nitrite solution could contain nitrates and that the ceric solution need not be free from other rare earths. No experimental data were given.

A solution of ceric sulfate, or of other ceric salts, was found by Sommer and Pincas[2] "to be ideal" for the quantitative oxidation of hydrazoic acid. The volume of nitrogen that was evolved was measured.

Quite recently Martin[3] has used ceric sulfate for the oxidation of hydra-

zine. The reagent was added in excess and an iodimetric back-titration was then made.

Hitherto, perhaps because of a lack of satisfactory indicators, no systematic study of the direct and indirect applications of ceric sulfate in volumetric analysis has been made. The author has found that ceric sulfate solutions that contain a moderate excess of sulfuric acid are quite stable, and he therefore proposes to make such a study. The familiar methods of potentiometric titration will be shown to be especially suitable for the determination of end-points.

Mention should be made of the fact that Van Name and Fenwick[4] have published graphs that represent the potentiometric titration of ceric with titanous sulfate. No data were given with regard to the accuracy, since these titrations were incidental to a study of bimetallic electrode systems. Recently Someya[5] has made a study of the potentiometric adaptation of Metzger's[6] bismuthate procedure for the oxidation of cerium. Someya titrates the quadrivalent cerium directly with standardized ferrous sulfate.

Preliminary qualitative orientation studies make it appear probable that a number of the titrations with ceric solution as reagent will be of both theoretical and practical interest.
