AN AUTOMATIC SAMPLE COLLECTING VACUUM PUMP[1]

BY E. R. WEAVER[2] AND MARTIN SHEPHERD[3]

RECEIVED SEPTEMBER 15, 1927 PUBLISHED JULY 6, 1928

The mercury displacement pump, which has been generally abandoned for the simple production of high vacua in favor of the more rapid mercury vapor pump, is still of value when the gas pumped is to be collected for further investigation. Numerous automatically operated pumps of the Töpler type have been described.[4] Without discussing the ingenious features of these systems, several of which are quite useful, it may be said that the majority of them have one or more of the following faults: (1) vortices are formed in the bulbs during operation; (2) the mercury entering the pump head when low pressure prevails is not sufficiently controlled to prevent fracture occurring here or in the delivery tube; (3) in order to avoid the first two faults, the operation of the pump is made excessively slow; (4) the mercury delivered from the pump has to be returned to the system by hand; (5) the mercury in the pump is not well enough protected from contamination and oxidation to permit the continued operation of the pump for long periods of time.

A pump designed by the senior author a number of years ago eliminates these and other faults and at least three pumps have been built and put into successful operation. The third pump to be constructed has been in continuous use for the past three years, and its behavior has proved entirely satisfactory. The design and operation of this unit will be described.

The pump control is by mercury displacement in a separate cycle made to operate on the suction of a water aspirator or any of the mechanical

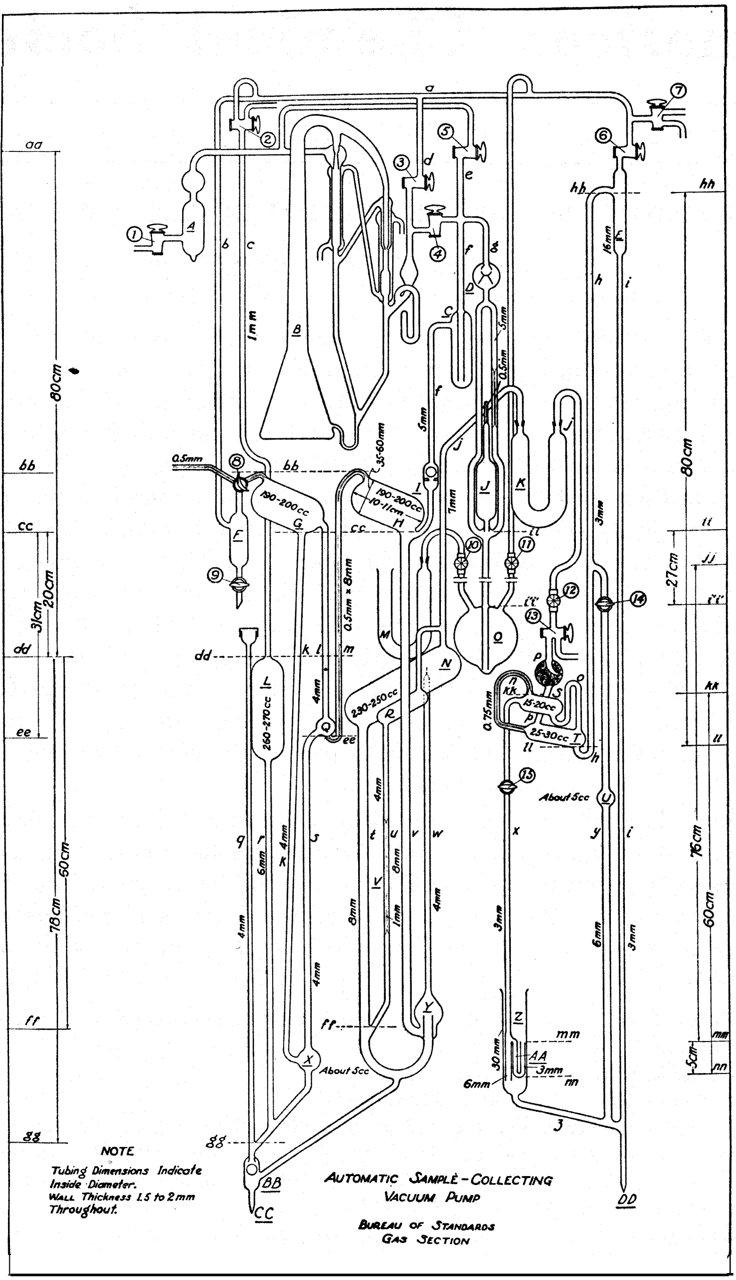

Fig. 1.—Automatic sample collecting vacuum pump.

vacuum pumps commonly on the market. Its operation may be described with reference to the line drawing (Pig. 1) while details of construction and assembly are apparent from a study of the photograph (Fig. 2).

The line drawing has been simplified by the following lettering system. (1) Figures designate stopcocks. (2) Capital letters designate bulbs or other major parts of the unit. (3) Lower case letters designate tubing connecting these parts. (4) Double lower case letters indicate dimensional levels.

The space to be evacuated is connected to the pump through cock 1 and drying tube *A* containing phosphorus pentoxide sublimed onto class wool. The gas may enter the displacement pump directly through *5* or through a mercury vapor pump of the Stimson[5] type located at B. The Stimson pump is capable of producing a high vacuum in an apparatus of reasonable size within a few minutes, with the comparatively high backing pressure of 2 to 4 cm. The displacement pump itself has, then, a very small volume to evacuate, that is, merely the connections f and g and bulb *C* and trap D.

In case gases condensable at liquid air temperatures are to be pumped, condensation bulb *C* is used. After condensation, stopcocks 4 and *5* are closed and the condensate is vaporized into H and *G* or by-passed to a storage system. This step often saves much of the time ordinarily spent in pumping.

10 and *11,* permits the operator to know the pressure at the inlet *f* of the displacement pump proper.

The controlling or actuating system, which connects to the pump reservoir N through tube *j,* comprises the system represented at the right side of the drawing by the bulbs *S* and *T*, reservoir *Z,* interconnecting tubes *h, i,* x, *y* and *z,* and cocks 12, 13, 14 and 15.

The operation of this control unit may be described by tracing one complete cycle. Its purpose is to apply alternate vacuum and atmospheric pressure to the pump reservoir N.

The reservoir *Z* is filled with mercury until the volume above level *nn* is nearly equal to the volume of bulb *S* and tube x, and barometric columns in tubes y and *i,* including bulb U. The mercury must fill *Z* somewhat above level *mm;* the correct amount may be determined by trial. A vacuum from an aspirator or other vacuum pump is maintained through one inlet of stopcock 7. This reduced pressure is communicated through tube *h,* bulb *T*, tube *n* and bulb *S* to tube x, drawing the mercury from *Z* into *x*, through stopcock 15, by which its flow may be regulated, into bulb S. *Simultaneously, this reduced pressure is communicated through the cycle h, T, p, mercury trap and dust filter* P, *and tube* **j** *to the pump reservoir N*. The mercury seal in U-tube ***AA*** is not broken until the mercury in *Z* reaches level *nn*. When this occurs, air rushes through ***AA*** and *x* into *S* and the sudden increase of pressure in *S* causes the mercury to begin to siphon through o into bulb T. The suction through 7 is immediately interrupted by a barometric column in *h*. *The main reservoir, N, of the pump is now open to atmospheric pressure through* ***AA,*** *x, S,* n, T, P, *and tube j*. Tube *y* and the lower part of *h* now serve as a siphon to return the mercury from *T* to *Z,* and the time required for this operation is controlled by stopcock 14. When *T* is empty, air enters *h*. The slug of mercury in *h* above **jj** is swept into trap E, from which it returns to *Z* through ***i***. Air also enters the upper end of y. Mercury flows but slowly through the partially closed cock 14. Air flows many times as fast as mercury through the same opening, hence, when air reaches 14 the mercury in y and *U* drops suddenly, covering the open end of ***AA*** and preventing the mercury in *Z* from being carried up in small portions by an "air lift" as it would be if all the mercury returned slowly to *Z*. When ***AA*** has been sealed over, the starting condition is restored and the cycle repeats itself. The air admitted to N is dried in K to prevent fouling of the mercury.

The displacement pump proper comprises the reservoirs N and R discharging through tubes *t* and *u* and air trap Y into pump chamber *H,* which in turn delivers the gas through fall tube *m* and trap Q into the sample storage reservoir G, whence mercury from *L* may be made to displace the gas through stopcock 8 for delivery to any other apparatus sealed to 8. A system terminating in float valve *BB* and connected through tubes *q, r, s,* and trap X effects the automatic return to the reservoir N of mercury delivered on the compression stroke from the pump head *H* to the collecting bulb *G*.

Very pure mercury is introduced into the system through tube *q,* which may then be closed or left open to the air through a drying tube and dust filter. The amount of mercury must be just sufficient to fill the interconnecting tubes k, l, *m,* ***r,*** *s, t, u,* ***v, w,*** trap *Y,* the reservoir G with a slight excess in L, and the pump head *H* when N and R are just empty. The amount of mercury should be finally adjusted by trial, operating with needle valve 12 nearly closed to avoid breaking the pump head if too much mercury is in the system. When correct adjustment is obtained, the mercury from N, which empties quickly through the large tube *t* just fails to fill the pump head *H* and so avoids fracturing this part. The small bulb R contains just a little more mercury than is required to complete the displacement stroke, and discharges slowly through tube *u* containing a capillary stricture V of sufficiently small bore to prevent the mercury striking sharply against the pump head.

Before beginning to collect a sample, vacuum applied through cock 7, tube *a*, mercury trap F and stopcock S is made to draw mercury from reservoir L, connected to the atmosphere through cock 2, into reservoir G. When G is completely filled, *8* is closed, 2 turned to connect L to the vacuum and mercury withdrawn from G into L, leaving a barometric vacuum in G into which gas from H is discharged. This arrangement permits placing the pump reservoir N below H, the chamber into which it discharges, and the consequent operation of the pump by vacuum and atmospheric pressure rather than vacuum and positive pressure.

The gas delivered from H is effectively prevented from returning by trap Q, which also prevents gas bubbles being carried down tube *s*. The mercury which follows the gas through delivery tube *m* automatically returns to the pump through valve *BB*[6] when vacuum is again applied to N. The reservoir N is made of a tube approximately ***35*** mm. in diameter and **30** cm. in length, sloped at an angle of about 30° from horizontal to prevent the vortex action invariably observed in the usual reservoir. Bulbs S and T in the control system must be relatively narrow inclined tubes for the same reason. The delivery tube *m* must be constructed of tubing of 0.5–0.7mm. bore, in order to be completely effective. Larger bores do not deliver the discharged gas properly, leaving films which prevent the obtaining of high vacua. It is perhaps superfluous to note that the construction of H and m presents an exacting problem to the glass blower, since any surface approaching the horizontal is apt to trap a gas film and ruin the efficiency of the pump.

---

[6] The float valves BB and I are solid glass balls ground perfectly spherical and fitting against a 45° ground seat. Floats of this type do not fail as long as they remain clean.

It should be noted that the specified levels indicated by the double letters are quite significant to successful operation of the pumping cycle as well as the control cycle. The level *aa–dd* need not be 80 cm. unless the pump is made to operate on a barometric valve in tube *f*. The glass float *I* is to be preferred at this point. Construction should closely adhere to the other levels specified.

It is apparent that pumping ceases when the pressure in *H* equals that in *G*. At this point the pump runs automatically without further transfer of gas from the pump head to the storage reservoir. The pump is then stopped at the termination of a compression stroke by turning cock 13 to the air, and the pumped gas transferred from *G* by mercury displacement from *L*, cock 2 being turned to the atmosphere for this purpose.

It is worthy of particular comment to note that the pumping cycle contains no stopcocks except the outlet cock No. 8. This is a very important feature, since stopcock lubricant will foul the mercury and make impossible the obtaining of high vacua. The mercury in contact with 8 is carried forward from the pump, and never backward into *G*. No lubricant can therefore be carried into the pumping system. The pump is so arranged that mercury must be added to the Töpler cycle through *q*, never through 8. In actual use, an original filling of pure mercury was perceptibly fouled at the end of two years' operation. If the outlet of *q* and inlet of *N* had been provided with suitable drying tubes, as suggested herein, it is believed the small amount of fouling that occurred over this long period might have been prevented. It is required, of course, that the mercury does not come into contact with a corrosive gas.

For draining and cleaning either the controlling or the pumping system, outlets are provided in the form of drawn-out glass tips at *CC* and *DD*.

The pump was mounted, as shown in the photograph, on a frame of angle iron, the bulbs containing heavy weights of mercury being set into plaster of Paris in suitable metal forms. This type of mounting is desirable when a permanent unit is to be set up. In the event of breaking any part, the whole is easily accessible to a hand torch.

The pump operates readily at a rate of one or two cycles per minute.

Summary

The automatic sample collecting vacuum pump here described has been in successful operation for several years. The pump is an automatic Töpler, which acts as the backing unit to a high speed mercury vapor pump. The automatic control is accomplished by an arrangement of mercury displacement within an auxiliary cycle, which can be operated by a water aspirator or any motor driven vacuum pump commonly on the market. No pressure above atmospheric is required for the operation of the pumping unit. The design incorporates features which prevent

fracture of the Topler pump chamber and delivery tube. Stopcocks have been eliminated from the pumping cycle and a minimum quantity of dried and filtered air comes in contact with the mercury in the pump reservoir; the mercury is consequently not fouled through contact with lubricants or moist air. The mercury delivered by the Töpler pump is automatically returned to the cycle, while the gas pumped is automatically collected and may be transferred as desired to other units.

The control system is entirely independent of the vacuum pump and may find other applications in which alternating vacuum and pressure are desired.

SOME PROPERTIES OF COLLOIDAL LEAD

BY HELEN QUINCY WOODARD

RECEIVED OCTOBER 14, 1927 PUBLISHED JULY 6, 1928

In the course of the preparation of colloidal lead suitable for clinical use a number of the properties of lead sols prepared by the Bredig method[1] have been studied. The more outstanding of these properties are presented below.

Apparatus and Method.—The apparatus was the same as that described by the author elsewhere.[2] The anode was $^1/_{16}$-inch commercial sheet lead from the National Lead Co. The cathode was a roll of "Pueblo" lead foil from the American Smelting and Refining Co. Baker's "C. P." reagents and Eimer and Amend's "C. P." and "Tested Purity" reagents were used and were not further purified. The approximate currents used at different times are given below, temporary fluctuations up to *10% of the values given being caused by irregularities in the arc: 1.4 amps., 40 volts; 3.8 amps., 50 volts; 7.0 amps., 60 volts. The temperature range was 10–35°.

Properties.—The colloidal lead was dark gray and fluorescent when first prepared, turning blue-black after being centrifuged or being allowed to stand for a few hours. It was brown by transmitted light. The particles carried a positive charge, as shown by their migration in an electric field. When a current passed directly through a sol, the lead coagulated to tree-like growths on the electrodes.

When protected from air by paraffin seals about 5 mm. thick the sols would keep for from three to nine weeks before coagulating. If, however, they were left with a large surface in contact with the air, they rapidly

[1] Bredig, Z. *angew. Chem.*, 12,951 (1898).

[2] Woodard, *Ann. Sur.*, 607, Oct., 1927.

developed an area of clear supernatant liquid, as observed by Stenstrom and Reinhard.[3] Sols left uncovered in this way soon settled out,

The colloidal lead was readily coagulated by electrolytes. Sulfuric acid, sodium carbonate, sodium bicarbonate, potassium hydroxide and sodium chloride, when added to sols stabilized by potassium hydroxide in amounts sufficient to bring the final concentration of added electrolyte to 0.001 N or higher, caused visible coagulation in a few minutes. The electrolytes mentioned had about equal precipitating power in equinormal concentrations, but acetic acid had much less effect. The coagulation time could not be determined accurately but was roughly inversely proportional to the age of the sol.

All the sols could be coagulated by shaking with air or with carbon dioxide. The time of shaking required to coagulate a sol under given conditions decreased with increasing age of the sol.

Series of sols were made by arcing in different electrolyte solutions. The concentrations of stable colloidal lead prepared under different conditions are shown in Table I, the criterion of stability being the ability of the sol to withstand centrifuging for five minutes at a force of 1000 X gravity. The average deviations from the average concentrations of sols in each electrolyte series are rather large in comparison to the differences in the average concentrations of sols in different series. Nevertheless, a comparison of the different series brings out the following relationships fairly clearly.

TABLE I

Electrolyte	PH of initial soln.	Current, amps.	Number of sols	Average concn., % Pb	Average dev. from av., %
0.00025 M HCl	3.6	1.4	15	0.038	±20
.000125 M H_2SO_4	3.6	1.4	5	.039	±19

.00022 M KOH	..	3.8	13	.152	*19
.00022 *M* KOH	..	7.0	29	.187	±18

(1) The concentration of colloidal lead stabilized by 0.00022 M potassium hydroxide at currents of 1.4-7.0 amps. is directly proportional to the current used.

---

[3] Stenström and Reinhard, *J. Biol. Chem.*, 69, 607 (1926).

(2) For the entire range of electrolyte solutions examined with the exception of the neutral salt sodium chloride, the concentration of colloidal lead stabilized by equinormal solutions of different electrolytes is a function of the PH of the initial solution; see Fig. 1. (Note that the *P*H values given in the table were obtained from solutions that had cooled from the boiling point in the apparatus in contact with the electrodes. Considerable lead is dissolved under these conditions.)

(3) For the electrolytes potassium hydroxide and sodium chloride, the concentration of stable colloidal lead dispersed by a given current rises with increasing electrolyte concentration up to a maximum which is reached in the neighborhood of 0.0003 *M*, and then falls; see Fig. 2. It could not be determined whether the curves finally drop to zero, owing to the extreme difficulty of maintaining an are in high electrolyte concentrations, and the latter portions of the curves are ill defined for the same reason.

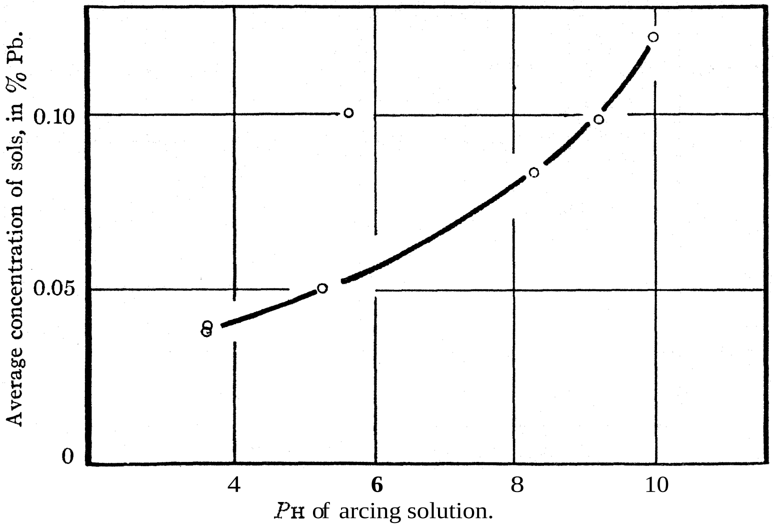

Fig. 1.—Lead sols in approximately 0.00025 *N* solutions of different electrolytes. Relation of concentration of sol to PH of arcing solution.

The relation of the concentration of lead sols to the weight of lead disintegrated from the cathode during the preparation of the sols offers an interesting contrast to the relationship found by the author and others for the similar sols of gold, silver and platinum.[4] Thus, the concentration of gold, silver and platinum sols rises to a maximum during arcing, and then, on further arcing, falls, sometimes rather rapidly, to zero. With lead sols, on the other hand, the concentration rises rapidly to a maximum during arcing, and further arcing, even when quite prolonged, does not show any tendency to cause the concentration of colloidal lead which is stable to five minutes centrifuging with a force of 1000 X gravity to fall below this maximum. This is true of sols in all the different electrolyte solutions examined. Table II gives a typical example. The relation for uncen-

trifuged sols is much less consistent than for centrifuged ones, and the maximum of concentration is reached latex.

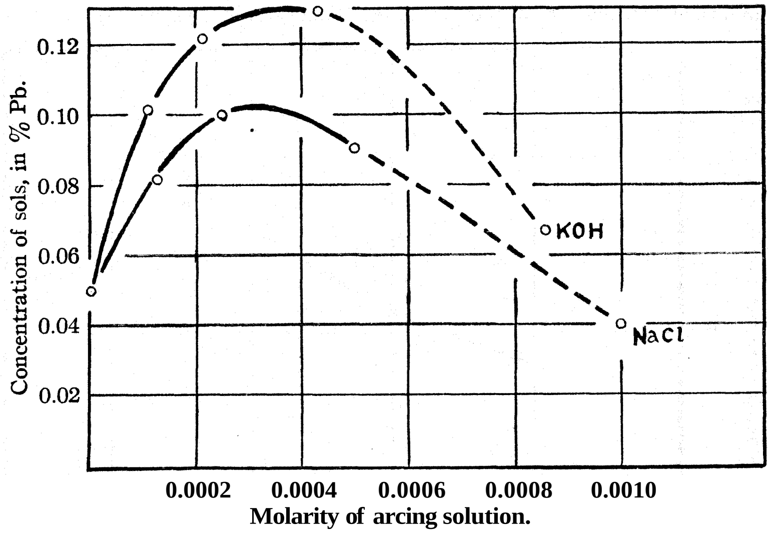

Fig. 2.—Lead sols in solutions of potassium hydroxide and sodium chloride. Relation of concentration of sol to concentration of arcing solution.

The behavior of lead sols under the influence of gravitational force also differs from the analogous behavior of gold sols under centrifugal force, and in general from the settling of dispersions of mixtures of particles of different degrees of stability.[6] This was shown by a study of uncentrifuged sols which were allowed to stand in cylinders 30 cm. high with an internal diameter of 4–4.5 cm. The surfaces of the sols were covered with paraffin. Samples were withdrawn for analysis from the center of the column of liquid from time to time. Typical curves obtained by plotting concentration against time of standing are shown in Fig. 3. These curves show, as expected, an initial rapid drop in concentration as the unstable particles settle out. This is followed by a period of nearly constant concentration, as with colloidal gold. After a time the influence of a cumulative precipitating is apparent. Visible coagulation begins and the con-

[6] Ayres, *Chem. Met. Eng.*, *16*, 190 (1917); Davidson, *Dissertation*, Columbia, 1924.

centration falls rapidly to zero. This was observed in sols stabilized by acids, neutral salts and alkalies alike. A similar but less marked effect was observed in sols which had been centrifuged for five minutes; see Table III. In view of the readiness with which the sols can be coagulated by shaking with air, it seems probable that the precipitation is caused by the oxygen and carbon dioxide which are absorbed through the paraffin seals.

8	20	89	5	45	17
8	25	83	5	50	9

Summary

The concentration of stable colloidal lead prepared by the Bredig method has been found to be proportional to the current used in the preparation of the colloid and to the PH of the initial solution in which the arcing is done.

The concentration of colloidal lead has been found to rise to a maximum with increasing concentration of stabilizing electrolyte used, and then to fall as the concentration of stabilizing electrolyte is further increased.

Some properties of Bredig colloidal lead have been compared with the corresponding properties of colloidal gold, silver and platinum.

THE CONDUCTIVITY AND VISCOSITY OF SOLUTIONS OF LITHIUM NITRATE IN CERTAIN MIXED SOLVENTS[1]

BY J. L. WHITMAN AND S. R. SPENCER

RECEIVED FEBRUARY 8, 1928 PUBLISHED JULY 6, 1928

As part of some investigations being carried on in this Laboratory, it was found desirable to make a series of measurements of the conductivity and viscosity of solutions of lithium nitrate in mixtures of methyl alcohol and ethyl alcohol, and of methyl alcohol and water. Such measurements have previously been made by Jones and Lindsay[2] and by Jones and Carroll,[3] but it seems desirable to report the more extended series of measurements which we have made.[4]

Materials

Lithium Nitrate.—This was prepared from pure lithium carbonate and C. P. nitric acid, was recrystallized five times from conductivity water and was then shown to be free from impurities by a spectroscopic test. The drying of the salt was found to be more difficult than would be indicated from the literature. Anhydrous material could only be obtained by prolonged heating at 150° in a vacuum. This probably accounts for the fact that the values here recorded are uniformly higher than the values previously reported.

Water.—Laboratory distilled water was electrically redistilled from alkaline permanganate and had a conductivity of 1 to 1.2×10^{-6}.

Alcohol.—A good grade of ethyl alcohol was successively treated with lime, metallic calcium, silver nitrate and finally again with lime prepared according to Danner and Hildebrand.[5] Thus prepared it had a conductivity of about 3×10^{-7}, while methyl alcohol prepared in a similar manner had a conductivity of 2×10^{-6}.

Solutions.—Dry lithium nitrate was weighed into a quartz flask, solvent of the required composition then being added to give a solution of the greatest desired concentration. More dilute solutions were made by adding solvent in the required amount to this stock solution.

Apparatus and Measurements

A Leeds and Northrup Kohlrausch slide wire bridge with extension coils, a microphone hummer, tunable head phones, Curtis coil resistance boxes, adjustable air con-

densers and the usual sheathings and shieldings were used. The grounded water-bath consisted of a heavy Pyrex vessel of about 12 liters' capacity, the temperature being regulated to 25 ± 0.01°. Washburn pipet cells were calibrated by the method of Kraus and Parker.[6] All other apparatus was carefully calibrated and from 8 to 15 resistance measurements were made on each solution used. All values were corrected for the conductivity of the pure solvent.

Viscosity measurements were made in an Ostwald type quartz viscosimeter.

Experimental

Methyl Alcohol–Ethyl Alcohol **Mixtures.**—The equivalent conductivities of solutions of lithium nitrate of various concentrations and in solvents ranging in composition from pure methyl alcohol to pure ethyl alcohol are recorded in Table I. In every solvent used the equivalent conductivity increases with dilution as is normally the case with water solution, but in no case does the Mass Law hold. For the more dilute solutions the conductivity is almost exactly a linear function of the composition of the solvent, and even for the 0.1 molar solution the deviation is small. The viscosities of a series of mixtures of the two alcohols are given in Table II, referred to water at 25° as unity.

TABLE II

THE VISCOSITY OF METHYL ALCOHOL–ETHYL ALCOHOL MIXTURES AT 25°

CH_3OH, %	Viscosity	CH_3OH, %	Viscosity	CH_3OH, %	Viscosity
100	0.5968	60	0.7800	20	1.0477
90	.6400	50	.8262	10	1.1310
80	.6826	40	.8785	0	1,2530
70	.7249	30	.9618	..	....

In Fig. 1, Curve 1, composition of solvent is plotted against equivalent conductivity for the most dilute solution; in Curve 2 composition is plotted against viscosity for the pure solvent. Viscosity determinations were made for a number of the more dilute solutions but the values obtained differed so little from those for the pure solvents of the same composition that the latter values have been used in all cases.

Methyl Alcohol–Water Mixtures.—Table III gives the equivalent conductivities for a series of solutions of lithium nitrate in various mixtures of methyl alcohol and water. Viscosities of the same mixtures are given in Table IV. Dilution was not carried as far as with the methyl alcohol–ethyl alcohol mixtures, since it was found that at a concentration of 0.00625 molar the viscosity of the solution did not differ appreciably from that of the pure solvent. The corresponding curves are shown in Fig. 2.

Ethyl Alcohol-Water Mixtures.—Data of previous authors are used for ethyl alcohol-water mixtures, conductivity data from Jones and Lindsay[2] and viscosity data from Noack.[7] Graphs are shown in Fig. 3. The conductivity data are unsatisfactory since values are given only for one mixture, that containing 50% alcohol. It is evident, however, and is so stated by Jones and Lindsay[8] that no minimum exists at 25°, although a slight minimum is found for certain concentrations at 0°. An examina-

tion of Fig. 3 shows that a decided maximum occurs in the composition–viscosity curve, in this respect being similar to the methyl alcohol–water mixtures.

Discussion

Jones and Lindsay[2] and Jones and Carroll[3] studied solutions of several salts in mixtures of methyl alcohol and water. Measurements were made at various concentrations and at 0 and 25°. They concluded that "the minimum of conductivity is caused primarily by the great decrease of fluidity resulting when the two components of the mixture are brought together."[9] Without considering the many dilutions used, 23 distinct cases were studied, of which 9 show a very pronounced minimum in the conductivity curve, 3 show a slight minimum, while 11 show no minimum.[10] The very marked minimum occurs only in the methyl alcohol–water mixtures, while in the ethyl alcohol–water mixtures the minimum occurs only at 0°, and then only occasionally. For calcium nitrate no minimum* appears under any conditions. These results are difficult to interpret in terms of viscosity, especially in view of the fact that one of the common arguments in favor of the relationship between viscosity and conductivity is that the temperature coefficients of the two are nearly the same.

We have verified and extended Jones' results for the methyl alcohol–water mixtures and have obtained data for methyl alcohol-ethyl alcohol mixtures. The work is being continued to include a number of the higher alcohols.

Summary

1. Measurements have been made of the conductivities and viscosities of solutions of lithium nitrate in water, methyl alcohol and ethyl alcohol, and in various mixtures of these solvents.
2. The difficulties involved in drying lithium nitrate have been pointed out and are shown to be a possible source of error in previous work.

THE IODIDE, IODINE, TRI-IODIDE EQUILIBRIUM AND THE FREE ENERGY OF FORMATION OF SILVER IODIDE

BY GRINNELL JONES AND B. B. KAPLAN

RECEIVED FEBRUARY 23, 1928 PUBLISHED JULY 6, 1928

Introduction

U. Fischer,[1] and Braune and Koref,[2] working in Nernst's laboratory, have made measurements of the free energy of formation (A) and heat of formation (U) of silver iodide from its elements. Nernst[3] has measured the specific heat of silver, iodine and silver iodide down to the temperature of liquid hydrogen. Fischer and Nernst regard the agreement between the measured heat of formation and the value computed indirectly from the free energy and specific heats by the aid of the Third Law of Thermodynamics as sufficiently close to furnish support for the Law.

Grinnell Jones and M. L. Hartmann[4] made measurements of the potential of cells of the type Ag, AgI, xKI, xKI + I_2 sat., Pt (similar in principle to the cell used by Fischer but differing in details) at both 25 and 0°. They were thus enabled to obtain a value for dA/dT, or the entropy of the reaction directly from their electromotive force measurements without using thermochemical measurements. They found a value for the entropy nearly twice that found by Fischer and criticize Fischer's work; they also point out that their results and Nernst's data on the specific heats of these substances are not reconcilable by the Third Law of Thermodynamics.

The essence of the Third Law of Thermodynamics is that, for a reaction between solids, the temperature coefficient of the free energy, dA/dT, or the entropy (S) of the reaction is a function solely of the specific heats of the substances involved and can be computed quantitatively if these specific heats are accurately known from absolute zero up to the working temperature. Therefore, as is pointed out by Jones and Hartmann, the sharpest test of the validity of the theory is obtained by comparing the values of dA/dT experimentally determined with that computed from the specific heats of the substances involved. Pischer's method of testing the theory, referred to above, requires not only accurate data on the specific heats and on the free energy of the reaction at one temperature but in addition requires accurate measurements of the heat of the reaction. Therefore, the unavoidable experimental errors in the calorimetric work increase the difficulty of testing the theory by this method. Electromotive force measurements are in

general more precise than calorimetric measurements and in the comparison of very similar measurements made at a slightly different temperature, the effect of systematic errors on the temperature coefficient may be largely eliminated.

This point of view is supported by the publications of G. N. Lewis, and especially by the work of R. H. Gerke,[5] which is in our opinion the most rigid test of the validity of the Third Law yet published, and which is based solely on the comparison of measurements of the temperature coefficient of the electromotive force of galvanic cells with the computations based on measurements of specific heat from absolute zero up to the usual working temperature. In the application of this method errors in the potential measurements which vary with the temperature should be guarded against with special care.

If the data of Nernst on the specific heats of silver iodine and silver iodide are correct, and if the Third Law is valid, the value of $\mathrm{d}A/\mathrm{d}T$ should be 2.19 calories per degree.

H. S. Taylor[6] and Taylor and Anderson[7] have discussed this discrepancy between the data of Jones and Hartmann and of Fischer but without definitely locating the cause of the discrepancy. In the meantime G. N. Lewis and his associates have published papers too numerous to refer to in detail which furnish stronger evidence of the validity of the Third Law of Thermodynamics than the numerous papers from Nernst's laboratory. The paper of Gerke[5] referred to above is especially significant. A recent paper by Webb[8] which summarizes and extends the work done on this subject at Princeton also supports the validity of the Third Law.

The discrepancy between the results of Fischer and of Jones and Hartmann has been studied by O. Gerth,[9] a student of Nernst, who duplicated the cells of Jones and Hartmann and of Fischer and repeated the measurements of electromotive force (E_1), and in both cases obtained results which agreed within a few tenths of a millivolt with those of the original authors and also checked the divergent temperature coefficients.

The iodine electrodes prepared either by the procedure of Fischer or by that of Jones and Hartmann were measured by Gerth against each other and agreed within ± 0.02 millivolt. Significant differences were found by Gerth when the two types of silver-silver iodide electrodes were measured against each other. Fischer used pure electrolytic crystals of silver. His silver iodide had been previously fused and then allowed to crystallize on cooling and then broken up into small pieces and added to the silver

electrodes as a depolarizer. The electrolytes were $N/2$, $N/3$ or $N/10$ solutions of potassium iodide. Jones and Hartmann covered a platinum spiral with silver by electroplating from a cyanide bath. The silver was covered with a paste of pure silver oxide in water, and then heated in an electric furnace to a low red heat to convert the silver oxide completely into spongy metallic silver. The electrodes were then coated with a thin layer of silver iodide by making them an anode in a solution of potassium iodide with a very low current density. These electrodes were then allowed to stand in a fresh solution of $N/10$ or $N/20$ potassium iodide.

Gerth measured silver–silver iodide electrodes of these two types against each other in $N/10$ potassium iodide. His measurements showed that the electrodes made according to the specifications of Jones and Hartmann were positive to those prepared according to Fischer by 0.54 millivolt at 25° and in general the difference is represented by the formula $E = 0.00090 - 0.000015\ t$.

This indicates that the crystalline form of silver iodide used by Fischer is more stable than the form used by Jones and Hartmann. Gerth says "The difference in the silver electrodes found by the preceding measurements explains a part of the discrepancy mentioned at the beginning." This conclusion does not seem to us to be justified because the potential readings of Jones and Hartmann are above those of Fischer, whereas if the only difference between the two types of cell had been that Fischer used a more stable form of depolarizer he should have obtained the higher readings. Thus, if to Gerth's value for the complete cell with the J + H type of electrode, $E_1 = 0.6934 + 0.000258\ t$, there is added the difference between the two kinds of electrodes, $E = 0.0000 - 0.000015\ t$, we obtain $E_1 = 0.6943 + 0.000243\ t$, which should be the same as Gerth's directly measured value for the complete cell of the Fischer type whereas the result obtained by Gerth by actual measurement was $E_1 = 0.6921 + 0.000302\ t$. Thus by taking account of the difference between the two types of electrodes as measured by Gerth, the discrepancy between the measurements of Fischer and those of Jones and Hartmann is made worse instead of being partially accounted for.

Even more important than the discrepancy between the experimental results of Fischer and of Jones and Hartmann is the difference in the computed corrections to allow for the disturbing effect of the formation of tri-iodides in the solution.

The iodide–iodine–tri-iodide equilibrium has been much studied in the past but a detailed review of this earlier work must be omitted to save space.[10] These researches have established that when free iodine is added

to a solution of an iodide the principal reaction that occurs is the formation of a tri-iodide according to the reaction $I^- + I_2 \quad I_3^-$. The equilibrium constant of this reaction, $(I^- \times I_2)/I_3^- = k$, is a true constant if the solution is sufficiently dilute in free iodine and iodide, but if the solution is saturated with iodine, especially if the iodide is 0.1 *N* or stronger, there is a decrease in the constant which indicates that some higher complex is present. The iodine electrode is reproducible, constant and reversible to an unusual degree, but in the interpretation of measurements made with it proper allowance must be made for the formation of tri-iodides and the conditions should be so chosen that the formation of higher polyiodides is negligible.

As a result of the formation of the tri-iodides, there is a difference in the concentration of the iodide ion in the two halves of the cell which requires that an osmotic work correction be applied by the Nernst Equation $E_o = RT/F \ln c_2/c_1$. Fischer not only omitted the liquid junction entirely but applied the osmotic work correction in a crude manner because of a lack of accurate knowledge of the tri-iodide equilibrium at the odd temperatures of his measurements. Jones and Hartmann utilized the results of Bray and MacKay[10g] on the tri-iodide equilibrium at 25° and made a study of this equilibrium at 0° themselves[10i] for the purpose. From their measurements with 0.1 *N* potassium iodide solutions, they found $dA/dT = 3.7$ cal. per degree; and from their measurements with 0.05 *N* potassium iodide solutions they found $dA/dT = 4.5$ cal. per degree. They regard the latter as the more reliable.

Gerth made new measurements of the potential of silver–silver iodide–iodine cells similar to those of Jones and Hartmann, using $N/20$, $N/40$ and $N/60$ potassium iodide solutions (E_1) and the results show the same systematic change with concentration.

Gerth then undertook to reduce the disturbing effect of tri-iodides by working with solutions unsaturated with respect to iodine but having a known vapor pressure of iodine. The osmotic work correction and the liquid junction correction are thus substantially reduced and replaced by a correction which can be computed by the Nernst equation $E_p = RT/2F \ln p_2/p_1$, from the vapor pressure of iodine from the solution actually

used (p_1) and the vapor pressure of solid iodine at the temperature of the cell (p_2). This is fundamentally a good idea because as a general rule the activity of un-ionized molecules such as I_2 is very nearly proportional to the vapor pressure and only slightly if at ail influenced by the concentration of the ions present, whereas the activity coefficient of the ions is appreciably different from the degree of dissociation as estimated from the conductivity even in solutions as dilute as 0.05 *N* and widely discrepant in solutions as concentrated as 0.5 N. But if the unsaturated iodine solution can be made sufficiently dilute to reduce the osmotic work correction and the liquid junction to a small figure of the order of one or two millivolts the error in this correction is probably negligible.

To prepare potassium iodide solutions with a small known iodine vapor pressure, Gerth passed nitrogen through a U-tube containing iodine maintained at 0°, thus saturating the nitrogen with iodine vapor at the vapor pressure of solid iodine at 0°. This nitrogen was then bubbled through a potassium iodide solution of known concentration at some higher temperature, until equilibrium had been established. The voltage of a platinum electrode in this solution against a platinum electrode in a solution of the same strength in potassium iodide but saturated with solid iodine was then measured (E_2). The measured potential includes the potential due to difference in iodide ion concentration (osmotic work) and to the liquid junction between the saturated and unsaturated solution as well as the potential due to the difference in the activities of the free iodine in the two solutions. If the vapor pressures are accurately known the latter potential can be computed with precision. This permits the sum of the osmotic work correction and the liquid junction correction to be determined experimentally with a precision greater than they can be computed from the theoretical formulas as was done by Fischer and by Jones and Hartmann. This method does not entirely eliminate the necessity of applying a computed correction for the osmotic work and liquid junction due to the formation of tri-iodides because there still remains a difference in the iodide ion concentration in the pure potassium iodide solution containing no iodine which surrounds the silver iodide electrode and in the solution which is unsaturated with iodine, used by Gerth in his measurements. This potential (E_4) must be computed by the methods criticized above. Gerth attempted to make the unsaturated iodine solution sufficiently dilute so that the error in this correction would be negligible.

Although the basic idea of Gerth's method is good, he lacked the data necessary for its successful execution. This method requires an accurate knowledge of the vapor pressure of iodine at each of the temperatures used in the experiments. Gerth did not determine the vapor of iodine at each of his working temperatures and does not even state directly the values which he used, but he refers to Abegg's "Handbuch," Vol. 4, part 2, p. 350 (1913), where a table of vapor pressures of iodine at various temperatures is given. These data by many different experimenters are obviously inconsistent and lacking in the precision needed for the purpose, as may be readily seen by plotting them on the same sheet with the data given in the "International Critical Tables," Vol. III, p. 201, which are based chiefly on the work of Baxter and Grose. The vapor pressure at 0° is especially important for Gerth's calculations but is so low (0.03 mm. of mercury) that it is difficult to determine with precision and is recorded to only one significant figure. It would seem to be over sanguine to claim that the figures used by Gerth are reliable within 10% and yet an error of 10% makes an error in the computed potential of 1.2 millivolts, whereas Gerth computes the corrections to tenths of millivolts.

Gerth still omits the liquid junction correction (E_j) on the assumption that the potential between the pure potassium iodide around the silver iodide electrode and the unsaturated iodine solution around the platinum electrode is negligible, but this is by no means true as may be seen by inspection of Tables I–V below. Moreover, since these solutions at 11.5' are approximately one-third saturated, and at 25° are only one-tenth saturated, the error due to this omission will have a marked temperature coefficient.

The essential idea of Gerth's new method is to replace the osmotic work correction, E_o, and liquid junction, E_j, which are computed by the Nernst and Planck equations, respectively, involving the concentration of the ions, by a direct measurement, E_2, and a computed correction, E_p, based on the vapor pressure of iodine. This change is partial only and the fraction of the total correction obtained by the old and by the new methods is different at different temperatures. A reference to Table 6 of Gerth's paper will show that at 25° the total correction is —0.0152 volt, of which —0.0133 is obtained by the new method and —0.0019 (or 12% of the total) is computed by the old method. At 11.5° the total correction is —0.0126, of which —0.0056 or 44% is obtained by the old method.

It is apparent that Gerth's new method would fail utterly at 0°, as at this temperature E_2 and E_p would become zero and the total correction would be E_o as computed by the old method (plus the liquid junction correction which Gerth omits). This in effect amounts to applying the correction by the new method at 25° and by the old method at 0° and if the two methods are different in effect, as Gerth contends, this procedure must introduce an error in dE/dT and in dA/dT or the entropy; but as was pointed out above it is especially important to avoid errors in dA/dT in attempts to test the validity of the Third Law of Thermodynamics.

More recently Gerke[11] has made measurements on three different cells

---

[11] R. H. Gerke, THIS JOURNAL, 44, 1703 (1922).

which can be combined so that the following results may be obtained indirectly for the reaction $Ag + \frac{1}{2} I_2 = AgI$, at 25°; electromotive force, 0.6858 volt; free energy, 15,825 calories; heat of formation, 14,814 calories; entropy, 3.4 calories per degree. Gerke, unlike any of the investigators referred to above, used precipitated silver iodide. Webb[8] has measured the heat of formation of silver iodide calorimetrically and obtained 14,975 calories. He combines this with the value of 15,767 calories for the free energy (based on the average of the data of Gerke, Gerth, Braune and Koref, Taylor, and Jones and Hartmann) and hence computes the entropy to be 2.6 calories per degree.

Experimental Part

Gerth's fundamental idea of using solutions unsaturated in iodine, thereby replacing the osmotic work correction and the liquid junction correction by another correction dependent on the vapor pressure (or activity) of the iodine, seemed to be a good one if it could be done in a way free from the objections pointed out above in Gerth's procedure. In particular we regard it as essential to use a method equally applicable at 0° and at 25°. We, therefore, undertook a new investigation of the iodine–iodide–tri-iodide equilibrium with special attention to dilute solutions (down to 0.01 N potassium iodide and from 2 to 33% of the amount of iodine necessary to saturate the solution with iodine). The results have been used in a redetermination of the normal potential of the iodine electrode.

Titration gives the sum of the free iodine and of the tri-iodide but does not distinguish between them. Earlier studies of this equilibrium discussed above have been based on the determination of the free iodine either by (1) distribution experiments with a non-miscible solvent such as carbon bisulfide or carbon tetrachloride, interpreted with the aid of data on the distribution of iodine between the solvent and pure water, or (2) analyses of potassium iodide solution saturated with solid iodine interpreted on the assumption that the concentration of the free iodine in the solution containing potassium iodide is the same as the solubility of iodine in water (corrected for hydrolysis).

Since we were interested in studying solutions containing very little free iodine, the second method was inapplicable. The first method was objectionable because the other solvent used is not entirely soluble in the water and thus changes the nature of the medium, and because the distribution ratio is extremely unfavorable. The distribution ratio of iodine between carbon tetrachloride and water is high and varies with the concentration (85–87.9) so that the merest trace of emulsified carbon tetrachloride in the water layer makes serious errors in the analysis. With carbon bisulfide this ratio is even more unfavorable and variable (585–652).[12]

---

[12] Jakowkin, *Z. physik. Chem.*, **18**, 586, 588 (1895).

These difficulties were overcome by the invention of a device which we call an equilibrator, which has been described in a separate article because of its suitability for the investigation of many similar problems.[13]

A potassium iodide solution of the desired concentration was prepared by weight, its density and conductivity were determined and one tube of the equilibrator (A) was filled with the solution. Sufficient dry iodine was then added to give approximately the concentration desired. A mixture of water and a saturated solution of iodine in water in the proper proportion to give approximately the desired concentration was placed in the other tube (B) of the equilibrator, and one drop of dilute sulfuric acid was added to prevent hydrolysis. Portions of the potassium iodide solution containing iodine were then blown from tube (A) into a pycnometer to determine its density, into a conductivity cell, into the electromotive force cell and into a weight buret. In a similar fashion the liquid from the water side of the apparatus (tube B) was blown into a pycnometer and weight buret.

The titrations for iodine were made by the Washburn method[14] using arsenite solutions and phosphate buffers with a starch indicator. The end-point is sensitive to 0.01 mg. of iodine. Its principal drawback is that the arsenite solution, if exposed to air, slowly changes its factor by oxidation. We, therefore, found it necessary to maintain an oxygen free atmosphere in the stock bottle. Compressed nitrogen from a steel tank passed through a suitable purifying train to remove all oxygen, then through a wash bottle containing some of the standard arsenite solution to bring it to the proper aqueous vapor pressure and then was delivered to the top of the stock bottle containing the reserve stock of standard arsenite solution.

The titration of the potassium iodide solution from tube (A) gives the sum of the free iodine (I_2) and the tri-iodide ($\Sigma I_3 = I_3^- + KI_3$). The titration of the water from the other tube gives the free iodine (I_2) which at equilibrium is the same in the two tubes. Hence the tri-iodide may be obtained by a simple subtraction, and the iodide remaining may be readily obtained by subtracting the tri-iodide from the original concentration of the solution. The equilibrium constant of the reaction $K^+ + I^- + I_2 \rightleftharpoons K^+ + I_3^-$ may then be readily calculated. This calculation assumes that the activity of the uncharged molecule I_2 is the same as its concentration in the dilute water solution in the other tube of the equilibrator with which it is in equilibrium, and that the activity coefficients of the iodide ion and the tri-iodide ion in the same solution are identical, so that the ratio of the activity of these ions in the common solution is the same as the ratio of their concentrations.

The electromotive force measurements were made in cells of the ground stopper type introduced by Laurie[15] and similar to those used by Jones and Hartmann except that the upper joints were glass stoppers. This type of cell has several important advantages over the other types in common use.

(1) It requires only a small amount of the solution used and makes good thermal contact with the constant temperature bath.

(2) It gives readings which are constant for long periods and easily reproducible.

(3) The liquid junction formed by diffusion in the ground joint realizes experimentally the theoretical conditions assumed by Planck in the derivation of the formula for the liquid junction potential and therefore this formula may be used with greater confidence for the computation of the diffusion potential than is possible with other types of liquid junctions which are not so well defined. This type of cell has the disadvantage of a high internal resistance, which greatly diminishes the sensitiveness of the galvanometer, especially if dilute solutions are used. This drawback is probably mainly responsible for the fact that this type has been comparatively little used in the past.

We have invented an improvement in the potentiometer which overcomes this difficulty entirely and makes the sensitiveness of the voltage measurement practically independent of the internal resistance. This improvement consists in adding a large electrostatic condenser in parallel with the galvanometer and its tapping key. Then with the tapping key open, the condenser will be charged to a potential equal to the difference between the potential of the cell and the setting of the potentiometer. A high resistance in the cell cannot prevent this charging of the condenser but can only delay it slightly. If the cell has a resistance of the order of one million ohms it is well to wait about one minute for the condenser to become charged. Then on closing the tapping key the condenser will discharge through the galvanometer but not through the cell and therefore a deflection of the galvanometer will not be influenced by the high resistance of the cell, but will show any slight error in the adjustment of the potentiometer in spite of the high resistance of the cell.

Of course this procedure requires a sensitive ballistic galvanometer in place of the dead-beat instrument commonly used. To bring the instrument quickly and conveniently to its zero reading it is advisable to shunt the galvanometer by a resistance equal to the critical damping resistance of the galvanometer and another tapping key.

The condenser actually used was made by soldering together in parallel enough Western Electric paraffined paper condensers to give a capacity of 44 microfarads (these cost approximately fifty cents per microfarad) mounted in a suitable wooden box carrying a double pole, single throw switch by which the condenser may be disconnected or connected as desired. It is well to have this switch open until an approximate balance (within a few millivolts) has been secured because if a high charge is impressed on the condenser it does not discharge itself completely on a single contact of the discharge key, since with paper condensers the charge is partly "absorbed" in the dielectric and can only be completely removed by tapping the key several times at intervals of a few seconds. Then the switch is closed and the key tapped several times to remove the absorbed charge. The galvanometer is brought to rest at its zero by the key in the critical damping circuit. After waiting a short time for the condenser to become charged (in extreme cases up to one minute) the key is tapped and the deflection of the galvanometer, if any, noted. Then the potentiometer is adjusted until the galvanometer reads zero when the key is tapped.

The effectiveness of the condenser is shown by a typical example. These measurements were made on a cell Ag, AgI, 0.01 N KI, 0.01 N KI + I_2, Pt at 0° in which the liquid junction was made inside of a well ground stopper which was pushed in tightly. The internal resistance of the cell was measured and found to be approximately 1,600,000 ohms, an exceptionally high value.

When the condenser was not used it was necessary to change the setting of the potentiometer by 3 millivolts in order to cause a deflection of 1 mm. on the scale and it was concluded that the potential of the cell was 0.646 volts with an uncertainty of 1 millivolt.

The condenser of 44 microfarads was then connected. It was found that a change in the setting of the potentiometer of 0.1 millivolt made a difference in the galvanometer reading of 3 mm. on its scale—a ninety-fold increase in sensitiveness. At balance the potentiometer reading was 0.64555, volt which was probably correct within 0.02 millivolt. With the condenser the sensitiveness of the potential measurement was found to be nearly independent of the internal resistance. With our potentiometer and galvanometer, which were high-resistance instruments, the condenser is not needed to measure the potential of cells having an internal resistance of 10,000 ohms or less. This modification of the potentiometer overcomes the principal difficulty in the use of cells of the Laurie type for measurement of electromotive force.

The results of the experiments with the equilibrator and the electromotive force measurements are recorded in Tables I–VI, in which the abbreviations have the following significance: CK is the concentration of the potassium iodide solutions used; *M* is the sum of the concentration of the free iodine (I_2) plus the iodine equivalent of the polyiodides present in the potassium iodide solution which is unsaturated with respect to iodine, as determined by titration of the liquid from one tube of the equilibrator; I_2 is the concentration of free iodine in each tube of the equilibrator as found by titration of the tube containing water (plus a trace of sulfuric acid to prevent the reaction $I_2 + H_2O = H^+ + I^- + HIO$). In the later calculations polyiodides higher than I_3, if present, are neglected; $\Sigma I_3 = M - I_2$, $\Sigma I = \Sigma K - \Sigma I_3$, $k = (\Sigma I \times I_2)/\Sigma I_3$, the equilibrium constant of the reaction $KI + I_2$ KI_3.

If it be assumed that the activity coefficient of the iodide ion and of the tri-iodide ion in the common solution is the same, then $k = (I^- \times I_2)/I_3^-$, where the symbols represent the activities of the respective molecular species. This assumption finds support in the following considerations. (1) There seems to be much evidence that activity coefficients are functions primarily of the valence of the ion and of the total ion concentration[16] and there is no change in valence and in total ion concentration due to the reaction $I^- + I_2 = I_3^-$. (2) There is no change in freezing point when iodine is added to a solution of potassium iodide. (3) The degrees of dissociation as computed from the conductivity of KI and of KI_3 are very nearly the same (probably equal within the experimental error as has been shown by Jones and Hartmann, see THIS JOURNAL, **37,** 250–251 (1915)).

The percentage of saturation is obtained by dividing the free iodine (I_2) by 0.00132 at 25° and by 0.000635 at 0°.[17]

E_1 (J. and H.) is the measured potential of the cell of the type, **Ag,** AgI, 0.1 N KI, 0.1 *N* KI + I_2 sat., Pt taken from the paper of Jones and Hartmann. E_2 is the result of our new measurement of the potential of cells of the type, Pt, 0.1 *N* KI + I_2 sat., 0.1 N KI + I_2 unsat., Pt, in which the solution unsaturated with respect to iodine was taken from the equilibrator and is a portion of the same solution whose analysis is recorded in the upper part of the table, and the solution saturated with iodine was made from the same original potassium iodide solution. By adding these two potentials, the osmotic work correction and the liquid junction correction applied by Jones and Hartmann is largely although not entirely eliminated, but a new correction (E_c) must be applied owing to the fact that the iodine around the electrode is unsaturated. This correction is computed by the Nernst formula, $E_c = RT/2F \ln I_2 \text{(sat.)}/I_2 \text{(unsat.)}$.

This computation assumes that the activity of the iodine is proportional to its concentration in its water solution. These solutions are dilute (0.00132 at a maximum) and contain no ions, and therefore the errors involved in this calculation are believed to be less than in the best estimate that can be made in regard to the activities of iodide ions in solutions of potassium iodide up to one-tenth normal.

E_o is the remaining osmotic work correction referred to above, which must be applied because the concentration of the iodide ion in the pure

---

[16] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1st ed., 1921, p. 374; E. Huckel, *Ergebnisse der exakten Naturwissenschaften,* 3, 243 (1924).

[17] Jones and Hartmann found the solubility of iodine in water to be 0.0006383 mole of I_2 per liter at 0°. From the conductivity of the solution they determined that the hydrolysis of iodine, $I_2 + H_2O = H^+ + I^- + HIO$, is responsible for the solution of 3.2×10^{-6} mole of iodine. Therefore the solubility of iodine as such (I_2) is 0.0006383 −0.0000032 or 0.000635. The figure 0.000638 given by Jones and Hartmann is incorrect owing to an arithmetical error made by them in this calculation.

potassium iodide solution used around the silver iodide electrode is not the same as the concentration of the iodide ion in the unsaturated iodine electrode. It is computed by the formula $E_o = (RT/F)$ ln $(C_2f_2/C_1f_1) = RT/F$ ln $\Sigma K/\Sigma I$, where C_2 (= ZK) is the concentration of the iodide in the original potassium iodide solution and C_1 represents the concentration of the iodide in the solution containing some free iodine (ZI). It is assumed that the conversion of a part of the iodide into tri-iodide does not change the activity coefficient ($f_2 = f_1$).

E_j is the correction for liquid junction potential because the liquid junction potentials in the two cells measured although nearly equal are not exactly so (Gerth makes an error in assuming them to be equal). The correction which must be applied is the potential between a pure potassium iodide solution and the same solution after a part of the iodide has been converted into the slower moving tri-iodide ion. It is computed by the

formula $E_j = RT/F \ln \Sigma C_A\Lambda_A/\Sigma C_B\Lambda_B$ where $\Sigma C_A\Lambda_A$ is the sum of the product of the concentration and the mobility of each of the ions in the pure potassium iodide solution and $\Sigma C_B\Lambda_B$ is the corresponding value for the solution containing free iodine. The addition of all of these potentials gives the effective electromotive force, E, of the cell Ag, AgI, I_2.

The results obtained with the tenth normal solution were still different from the results obtained with the twentieth normal solution. Therefore it seemed desirable to work with still more dilute solutions. Jones and Hartmann had made an attempt to do this but had abandoned it owing to the

fact that their cells containing dilute solutions had such a high resistance that their galvanometer was not sufficiently sensitive. This difficulty we have overcome by the invention of an improvement to the potentiometer system described above. In this work with more dilute solutions the iodine solutions containing dilute solutions from the equilibrator were measured directly against the silver–silver iodide electrode prepared by the method of Jones and Hartmann without using saturated iodine electrodes. The electromotive force, E_u, thus obtained is equivalent to $E_1 - E_2$ shown in the table above.

These experiments using unsaturated iodine solutions show a reduction in the osmotic work correction and liquid junction correction as compared with all previous work in this field. With saturated solutions the osmotic work correction is about 18 millivolts at 25° and 15 millivolts at 0°, whereas in some of the above experiments the osmotic work correction was reduced to 0.6 millivolt while the average of all at 25° was 2.04 millivolts and at 0°, 1.3 millivolts. These averages include some experiments in which the solutions were purposely made stronger in iodine than is necessary in order to detect a possible trend, but there is no evidence of such a trend. In Gerth's experiments the osmotic work correction was of about the same magnitude at 25° and from 5.1 to 5.6 millivolts at 11.5'. Gerth does not give data as to tri-iodide formation, so that it is impossible to check his calculations. The liquid junction potential has been reduced from about 3.0 millivolts with saturated solutions to less than one-tenth of this value in our unsaturated solutions but it is not negligible as is assumed by Gerth. A comparison of the results for the equilibrium constant, k, the electromotive force, *E*, and free energy, A, and its temperature coefficient, d*A*/d*T*, indicates that there is no systematic variation with the concentration in the range 0.05 to 0.01 N, but the data obtained with 0.1 N appear significantly different, thus indicating that higher polyiodides are present in sufficient amount to invalidate the results with the more concentrated solutions. In order to test this hypothesis and check still further the work of Fischer it was decided to work with *N*/3 KI also.

Cells of the type Ag, AgI, *N*/3 KI, *N*/3 KI + I_2 sat., Pt were prepared and the potential measured at 25 and 0°. Some of the *N*/3 solution was also used in the equilibrator with less iodine than required for saturation and the distribution constant determined at 25°. Unfortunately, the electromotive force measurements on these dilute solutions were lost owing to an accident and there was no time available to repeat them. The results are shown in Table V.

and tri-iodide ions in their common solution are identical. The data for the saturated solutions (except $N/3$ KI, which are from Table V) are taken from Bray and MacKay at 25° and Jones and Hartmann at 0°, recomputed on the above basis.

The solutions unsaturated with iodine show no evidence of a systematic trend in spite of a variation in iodine content from 2 to 34% of saturation and in KI concentration from 0.01 N to $N/3$; in view of the low concentration of free iodine in some of the solutions the concordance is satisfactory. It is more difficult to secure concordant results at 0° than at 25°, owing to the smaller vapor pressure of iodine, the weaker solutions used and the greater difficulty of maintaining temperature constancy over the longer periods required for the experiments. The equilibrium constant may be taken as 0.00140 at 25° and 0.00072 at 0°, but the solutions which are saturated with iodine show clearly a systematic decrease of the constant with increasing concentration which is clearly evident with the $N/3$ solution. The variation is greater at 25° than it is at 0°. These data emphasize the importance of working with dilute solutions of potassium iodide unsaturated with iodine when using iodine electrodes. The fact that there appears to be a greater tendency to form the more complex polyiodides at 25° than at 0° shows that when working with strong solutions saturated with iodine as Fischer did the error will have a temperature coefficient. The experimentally determined values for E, dE/dT, A, dA/dT and U for the reaction Ag + $^1/_2$ I_2 = AgI are summarized in Table VII.

The results with the $N/3$ solutions are not directly comparable with those obtained with the more dilute solutions because no experiments using the equilibrator and dilute solutions were completed with $N/3$ KI, but these data are comparable with Fischer's measurements. These data indicate that the results are unreliable in solutions 0.1 N or stronger, probably owing to the formation of polyiodides more complex than the tri-iodide or possibly a complex formed by action of potassium iodide on silver iodide, but that in solutions as dilute as 0.05 N and below no such disturbing effect is observed. We therefore believe that the new results obtained with dilute solutions unsaturated with iodine are the most reliable.

The results of the different experimenters on the entropy of the reaction $Ag + \frac{1}{2} I_2 = AgI$, are summarized in the following table, arranged in chronological order and also arranged to show the influence of the concentration of the potassium iodide on the results, except in the case of Gerke, who did not use potassium iodide at all.

If the specific heat measurements on silver, iodine and silver iodide determined by Nernst are reliable and the Nernst-Lindemann formula is used to extrapolate the data down to absolute zero, the value 2.19 calories per degree would be a confirmation of the Third Law.

It will be noticed that Fischer's temperature coefficients of the free energy vary greatly with the concentration but in no systematic manner. For the purpose of testing the Third Law, Fischer averages the results obtained with the $N/2$ and $N/3$ solutions and rejects the results obtained with the $N/10$—an objectionable procedure. Moreover, inadequate allowance for the influence of tri-iodides and higher polyiodides in these strong solutions saturated with iodine vitiates the results. Gerth's results come close to the figure 2.19 which, assuming the accuracy of the specific data obtained in the Nernst laboratory, would support the validity of the Third Law; but as has been pointed out in more detail above, Gerth's new method of surmounting the difficulties due to the formation of tri-iodides fails completely at 0°, and at other temperatures the manner of applying the correction varies considerably with the temperature, thus introducing an error into the temperature coefficient, dA/dT. Moreover, the vapor pressure of iodine is not known as a function of the temperature with sufficient accuracy for the purpose. Our new method of using the equilibrator is a considerable improvement over Gerth's method in principle and radically different in technique. It is equally usable at 0° and at 25° and permits working with solutions more dilute in iodine than Gerth's method. The work of Jones and Hartmann, although improved upon, is confirmed and the opinion that they expressed as to the greater reliability of the data obtained with dilute solution is confirmed.

Since the papers of Fischer and of Jones and Hartmann were published, new determinations of the specific heat of iodine at low temperatures have been published by Günther[18] and by Lange.[19] Günther's results agree substantially with the earlier results obtained by Nernst at temperatures above 30° absolute but differ considerably between 20 and 30° absolute. Günther has proved that there is a transition between two allotropic forms of iodine which occurs at some temperature between 20 and 30° absolute but this transition is a slow one and his data do not make it possible to determine the heat of transition, the specific heat of the form stable at the lower temperature, or the exact temperature of transition. Recently, the heat capacity of iodine has been redetermined by Lange within the range 10 to 52° absolute. He obtained lower results than Nernst, and Gunther.

Lange obtained no indication of the existence of a transition temperature between allotropic forms within this range but of course that does not disprove the existence of another form more stable at low temperatures. Lange combines his data at low temperatures with Nernst's at temperatures above 52° and gives a table from which the entropy of iodine at 25° may readily be computed to be 13.95 entropy units. If this is correct and if Nernst's data on silver and silver iodide are correct, then the value of the entropy change during the formation of silver iodide which would be predicted from the heat capacities by the Third Law is $26.6 - 13.95 - 10.25 = 2.6$ instead of 2.19 based on the measurements of Nernst. If Gunther's observations are correct, Lange was probably working with an unstable modification of iodine at the lower temperatures and unstable forms commonly have a higher heat capacity than the stable form. Moreover, Lange's work shows that the data of Nernst are too high in the lower range of temperature and makes it probable that they are too high in the upper range also. If this is correct the value 13.95 for the entropy of iodine may be too high and this would make the value 2.6 for the entropy of formation of silver iodide too low.

Therefore the value of 2.19 for the entropy of formation of silver iodide based on the specific heat of measurements of Nernst can no longer be regarded as having a sound experimental basis, and the fact that the electromotive force measurements of Fischer and Gerth, which are shown above to be faulty, agree with this figure cannot furnish proof of the validity of the Third Law of Thermodynamics. But a conclusion that the theorem is not valid cannot be drawn from the available evidence of this case because of the uncertainty as to the entropy of iodine. The essence of the theorem is that at absolute zero temperature the entropy of chemical reactions is zero and therefore the entropy at any other temperature is a

[19] F. Lange, *Z. physik. Chem.,* 110,352 (1924).

function of the specific heats alone. In the past decade evidence supporting the validity of the Third Law of Thermodynamics has accumulated, especially by the work of G. N. Lewis and his associates at the University of California and by the work of H. S. Taylor and his students at Princeton, but more extensive and reliable data on the heat capacities from absolute zero to room temperatures and on the heat effect of any changes of crystalline form that occur within this range of temperature are urgently needed to test this very important theoretical principle.

Summary

1. The earlier work on the free energy of formation of silver iodide is reviewed.

2. The equilibrium constant, $(I^- \times I_2)/I_3 = k$, of the reaction $I^- + I_2 \rightleftharpoons I_3$ was found to be 0.00140 at 25° and 0.00072 at 0°. The results show no systematic variation with the concentration of the iodine between the limits of 2 and 33% of saturation and no systematic variation with the concentration of the iodide between the limits 0.01 and 0.1 N. Solutions saturated with iodine give a lower value for the constant especially in the more concentrated solutions of iodide. This indicates that in the stronger solutions some higher polyiodides are formed.

3. A modification of the potentiometer by replacing the usual dead-beat galvanometer with a ballistic galvanometer and shunting an electrostatic condenser of high capacity across the galvanometer and its tapping key has made it possible to determine the potential of a cell having an internal resistance of 1,600,000 ohms within 0.02 millivolt. This invention overcomes the principal difficulty in the measurement of the potential of cells having the liquid junction within a ground glass joint.

4. Measurements have been made of the potential of iodide concentration cells with one electrode consisting of a platinum electrode dipping in a solution of potassium iodide saturated with iodine and the other electrode being similar except that it is unsaturated but with the free iodine activity fixed by the equilibrator.

5. Determinations were made of the solubility of iodine in $N/3$ potassium iodide solution at both 25 and 0°.

6. The free energy of formation of silver iodide has been determined by the aid of the equilibrator, using solutions containing much less iodine than is necessary to produce saturation so that disturbances due to the formation of polyiodides are minimized and can be allowed for by the use of the data supplied by the equilibrator. The results show no systematic variation with the concentration within the range 0.01 to 0.05 N, but do show a slight variation at the higher concentration.

7. The average results obtained with the most dilute solutions (0.01 to 0.05 N) are: free energy at 25°, 15,802 calories; free energy at 0°

15,680 calories; change in free energy per degree, or entropy change, 4.8; heat of formation at 25°, 14,354 calories.

8. The bearing of these data on some earlier attempts to verify the Third Law of Thermodynamics is discussed.

NOTE ON MEASUREMENTS OF THE RATE OF DECOMPOSITION OF NITROGEN PENTOXIDE AT VERY LOW PRESSURES[1]

BY ALBERT G. LOOMIS[2] AND DAVID F. SMITH[2]

RECEIVED MARCH 7, 1928 PUBLISHED JULY 6, 1928

Introduction

The decomposition of nitrogen pentoxide is one of the most interesting and most extensively studied of the few known unimolecular reactions. Data on the rate of its decomposition are of great importance to the advancement of our knowledge of the mechanism of chemical reaction.

Although the decomposition of nitrogen pentoxide has finally been shown to be strictly unimolecular over a considerable pressure range,[3] the measurements of Hirst and Rideal[4] would seem to indicate a quite unexpected increase in the specific rate of decomposition at very low pressures. These authors state that, after a critical consideration of their data, they are of the opinion that the increase is real and outside of the experimental uncertainty. Just preceding the presentation of our data, Hibben,[5] by a method similar to Hirst and Rideal's, the details of which are not given, fails to agree with Hirst and Rideal and concludes that the normal rate obtains down to very low pressures.

Since Hirst and Rideal's result is totally unexpected and requires a unique theoretical treatment,[6] it was thought advisable to repeat these measurements by the method which would avoid or at least detect the presence or absence of what seemed to us some objectionable features in Hirst and Rideal's experiments. Especially does this seem desirable since another investigator, using a method similar to Hirst and Rideal's, has obtained a totally different result.

The possible objections to Hirst and Rideal's method that occurred to us were the following. First, unless the apparatus were of proper design,

the condensation of a heavy gas in the presence of a noncondensable gas might be a relatively slow and incomplete process even at low pressure. Second, condensation of the heavy gas might involve a considerable amount of occlusion of the lighter gas. Third, adsorption effects, which would be inappreciable at high pressures, might at low pressures be relatively large compared to the total amount of gas present.

Experimental Method

The authors' apparatus and experimental procedure may be understood by reference to Pig. 1. The nitrogen pentoxide prepared in the usual way by dehydrating pure nitric acid with phosphorus pentoxide, was first distilled into a receiver (not shown in the figure) cooled by ice and salt. A small part of this, as needed, was distilled in a stream of dry ozone into the tube a, which was kept cold. The purified crystals in *a* were then pumped off at 0 and -20° by means of an oil pump connected through a liquid-air trap. They were then pumped off at -100° with a mercury diffusion pump. After the whole apparatus had been thoroughly baked and pumped out with the diffusion pump until a spark discharge gap showed perfectly dark (pressure $< 10^{-5}$ mm.), the tube a was brought to 0° and the pipet c kept at about 1° while the latter was filled with nitrogen pentoxide at its vapor pressure at 0" (50 mm.). The volume of the pipet c was such as to give the required pressure when its contents were admitted to the 5-liter flask g. The nitrogen pentoxide from the pipet was allowed to pass over and condense in the U-tube f, which was cooled by liquid air. After sufficient time had elapsed to allow complete condensation in the U-tube, the apparatus was evacuated again through the stopcock d while the tube was sealed off at e. At no time did the spark gap show the presence of any oxygen at this point.

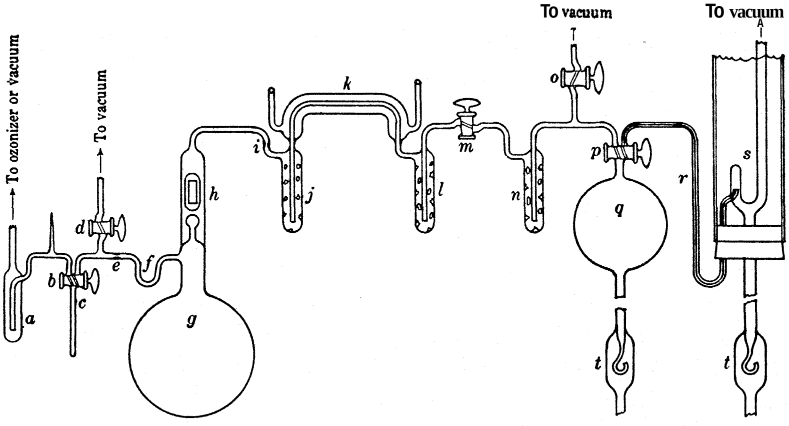

Fig. 1.—Diagram of apparatus.

The 5-liter flask g was provided with a thin glass bulb by means of which communication could be established with the rest of the apparatus by applying a magnet to raise and lower the piece of iron enclosed in a glass tube at *h*, thus breaking the thin bulb. The flask g, after removal of the liquid air from the U-tube, was placed in a thermostat at 30.00°, at which temperature nitrogen pentoxide decomposes at a convenient rate. During the time the decomposition of the nitrogen pentoxide was taking place, the flask was sealed onto the rest of the apparatus, and the connecting tubes were baked out and thoroughly evacuated with the diffusion pump. The small glass tubes *j*, *l* and *n* are filled with glass beads to serve as condensers; k is a jacket through which cold air could be passed to prevent decomposition of nitrogen pentoxide if it was desired to distil the nitrogen pentoxide back and forth between *j* and 1.

After an experiment the oxygen was pumped out of g by means of a large (2-liter) Toepler pump *q*, the heavy gases being retained in the liquid-air condensers *j* and *l*. The oxygen was delivered from the Toepler pump into the calibrated pipet *s* containing mercury and surrounded by a jacket filled with water at a uniform temperature. Pressures and volumes were measured in the pipet by means of a high-grade cathetometer. Air traps were provided, as at t, wherever there was danger that air might be carried into the apparatus by the mercury. Great care was taken to pump out thoroughly every part of the apparatus and to avoid subsequent entrance of traces of air. Points on the apparatus where seals were later to be made were always previously heated to the softening temperature and pumped off in order to avoid driving out gas from the glass during sealing.

After the flask g was pumped out, it could be sealed off at *i*. The total nitrogen pentoxide present was determined by closing the stopcock *m* and heating the condensers to decompose all the nitrogen pentoxide. The resulting oxygen was then pumped over into the pipet *s* as before, a third liquid-air trap at *n* assuring that no heavy gases escaped into the Toepler pump.

Adsorbed gas in g could be obtained by heating and further pumping. Occluded gas in the traps *j* and *l* could be obtained, after sealing off at *i*, by distilling the condensate back and forth between *j* and *l* and pumping off the gas so liberated.

Experimental Results

Experiment 1.—As a check on our method, an experiment was made first at moderate pressure. The oxygen from the decomposition that took place in seventy minutes at a temperature of 30.00° occupied a volume of 3.2909 cc. at a pressure of 104.22 mm and a temperature of 26.59°. The oxygen from complete decomposition had a pressure of 366.81 mm. at the same volume and temperature. The reaction rate constant for the decomposition of nitrogen pentoxide is thus calculated from these data to be $k = 4.7 \times 10^{-3}$. Calculated from the experiments of Daniels and Johnston, the constant at high pressures is 4.1×10^{-3}. We considered this agreement to be as close as could be expected. The original pressure of nitrogen pentoxide in the 5-liter flask in this experiment was thus about 0.25 mm.—the pressure below which Hirst and Rideal state that the constant begins to increase. The total oxygen obtained is roughly that which we expected from the amount of nitrogen pentoxide injected into the reaction flask.

Experiment 2.—An experiment was next made at a pressure which, judging from Hirst and Rideal's results, would be low enough to effect a marked increase in the rate of decomposition. Approximately 1.4 cc. of nitrogen pentoxide at a pressure of about 50 mm. was put into the reaction flask. The results are as follows: time of reaction at 30°, 105 min.; oxygen from reaction, 0.7580 cc. at $p = 12.90$ mm. and $t =$ 24.50"; oxygen from complete decomposition, 0.7580 cc. at $p = 17.99$ mm. and $t =$ 24.50°. From the oxygen recovered, the pressure in the reaction flask is calculated to be 0.0055 mm. The rate constant from these data is 12 X 10^{-3}, which would seem to confirm Hirst and Rideal's results. However, the amount of nitrogen pentoxide calculated from the oxygen recovered is but about 40% of that actually put into the apparatus. This fact suggested the existence of adsorption or occlusion effects.

Experiment 3.—Experiment 3 was designed to determine the extent to which the heavy gases condensed in the two liquid-air traps had occluded oxygen. Approximately 1.0 cc. of nitrogen pentoxide at 50 mm. was injected into the 5-liter reaction flask: time of reaction at 30°, 102 min.; oxygen from the decomposition taking place in this time, 0.4908 cc. at $p = 11.13$ mm. and $t =$ 26.33"; oxygen from complete decomposition of the nitrogen pentoxide, 0.4908 cc. at $p = 13.53$ mm. and $t =$ 26.33" (includes preceding amount of oxygen); oxygen after repeatedly redistilling and pumping condensate, 0.4908 cc. at $p = 16.73$ mm. and $t =$ 26.33" (includes both preceding amounts of oxygen). The oxygen occluded is thus about 24% of the oxygen which would otherwise be obtained. The total oxygen recovered would correspond to a pressure of nitrogen pentoxide in the 5-liter flask of 0.0033 mm. This is but 30% of the nitrogen pentoxide actually used.

Experiment 4.—An attempt was made to determine the amount of adsorption of nitrogen pentoxide in the 5-liter reaction flask. One cc. of nitrogen pentoxide at approximately 50 mm. was injected into the reaction flask. To show further that no nitrogen pentoxide had decomposed during its injection into the reaction flask, the apparatus was pumped out with the Toepler pump at this stage of the experiment, with the liquid air still in the U-tube f of Fig. 1. No oxygen was obtained. The liquid air was then removed from the U-tube, the apparatus having been provided with a stopcock at e in place of the seal at *h*. The flask was allowed to stand at room temperature for ten minutes. The stopcock was then opened to the liquid-air-cooled condensers *j* and *l* and the flask pumped out with the Toepler pump. The amount of oxygen obtained was 0.6100 cc. at $p = 6.00$ mm. and $t =$ 27.04'. (At this point the reaction flask was heated with a flame and pumped out several times.) The oxygen obtained, including the previous amount, was 0.6100 cc. at $p = 10.64$ mm. and $t =$ 27.04°. The stopcock at e was then closed and the remaining nitrogen pentoxide decomposed. The oxygen obtained, including both previous amounts, was 0.6100 cc. at $p = 16.41$ mm. and $t =$ 27.04'. The nitrogen pentoxide adsorbed in the 5-liter reaction flask was thus 25% of the total accounted for nitrogen pentoxide.

Experiment 5.—Although it was not thought that oxygen would be appreciably adsorbed on the glass in the presence of the heavier gases, an experiment was made to determine the magnitude of adsorption effects with pure oxygen. Accordingly about 1.5 cc. of oxygen at 40 mm. was injected into the 5-liter flask, provided with a stopcock as before. After a few minutes' standing at room temperature, the oxygen was pumped out with the Toepler pump. The amount of oxygen obtained was 0.7300 cc. at $p =$ 71.63 mm. and $t = 26.41°$. The additional amount of oxygen obtained by heating the 5-liter flask was $v = 0.7300$ cc. at $p = 2.54$ mm. and $t = 26.41°$. The stopcock at e was then closed, the liquid air was removed from the condensers *j* and *l*, and the condensers were heated with a flame while the adsorbed oxygen was pumped out. An additional amount of oxygen was obtained from the condensers of 0.7300 cc. at $p = 6.71$ mm. and $t = 26.41°$. The oxygen adsorptions might be still smaller in the presence of the heavier gases.

Experiment 6.—In order to furnish a more conclusive demonstration that surface effects were causing the discrepancy, an experiment was made in the same reaction flask in which had been placed, after careful cleaning and drying, about 24 meters of tubing (of Pyrex glass the same as that of the reaction flask) of 3 mm. internal and 5 mm. external diameter, cut into 3.5-cm. lengths. This tubing increased the ratio of surface to volume in the reaction flask from 0.28 to 1.52 or about 5.4-fold.

The nitrogen pentoxide injected into the flask was 1.4 cc. at about 50 mm. The oxygen obtained after seventy-four minutes' decomposition at 30.00" was 0.5217 cc. at $p = 1.55$ mm. and $t = 25.72$". The oxygen from complete decomposition of the nitrogen pentoxide caught in the condensers *j* and 1 was 0.5217 cc. at $p = 3.19$ mm. and t = 25.72" (including the previous amount of oxygen). The reaction velocity constant calculated directly from these data is 9 X 10^{-3}. The total oxygen recovered, however, corresponds to but 4.6% of the amount of nitrogen pentoxide injected into the reaction flask.

Discussion of the Results

Our data show that adsorption and occlusion effects involve a large fraction of the gas present at low pressures. It is likely that surface conditions changed during the course of the experiments and, since they were not well defined, the quantitative reproducibility of surface effects could not be expected. Experiment 6, however, aside from any quantitative data, conclusively shows the large part played by surface effects. Thus, with an increase of roughly 5-fold in the ratio of surface to volume, the amount of nitrogen pentoxide accounted for in our ordinary procedure was at most only about 15% of the usual recovery. We believe that the effect in this experiment is entirely outside of any possible experimental uncertainty.

Because of the conditions mentioned, we considered it inadvisable to attempt further work by this method on the reaction in glass apparatus at very low pressures. Some of the complications involved are the following: the reproduction of surface conditions and the necessary uniform treatment of the surfaces involved, in regard to heating and pumping off adsorbed gases, would be troublesome if not impossible; the measurement of oxygen adsorptions in the presence of nitrogen pentoxide at these temperatures could not well be accomplished; the amount of occlusion doubtless depends not only upon the quantities of gases present, but also on the rate of condensation of the heavy gas; the rate of decomposition of the nitrogen pentoxide which is attached to the walls of the apparatus is not known; and during the time taken to pump out the reaction flask the adsorbed nitrogen pentoxide would be decomposing and contributing an indeterminate amount of oxygen. We have therefore been content to demonstrate the existence of these effects without attempting to estimate quantitatively the true homogeneous rate of the reaction. However, although the application of corrections to the rate on the basis of our data is somewhat arbitrary, it seems likely that a reasonable account of these effects would tend toward giving about the normal rate of decomposition.

Although we do not know how different, if at all, these adsorption and occlusion effects were in the apparatus used by Hirst and Rideal and by Hibben, the presumption is that these effects were present to some degree in their experiments also. Results at these low pressures which do not take account of adsorption and occlusion effects when present we feel are fictitious, and we believe that the information previously obtained on the rate of decomposition of nitrogen pentoxide at very low pressures is open to serious question. Without knowing more of the details of the apparatus and procedure used by the other investigators, we are, of course unable to say in what way, if in any, their results may have been influenced by effects such as we found.

In the light of previous knowledge of adsorption phenomena, it is readily seen why adsorption does not appreciably affect experiments in which comparatively large quantities of gas are used. The nitrogen pentoxide adsorption is evidently that type which, at very low pressures, increases with increasing pressure only up to the point at which the surface becomes completely covered with adsorbed gas. Occlusion effects in any method involving condensation of the heavier gases might be appreciable, even at higher pressures; in fact, our first experiment seems to indicate this.

Summary

1. Objectionable features in previous methods for the study of the decomposition of nitrogen pentoxide at very low pressures have been painted out and the reaction has been studied by a new method.

2. At very low pressures the adsorption of nitrogen pentoxide on the walls of our Pyrex glass apparatus and the occlusion of oxygen as the heavier gases are condensed have been shown to involve a large fraction of the total amount of gas present.

3. It is believed that experiments formerly thought to indicate an increased rate of decomposition of nitrogen pentoxide at low pressures are open to serious question, and that any experiments by the method hitherto used would yield fictitious results when adsorption and occlusion effects are present and not taken into account.

THE PRODUCTS OF THE PHOTOCHEMICAL DECOMPOSITION OF HYDROGEN AZIDE

BY ARNOLD O. BECKMAN AND ROSCOE G. DICKINSON

RECEIVED APRIL 11, 1928 PUBLISHED JULY 6, 1928

Introduction

Since the first preparation of hydrogen azide by Curtius[1] in 1890, this substance and its salts have been the subject of many investigations. The anhydrous material[2] is a moderately volatile (b. p. 37°), colorless liquid. Although the anhydrous liquid is violently explosive, the vapor may be handled at somewhat reduced pressure without difficulty. Since the gas is colorless, visible radiation may be anticipated to be without photochemical effect. However, we have found the gas to be decomposed by ultraviolet radiation of a sufficiently short wave length; the present paper is concerned chiefly with an examination of the products of this decomposition.

We are indebted to Dr. Don M. Yost for his interest in this work. Financial assistance has been received from a grant made to Professor A. A. Noyes by the Carnegie Institution of Washington.

Preparation of Hydrogen Azide

Sodium azide, NaN_3, was purified by acidifying and distilling an aqueous solution of the salt. The aqueous distillate was just neutralized with carbonate free sodium hydroxide and evaporated to dryness.

Gaseous HN_3 was obtained[3] by dropping sulfuric acid (2 vols. concd. H_2SO_4, 1 vol. H_2O) on solid NaN_3. The HN_3 evolved was swept by a current of air (previously passed through a liquid air trap) through a long calcium chloride tube into a trap immersed in liquid air. The generating flask was then sealed off and the trap and a 1-liter storage bulb attached to it were evacuated. The liquid air was then removed, allowing the HN_3 to volatilize into the storage bulb; the HN_3 pressure was about 13 cm. of mercury.

Apparatus and Procedure

A diagram of the apparatus is shown in Fig. 1. The HN_3 was stored in the flask, A. With the aid of two stopcocks, B, small amounts of HN_3 were admitted to the vacuum system; the mercury cut-offs C and D were kept closed when this occurred. The HN_3 was frozen out by applying liquid air at E, and traces of non-condensable gas pumped off. Then with the cut-offs and the McLeod gage closed, the liquid air was removed from E and the gas illuminated in the quartz tube, F, which was joined to the glass apparatus through a graded seal.

The source of radiation was a condensed, high frequency spark between aluminum electrodes, located about 30 cm. from the tube, F. The electrical energy was supplied through a step-up transformer, the primary current being 50–100 amperes[4] at 220 volts,

[4] Such an intense source was not essential to the present experiments but was used because it was at hand for other purposes.

50 cycles per second. The secondary voltage was 13,000 volts. A 0.1 mf. condenser was shunted across the spark. The spark was blown out by a blast of air.

At the close of the illumination, liquid air was applied at E or G. The cut-off D was opened and readings were made with the McLeod gage and quartz fiber gage,[5] H. This gage was of the bifilar type[6] and was arranged with the magnetic starting device already described by one of us.[7] Liquid *air* was maintained at the U-tube, J, throughout the experiment. In some cases the condensable constituents were frozen out in one of the bulbs, G, which was then sealed off for analysis.

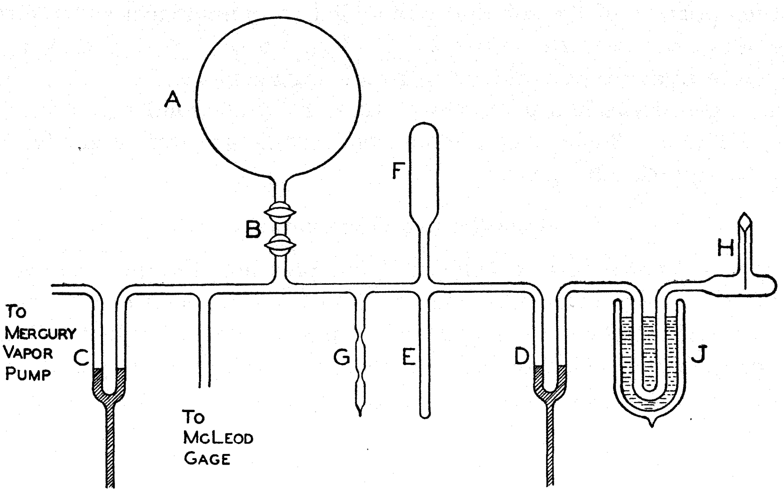

Fig. 1.

Qualitative Observations

It was found that brief illumination of gaseous HN_3 produced a gas non-condensable in liquid air. Somewhat longer illuminations, especially at higher HN_3 pressures (about 5 cm.), produced a white solid on the inside wall of the reaction bulb nearest the spark.

These effects were absent when the radiation was filtered through 5 mm. of 66% acetic acid in a quartz container. The acetic acid removed[8] radiation of wave lengths shorter than 2400 Å. Photographs of the absorption of gaseous HN_3 made with a quartz spectrograph showed that appreciable absorption set in at about 2200 Å. and increased toward shorter wave lengths. Accordingly, short wave length radiation was clearly necessary for the photochemical effects; the important radiation was probably the strong lines at 1854, 1862, 1935 and 1990 Å.

The white solid was volatile, subliming to a cooler portion of the tube when the tube was slightly warmed with a flame; when the tube was

evacuated the solid quickly disappeared. In one experiment, after some of the solid had been formed, the quartz tube, F, was cut off from the apparatus and a little of the solid removed for examination. The polarizing microscope showed the solid to be composed of small optically anisotropic crystals. The remaining solid quickly dissolved in a small amount of water added to the tube. The solution gave with Nessler's reagent the heavy, yellowish-brown precipitate characteristic of ammonia. Another portion of the solution was added to ammoniacal silver nitrate; there was no trace of a mirror or a coloration on heating, showing the absence of hydrazine or other strong reducing agent.

These properties and tests showed that the white solid was ammonium azide, NH_4N_3. Analyses of the non-condensable gas were made with the aid of the quartz fiber gage.

Quantitative Observations

It is well known that at sufficiently low pressures the quartz fiber gage can be used to measure the value of $\Sigma(p\sqrt{M})$, the sum of the products of the partial pressures of the separate components of the gas into the square roots of their molecular weights. Indeed, if τ is the time required for the amplitude of the vibrations to decrease by some definite fraction of its value,[5]

$$\frac{1}{\tau} = a\,\Sigma(p\sqrt{M}) + b \tag{1}$$

where a and b are apparatus constants.

Since, in the present case, the non-condensable gas can contain only nitrogen and hydrogen, we may write

$$\Sigma(p\sqrt{M}) = x(\Sigma p)\,\sqrt{M_{H_2}} + (1 - x)\,(\Sigma p)\,\sqrt{M_{N_2}} \tag{2}$$

where x is the mole fraction of hydrogen and M_{H_2} and M_{N_2} are the molecular weights of hydrogen and nitrogen, respectively. Solution of this equation for x gives[9]

$$x = \frac{\sqrt{M_{N_2}} - \dfrac{\Sigma(p\sqrt{M})}{\Sigma p}}{\sqrt{M_{N_2}} - \sqrt{M_{H_2}}}$$

Measurement of $\Sigma(p\sqrt{M})$ with the fiber gage, and of Σp with the McLeod gage then permits the calculation of x.

The gage was calibrated with air, nitrogen and hydrogen. The calibration plot of $1/\tau$ *vs.* $\Sigma(p\sqrt{M})$ was a straight line at pressures below 2×10^{-2} mm. When the products had higher pressures, a portion was confined (for example in the McLeod gage) and was expanded after the remainder had been pumped off. The gage was tested as an analytical instrument by making measurements of the mole fraction of hydrogen in

---

[9] Dickinson and Mitchell, Proc. Nat. *Acad.*, *12*, 694 (1926).

hydrogen–nitrogen mixtures made up to a known composition. The results of these tests are given in Table I.

TABLE I

ANALYSIS OF KNOWN MIXTURES OF HYDROGEN AND NITROGEN

Σp, mm.	$\Sigma(p\sqrt{M})$	x_{H_2}, by analysis	x_{H_2}, by synthesis	A
0.935×10^{-2}	4.60×10^{-2}	0.098	0.093	+0.005
.987	4.69	.139	.142	− .003
.625	2.82	.219	.218	+ .001
1.371	3.30	.746	.760	− .014

Analyses of the non-condensable gas resulting from illumination of HN_3 showed 10 to 15 mole per cent. of H_2. There are several possible ways in which H_2 and N_2 as well as NH_4N_3 might result: (1) decomposition of HN_3 into NH_4N_3 and N_2, and subsequent decomposition of NH_4N_3 (or NH_3) into N_2 and H_2; (2) decomposition of HN_3, giving simultaneously NH_4N_3, N_2 and H_2; (3) decomposition of HN_3 into N_2 and H_2 and subsequent formation of NH_3 (as, for example, by $H_2 + HN_3$ (activated) $= NH_3 + N_2$). Experiments in which sufficiently little decomposition is allowed to take place should in case (1) lead to $x_{H_2} \cong 0$, in case (3) to $x_{H_2} \cong 0.25$ and to intermediate values in case (2).

A series of exposures was made in which the time of illumination and the pressure of HN_3 were chosen to give amounts of products covering a wide range. The results are given in Table II.

TABLE II

DEPENDENCE OF COMPOSITION OF PRODUCTS ON EXTENT OF DECOMPOSITION

p_{HN_3}, mm.	Time, sec.	$p_{H_2+N_2}$, mm.	x_{H_2}
1.5	25	3.21×10^{-2}	0.091
12	7	5.37	.098
12	10	6.42	.091
29	56	32.1	.112
16	90	54.6	.147
7.5	240	62.0	.136
18	90	64.9	.153

Although the amount of non-condensable products was varied 20-fold, there appears to be no tendency for x_{H_2} to approach either 0 or 0.25 at zero decomposition. It is concluded, therefore, that the formation of N_2 and H_2 and of NH_4N_3 occurs simultaneously (case (2)). Since the mole fraction of H_2 is increased somewhat by prolongation of exposure, it appears that subsequent decomposition of NH_4N_3 or NH_3 occurs. NH_3 is known[10] to be photochemically decomposed by radiations of the wave lengths 2025–2139 Å.

Since, in the decomposition products, the total number of gram atoms of nitrogen must be three times the total number of gram atoms of hy-

---

[10] Warburg, *Sitzb. preuss. Akad. Wiss.*, **1912**, p. 216.

drogen, the amount of ammonia in the products can be predicted from the amounts of nitrogen and hydrogen if no other products are formed. The number of moles of ammonia expected to be finally present can be easily shown to be given by

$$N_{NH_3} = \frac{pv}{4\,RT}(1 - 4x_{H_2})$$

where p, v and T are the total pressure, volume and temperature of the nitrogen–hydrogen mixture. A determination of the amount of ammonia formed was made at the end of each of three illuminations. For this purpose the liquid air was applied, not at E but at the end of the chain of bulbs, G, the last of which was then sealed off. This bulb was dipped in liquid air and its tip then broken under ammonia free water, the water rushing in and filling the bulb. By then breaking the tip at the other end of the bulb, the contents were transferred to a 2cc. colorimeter tube containing 1 cc. of Nessler's reagent. The same amount of Nessler's reagent was added to each of two other colorimeter tubes and these were made up with measured amounts of **0.000474** M NH_4Cl solution to colors which approximated and bracketed the color of the unknown. The results are given in Table III.

TABLE III

COMPARISON OF AMOUNTS OF NH_3 EXPECTED AND FOUND

$p_{H_2} + p_{N_2}$ (mm. Hg)	v, cc.	x_{H_2}	NH_4Cl soln., cc.	N_{NH_3} calcd. micromoles	N_{NH_3} found, micromoles
0.0617	476.5	0.1122	0.511	0.219	0.242
.1054	478	.1532	.666	.317	.315
.1214	480	.1365	.740	.358	.351

The number of moles of NH3 calculated from the composition of the non-condensable gas and the number found by colorimetric analysis agree well within the error of the latter determination; hence it appears unlikely that any products other than H_2, N_2 and NH_3 are iormed in considerable amount. The mole fraction of hydrogen, 0.09, in the non-condensable gas initially produced (Table II) corresponds stoichiometrically to **73%** decomposition of the HN_3 into NH_3 and N_2 and 27% into H_2 and N_2.

The Molecular Weight of Hydrogen Azide

In the literature, the conclusion that hydrogen azide vapor consists of unassociated HN_3 molecules appears to be based upon a single vapor density determination by the Victor Meyer method at the boiling point of chloroform.[3] In extension of this result, we have made several molecular weight determinations by means of the quartz fiber[11] and McLeod gages.

---

[11] **A new fiber gage was used in these measurements. It differed from the first only in having a** *single* **flat fiber** *4* **cm. long and was found entirely satisfactory. A single fiber with elliptical cross section has been used by Coehn and Jung,** *Z. physik. Chem., 110,* **709 (1924).**

The hydrogen azide was admitted in the usual manner. It was then pumped down to a pressure of about 0.02 mm. The trap, J, was packed in ice and readings of the two gages were made. From the value $\Sigma(p\sqrt{M})$ obtained from the fiber gage was subtracted 0.0030 mm. corresponding to the $p\sqrt{M}$ of the mercury vapor present. The remainder, divided by the pressure, as read on the McLeod gage, gave $\sqrt{M}$. The results are given in Table IV.

TABLE IV

MOLECULAR WEIGHT OB GASEOUS HN_3

p (mm. X 10^2) (McLeod)	$\Sigma(p\sqrt{M}) \times 10^2$ (Quartz fiber)	M	Dev. from av.
2.26	15.46	44.9	1.3
2.00	12.90	39.7	3.9
1.47	9.96	43.3	0.3
1.24	8.75	46.5	2.9
		Av. 43 6	2.1

Summary

Gaseous hydrogen azide has been found to be decomposed by ultraviolet radiation from an aluminum spark, giving hydrogen, nitrogen and ammonia (ammonium azide). These products are formed by concurrent reactions; on brief illumination 27% of the decomposition gives H_2 and N_2 and 73% gives NH3 and N_2.

By means of the quartz fiber and McLeod gages, the molecular weight of hydrogen azide has been determined as 43.6 ± 2.1.

PASADENA, CALIBORNIA

THE SPECIFIC HEATS AT LOW TEMPERATURES OF MANGANOUS OXIDE, MANGANOUS-MANGANIC OXIDE AND MANGANESE DIOXIDE[1]

BY RUSSELL W. MILLAR[2]

RECEIVED APRIL 13, 1928 PUBLISHED JULY 6, 1928

The present article is one of a series from this Laboratory dealing with the thermodynamic properties of the oxides of metals which are important in metallurgical processes. Preceding articles have dealt with zinc oxide,[3] but it is now proposed to extend the investigations to many other oxides, as well as to several sulfides.

The specific heats of the oxides of manganese so far determined have been confined, with the exception of those of Russell[4] at low temperatures,

MnO_2	−187–78.0	8.50	Russell
MnO_2	−78.2–0	12.23	Russell
MnO_2	2 448.3	14.27	Russell
MnO_2	1748	13.8	Kopp

The method of the present investigation was that originally used by Eucken[7] in Nernst's laboratory, and has since been adopted by almost all investigators in this field.

The apparatus differed but little from that of Gibson and Giauque,[8] who improved considerably on the original design. Changes, however, were made, some of which have been described by Giauque, Buffington and Schulze.[9] The vacuum jacket, 10 by 25 cm. in size, was of brass tubing with walls 3 mm. thick. The cover, which was of brass 13 mm. thick, was soldered onto the jacket. The heavy protecting shield was of lead poured between concentric copper tubes. The wall of the outer tube was made 6 mm. thick, in order to distribute rapidly the heat generated in a coil of constantan wire wound in grooves on the outer surface. A copper sheath protected the shield from radiation. The protecting shield, with its cover, weighed 8 kilograms.

The cover of the shield, of 2.5cm. copper sheet, was secured by machine screws. In it were Bakelite conduits through which passed the wires leading to the calorimeter. Each wire, before passing through the cover, was soldered to one end of a strip of thin copper clamped by a screw to the cover but insulated from it by very thin mica. Beat passing down the wire thus found its way to the shield of high heat capacity instead of to the calorimeter.

The calorimeter, of copper tubing 3.7 by 13 cm., was wound with about 260 feet of No. 40 B. & S. gage double silk covered copper wire, which served as both thermometer and heating coil. Additional insulation and thermal contact were obtained with Bakelite varnish. The calorimeter was protected from radiation by a sheath of copper, 0.025 mm. in thickness, which was stuck on by Bakelite varnish. Rapid distribution of heat was obtained by means of sheets of 0.13mm. copper, parallel to each other and to the axis of the calorimeter, which were soldered at their edges to the inner wall. Since these sheets were spaced at 3 mm. and the voids between the particles of the sample were filled with hydrogen, the distribution of heat was so rapid that thermal equilibrium was obtained in three to ten minutes. The volume of the calorimeter was 130 cc., the weight, 115g.

With respect to the vacuum system and the electrical wiring, the apparatus was similar to that of Gibson and Giauque. Electrical measurements were made with a White double potentiometer and time measurements with an accurately calibrated stop watch.

The copper resistance thermometer was calibrated during the specific heat determinations for each substance by means of a single junction copper–constantan thermocouple soldered to the bottom of the calorimeter. This thermocouple was made of wire

from the same spool as thermocouple No. 17 of Giauque, Buffington and Schulze.[9] This thermocouple was compared with No. 17 through a secondary standard, and No. 17 was itself compared by Giauque, Buffington and Schulze with the hydrogen gas thermometer, and with the hydrogen and oxygen vapor pressure thermometers by Giauque, Johnston and Kelley.[10]

The correction for the exchange of heat between the calorimeter and its surroundings was made by the assumption of Newton's law of cooling. The small correction for the difference in temperature between the thermometer wire and the average temperature of the calorimeter described by Giauque and Wiebe[11] was calculated and applied. At room temperature this correction often amounts to as much as 1% and occasionally 2%, but at liquid air temperatures only about 0.1% correction is necessary on this account. The effect of the correction is to lower the calculated value of the specific heat.

Materials.—Manganous–manganic oxide was prepared by igniting a good grade of C. P. manganous sulfate in platinum at 1100°. The sample was heated for a week, pulverized and heated again as before. It was then heated in a current of gaseous hydrochloric acid according to St. Clair-Deville;[12] nitrogen was passed over the hot crystals for three hours to displace the hydrochloric acid, and the product was cooled. The product was finely crystalline. The preparation showed 1.006 times the oxidizing power of pure manganous–manganic oxide toward oxalic acid. Although Meyer and Rötgers[13] state that oxidation of manganous–manganic oxide prepared by the ignition of manganese dioxide does not occur in air, possibly under the conditions of the present test this particular sample combined with the small amount of oxygen in the nitrogen.

Manganous oxide was prepared by reduction of amorphous manganous–manganic oxide by hydrogen and crystallization by gaseous hydrochloric acid. A finely crystalline, bright green product resulted. This product showed no oxidizing power toward oxalic acid but the total manganese determined by oxidation to manganese dioxide with standard potassium permanganate corresponded to only 99.0% manganous oxide. Correction was made in the specific heats for the impurity, which consisted of small flakes of silica from the wall of the preparation flask.

Manganese dioxide was prepared by heating the nitrate at 170° until the evolution of the oxides of nitrogen had ceased. The product was 99.6% manganese dioxide.

The results are given in Tables II–V.

[a] **Run No.** 26. **Heat absorption between** 87.743°K. **and** 98.437°K. = 76.35 **cal./mole.**

The figure accompanying this text displays the results for all three oxides. Table III shows the heat input for the points which fall on the steep slopes of the specific heat curve for manganous oxide, and the initial and final temperatures. Obviously the curve rises so rapidly that the recorded heat capacities at the average temperatures are not valid and cannot be plotted; in the figure they are used only to indicate the course of the curve.

No reason can be given for the discontinuities in the curves for manganous oxide and manganese dioxide. Although it might be suspected that the maximum in the curve for manganese dioxide was due to an impurity of the manganous oxide, this could not have been true, since Meyer and Rötgers[13] found that manganese dioxide was stable in air at 530°, and the sample used here was heated only to 170°. Furthermore, manganous–manganic oxide is certainly stable at 1100°, and the curve for this substance showed no discontinuity in the temperature range of the experiments.

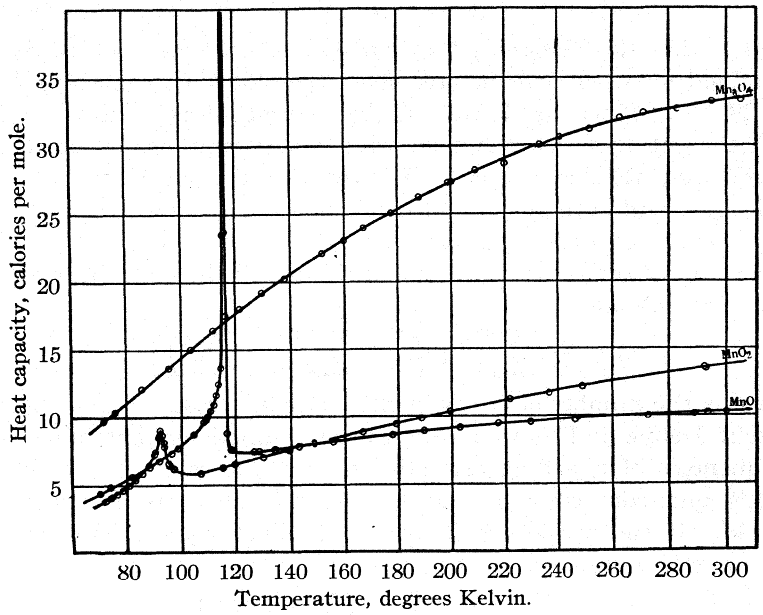

Fig. 1.—The molal heat capacities of MnO, Mn_3O_4 and MnO_2.

Attention should be called to the fact that points on the steep portions of the curves for manganous oxide and manganese dioxide are perfectly reproducible and that the specific heats in the regions of the discontinuities are independent of the history of the substance. Thus, in Table II we note that a continuous series of runs extended from 70.4°K. to 134.5°K., and that the sample was cooled to about 116°K., where two runs were made. The sample was then allowed to come to room temperature, cooled to 92°K. and a continuous series of runs was made from that temperature to room temperature. An examination of Table V shows that the sample was cooled to liquid air temperatures three times—for runs 1, 14 and 30—but that the points obtained near 97°K. fall on the same smooth curve independently of the history of the substance.

Ewald[14] found that ammonium chloride had a higher specific heat between −80 and 0° than between 0 and 50°, but dilatometric measurements in the lower range failed to reveal a volume change. Simon[15] has measured the true specific heat of this salt and found at 242.6°K. a change greatly resembling that of manganous oxide. Parks and Kelley[16] measured the heat effect for a similar change in magnetite at 115°K. Measurements in this Laboratory, soon to be published, show the curve for magnetite to be similar to that of manganous oxide.

In order to calculate the entropy at 298°K., it is necessary to integrate graphically the equation

$$\int \mathrm{d}S = \int C_p \, \mathrm{d} \ln T$$

from 0 to 298°K. Assuming the third law of thermodynamics, $S_0 = 0$, it remained for us to find the area under the plot of C_p against ln T from 0 to 298°K. Since the lowest of the present measurements is about 70°K., the extrapolation was made with the assumption that at very low temperatures, that is, about 30°K., the equation of Debye gives the specific heat and entropy. In all that follows, the teferences are to plots of log T as abscissa and C_p as ordinate.

According to the theory of Born and Kármán,[17] the molal heat capacity at constant volume

$$C_v = \frac{1}{3P}\left[\sum_1^3 D\left(\frac{\beta v_i}{T}\right) + \sum_{j=1}^{3(p-1)} E\left(\frac{\beta v_j}{T}\right)\right] \qquad (1)$$

where p is the number of atoms in the molecule, $D(\beta v_i/T)$ and $E(\beta v_j/T)$ represent Debye and Einstein heat capacity functions containing values of frequencies of v_i and v_j, respectively; β is the ratio h/k, where h is Planck's quantum constant and k is Boltzmann's gas constant for 1 molecule. If the frequencies in the three directions are assumed to be the same, the equation reduces to

$$C_v = \frac{1}{p}\left[D\left(\frac{\beta v}{T}\right) + \sum_{j=1}^{p-1} E\left(\frac{\beta v_j}{T}\right)\right] \qquad (2)$$

These equations may be expected to hold only at low temperatures; for the substances for which data are shown here, Equation 2 holds only to about 150°K., and it is not expected that Equation 1 will hold at temperatures much higher. No attempts were made to use Equation 1. At very low temperatures the Einstein terms disappear and the heat capacity is represented solely by the Debye terms.

---

[14] Ewald, Ann. *Physik,* [4] 44, 1213 (1914).

[15] Simon, *ibid.,* [4] 68, 241 (1922).

[16] Parks and Kelley, *J. Phys. Chem.,* 30, 47 (1926).

[17] Born and Kármán, *Physik. Z.,* 13, 297 (1912); 14, 15, 65 (1913); Born, "Dynamik der Kristallgitter," Teubner, Leipzig and Berlin, 1915.

According to Equation 2 the heat capacity per mole of manganous oxide should be represented by the sum of one Debye and one Einstein function. It was found that the experimental curve (C_p – log T coördinates), extending down to only 70.4°K., could be extrapolated to meet, without an abrupt change of direction, the Debye function of frequency $\beta v = 231$. A curve was then drawn representing the probable course of the curve without discontinuity, and the differences between this curve and the Debye function were plotted. As high as 178°K. these differences could be represented, within the accuracy of the experimental data, by an Einstein function of frequency $\beta v = 502$. Above 178°K. the differences fell below the Einstein curve, instead of above it, as we should expect, since C_p and not C_v was measured. In reality, the values of C_v, if the necessary data for the calculation from C_p were available, would probably not fit the theoretical curves above 150°K.

The entropy at 35.48°K., as given by the Debye function, is 0.514. The area under the curve and its extrapolation to 35.48°K. between this temperature and 298°K. amounts to 14.406. We have, for MnO, $S_{298} = 14.92$ cal./deg.

For manganous–manganic oxide we should have $C_v = D(\beta v_i/T) + 6E(\beta v_j/T)$, where v_j may have the same or different values for the six terms. It was found convenient, however, to represent the data by three Debye and four Einstein functions, using values of $\beta v = 278$ and 611, respectively. The agreement with the data was excellent up to 158°K., and with true values of C_v probably up to 140°K. The Debye entropy below 31.62°K. is 0.704, and the remainder below 298°K. is 35.022. We have for Mn_3O_4, $S_{298} = 35.73$ cal./deg.

For manganese dioxide one Debye function with $\beta v = 268$ and two Einstein functions with $\beta v = 653$ fit the data to 140°K. The Debye entropy below 31.62°K. is 0.257 and the remainder below 298°K. is 13.677. For MnO_2, $S_{298} = 13.93$ cal./deg.

In each extrapolation it was found that even though the Debye curve were shifted along the axis of abscissas to positions so unreasonable that sharp breaks were necessary to join it with the experimental curve, such shifting of the Debye curve did not change the entropy at 298°K. more than 0.1 unit. Simon[15] has shown that it is possible, in fitting theoretical curves to the experimental data on complicated substances, to obtain satisfactory combinations other than those demanded by the Born-Kármán theory, and even to fit the values of C_p rather than those of C_v.

The free energies were calculated from the equation

$$AF = AH - TAS$$

where AF is the change in free energy in forming the oxide from its elements, AH the heat of formation and AS the change in entropy, all at the temperature T.

In order to calculate the entropy of formation, the entropy of oxygen at 298°K. must be known. The calculations of Lewis, Gibson and Latimer[18] give for O_2, $S_{298} = 48.0$ as the weighted mean of 3 values—namely, from Eucken's[19] specific heats and heats of transition of the several forms of oxygen and the third law of thermodynamics, they give Lewis and Gibson's[20] calculation of O_2, $S_{298} = 48.23$; from the data for the reaction $C_G + {}^1/_2O_2 = CO$, they give for O_2, $S_{298} = 45.6$; from the entropy of mercuric oxide and mercury and the entropy change in the formation of mercuric oxide from its elements, they give for O_2, $S_{298} = 49.2$.

Giauque and Johnston,[21] who have recently repeated very accurately the work of Eucken on oxygen, have given 40.8 as a preliminary value of the entropy per mole of oxygen at its boiling point. Millar and Sullivan[22] have calculated, from the data of Scheel and Heuse,[23] the increase in entropy of gaseous oxygen at 1 atm., when heated from the boiling point to 298°K., to be 8.36. The sum, 49.16, agrees almost exactly with the result of Lewis, Gibson and Latimer obtained from the entropy change of the reaction $Hg + {}^1/_2O_2 = HgO$. The value chosen for O_2 is $S_{298} = 49.2$.

The entropy of manganese, $S_{298} = 7.3$, is taken from Lewis and Gibson.[20]

The heats of formation of these oxides have been determined by both Berthelot[24] and LeChatelier[25] with much better agreement than is usual with data of this kind. For manganous oxide Berthelot gives 90,900 cal.; LeChatelier, 90,800. For manganous–manganic oxide both give 328,000, while Ruff and Gersten[26] give 329,000 ± 740. For manganese dioxide Berthelot gives 125,300 and LeChatelier 126,000, while Mixter[27] gives 119,600 cal., but he states that this value is only an approximation, and that LeChatelier, who used pure natural pyrolusite, probably gives a more accurate value for crystalline manganese dioxide. Although the manganese dioxide used in the present investigation was similar to that used by Mixter, Berthelot's value will be used because of errors in Mixter's work which he himself points out.

Table VI exhibits the data used and the resulting values of the free energy of formation of the oxides.

It is hoped that the specific heats necessary to extend these calculations of the free energies of formation to high temperatures will some day be available.

Summary

The specific heats of manganous and manganous–manganic oxides and of manganese dioxide have been measured from 70 to 300°K.

With the aid of the third law of thermodynamics, the free energies of these substances at 298° K. have been calculated.

THE DIELECTRIC POLARIZATION OF LIQUIDS. III. THE POLARIZATION OF THE ISOMERS OF HEPTANE

BY C. P. SMYTH AND W. N. STOOPS

RECEIVED APRIL 14, 1928 PUBLISHED JULY 6, 1928

Accurate measurements of the dielectric constants of methane, ethane and hexane over a wide range of temperature[1] have made it possible to calculate that the molecules of these substances have no electric moments and calculations made by an approximate method have also indicated the, absence of an electric doublet in the molecules of octane and decane.[2] This is in accord with the fact that, according to calculations from molecular structure,[2] it should be possible to replace a hydrogen atom attached to a carbon atom by a methyl group without altering the electric symmetry of the molecule unless the bulk of the methyl group causes distortion of the structure or unless the methyl group itself is distorted due to small shifts of electrons in the field of a doublet already present. Since, with the exception of methane which, as the first member of the series, might be expected to be abnormal, all of the hydrocarbons studied had contained an even number of carbon atoms, it seemed desirable to investigate an odd member of the series, which, of course, would contain an even number of C–C bonds. Measurements made upon pure samples of all of the isomers of heptane very kindly loaned to us by Dr. Graham Edgar of the Ethyl Gasoline Corporation have made it possible to determine the electric symmetry of nine different arrangements of six C–C bonds. An octane, 2,2,4-trimethylpentane, loaned by Dr. Edgar, has also been studied.

[2] Smyth, THIS JOURNAL, 46,2151 (1924).

In the first of this series of papers[3] the method of obtaining the electric moment of the molecule of a substance has been discussed. The molar polarization of a substance, $P = (\epsilon-1)/(\epsilon + 2) \times M/d = P_E + P_A + P_M$, in which ϵ = the dielectric constant, M = the molecular weight, d = the density, $P_E + P_A$ = the polarization due to shifts of charges in the molecule inducible by an external field and P_M = the polarization due to the orientation of the permanent electric doublets of the molecules. When P_M is 0, the moment of the molecule must be 0. P_E may be calculated as the molar refraction for light of infinite wave length, MR, = $(1-\lambda_0^2/\lambda^2)[(n^2-1)/(n^2 + 2) \times M/d]$, where n is the index of refraction for light of wave length λ and λ_0 is the wave length corresponding to a characteristic vibration frequency in the ultraviolet region. P_A, the difference between P_E, the polarization due to electronic shifts, and the total induced polarization, is commonly attributed to induced shifts of atoms or radicals.

The refractive indices were measured by Mr. E. W. Engel with the assistance of one of the writers. A Pulfrich refractometer was used and accurate temperature control was obtained by a flow of water from carefully regulated thermostats. A complete series of measurements was made for the sodium D line. A month later, after readjustment of the instrument and installation of a new prism, measurements were made again for the D line and also for the α, β and γ hydrogen lines. The new values for the D line showed an average difference from the old values of only 0.00009, the sign of the difference being disregarded. The molar refractions for the different wave lengths are given in Table I, with the refractive[4] indices. These molar refractions were used to calculate the values of MR_∞, given in Table IV as P_E, by the substitution of the corresponding values of MR and X. As four equations were thus obtained for each substance and only two were necessary in order to solve for MR,, a test of the equation and the data was made by calculating MR, first from MR, and MR, and then from MR_β and MR_D. Although this method of combining the values is the one best calculated to make any error apparent, the greatest difference found between the values obtained from the two pairs of refractions was 0.02. The dispersions calculated from these data are given in Table IV.

The densities and dielectric constants were measured with the apparatus described in the first two papers of this series,[1c,3] the dielectric constant of the benzene used in calibrating the condenser being taken as 2.279 at 25°. Measurements were made upon three heptanes of markedly different structure and upon the octane, 2,2,4-trimethylpentane, over the entire range of temperature within which they were liquid. The dielectric constants were measured at intervals of about 15° and the densities at intervals of about 20°. As the temperatures were not the same for different

larization calculated from them, are given in Tables II and III. Since the three heptanes and the octane showed similarity of behavior in their slight variation of the polarization with temperature as represented in Fig. 1, the other heptanes were measured only at 20 and 30". For the sake of comparison, Table IV gives for each of the heptanes and for the 2,2,4-trimethylpentane at 20°, the dielectric constant, the temperature coefficient of the dielectric constant calculated from the values at 20° and 30°, the density, the molar polarization, P, and the molar refraction for light of infinite wave length = P_E. The values of P_A are calculated as $P-P_E$, which will be discussed later. The densities of all the heptanes at 20 and 30° have been determined by Dr. Graham Edgar. As the values which we have obtained at these temperatures are in excellent agreement with those of Dr. Edgar, we have used his values for four of the substances as indicated. The viscosities in c.g.s. units at 20°, measured by Mr. H. E. Rogers with a Bingham viscometer, as well as the dispersions calculated from the data in Table I, are included.

In Fig. 1 the scale on which the polarization is plotted against temperature is so large that many of the points appear to lie some distance from the straight lines which best represent them. Actually, the polarization of these substances varies little with temperature, but the variation, such as it is, is an approximately linear increase with increasing temperature, while, if the molecules possessed electric moments, the polarization would normally decrease with rising temperature. The increase, less than 2% for a 200° change of temperature, is not predicted by the theory of dielectric constants. As a small increase in refraction with rising temperature has been observed for a number of liquids, while vaporization also appears to bring about a slight increase in refraction,[4] it seems possible that the force fields of adjacent molecules reduce the mobilities of the bound electrons to a small extent, thereby reducing the refraction. As the molecular separation and motion increase with rising temperature, the effect of the force fields upon the electrons is decreased, the refraction, and hence the

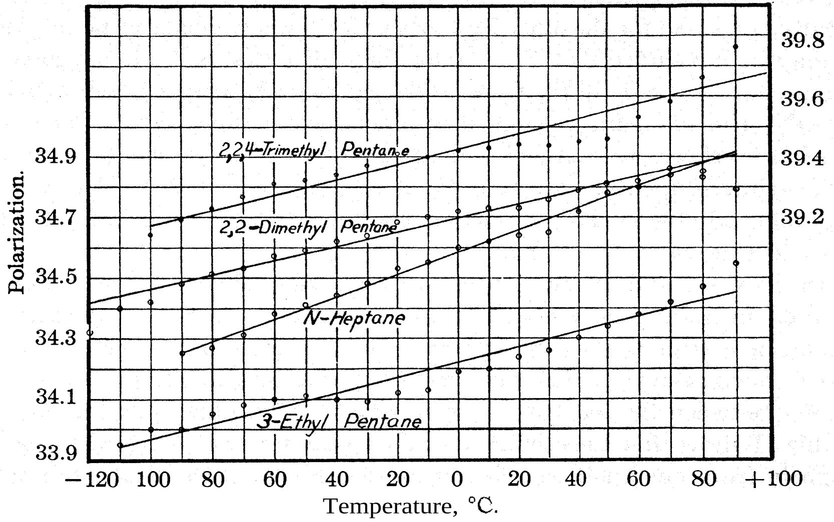

Fig. 1.—Variation of polarization with temperature. The values for the polarization of 2,2,4-trimethylpentane are shown at the right.

[4] (a) Eisenlohr, "Spektrochemie organischer Verbindungen," F. Enke, Stuttgart, 1912, p. 19; (b) Lorenz, *Ann. Physik*, 11, 70 (1880); (c) Brühl, *Z. physik. Chem.*, 7, 1 (1891).

polarization, thus being increased. Another and perhaps more important factor is the increase in the number of degrees of freedom with increasing temperature, which should facilitate the displacement of charges in the molecules and, hence, increase the polarization. As change of temperature alters the degree of molecular association or orientation, which has a great effect upon the polarization, the small effects just described may often be so masked as not to be apparent. Hexane, benzene and a few other substances which have electrically symmetrical molecules also show a slight increase in polarization with rising temperature.[1c,5]

The curves in Fig. 1 may be regarded as establishing the absence of any measurable electric moment in the molecules of the four substances represented. Consequently, $P_M = 0$ and $P_A = P-P_E$. As $P-P_E$ is practically the same for the other heptanes as for these which have no moment, it may be concluded that $P_M = 0$ for them also, that is, that they have no moments. Indeed, if P_A were neglected entirely and P_M set equal to $P-P_E$, the moments calculated would be exceedingly small. The conclusion is, therefore, justified that the moments of all the heptanes and of 2,2,4-trimethylpentane are zero or, at least, too small to be detected by any method now available, which, of course, is all that can be said as to the electric symmetry of any molecule.

In Tables I and IV the isomers are arranged in the order in which many of their properties have been found by Edgar and Calingaert[6] to fall. As would be expected, the dielectric constants, densities and refractive indices vary concomitantly. The temperature coefficients of the dielectric constants between 20 and 30° are approximately the same, but the data of Table II show that the coefficients over a wide range of temperature differ slightly from one another. The viscosities show a much greater variation in values than do any of the other properties listed and the first five in the list depart markedly from the regular order observed, at least approximately, for the other properties. The values of the dispersion, $n_\gamma - n_\alpha$, are approximately the same for all the heptanes, a marked rise being apparent on passing to the octane. The values of the molar dispersion, $MR_\gamma - MR_\alpha$, vary little, if any, more than might be caused by experimental error, but there appears to be a slight decrease in going down the list. A slight and irregular decrease is also apparent in going down the column of P_A values for the heptanes. The absolute variation in the values of P_A is much less than that in the values of P and P_E, which fall approximately in the usual order and vary concomitantly. As the refraction and polarization depend upon the mobility of the outer electrons of the molecule, the small but concomitant variations of P and P_E show that variation in the positions of the atoms in the molecules has a detectable effect

---

[6] Private communication to the authors.

upon the mobilities of the binding electrons, the average mobility decreasing slightly in the order indicated by the decreasing values of P and P_E.

The conclusion to be drawn from these results, taken in conjunction with the work on other hydrocarbons, is that the atoms in a saturated hydrocarbon molecule may be joined together in every possible configuration without giving rise to any measurable lack of electric symmetry. This has a very definite bearing upon the electronic theories of valence in organic compounds, for the heptane molecules may be resolved into the various alkyl radicals to which it is customary to assign varying degrees of electronegativity, the formulas of the radicals being represented with a pair of bonding electrons at varying distances from their carbon atom.[7] If such a variation is an inherent property of the radicals, it should exist when the radicals occur in the heptane molecules and give rise to electric moments of varying sizes and, hence, to different values of P_M. It has been concluded that P_M differs from zero by a negligible amount. If it is not actually zero, any variation in its value must be included in that of P_A as calculated. The largest difference observed between the values of P_A for any two isomers, namely, that of 0.20 between 2,4-dimethylpentane and 3-ethylpentane, would, if due to but one pair of electrons, correspond to a displacement of the effective position of the charges of less than 3×10^{-11} cm. from a symmetrical location. It seems improbable that such a displacement and the very small change in forces which it must cause would have an appreciable effect upon the properties of the molecule. It must be further remembered that the possible displacement which has been estimated is the greatest that could occur and is probably much larger than any actually existing in these molecules. This does not preclude the possibility that the bonding electron pairs of different alkyl groups may be differently affected when they hold more polar groups in combination, but the relatively small variation in the electric moment of the molecule among the different alcohols and among the members of other series provides strong evidence[8] against the assumption of any considerable variation in the position of the bonding electron pair. The hypothesis of a bonding electron pair located in positions of varying unsymmetry thus receives no support from the physical evidence here considered.

Summary

The dielectric constants, densities, refractive indices, dispersions and viscosities of the isomers of heptane and of 2,2,4-trimethylpentane have been measured. The polarizations of three of the heptanes and of the octane calculated from dielectric constant and density measurements over

the entire range of temperature within which the substances are liquid increase very slightly with temperature, indicating that the molecules contain no electric moments. The very small differences between the polarizations and the molar refractions extrapolated to infinite wave length for all of the substances show the absence of a measurable moment in their molecules. It is concluded that the atoms in a saturated hydrocarbon molecule may be joined together in every possible configuration without giving rise to any measurable lack of electric symmetry, although very small differences in the rigidity of binding of the electrons are detected. The electrical symmetry of the molecules gives no evidence of a difference in the electronegativities of the various constituent radicals.

SOLUTIONS OF SALTS IN PURE ACETIC ACID. I. PRELIMINARY PAPER[1]

BY ARTHUR W. DAVIDSON

RECEIVED APRIL 14, 1928 PUBLISHED JULY 6, 1928

Introduction

The study of the solubilities and chemical reactions of salts in non-aqueous solvents reveals certain analogies between these solutions and the more familiar solutions in water. These analogies have been most extensively developed, by the well-known researches of Franklin and his co-workers, for solutions in liquid ammonia. Despite the large amount of work that has been done with other non-aqueous solvents, our knowledge of such solutions is still so fragmentary that the accumulation and organization of much additional information would seem to be desirable.

In a previous paper,[2] the writer described an attempt to study the solubilities and reactions of salts in anhydrous sulfuric acid, a liquid of very different nature from those non-aqueous solvents which have been most widely examined. It was found that the range of investigation in this solvent was severely limited by the fact that, due to the large self-ionization of sulfuric acid, reactions of a solvolytic nature were of such general occurrence as greatly to interfere with the study of other reactions. It was decided to investigate, from the same point of view, solutions of salts in anhydrous acetic acid, this liquid being sufficiently polar in nature to be a fairly good solvent for many salts, while its self-ionization is apparently very small, since its specific conductivity is of the order of 2×10^{-8} reciprocal ohm.

---

[1] Presented before the Division of Physical and Inorganic Chemistry of the American Chemical Society at the St. Louis meeting, April, 1928.

[2] Davidson, THIS JOURNAL, 47, 968 (1925).

The information that; has hitherto been gathered concerning the solubilities and reactions of salts in acetic acid is decidedly meager. It was thought until rather recently that this liquid was a very poor solvent for inorganic salts.[3] Such data as have been obtained are very widely scattered. Many of the results of investigations previous to 1924 have been collected by Walden, in his "Elektrochemie Nichtwassriger Lösungen,"[4] although even here the data must be sought under several different headings. Quantitative measurements of solubility at various temperatures have been reported for mercuric chloride, uranyl nitrate, magnesium bromide and iodide, calcium chloride, antimony chloride and bromide, and the acetates of sodium and silver.[5] In addition, several addition compounds between .salts and acetic acid have been isolated, including compounds with the acetates of the alkali metals,[6] and compounds with aluminum chloride, magnesium bromide and iodide, calcium chloride, antimony chloride and sodium iodide.? Conductivity measurements have been made on solutions of the alkali acetates and of several other salts.[8]

There have been a few scattered observations concerning reactions of metallic oxides with acetic acid, limited for the most part to the formation of acetates in which the metals exhibit unusually high valences.[9] The best known example of this is the formation of lead tetra-acetate from red lead.

Since the publication of Walden's text there have appeared, so far as the writer has been able to ascertain, three articles bearing on this subject. Webb[10] studied the activities of several salts in acetic acid solution, using the freezing-point method, and discussed the results on the basis of the assumption of practically complete ionization and the Debye-Hückel theory. Stranathan and Strong,[11] from the viscosities and conductivities of acetic acid–stannic chloride solutions, deduced the existence of an addition compound which, however, was not isolated. Still more recently, Hall and Conant,[12] in a study of hydrogen ion activities in what they

propose to call "superacid" solutions, have described the neutralization of various organic bases by acids in glacial acetic acid, and have given some interesting speculations on the results, in terms of Bronsted's theory of acids and bases.

Object of the Present Work

In the investigation which is now in progress in this Laboratory, it is the writer's intention to extend the solubility data for salts in acetic acid by the determination of a large number of solubilities qualitatively, and a few typical ones quantitatively, and to make a study of reactions which take place between ionized salts in this medium, this being a field which has scarcely been touched. Only salts of inorganic bases will be considered.

The present paper reports the results of some preliminary experiments of a qualitative nature, which appear to the writer to be of interest. Quantitative experiments are in progress.

Experimental Part

The solvent used in these experiments was a special grade of C. P. glacial acetic acid, which had a melting point of 16.4°. The salts were of a reliable C. P. grade and were dried under suitable conditions. The anhydrous sulfuric acid used was prepared as described by Kendall and Carpenter,[13] and had a melting point of 10.4°.

1. Solubilities of Salts in Acetic Acid.—The number of salts which were found to be appreciably soluble was considerably larger than might be supposed from the meager data in the literature. The results of qualitative tests of solubility are given below.

The following salts were found to be readily soluble at room temperature: $LiNO_3$, $Ca(NO_3)_2$, NH_4NO_3, $Cu(NO_3)_2$, $CaCl_2$, $ZnCl_2$, $FeCl_3$, $SbCl_3$, BaI_2, ZnI_2, NH_4SCN, KCN, $LiC_2H_3O_2$, $KC_2H_3O_2$, $NH_4C_2H_3O_2$, $Pb(C_2H_3O_2)_2$, $Cd(C_2H_3O_2)_2$.

The following were found to be somewhat less soluble than the above: $AgNO_3$, $AlCl_3$, $HgCl_2$, HgI_2, $CoCl_2$.

The following were appreciably, though slightly, soluble (apparently less than one part in one hundred of solvent at ordinary temperature): NaCl, KCl, KBr, KI, NH_4Cl, NH_4Br, NH_4I, $NaNO_3$, KNO_3, $BaCl_2$, $KClO_3$, Na_2SO_4, $(NH_4)_2SO_4$, $Cu(C_2H_3O_2)_2$.

The following salts were found to be practically insoluble: AgCl, AgBr, AgI, AgCN, AgSCN, $PbCl_2$, PbI_2, HgCl, CdI_2, $Ba(NO_3)_2$, $Ca_3(PO_4)_2$, $Cu_3(PO_4)_2$, $CaCO_3$; also the sulfates of Li, K, Cu, Ag, Ca, Ba, Mg, Zn, Cd, Hg(-ous and -ic), Al, Pb, Mn, Ni, Co and Fe(-ous and -ic).

2. Double Decomposition Reactions in Acetic Acid.—Double decomposition reactions were found to take place in this solvent as readily

---

[13] Kendall and Carpenter, THIS JOURNAL, 36, 2498 (1914).

as in water, the course of such reactions being determined largely by the solubilities of the several salts in question. In many cases these reactions were similar to familiar phenomena in aqueous solution. Thus silver chloride, bromide, iodide, cyanide and thiocyanate were each precipitated upon the addition of a solution of a salt containing the corresponding anion to a solution of silver nitrate. The silver cyanide precipitate, however, failed to dissolve in an excess of potassium cyanide solution. Lead chloride and lead iodide were precipitated from lead acetate solutions by sodium chloride and potassium iodide solutions, respectively. Solutions of cadmium acetate, lead acetate, zinc chloride, antimony chloride and silver nitrate all readily gave precipitates of the corresponding sulfides upon the introduction of hydrogen sulfide gas.

A solution of ferric chloride[14] gave, with ammonium thiocyanate solution, a deep red color, but no precipitate, just as in aqueous solution.

In many other cases, however, the reactions followed a less familiar course. A few examples of this will be described. When a solution of copper nitrate was treated with sodium acetate, a finely-divided, green crystalline precipitate of copper acetate was formed. A barium iodide solution, upon the addition of sodium nitrate, gave a finely-divided, white crystalline precipitate, which was shown to be barium nitrate. Any of the sulfates could be precipitated by the addition of a drop of anhydrous sulfuric acid, or a small amount of a solution of sulfuric acid in acetic acid, to a solution of a soluble salt of the metal in question. These came down as amorphous, flocculent precipitates from dilute solutions, or as gelatinous masses from concentrated ones. Even the sulfates of the alkali metals were readily precipitated in this way, although very dilute solutions of sodium and ammonium salts gave no precipitate. In connection with the general insolubility of sulfates in acetic acid, it is an interesting fact that sulfates which normally form hydrates can be precipitated in the anhydrous condition even when the solution contains some water. Thus, when *hydrated* cupric nitrate was dissolved in acetic acid and a little concentrated sulfuric acid added, a white precipitate of anhydrous cupric sulfate was obtained. Similarly, hydrated nickel nitrate gave yellow anhydrous nickel sulfate, and hydrated cobalt nitrate, pale pink anhydrous cobalt sulfate. It is worthy of notice that sulfates are insoluble in liquid ammonia, also.[15]

The only salt that was found to be noticeably solvolyzed by acetic acid was sodium carbonate with which, even at ordinary temperature, the solvent reacted fairly vigorously, with the evolution of CO_2. The reaction

---

[14] According to Weinland, a solution of ferric chloride in 96% acetic acid contains the cation $Fe_3(C_2H_3O_2)_6^{+++}$. See, for instance, Weinland, Kessler and Bayerl, *Z. anorg. allgem. Chem.*, 132, 209, 225 (1924).

[15] Franklin and Kraus, *Am. Chem. J.*, 21, 8 (1899).

was, of course, not nearly so vigorous as in the case of aqueous acetic acid. Sodium bicarbonate was solvolyzed only very slowly, and calcium carbonate not at all.[16]

3. Effect of Sodium and Ammonium Acetates upon Solubilities of Certain Other Salts.—The acetates of the metals may be regarded as bases in acetic acid, since they presumably have the same negative ion as the solvent.[17] This being the case, it might be expected that in this solvent they would exhibit properties analogous to those of the hydroxides in water. The following observations support this hypothesis.

Zinc acetate is practically insoluble in acetic acid,[18] even at the boiling point. It was found, however, to dissolve quite readily in a sodium acetate solution (about 5 mole per cent. of sodium acetate). This is analogous to the solubility of zinc hydroxide in aqueous sodium hydroxide solution, and would appear to be due to the amphoteric nature of zinc. The solubility of copper acetate in acetic acid was not increased by the presence of sodium acetate.

Ammonium acetate, in acetic acid, may be regarded as the analog of ammonium hydroxide in water. That this analogy is far from being merely a formal one is indicated in a rather striking manner by the following facts. Zinc acetate was found to dissolve readily in ammonium acetate solution (about 5 mole per cent. of ammonium acetate), as does zinc hydroxide in water. Copper acetate, which was found to be only slightly soluble in acetic acid to give a greenish solution, and which could, in fact, be precipitated from a solution of a soluble copper salt by the addition of a small amount of ammonium acetate solution, not only dissolved readily in excess of this solution, but gave a dark blue color when so dissolved. When this solution was heated, its color gradually deepened, until at the boiling point it became a very intense purplish-blue, which was practically identical with the characteristic color attributed to the copper–ammonia ion in aqueous solution. On cooling this characteristic purplish tinge disappeared. It seems reasonable to suppose that ammonium acetate reversibly dissociates to some extent into free ammonia and acetic acid as the solution is heated, and that the purplish-blue color is due to an ion of similar nature to that which gives rise to it in aqueous solutions. Ammonium acetate was also found to dissolve other difficultly soluble salts, notably silver chloride, cupric sulfate, cobalt sulfate and nickel sulfate. All these phenomena are being investigated further, and will be discussed in a subsequent paper.

---

[16] In connection with solvolysis by acetic acid, it should be mentioned that Rosenheim and Miiller, *Z. anorg. Chem.*, 39, **175** (1904), found that ferric chloride and ferric bromide crystallized from anhydrous acetic acid as $Fe(C_2H_3O_2)_2Cl$ and $Fe(C_2H_3O_2)_2Br$, respectively.

[17] Compare ref. **2,** p. 969.

[18] See ref. 5e, p. 1478.

Summary

1. A fairly large number of salts, especially halides and nitrates, have been found to be soluble in acetic acid. All sulfates are very slightly soluble.

2. Double decomposition reactions have been found to take place quite readily in this solvent, A number of such reactions have been described.

3. Solvolysis does not occur in acetic acid solutions to any marked extent.

4. Analogies have been pointed out between the behavior of certain acetates in acetic acid and that of the corresponding hydroxides in water.

THE MOLECULAR HEAT AND ENTROPY OF HYDROGEN CHLORIDE CALCULATED FROM BAND SPECTRA DATA

BY ELMER HUTCHISSON

RECEIVED APRIL 14, 1928 PUBLISHED JULY 6, 1928

I. Introduction

It is well known that the heat capacity of gases decreases with temperature in the neighborhood of absolute zero. The temperature variation of the molecular heat of gaseous hydrogen chloride is especially interesting because it may be used to confirm the interpretation which the new quantum mechanics places upon band spectra. The computation of molecular heats, by means of the energy levels derived from band spectra, was first carried through by Hicks and Mitchell.[1] They made use of the spectral measurements of Imes and of Colby, Meyer and Bronk and assumed the "*a priori* probabilities" or weights of the quantum states to be 2, 4, 6, 8, etc., corresponding to those states characterized by the rotational quantum numbers $^1/_2$, $^3/_2$, $^5/_2$, $^7/_2$, etc. Van Vleck[2] and others have pointed out that according to the new quantum mechanics the *a priori* probabilities must be 1, 3, 5, 7 for the states $^1/_2$, $^3/_2$, $^5/_2$, $^7/_2$ for simple polar molecules like HCl. Experimental proof that these probabilities are correct is furnished by Bourgin's[3] measurements of the absorption intensities of hydrogen chloride.

The band spectra measurements of Colby, Meyer and Bronk have been recalculated by Kemble,[4] who has obtained equations expressing the energy levels as a function of the vibrational and rotational quantum numbers.

---

[1] Hicks and Mitchell, THIS JOURNAL, 48, 1520 (1926).

[2] Van Vleck, Phys. *Rev.*, 28, 986 (1926); see also Hutchisson, ibid., 29, 360A (1927).

[3] Bourgin, *ibid.*, 29, 794 (1927).

[4] Kemble, J. Opt. *Soc. Am.*, 12, 1 (1926).

The calculations made in this paper are based on Kemble's values for the energy levels and the a *priori* probabilities assigned by the new mechanics. Besides the molecular heats, the entropy values of hydrogen chloride at the various temperatures are calculated in accordance with the method given by Giauque and Wiebe.[5] The calculated results are then compared with experiment.

II. Calculations

The molecular heat of a gas is obtained by differentiating the energy of a mole of the gas with respect to the temperature. The translational energy of the gas remains constant and may therefore be left out of consideration. The rotational and vibrational energy may be obtained by summing up the different energy levels obtained from band spectra data. The expression for the molecular heat is well known and has been used by several investigators. It may be written as

$$C = \frac{N}{J}\frac{d}{dT}\frac{\Sigma_n \Sigma_m\, p^n_m\, W^n_m\, e^{-\frac{W^n_m}{kT}}}{\Sigma_n \Sigma_m\, p^n_m\, e^{-\frac{W^n_m}{kT}}}$$

where p^n_m is the *a priori* probability of the m^{th} rotational state and the n^{th} vibrational state, J is the mechanical equivalent of heat and N is Avogadro's number. For purposes of computation a more convenient form is as follows

$$C = \frac{Nk}{J}\left[\frac{P_3}{P_1} - \left(\frac{P_2}{P_1}\right)^2\right]$$

in which

$$P_j = \Sigma_n \Sigma_m\, p^n_m\, (\sigma^n_m)^{(j-1)}\, e^{-\sigma^n_m} \text{ and } \sigma^n_m = \frac{\epsilon^n_m\, ch}{kT}$$

where e^n_m are the band spectra wave numbers expressed in cm.$^{-1}$.

Kemble's equations for the spectral energy levels may be written[6] (expressed in cm.$^{-1}$)

$$F_m(m) = A_n + 2\delta\, m + B_n\, m^2 + D_n\, m^4$$

where

$A_0 = 0$ $B_0 = 10.4469 \pm 0.0050$ $D_0 = -0.000529$
$A_1 = 2887.19 \pm 0.053$ $B_1 = 10.1417 \pm 0.0050$ $D_1 = -0.000522$
$A_2 = 5667.23 \pm 0.17$ $B_2 = 9\ 8624 \pm 0\ 0023$ $D_2 = -0.000514$

and $\delta = 0.078 \pm 0.012$. In the 600° K. calculation 28 terms for $n = {}^1/_2$, 24 terms for $n = {}^3/_2$, and 12 terms for $n = {}^5/_2$, are needed. In these calculations m takes the value ${}^1/_2$, ${}^3/_2$, ${}^5/_2$, ${}^7/_2$, etc.

The results of the computations are given in Table I. The constants used in all the results are those found in the "International Critical Tables."

---

[5] Giauque and Wiebe, THIS JOURNAL, *50*, 101 (1928).

[6] In this equation our m is the same as Kemble's $(j - {}^1/_2)$.

The probable error in the value of molecular heat may be indicated by making use of the probable errors assigned to the band spectra constants by Kemble. For instance, in the computation for 0° (273.1°K.) the B_0 term is the major portion of important energy levels so that the percentage probable error remains constant for all terms. A change may therefore be made in the temperature which will balance the change in ϵ_m^n and still keep σ constant. The required change in temperature is ± 0.13°K. This change in temperature would produce a change of only a few units in the fifth decimal place. Kemble's constants and therefore the molecular heats are given for the lighter isotope of HCl. The change produced by the other isotope would be very small.

TABLE I

RESULTS OF COMPUTATIONS

T, °K.	C(Rot. + Vib.) cal. deg.$^{-1}$ mole^{-1}	C_v cal. deg.$^{-1}$ mole^{-1}	$\int_0^T C/T\,dT$ Entropy units per mole	T, °K.	C(Rot. + Vib.) cal. deg.$^{-1}$ mole^{-1}	C_v cal. deg.$^{-1}$ mole^{-1}	$\int_0^T C/T\,dT$ Entropy units per mole
600	2.1010	5.0814	9.354	13	2.1782	5.1586	1.619
450	2.0182	4.9986	8.761	11	2.1630	5.1434	1.255
373.1	2.0023	4.9827	8.385	8	1.7235	4.7039	
273.1	1.9962	4.9766	7.761	6	0.9517	3.9321	
200	1.9945	4.9749	7.140	5	.5140	3.4944	
120	1.9933	4.9737	6.121	4	.1799	3.1603	
60	1.9954	4.9758	4.739	3	.0259	3.0063	
30	2.0110	4.9914	3.352	1	.0000	2.9804	
15	2.1386	5.1190	1.928				

In Fig. 1 the molecular heats are plotted against the temperature.[7] This graph shows the sharp maximum which occurs at about 12.5°K. The shape of this curve is markedly different from the experimental molecular heat–temperature curve for hydrogen, which has a gradual monotonic increase in C_v from $^3/_2$ R at 60°, to approximately $^5/_2$ R at room temperature. The explanation[8] of the absence of a maximum on the basis of the quantum theory in the case of hydrogen, is that the gas is made up of a mixture of molecules of different types (those having symmetrical and those having antisymmetrical "eigenfunctions"). The molecular heat of this mixture gives a curve which agrees well with experiment at low temperatures[9]

There are not many accurate determinations of the molecular heat of gaseous hydrogen chloride. Observations have been made by Masson,[10]

---

[7] It should perhaps be noted that these calculations take no account of the Van der Waals forces. However, the experimental values have been reduced to the ideal state so that the calculated values should agree with experiment. The possible existence of $(HCl)_2$ molecules has been neglected.

[10] Masson, *Phil.* Mag., 13, 533 (1857).

Regnault,[11] Strecker[12] and Muller,[13] but their values disagree among themselves so much that it is difficult to have much faith in any of them. Pier[14] measured the molecular heat of HCl from 0 to 1600°, using the bomb method, and obtained the equation $C_v = 4.90 + 0.0009\,\Theta$, where Θ is the centigrade temperature. The values obtained from his equations are included in Fig. 1. Pier's data for hydrogen appear to be too low at room temperature, so it is possible that the same is true for hydrogen chloride.

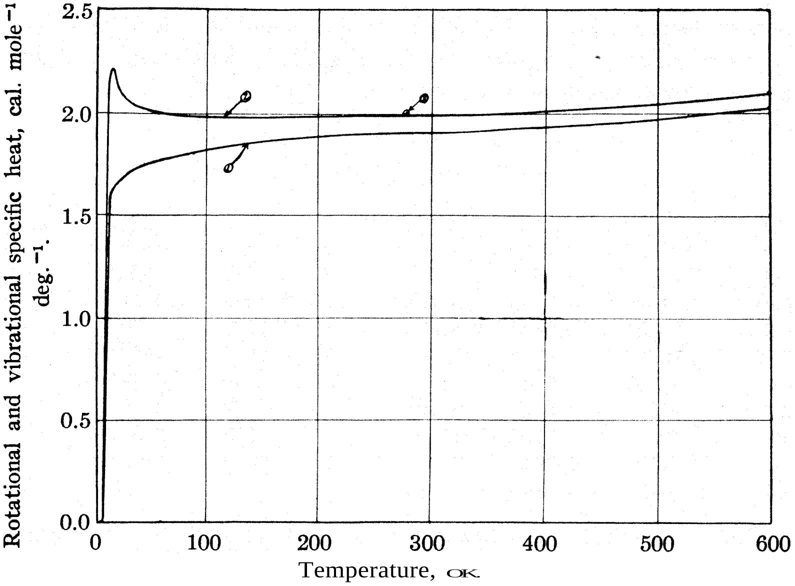

Fig. 1.—Graph showing the variation of the specific heat of hydrogen chloride with temperature calculated from band spectra data. Curve **1** is taken from Hicks and Mitchell's data. Curve **2** shows the values calculated in this paper based upon the a *priori* probabilities indicated by experiment and the new quantum mechanics. The single reliable experimental point is shown at **(3)**.

The most accurate measurements are, without doubt, those of Schweikert,[15] using the velocity of sound method. His values have been slightly corrected by Partington and Schilling.[16] His value for C_v at 0° is 4.995 cal. mole^{-1} deg.$^{-1}$, which agrees well with the calculated value ($C_v = 4.977$) given, and certainly confirms this result rather than the calculated value of $C_v = 4.879$ on the basis of the older quantum mechanics.

---

[11] Regnault, *Mem. Acad.*, **26**, 1 (1862).

[12] Strecker, *Wied. Ann.*, **13**, 20 (1881); **17**, 85 (1882).

[13] Muller, *ibid.*, **18**, 94 (1883).

[14] Pier, *Z. physik. Chem.*, **66**, 759 (1909); Nernst, *Z. Electrochem.*, **17**, 272 (1911).

[15] Schweikert, *Ann. Physik*, **48**, 593 (1915).

[16] Partington and Schilling, "Specific Heat of Gases," Ernst Benn, Ltd., London, 1925.

Giauque and Wiebe have shown that the same terms used for specific heats may be used to evaluate $\int_0^T C/TdT$ for entropy calculations. In our notation their equation may be written

$$S_2 = \int_0^T CT/dT = R\left[\ln P_1 - \frac{P_2}{P_1}\right]$$

The values of this integral for the various temperatures are included in Table I. The total entropy may then be obtained by using the Sackur equation for the entropy due to the translational energy

$$S_1 = \frac{3}{2} R \ln M + \frac{3}{2} R \ln T + R \ln V + S_0$$

where S_0 has the values -11.06 (Tetrode) or -11.38 (Lewis) entropy units per mole. Giauque and Wiebe have given, as the experimental value of the entropy per mole, 41.2 Entropy Units at the boiling point (188.07°K.). Extrapolating between the values given in Table I, we obtain $S_2 = 7.02$ at 188.07°K. Using the values given in the "International Critical Tables," S_1 is found to be 34.35 or 34.03, depending upon the value of S_0. Our value for the total entropy per mole at the boiling point is therefore 41.45 or 41.13 E. U., while the experimental value given by Giauque and Wiebe is 41.3 when corrected to the ideal state. At 298.1°K. our calculated value of the entropy is 44.65 or 44.33, while the experimental value is given as 44.5. The calculated values at 298.1°K. are 0.01 E. U. higher than those given by Giauque and Wiebe. At 0° the total entropy per mole amounts to 44.04 or 43.72 E. U.

If we make use of the value of S_2 taken from Hicks and Mitchell's data, which is given as 6.75 at 298.1°, we may compare the entropy results of the older quantum theory with those of the new mechanics. It was noted by Giauque and Wiebe that Hicks and Mitchell neglected the zero point entropy. It may also be noted that Hicks and Mitchell have an error in summing up the components of the entropy, S_1 and S_2, to obtain their final entropy value in the case that uses the Tetrode constant. Using S_2 as given, the entropy per mole at 298.1°K. is 44.85 or 44.53 E. U. as compared with the experimental value of 44.5 E. U. In this case, also, the present calculations give slightly better agreement than those based on the older quantum theory, although the agreement is not decisive because of the large probable error in the experimental result.

Summary

The molecular heat of gaseous hydrogen chloride is computed from band spectra data for temperatures from 1°K. to 600°K. It is shown that the curve obtained by plotting the molecular heat against temperature rises to a maximum at 12.5°K. At 0° the calculated molecular heat agrees very well with the single reliable experimental value, while the earlier calculations of Hicks and Mitchell give a value about 0.1 cal. mole–' deg.$^{-1}$ too low.

The values of $\int_0^T C/TdT$, which may be used to calculate the entropy

for the various temperatures, are calculated by the method suggested by Giauque and Wiebe. The entropy at 0° is found to be 44.04 or 43.72 Entropy Units per mole, depending upon whether the Tetrode or Lewis value of the chemical constant is used.

A RAPID METHOD FOR THE SEPARATION OF ALUMINUM AND BERYLLIUM

BY I. M. KOLTHOFF AND ERNEST B. SANDELL

RECEIVED APRIL 23, 1928 PUBLISHED JULY 6, 1928

From the voluminous literature on the subject of the separation of aluminum and beryllium it may be concluded that the estimation of these elements in the presence of each other is of great difficulty, and that there is no simple, satisfactory method for their accurate determination. An excellent summary of the older methods for the separation of aluminum and beryllium will be found in C. L. Parsons' "The Chemistry and Literature of Beryllium." H. T. S. Britton[1] concluded from an experimental study of the more important methods proposed that the only four which were capable of giving satisfactory results, if the details of the respective procedures were carefully adhered to, were the following. 1. Decomposition by boiling of sodium hydroxide solutions of aluminum and beryllium.[2] Sodium beryllate is hydrolytically decomposed, giving a precipitate of beryllium oxide; sodium aluminate remains in solution. 2. Parsons and Barnes" method.[3] Beryllium hydroxide is dissolved by hot sodium bicarbonate solution; aluminum hydroxide is not dissolved. 3. Method of Wunder and Wenger.[4] The oxides are fused with sodium carbonate and the residue is extracted with water. Aluminum goes into solution. 4. F. S. Havens'[5] ether–hydrochloric acid method. Beryllium chloride alone is soluble in a mixture of hydrochloric acid and ether saturated with hydrogen chloride. Of these methods, Britton considered 1 and 4 to be the most satisfactory. For discussion and criticism of these methods, see Hellmut Fischer[6] and also L. Moser and M. Niessner.[7] A method which appears to be superior to any hitherto proposed has recently

been described by L. Moser and M. Niessner,[7] in which aluminum alone is precipitated by a saturated solution of ammonium acetate containing 3% of tannin. The tannin must be destroyed in the filtrate before the beryllium can be precipitated. The method which is described below is simpler and more rapid.

R. Berg[8] has recently introduced the use of o-hydroxyquinoline (called "oxine" by F. L. Hahn)[9] for the separation and determination of various metals. According to our own experience, this new reagent is very useful in many different analytical procedures.

In a solution weakly acid with acetic acid and containing ammonium acetate, aluminum is precipitated quantitatively by a solution of oxine as $(C_9H_6ON)_3Al$. Beryllium is not precipitated under these conditions. On the addition of ammonium hydroxide to the filtrate from the aluminum precipitation, beryllium gives a precipitate of indefinite composition which appears to be beryllium hydroxide containing adsorbed oxine. Addition of oxine and ammonium hydroxide to a solution of a beryllium salt containing sufficient sodium potassium tartrate to prevent precipitation of beryllium hydroxide gives a yellow precipitate, somewhat difficult to filter, which unfortunately cannot be used in the estimation of the element, both on account of its solubility and its variable composition.

The procedure adopted is based on the following facts. (a) From a weakly acid solution containing aluminum and beryllium, aluminum is quantitatively precipitated by the addition of an acetic acid solution of oxine and an excess of ammonium acetate. The precipitate of $(C_9H_6ON)_3Al$ is weighed after drying at 120–140°.

(b) In the filtrate from the aluminum precipitation beryllium hydroxide is precipitated by the addition of ammonia and ignited to the oxide.

Procedure

Reagent.—R. Berg,[8] F. L. Hahn[9] and I. M. Kolthoff[10] all worked with a 5% solution of oxine in 95% alcohol when precipitating aluminum. Kolthoff found the results with aluminum to be about 0.4% too low when thus precipitated. We confirmed these results and found the low values obtained to be due to the solubility of aluminum *o*-hydroxyquinoline in the warm dilute alcoholic solution from which it is precipitated. We therefore recommend that an acetic acid solution of oxine be used in the precipitation of aluminum and possibly also with other metals. Moreover, the acetic acid solution of the reagent has the added advantage over the alcoholic solution that it is more stable and may be kept for many weeks without change. The reagent is prepared by dissolving a

sufficient amount of finely powdered o-hydroxyquinoline in 2 *N* acetic acid to form a 5% solution. Ten cubic centimeters of reagent thus prepared are sufficient to precipitate one millimole of aluminum.[11]

Determination of Aluminum.—The solution of aluminum and beryllium salts (containing not more than 100 mg. of either oxide per 100 cc.) which should be only slightly acid is warmed to 50–60° and treated with an excess of the acetic acid solution of oxine. A solution of 2 N ammonium acetate is slowly added until a permanent precipitate is obtained and then 20–25 cc. more of ammonium acetate is added to insure the complete precipitation of aluminum. When the aluminum o-hydroxyquinoline has settled, the liquid is poured through a Jena glass or porcelain filter crucible (more convenient to use in this case than a Gooch crucible). The precipitate is washed with cold water and dried at 120–140°. It then has the composition $(C_9H_6ON)_3Al$ and contains 11.10% of Al_2O_3.

Determination of Beryllium.—The filtrate from the aluminum precipitation is heated nearly to boiling and ammonium hydroxide is cautiously added to the liquid until it smells faintly of ammonia. The beryllium hydroxide thus precipitated is colored yellow or brown by adsorbed oxine. It is filtered off and washed thoroughly with a hot dilute solution of ammonium acetate containing a few drops of ammonium hydroxide. The precipitate may be dried directly over a low flame and ignited (without the addition of oxalic acid) in a platinum crucible over a blast lamp. The beryllium oxide thus obtained is somewhat more hygroscopic than the form ordinarily obtained by ignition of beryllium hydroxide precipitated in the absence of oxine and it must therefore be weighed quickly. The single deflection method of weighing, as described by P. H. M.-P. Brinton[12] may be advantageously used.

Analytical Results

The standard solution of aluminum used was prepared by weighing out potassium alum obtained by recrystallization of *a* very pure product. The beryllium nitrate solution employed was standardized by careful gravimetric analyses according to the method of Parsons, the platinum crucibles used being reweighed after ignition.

In solutions containing only aluminum, or aluminum in the presence of alkali salts, results of a high degree of accuracy are obtained by the use of an acetic acid solution of o-hydroxyquinoline, as the following table shows.

If ferric iron is present it will be precipitated with the aluminum. Two separations of beryllium from ferric iron were made. A solution containing 1 g. of ferric alum and 0.0927 g. of BeO in about 100 cc. was treated with an excess of oxine, as described in the aluminum precipitation, and the black ferric o-hydroxyquinoline was filtered off and beryllium determined in the filtrate in the usual way. The weights of beryllium oxide obtained were 0.0931 and 0.0937 g. The separation is therefore satisfactory.

Prom the table of results given above it will be seen that the weight of beryllium oxide found is a little high in most cases. This is partially to be ascribed to a slight solubility of aluminum o-hydroxyquinoline in water, which was found to be increased to some extent by beryllium salts. An excess of oxine will, however, reduce the solubility of the aluminum compound. Therefore in those cases where there is much beryllium and little aluminum present, it is advisable to add at least 50% of oxine in excess. In ordinary cases where aluminum, and not beryllium, preponderates, an excess of 10–20% of oxine is sufficient.

If the amount of beryllium is quite small, it is best to convert the oxide to the sulfate and weigh the latter. Anhydrous beryllium sulfate has already been proposed as a weighing form for beryllium by Taboury.[13] A few drops of sulfuric acid (1:1) are added to the oxide, and then the water and most of the excess sulfuric acid are evaporated off. The residue may be safely heated to constant weight at temperatures from 350 to 400°. Satisfactory results with known amounts of beryllium oxide have been obtained.

Summary

A simple and rapid method has been described for the separation of aluminum and beryllium by the use of an acetic acid solution of *o*-hydroxyquinoline. Beryllium is also separated from ferric iron by means of this reagent.

MINNEAPOLIS, MINNESOTA

A NEW DESIGN OF APPARATUS FOR THE MOVING BOUNDARY METHOD OF DETERMINING TRANSFERENCE NUMBERS[1]

BY EDGAR REYNOLDS SMITH[2]

RECEIVED APRIL 26, 1928 PUBLISHED JULY 6, 1928

During the past few years several designs of cells for the determination of transference numbers by the moving boundary method have been described.[3] In each of these, the boundary moves through a calibrated tube and the number of coulombs which pass through the circuit, while the boundary moves through a predetermined volume, is measured. The purpose of this article is to describe an apparatus which has two unique features. (a) A calibration of the measuring tube is not required. (b) After the boundary has traversed the length of the measuring tube, it can be returned to the starting point for a fresh determination. This operation can be repeated any number of times without changing the solutions.

Apparatus and Manipulation

The cell is shown in the figure. The boundary tube B (of approximately 0.3 cm. inside diameter), the electrode tube C and their connecting tube are filled with the solution to be measured. The tube H contains mercury and the remainder of the cell is filled completely with the indicator solution to a point well above the stopcock D. The method of forming the boundary, except for a slight modification, is the one described by MacInnes and Smith.[3a] In this modified cell the boundary tube B projects about 0.3 cm. into the indicator reservoir I and its opening is ground flat, thus presenting a true surface for contact with the plunger F. The latter is fitted with a rubber cap to which two small hooks are attached. Rubber bands stretched between these hooks and the glass projections J serve to hold the plunger firmly against the top of B before beginning the measurement. For precise work it would be safer to sub-

[3] (a) MacInnes and Smith, THIS JOURNAL, 45, 2246 (1923); (b) Smith and MacInnes, *ibid.*, 46, 1398 (1924); (c) MacInnes and Brighton, *ibid.*, 47, 994 (1925); (d) Smith and MacInnes, *ibid.*, 47, 1009 (1925); (e) MacInnes, Cowperthwaite and Huang, *ibid.*, 49, 1710 (1927).

stitute ground glass stoppers in place of the rubber stoppers on the closed side of the apparatus.

As soon as the electrical circuit is closed, the rubber bands are removed and, with stopcock E closed and D open, F is gently loosened. When the boundary appears in B, F is carefully raised to about a centimeter above the top of B. Stopcock D is then closed and E is opened. Just as the boundary reaches a mark m, a coulometer is connected into the circuit. After the boundary has moved through a suitable volume, depending on the deposit desired in the coulometer, mercury is slowly withdrawn from H into a weighing flask until the boundary has been raised slightly above m. When the boundary again crosses m, the coulometer is disconnected and at the same time a second coulometer can be connected into the circuit for a second measurement.

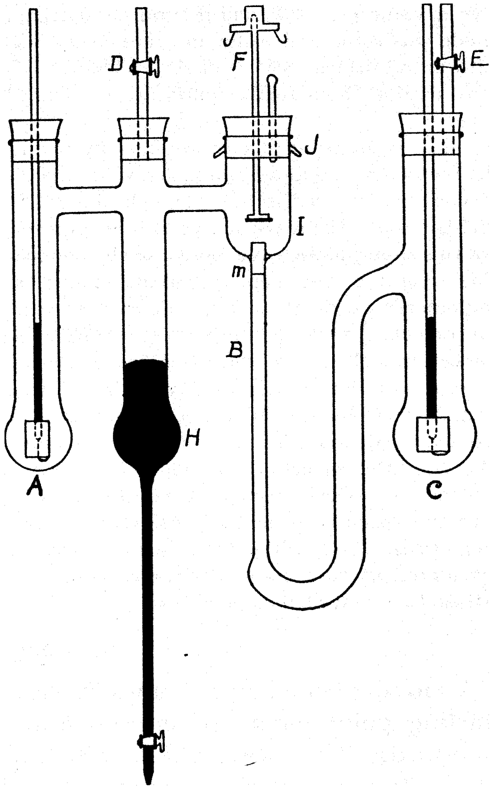

Fig. 1

From the weight of mercury and of the deposit in the coulometer, the transference number is calculated by means of the equation[3d]

$$T = \frac{VF}{\phi Q} \pm \frac{\Delta v}{4} \qquad (1)$$

where V is the volume through which the boundary has moved (the observed weight of mercury divided by its density), ϕ is the equivalent volume of the measured solution, F is the faraday, Q is the number of coulombs passed and Δv is the correction[4] for the volume change per faraday due to the electrode reaction and to transference in the closed side of the cell.

Experimental Test

A preliminary experiment showed that the boundary could be raised any desired number of times without distortion provided the rate of withdrawal of the mercury was not fast enough to produce turbulence. An

[4] Lewis, This Journal, 32, 862(1910).

attempt to hold the boundary stationary at a definite position by withdrawing the mercury at exactly the rate of motion of the boundary was abandoned because of the constant attention required.

Since the object of this investigation was to test the practicability of the apparatus, a measurement of the cation transference number of **0.1** weight normal potassium chloride was performed with **0.065** weight normal lithium chloride for the indicator solution, This combination has been well investigated by other methods[3,ab,c,d] which give a value of **0.492,** and it furnishes a reliable check on the present method. The anode was a piece of platinum gauze coated with silver and the cathode was the same with an additional coating of silver chloride. Dried salts of analytical reagent quality were used without further purification. The silver coulometer was of the porous cup type.

The coulometer was thrown into the circuit when the boundary reached m. After the boundary had moved through a volume of about 1 cc. it was raised and then allowed to continue down the tube through about **1.7** cc. It was then raised to a position slightly above the mark and when it again reached m the coulometer was disconnected. By this manipulation the motion of the boundary after having been raised is included. The weight of the mercury withdrawn was **36.65** g. and the silver deposited in the coulometer weighed **0.0588** g. From these weights the values of V/ϕ, F/Q and of T_K (uncorrected) were, respectively, **0.0002688, 1835** and **0.493.** Since the anode side of the cell was closed, the correction ($\Delta v/\phi$ in equation **1)** to be applied in this case is calculated as follows. Per faraday at the anode, **1** molecular weight of silver chloride is formed. 1 atomic weight of silver disappears and T_{Li} equivalents of lithium chloride are lost by migration. The accompanying volume change is an increase of approximately **14** cc. and the correction, which in this case is appreciable, amounts to **0.001** and must be subtracted. The corrected value of the transference number is therefore **0.492.** identical with the value by other methods. However, the experiment was carried out at room temperature **(22°)** without the use of a thermostat, and the result obtained is not to be considered as an accurate determination of the transference number but merely as a satisfactory test of the apparatus.

Summary

A moving boundary cell in which the boundary may be returned to the starting point for a new measurement any number of times has been described. The measurements with this apparatus are independent of any tube calibration. The method consists in closing one side of the cell and withdrawing mercury from the closed side so as to oppose the motion of the boundary. The mercury withdrawn is weighed to obtain the volume through which the boundary has passed.

SPECTROPHOTOMETRIC DETERMINATION OF HYDROGEN ION CONCENTRATIONS AND OF THE APPARENT DISSOCIATION CONSTANTS OF INDICATORS.

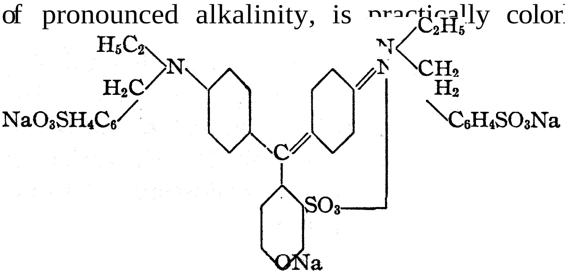
V. FAST GREEN F C F

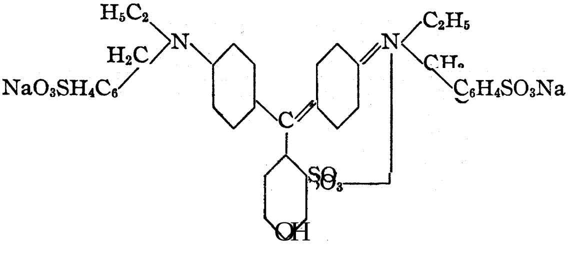
By W. C. Holmes and E. F. Snyder

Received April 30, 1928 Published July 6, 1928

Fast green F C F, or p-hydroxyerioglucine A (C. I. No. 671), is the most recent addition to the group of artificial coloring matters, the use of which is sanctioned in coloring foods.[1] It appears probable, also, that it will prove to be a very valuable biological stain.[2] The dye undergoes several color transformations with variation in hydrogen ion concentration. Since these phenomena might, in some measure, affect its utility in the application referred to and might, on the other hand, render it of use in indicator practice, their investigation was undertaken.

The tetrasodium salt of the dye, which is formed under conditions of pronounced alkalinity, is practically colorless. The trisodium salt is blue, having an absorption band with a maximum at approximately 611 $m\mu$. In passing from about P_H 10 to about P_H 6, the dye is transformed to the disodium salt which is green and has an absorption band with a maximum at approximately 628 $m\mu$. A further decided modification in color is formed in the region of pronounced acidity, consequent upon acid salt formation at the unsaturated amino group of the





---

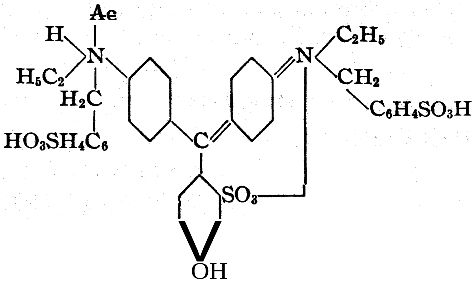
[2] R. Haynes, *Stain Technology*, 3, 40 (1928).

dye. The polyacidic salt formed is yellow and is doubtless to be considered as a yellow of the second order.



The two dissociation ranges of possible indicator utility are those of **the** polyacidic salt and of the phenolic salt.

The acid indicator range of the dye was investigated only in a preliminary manner. It was found that the conversion to the polyacidic dye salt was very nearly but not quite complete at P_H^{-1}. Spectrophotometric measurements carried out with buffered solutions of the dye over the range between P_H 0.87 and P_H 2.00 gave calculated values for apparent dissociation constants which increased with each step in the reduction of the acidity of the solution. Two intermediate products are formed in passing from the polyacidic salt of the dye to its disodium salt; the color acid and the monosodium salt. It was evident that the dissociation ranges of these various products overlapped and that their dissociation constants could not be determined by the methods at hand. It would have been possible to carry out an arbitrary calibration of a spectrophotometric ratio against hydrogen ion concentration in this region, but this was not undertaken, since the preliminary data indicated that the color of the dye was distinctly less sensitive to minor variation in acidity than is that of sulfonephthaleins available for employment in the same region.

The alkaline indicator range was investigated more thoroughly. The equipment and technique employed were those outlined in previous papers.[3] The ratio of the extinction coefficients of the solutions at 600 mμ to their extinction coefficients at 640 mμ was selected as the standard spectrophotometric ratio. Since a ratio of this type (R_2) is unaffected by variation in indicator concentration, no effort was made to avoid minor variation in that particular. All solutions, however, contained approximately 17.3 parts of dye per million parts of solvent. The temperature at which the spectrophotometric measurements were made was approximately 29°, and the Sørensen values of solutions recorded below have been corrected, when necessary, to conform to that temperature.

The dissociation of the indicator with increasing alkalinity appears normal until approximately P_H 9.8 is reached, at which point the forma-

TABLE I

STANDARDIZATION OF FAST GREEN F C F AGAINST SØRENSEN VALUES

PH	E at 600 mμ (Av.)	E at 640 mμ (Av.)	R_2	PH	E at 600 mp (Av)	E at 640 mμ (Av.)	R_2
6.14	1.18	1.50	0.79	8.55	1.425	1.02	1.40
6.68	1.21	1.46	.83	8.81	1.47	.97	1.52
7.12	1.26	1.43	.88	9.02	1.51	.95	1.59
7.62	1.29	1.31	.98	9.53	1.53	.90	1.69
7.82	1.30	1.25	1.04	9.80	1.54	.88	1.74
8.03	1.33	1.18	1.12	10.06	1.52	.85	1.77
8.22	1.37	1.12	1.23	10.41	1.50	.83	1.80
8.41	1.40	1.05	1.34	10.91	1.46	.805	1.81

tion of the trisodium salt is about 98% complete. Beyond that point it is evident that the further formation of the trisodium salt is accompanied by conversion of trisodium salt into the colorless tetrasodium salt. That circumstance is without effect upon spectrophotometric: application but renders suitable precautions advisable if the indicator is used in conjunction with drop ratio colorimetric practice. In drop ratio technique it is recommended that the color standards be prepared with buffer solutions of *PH* **9.8** and *PH* 6.5, whereby the indicator will be obtained in approximately 98% of its respective forms. Error will result if the alkalinity specified is exceeded.

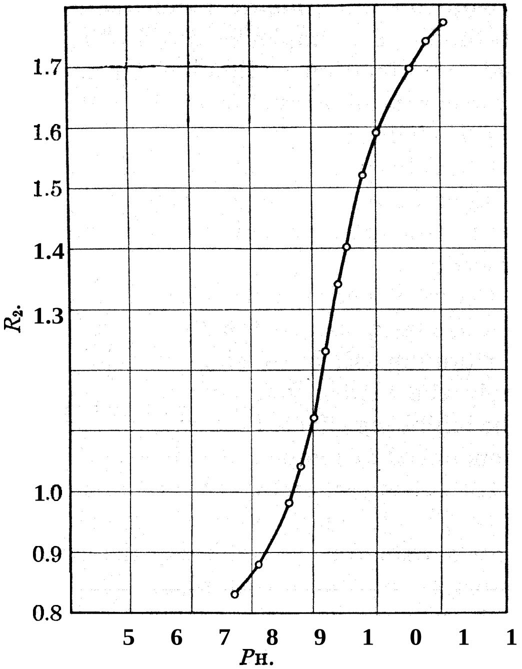

Fig. 1.—Fast green F C P. $R_2 = E$ at 600 mμ/E at 640 mμ. Temperature, 29° alkaline range.

The apparent dissociation constant of the indicator in this range is approximately 8.1(5). This calculated value was checked by measuring the combined absorptions of two solutions at *PH* 9.8 and *PH* 6.5, respectively, contained in cells of equal thickness.

Spectrophotometric technique in the alkaline range of Fast Green F C F is slightly less accurate than with such other indicators as have been investigated previously. Minor discrepancies were noted in duplicate determinations, which arose, apparently, from readjustments in physical equilibria, and the spectral interval between the bands of the dye forms is smaller than is desirable. Whereas, however, the sulfonephthaleins are to be preferred in general indicator application, Fast Green F C F may well prove useful under some circumstances.

Summary

Spectrophotometric data are supplied for the determination of hydrogen ion concentrations over the PH range between 6.7 and 10.0 with Fast Green F C F.

The apparent dissociation constant of the dye in this range is approximately 8.1(5) at 29°.

WASHINGTON, D. C.

NOTE

Note on Colorimetric Estimation of Titanium by Hydrogen Dioxide Method.—The employment of hydrogen dioxide as reagent in the colorimetric estimation of titanium compounds, in acid solution, constitutes an accurate and rapid method for the determination of small quantities of this element.

It has been ascertained[1] that the presence of phosphoric acid produces a slight fading of the yellow to orange coloration, even when present in small amounts, rendering corrections essential to the accuracy of the procedure.

During experimental work undertaken and carried out by the writer, the fact has been observed that the addition of uranium acetate to the solution of titanium salt in solutions containing free hydrogen ions eliminates entirely the tendency to fading, at temperatures ranging from 20 to 50°. The inhibiting effect of the uranium compound upon the $PO_4^{\equiv}$ ion is not so pronounced at temperatures in excess of the maximum figure furnished.

It has been found that the uranium compound, in the proportion of 1 cc. of 0.1% solution to each 0.1 mg. of the element under examination, is most satisfactory in stabilizing the coloration produced by the action of hydrogen dioxide on titanium salts in solutions containing phosphoric acid, thus counteracting the tendency of the acid in question to decrease the intensity of the original coloration obtained.

The effect of the uranium acetate solution is independent of the amount or quantity of phosphoric acid or its compounds present in the solution under investigation.

AN INVESTIGATION OF THE HYPOTHETICAL COMBINED PENTOSE AND THE SO-CALLED FREE PENTOSE WITH INFERENCES ON THE COMPOSITION OF PECTIN

BY RONALD B. MCKINNIS

RECEIVED JANUARY 5, 1928 PUBLISHED JULY 6, 1928

Introduction

In connection with a study of the carbohydrate changes in apples, a question arose as to the pentose content. A study of the literature revealed the fact that very little had been done by other workers. The results obtained from this investigation point to some very significant and interesting facts concerning pectin and pentose.

Occurrence

Pentoses are commonly assumed to be components of leaves and other portions of plants. Spoehr[1] states that the existence of free pentoses in leaves is entirely uncertain. Colin and Franquet[2] question the findings of Davis and Sawyer and state that pentoses, if present at all, are there in very slight quantity.

The pentoses are widely distributed in a hypothetical combined form as components of complex substances such as glucosides, nucleinic acids and most commonly as anhydride-like condensation products of unknown molecular weight and structure.

On preliminary inspection it seems probable that the main source of pentose in apples would be the pectins and hemicelluloses. The existence of free pentoses would, then, be dependent upon the hydrolysis of the pectins.

Method of Determining Pentoses

Although many methods have been used for determining pentoses, none is entirely satisfactory. The method used in this work is similar to the Official Method,[3] with the exception that steam is slowly passed through the mixture to carry off the furfural, and at the same time maintain the volume of the mixture more constant. Distillation is stopped when the distillate fails to give a red color with freshly prepared aniline acetate test paper. Phloroglucinol is used to determine the furfural.

Free Pentoses

It is evident that before estimating free pentoses there must first be made a separation from pectin, pectic acids and galacturonic acids, be-

---

[1] Spoehr, "Photosynthesis," A. C. S. Monograph, Chemical Catalog Co., New York, 1926, pp. 189–194.

[2] Colin and Franquet, Bull. *soc. chim. biol.*, 9, 114 (1927).

[3] "Official and Provisional Methods of Analysis," U. S. Dept. of Agr., Bur. of Chem., *Bull.* No. 107, 54–55 (1912).

cause these give a considerable yield of furfural. This separation can probably be best obtained by extraction with 95% alcohol, keeping the concentration of the alcohol on the apples at least 80%. The free pentoses will be found in the alcohol extract along with the hexoses. Such an extract, from Delicious apples, failed to give an estimable precipitate of furfuralphloroglucide. This is significant as it shows that free pentoses are absent, or are present in only small amounts.

Combined Pentoses. Pentoses in Pectin

In estimating the total, or combined pentoses, an error will result due to the furfural from the pectin. Various workers, but especially Ehrlich[4] and Dore,[5] have shown that pectin and the galacturonic acids yield considerable quantities of furfural. All pectic substances contain galacturonic acid as an essential constituent.

Due to the fact that pectin yields furfural on distillation with hydrochloric acid, it has generally been assumed that pectin contains a pentose, probably arabinose. Nanji, Paton and Ling[6] include one arabinose molecule in their hexa-ring formula for the structure of pectin.

Ahmann and Hooker[7] state that the pentose of pectin probably does not exist as such, but is a decomposition product of galacturonic acid, which in turn is derived from pectin.

According to Ehrlich,[4] even so mild an hydrolysis as boiling with water splits off the araban portion of the pectin complex in a form soluble in 70% alcohol. Since all ordinary pectin preparations are produced by a treatment at least as drastic as boiling with water, it would appear that the arabinose-containing fraction of pectin could be leached out by digesting in 70% alcohol. The furfural yield of the residue might then be a measure of the galacturonic acid content and the furfural yield of the extract a measure of the pentose. Dore,[5] however, found that the furfural yield of the residue varied and that after two successive digestions the yield was much less and constant.

According to Nanji, Paton and Ling,[6] in their hexa-ring formula for pectin, arabinose is within the ring. For this reason it does not seem probable that arabinose within could be split off with 70% alcohol. According to Dore,[5] an extraction with 70% alcohol might extract arabinose extraneous to the ring. His results show that this is possible, as his furfural yields vary accordingly.

If the furfural error due to galacturonic acid could be found, an estimation of pentose would be possible. One molecule of galacturonic acid will

---

[4] Ehrlich, *Chem.-Ztg.*, **41,** 197 (1917).

[5] Dore, THIS JOURNAL, 48, 232 (1926).

[6] Nanji, Paton and Ling, *J. Soc. Chem. Ind.*, **44,** 253T (1925).

[7] Ahmann and Hooker, *Univ. of Missouri Agr. Expt. Sta. Res. Bull.*, 1925, p. 77.

theoretically yield either one molecule of mucic acid or one molecule of furfural.

$$\mathrm{COH(CHOH)_4COOH} \xrightarrow{\mathrm{HNO_3}} \underset{\text{mucic acid}}{\mathrm{COOH(CHOH)_4COOH}}$$

$$\mathrm{COH(CHOH)_4COOH} \xrightarrow{\mathrm{HCl}} \underset{\text{furfural}}{\mathrm{C_4H_3O.CHO}} + \mathrm{CO_2} + \mathrm{3H_2O}$$

The furfural yield of the galacturonic acid could be estimated from the yield of mucic acid if we knew what fraction of the theoretical yield would be obtained in practice and that no galactose would take part in the reaction. Interference is quite probable since galactose is included in the hexa-ring formula of the pectin molecule. The estimation of galacturonic acid by determining the mucic acid yield would, therefore, be unsatisfactory.

The amount of carbon dioxide evolved, however, is theoretical and provides an accurate estimation of the galacturonic acid. This method is specific for the glucuronic acids and it can be assumed that the other isomeric glucuronic acids are absent.

Method of Determining Galacturonic Acid

For the determination of galacturonic acid, a modification of the Lefevre-Tollens method for glucuronic acid was used. Briefly stated, the method consists of decomposing the substance by heating with 12% hydrochloric acid and absorbing the evolved carbon dioxide in scrubbing towers containing a known volume of standard barium hydroxide solution. A current of carbon dioxide free air drawn by suction carried the carbon dioxide away from the surface of the liquid through a reflux condenser, which returned the condensable matter. For precaution, an absorption tower filled with granulated zinc was placed between the condenser and the carbon dioxide scrubbing towers. After the scrubbing towers came a guard tube of soda lime and an expansion chamber which was connected with the vacuum supply through a release valve which served to regulate the current.

Correlation between Galacturonic Acid Content and Furfural Yield

The samples used in all determinations were from ripe Winesap apples, grated and thoroughly mixed to get comparable samples. These samples, of 25 g. each, were preserved in sufficient strong alcohol to keep the alcohol concentration above 75%. All determinations were made on the whole 25g. sample, the alcohol being slowly evaporated off just before use.

The following results were obtained with the furfural distillation method already mentioned, without alcohol extraction of the phloroglucide.

Sample	1	3	4	5	Avg.
Furfural, g.	0.1013	0.1163	0.1025	0.1132	0.1083

With alcohol extraction lower results were obtained.

Sample	6	7		
Furfural, g.	0.0950	0.0790	Av.	0.0870

The galacturonic acid determinations gave the following results

Sample	9	10		
Carbon dioxide, g.	0.1125	0.1200	**Av.**	0.1162

0.1162 g. of carbon dioxide would be derived from 0.4885 g. of digalacturonic acid.

To check the actual furfural yield, Ehrlich's digalacturonic acid was isolated as follows. A water extract of the apples was prepared by repeated digestion with hot water. The apple extract was saponified by the addition of sodium hydroxide and boiled with hydrochloric acid. This, according to Ehrlich,[4] gives digalacturonic acid. These processes were repeated and the precipitate was dried and weighed. The procedure was similar to that used by Rowell,[8] for the determination of pectin. To the 200 cc. of apple extract obtained from 25 g. of apples, was added 10 cc. of 10% sodium hydroxide and the mixture was allowed to stand for fifteen minutes. Twenty cc. of 10% hydrochloric acid was then added. The mixture was boiled for five minutes and filtered on a fluted filter paper; the precipitate, washed with a small amount of hot water, was returned to the beaker and made up to 100 cc. Treatment with base and acid, boiling and filtration was repeated. Two hundred cc. volume was used for the boiling with acid. The precipitate was washed with hot water until the filtrate showed only a slight acidity, transferred to a tared Gooch crucible, dried first at 55-60', then overnight at 95° and weighed. The average yield from the 25g. samples of apples was 0.0955 g.

The acid has been shown by Ehrlich to be free from pentoses. It is prepared in the same way as the pectic acid of Wichmann and Chernoff, which Nelson[9] has shown to be identical with the digalacturonic acid of Ehrlich and Sommerfeld.[10]

Furfural determinations on the digalacturonic acid gave results as follows.

Sample, g.	0.0942	0.0968	Av.	0.0955
Furfural, g.	0.0166	0.0164	**Av.**	0.0165

0.0955 g. of digalacturonic acid would give a theoretical furfural yield of 0.0495 g., which makes the actual yield of 0.0165 g., 33.3% of the theoretical yield. From the 0.4885 g. of digalacturonic acid found by the carbon dioxide determination, a theoretical furfural yield of 0.2534 g. would be obtained. Actually the yield would be 33.3% of the theoretical or 0.0844 g. This checks well with the actual yield of 0.0870 g. found.

This relation of digalacturonic acid to pentose is more clearly shown by calculating the ratio of the furfural and carbon dioxide yields for the whole apple and the digalacturonic acid. The ratio, furfural/carbon dioxide

---

[9] Nelson, THIS JOURNAL, 48,2412 (1926).

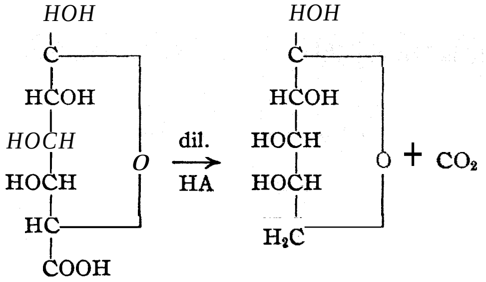
[10] Ehrlich and Sommerfeld, *Biochem. Z.*, 168,263 (1926).

for the apple sample was found to be 0.75, and for the digalacturonic acid, 0.74.

From this it seems evident that the apples contained no pentose whether free or combined and that the assumed pentose of pectin does not exist.

The Significance of Galacturonic Acid

It has been shown that pectin does not contain a pentose sugar. Ehrlich, however, has isolated by boiling with dilute organic acids, d-rotatory *l*-arabinose. This statement is not contradictory to what has just been found. With dilute weak acid hydrolysis, d-galacturonic acid very probably gives *l*-arabinose, as follows.



d-galacturonic acid *l*-arabinose

If stronger acid is used, furfural is formed from the arabinose. This accounts for the pentose confusion as being due to the fact that galacturonic acid with dilute acids gives 1-arabinose, while with more concentrated acid it gives furfural.

The digalacturonic acid of Ehrlich is probably a compound formed from d-galacturonic acid, as follows.

$$2COH(CHOH)_4COOH \longrightarrow [COH(CHOH)_4COOH]_2-H_2O$$

d-Galacturonic acid Digalacturonic acid

Pectin is probably composed of a number of these groups, with part or all of the carboxyl groups occupied by methoxyl or other esterifying or salt-forming groups, though it is not certain. The work is being extended to other fruits and the isolation and properties of digalacturonic acid are being investigated.

Summary

It has been shown that apples and apple pectin contain no pentose, either free or combined. The furfural comes from arabinose, which in turn is derived from the galacturonic acid. Arabinose is only an intermediate product in the formation of furfural from galacturonic acid. With weak acids some arabinose can be obtained before it is decomposed. The digalacturonic acid is probably the nucleus unit of the pectin molecule.

THE CATALYTIC ACTION OF NEUTRAL SALTS. THE EFFECT OF NORMAL ALKALI SULFATES ON ALKALI ACID SULFATES IN THE KETONIC SPLITTING OF ETHYL ACETOACETATE

BY E. A. GOODHUE AND H. L. DUNLAP

RECEIVED FEBRUARY 2, 1928 PUBLISHED JULY 6, 1928

In this work the action of normal potassium and sodium sulfates has been investigated with two concentrations of their corresponding acid salts. The compound used for studying this effect is ethyl acetoacetate, which gives carbon dioxide upon its ketonic splitting in an acid solution, thus serving as a means for carefully following the course of the reaction. Also, this reaction is irreversible, as one of the products of the reaction is removed as a gas.

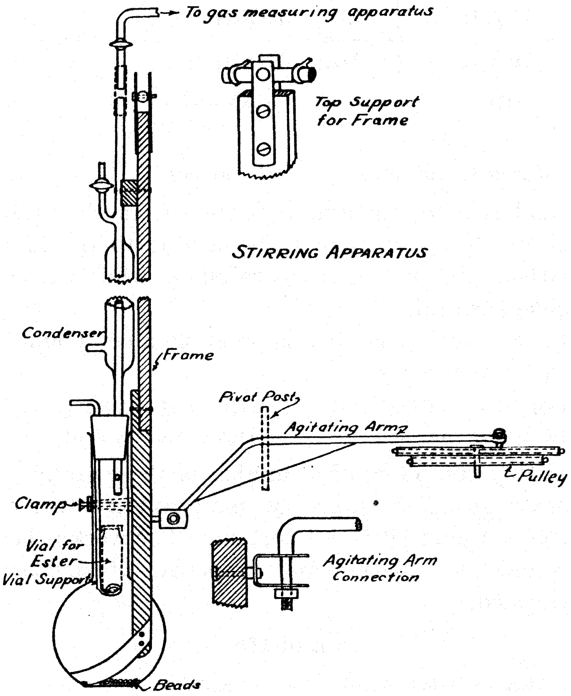

Fig. 1.

Bürki[1] used ethyl acetoacetate in his study of the hydrolysis reactions with sulfuric, hydrochloric and nitric acids and found that this ester was completely decomposed above 40°. The advantage in using this ester

---

[1] Bürki, *Helv. Chim. Acta*, 1, 231 (1918).

is that the carbon dioxide evolved can be easily measured to follow the course of the reaction over a long period of time. The classical method[2] of halting the reaction, if this is possible, and determining by titration the amount of ester hydrolyzed at intervals, is subject to considerable error.

Experimental Part

Materials.—The best grade of ethyl acetoacetate was redistilled under reduced pressure and the middle half of the distillate used. This was stored in amber colored bottles, each containing enough for a few determinations, in order not to expose the ester to air over too long a period. The ethyl alcohol was dehydrated over lime and anhydrous copper sulfate in the usual manner.

The best grades of sodium and potassium sulfates and acid sulfates were each recrystallized from water several times, dried to constant weight and analyzed for their sulfate content. The various stock solutions of these salts were analyzed for their sulfate content to make sure that all solutions were of known concentrations. Aliquot parts of these stock solutions were taken for dilution to their required normalities.

Apparatus.—The apparatus used in the work was developed by Dr. C. E. Boord and H. L. Dunlap in an unpublished work on the study of alkali and alkaline earth chlorides with hydrochloric acid on the hydrolysis of this same ester. The thermostat was electrically heated and the temperature controlled to a tenth of a degree. The flasks were made specially for this work, having a capacity of two hundred cc. and with necks five inches in length. These were connected to a condenser (Fig. 1) by means of a two-holed rubber stopper, one for the condenser and the other for the stiff platinum wire which held the vial containing the ester. The flask and condenser were firmly fastened to a frame which was suspended at the top, the lower part being connected to a pivoted arm from a pulley. In operation, this gave the flask a circular motion in the bath and thus agitated its contents. The neck of the flask extended three inches above the thermostat liquid and thus permitted the watching of the

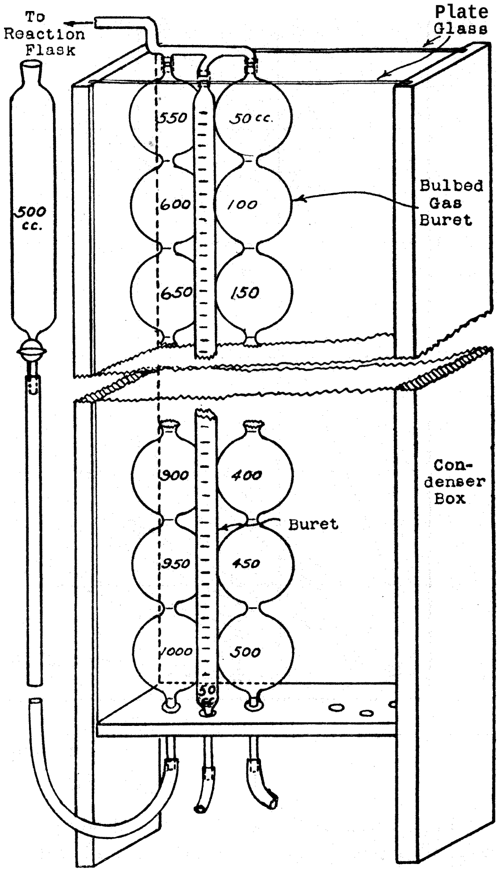

Fig. 2.—Gas measuring apparatus.

---

[2] Ostwald, *J. prakt. Chem.*, **28**, 449 (1883).

vial before its release. The side arm at the top of the condenser permitted the adjusting of the pressure within the apparatus before tripping the ester into the solution for starting the reaction.

The gas measuring apparatus (Fig. 2) is a modified Blier-White chain of bulbs type. A three-way manifold connects all compartments of the condenser and leveling bulbs. These gas measuring compartments were all carefully calibrated and the volume of gas at any time could be read to one-tenth of a cc. The whole gas train was immersed in a water-filled box which had two opposite sides of glass. The temperature of the surrounding water was recorded with each reading for correcting the volume of the gas to standard conditions. Two sets of flasks were used in the thermostat, thus permitting of two determinations at the same time. Readings were taken at five-minute intervals.

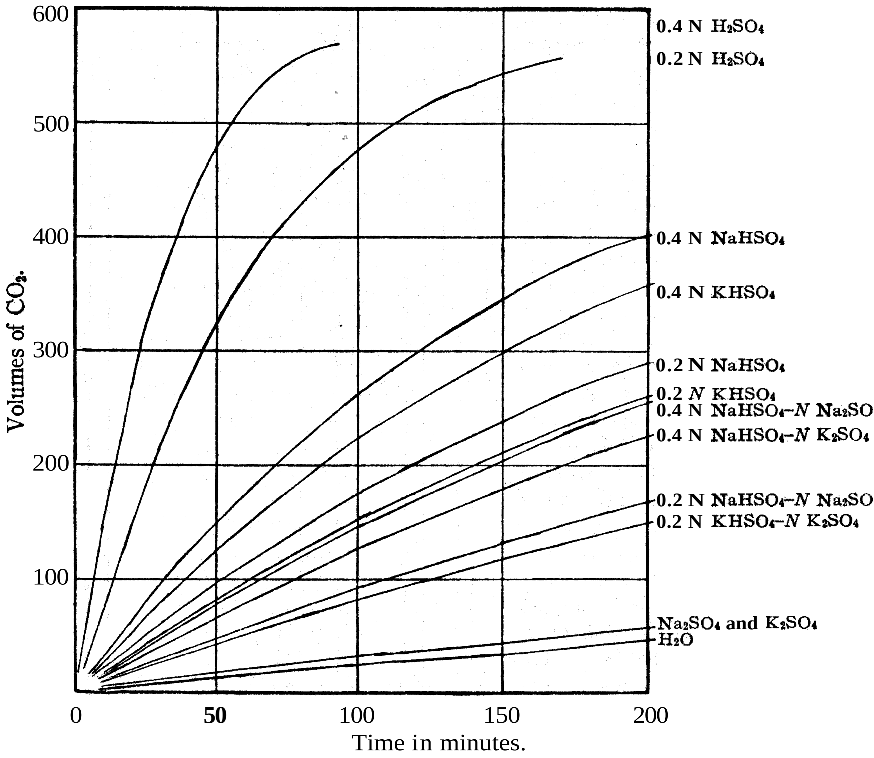

Fig. 3.—Hydrolysis of *N*/2 ester at 90°.

Experimental Procedure.—The desired concentration of salts was placed in the flasks along with one cc. of alcohol and water to make 46.8 cc. and when the ester (3.2527 g.) was introduced, this made 50 cc. of a half molar solution of ester. The capped vials containing the ester were held in place until the temperature of the flask and contents became that of the bath. After adjusting the measuring bulbs and starting agitation, the outside connection was closed, the vial dropped and the zero reading taken. As soon as 50 cc. of gas is collected in the burets, this is simply transferred to one of the 50-cc. bulbs. Checks were run in all cases with an allowable variation of three-fourths of one per cent. Vapor pressure corrections were made in all cases as that of pure water, which is in slight error but it is the same for all determinations.

The volume of carbon dioxide was reduced to standard conditions and graphs were plotted for the five minute intervals. The data are condensed in Tables I to VII. The reaction constant is calculated according to the formula

$$K = \frac{1}{t} \log_{10} \frac{560.3}{560.3 - V_t}$$

where V_t represents the corrected volume of carbon dioxide collected in time "t" and 560.3 is the volume of the gas which could be obtained by complete decomposition of the ester. The third column gives the various values for "k," the constant for a first order reaction.

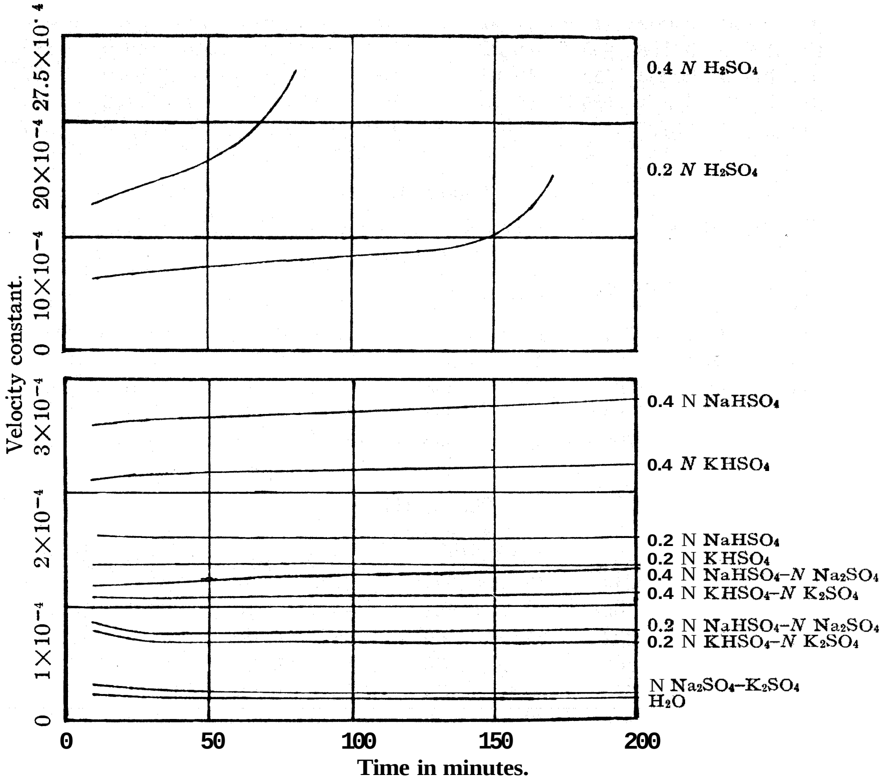

Fig. 4.—Reaction constants for hydrolysis of esters at 90°.

Data obtained with hydrolysis of the ester at 90° are shown graphically in Fig. 3 and the variation of the velocity constants with time is shown in Fig. 4. Similar curves are obtainable at other temperatures.

Discussion of Data.—It might be expected in the hydrolysis of the ester with pure acid that the reaction constant would increase with time as the more active hydrogen would be affected by the increasing concentration of the alcohol and acetone from the decomposition of the ester.

The greater the concentration of the acid, the greater we should expect the variation of this reaction constant. Data in Table I show this to be true.

The effect of the neutral salt on the rate of hydrolysis may be shown by calculating the ratio of the time required with the acid sulfate plus the neutral salt for producing 75 and 150 cc. of carbon dioxide, to the time required with the acid salt alone for producing the same quantity of carbon dioxide. In this manner the constituents in the solution will be the same at the time of comparison. These calculations are given in Table VIII for potassium salts and calculations for sodium salts give very similar results.

Summary

An apparatus has been devised for accurately measuring the velocity of reactions at higher temperatures and over a long period of time with substances evolving a gas.

The effects of normal sodium and potassium sulfates on their corresponding acid sulfates in the hydrolysis of ethyl acetoacetate have been studied at the temperatures of 80°, 90° and 95°.

CARBONIC ACID AZIDES

BY CHARLES VINTON HART[1]

RECEIVED FEBRUARY 13, 1928 PUBLISHED JULY 6, 1928

Accepting the view of Franklin and his collaborators to the effect that guanidine, cyanamide, dicyandiamide and melamine are ammono carbonic acids,[2] then the compounds named and formulated as follows: (1) guanylazide, $HNC(NH_2)N_3$, (2) cyanazide, NCN_3, (3) dicyanamidazide, $NCNC(NH_2)N_3$, (4) dicyandiazide, $NCNC(N_3)_2$, (5) cyanuramiddiazide, $C_3N_3(N_3)_2NH_2$ and (6) cyanurtriazide, $C_3N_3(N_3)_3$, are to be looked upon as carbonic acid azides.

Dicyandiiide, $NCNC(N_3)_2$, and Dicyanamidazide, $NCNC(NH_2)N_3$.—By the action of cyanogen bromide on sodium azide in water solution, Darzens[3] obtained a crystalline product, formed as he believed in accordance with the equation, $NCBr + NaN_3 = NCN_3 + NaBr$, to which he gave the name carbon pernitride.

[3] Darzens, *Compt.* rend., 154,1232 (1912).

Looking upon cyanogen bromide and sodium azide as a carbonic acid bromide and sodium ammono nitrate, respectively, then Darzens' compound, represented by the formula, $\mathrm{N}\overset{-}{\underset{-}{\equiv}}\overset{+}{\underset{+}{\ddagger}}\mathrm{C}+\,-\mathrm{N}=\,\ddagger\mathrm{N}\overset{+}{\underset{+}{\ddagger}}\overset{+}{\underset{-}{=}}\mathrm{N}$, would be a mixed carbonic-nitric anammonide.[4]

It was in an attempt to determine whether Darzens' compound would be converted into a mixture of cyanamide and hydrazoic acid by the action of ammonia that the investigation described in this paper had its origin.

When, accordingly, a current of dry ammonia gas was passed into an ether solution of Darzens' compound, ammonium azide was obtained as expected but instead of cyanamide the other product of the reaction proved to be a hitherto unknown compound of the formula, $NCN(NH_2)N_3$, to which the name dicyanamidazide has been given.

The formation of this carbonic acid azide is readily explained on the assumption that Darzens had the dimer of cyanazide in his hands, which under the action of ammonia is ammonolyzed as represented by the equation, $NCNC(N_3)_2 + NH_3 = NCNC(NH_2)N_3$, into dicyanamidazide and hydrazoic acid.

Hydrolysis of Dicyandiazide.—Darzens states that when his azide is hydrolyzed with boiling water, carbamic acid azide is first formed, which, being unstable, decomposes to give carbon dioxide and hydrazoic acid. The present investigation showed the hydrolysis to proceed in conformity with the equation

$$NCNC(N_3)_2 + H_2O = NCNC(OH)_2 + 2HN_3 = CO_2 + 2HN_3 + H_2NCN$$

The hydrazoic acid and cyanamide were not formed quantitatively for the reason that a certain portion of each disappeared to form 5-aminotetrazole.[5] When a sodium hydroxide solution was used in place of pure water for the hydrolysis, sodium azide and sodium cyanamide were formed almost quantitatively.

Reduction of Dicyandiazide and Dicyanamidazide.—Dicyandiazide is reduced to dicyandiamide in accordance with the equation, $NCNC(N_3)_2 + 2H_2S = NCNC(NH_2)_2 + 2S + 2N_2$, when treated with hydrogen sulfide. It is interesting to interpret the reactions involved as consisting in the reduction of a mixed carbonic-nitric anammonide to a mixed carbonic-nitrous acid which breaks down into a carbonic acid and nitrous anammonide, $\mathrm{NCNC}\ddagger(-\mathrm{N}=\,\ddagger\mathrm{N}\overset{+}{\underset{+}{\ddagger}}\overset{-}{\underset{-}{=}}\mathrm{N})_2 + 4\mathrm{H} = \mathrm{NCNC}\ddagger(-\mathrm{N}=\,\ddagger\mathrm{N}+\,-\mathrm{NH}_2)_2$ or $\mathrm{NCNC}\ddagger(-\mathrm{NH}-\,+\mathrm{N}\ddagger=\mathrm{NH})_2 = \mathrm{NCNC}(\mathrm{NH}_2)_2 + 2\mathrm{N}_2$.

Dicyanamidazide is reduced to dicyandiamide in a similar manner.

Tests for the Presence of Azide Groups.—During the early part of

---

[4] An ammonia analog of a purely hypothetical carbonic-nitric anhydride, $OC(ONO_2)_2$.

[5] Hantzsch and Vagt, Ann., 314,362 (1900).

this investigation, some doubt was entertained as to whether or not we were dealing with azide groups in these compounds since azides tend to revert to the more stable isomeric tetrazoles. Although sodium azide is formed when dicyandiazide and dicyanamidazide, respectively, are warmed with sodium hydroxide solution, yet the literature concerning tetrazoles does not seem to exclude similarly acting substances from being ring compounds.[6] Tetrazoles are generally very resistant to the action of alkali or acid, so the formation of sodium azide by treating a compound with sodium hydroxide solution would strongly indicate the presence of a free azide group and not a stable ring compound. It is highly desirable that we have some other test to substantiate this one.

Turrentine[7] has shown that hydrogen sulfide reduces hydrazoic acid in the cold to nitrogen and ammonia. Thiele[8] in his investigation of guanylazide reduced this compound to guanidine with hydrogen sulfide, sulfur being precipitated and nitrogen evolved while in a similar manner Hantzsch and Vagt[9] reduced carbamic azide to urea.

These reactions together with experience to the effect that all the azides described in this paper readily undergo reduction when treated with hydrogen sulfide lead us to emphasize two tests for proving the presence of azide groups, (1) heating the substance with sodium hydroxide solution to form sodium azide and (2) the reduction of the azide group to the amino group by means of hydrogen sulfide with simultaneous evolution of nitrogen and the precipitation of sulfur.

Dicyanphenylamidazide and Phenyldicyandiamide.—When an alcoholic solution of dicyandiazide is treated with aniline, dicyanphenylamidazide is formed as represented by the equation, $NCNC(N_3)_2 + C_6H_5NH_2 = NCNC(N_3)NHC_6H_5 + HN_3$.

Dicyanphenylamidazide is a phenyl ester of a carbonic acid azide containing one unreplaced acid hydrogen atom in consequence of which it should show distinctly the properties of an acid. A sodium salt, stable in the presence of water, has been prepared.

When treated with hydrogen sulfide dicyanphenylamidazide is reduced to phenyldicyandiamide, $NCNC(NH_2)NHC_6H_5$, which is probably identical with phenylcyanguanidine.[10]

α-Naphthylamine, methylamine, ethylamine and phenylhydrazine were found to enter into reactions with dicyandiazide. With the exception of dicyan-α-naphthylamidazide the products formed were not purified and analyzed.

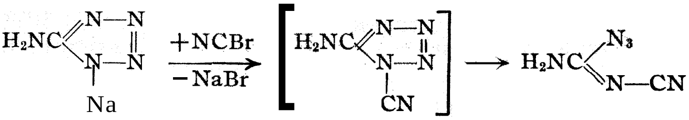
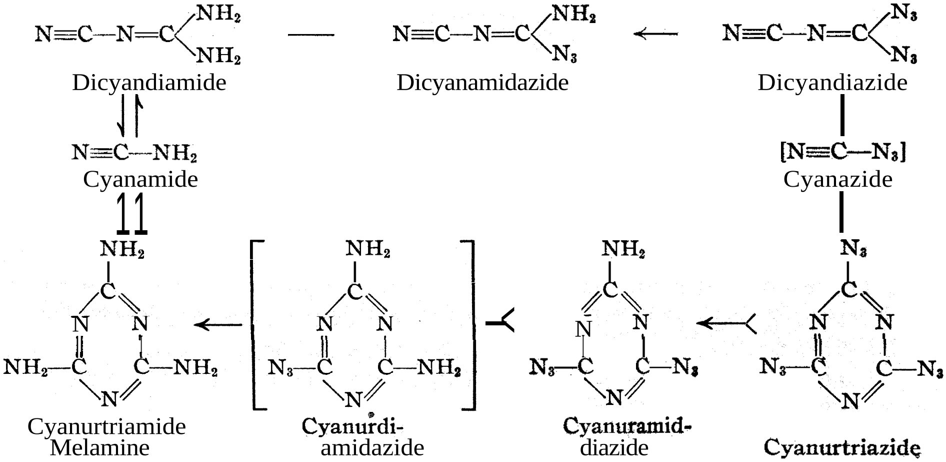
The Opening of a Tetrazole Ring.—An attempt was made to prepare 1-cyan-5-aminotetrazole, a tetrazole isomer of dicyanamidoazide (formula in bracket below) by treating the sodium salt of aminotetrazole with cyanogen bromide. Instead of the expected compound dicyanamidazide was obtained, the reaction taking the course represented by the scheme



Since aminotetrazole is formed from guanylazide by isomerization and the former is converted to dicyanamidazide by replacement of a hydrogen atom by a cyanogen group, the transformation of a compound possessing an azide group to a tetrazole, and from a tetrazole again to a compound having an azide group, has been effected.

Cyanurtriazide, $C_3N_3(H_3)_3$.—It will be recalled that cyanamide is capable of forming a trimolecular polymer known as melamine from which cyclic ammono carbonic acid three azides are theoretically derivable, depending upon whether it is considered as reacting with one, two or three molecules of hydrazoic acid.

Certain considerations led Ott, who first prepared this triazide, to assume that one or more tetrazole groupings might be present in the cyanurtriazide configuration. Referring to the two general tests already mentioned in this paper for the identification of azide groups, it is seen that the hydrolysis of cyanurtriazide into sodium azide and cyanuric acid by the action of hydroxide solution[6c] indicates the presence of three azide groups. In order to strengthen the evidence that cyanurtriazide contains three azide groups, it was subjected to the action of hydrogen sulfide, whereupon melamine was formed in accordance with the equation, $C_3H_3(N_3)_3 + 3H_2S =$



$C_3N_3(NH_2)_3 + 3S + 3N_2$. It must therefore be concluded that cyanurtriazide does not contain a single tetrazole group.

Cyanuramiddiazide, $C_3N_3(NH_2)(N_3)_2$ and Cyanurdichlorazide, $C_3N_3(Cl_2)N_3$.—The first compound was prepared by passing gaseous ammonia into an ether solution of cyanurtriazide; the second was obtained by treating one mole of cyanurtrichloride with one mole of sodium azide. Cyanuramiddiazide was reduced to melamine by the action of hydrogen sulfide.

Carbonic Acid Azides.—The scheme given above summarizes the relationships which have been established between three ammono carbonic acids and their azides.

Experimental Part

Preparation of **Dicyandiazide.**—To a solution of 25 g. of sodium azide in 100 cc. of water maintained at 0°, 45 g. of freshly prepared cyanogen bromide was added in small amounts with continuous stirring. After all of the cyanogen bromide was dissolved, the flask was removed from the ice-bath and allowed to stand three or four hours at room temperature, whereupon a colorless or slightly yellow oil separated at the bottom of the flask. The oil was extracted with alcohol free ether, washed once with a little water and then dried over anhydrous sodium sulfate. After one hour the ether solution was filtered into several evaporating dishes and the ether removed by a current of dry air. Some crystals usually formed on the sides of the dish and were carefully removed with a piece of filter paper and saved for future seeding. As a rule after the ether had disappeared, an oil remained to which a crystal of the substance had to be added in order to start the crystallization. After washing with a very small amount of anhydrous ether, the product was obtained in the form of needle-like crystals by recrystallization from pure, dry ether. The crystals were removed from the dish to a filter paper by the use of a horn spatula and dried in *vacuo* over phosphorus pentoxide. The yield was about 55%.

The purest reagents were used in this preparation since small amounts of impurities prevented crystallization even after seeding. If the crystals were not pure, or in case they were allowed to stand in contact with the mother liquor, a substance was formed after a time which was insoluble in ether and water, and was not exploded by shock. This fact was noted by Darzens, and believed by him to be evidence of the formation of a polymer of cyanogen azide. Furthermore, a well crystallized, explosive, water soluble compound showing no definite melting point was isolated from the reaction mixture. Unfortunately neither of these compounds was further investigated.

Dicyandiazide, especially when impure, is dangerously explosive. It is soluble in water, ether, chloroform and alcohol, but insoluble in petroleum ether. The purest crystals obtained in this investigation melted at 40.3° (corr.). Darzens gives the melting point, 35.5–36.0°. At a temperature of about 70°, it commences to decompose, and it explodes with extreme violence at about 170".

The analysis of this compound was made by mixing the powdered sample intimately with powdered cupric oxide and so regulating the combustion that the substance decomposed at a little above 100".

Hydrolysis of Dicyandiazide by Boiling Water.—The apparatus and procedure used were essentially those used in the determination of carbon dioxide in rock analyses with the exception that a tube containing a 5% solution of silver nitrate was interposed between the reflux condenser and the drying tubes in order to absorb the hydrazoic acid. In solution in boiling water decomposition of the compound was rapid. The silver azide formed was filtered on a Gooch crucible and weighed as such. The carbon dioxide evolved was absorbed in a soda-lime tube at the end of the apparatus. The cyanamide remaining in solution in the reaction flask was determined by precipitation as the silver salt from a slightly ammoniacal solution. When the filtrate from this salt was acidified with dilute nitric acid, a gelatinous silver precipitate was formed which was not further investigated (dicyandiamide).

Anal. Calcd. for CO_2: 32.3. Found: 29.0. Calcd. for HN_3: 63.2. Found: 43.4. Calcd. for $NCNH_2$: 30.9. Found: 21.0.

Although the analytical data show the carbon dioxide which was formed to approximate the theoretical, the hydrazoic acid and the cyanamide obtained are far below the calculated amount.[5]

Hydrolysis of Dicyandiazide with Sodium Hydroxide Solution.—To a suspension of 0.1 g. in 10 cc. of water, 0.6 g. of sodium hydroxide was added and the solution was heated to about 70° for some two minutes. After dilution to about 100 cc.. the cyanamide was precipitated from the slightly ammoniacal solution by adding a solution of silver nitrate. The silver azide was precipitated from the filtrate by acidifying with dilute nitric acid.

Anal. Subs., 0.1000: Ag_2NCN, 0.1926; AgN_3, 0.2115. Calcd. for $NCNH_2$: 30.9. Found: 31.6. Calcd. for HN_3: 63.2. Found: 60.7. 0.1926 g. of Ag_2NCN gave 0.2137 AgCl. Calcd. for Ag: 84.3. Found: 83.5. 0.2115 g. of AgN_3 gave 0.1971 AgCl. Calcd. for Ag: 71.9. Found: 70.2.

Reduction of Dicyandiazide to Dicyandiamide.—One gram of dicyandiazide was dissolved in about 5 cc. of alcohol. After diluting with 30 cc. of water, hydrogen sulfide was passed through the solution. Nitrogen was evolved and sulfur was precipitated immediately. After heating to 80° for a few minutes to coagulate the sulfur, the solution was filtered and the filtrate was evaporated with a current of dry air. The crystals of dicyandiamide thus obtained were, after recrystallization, found to melt at 207.4'. When mixed with pure crystals of dicyandiamide melting at 207.8' the mixture melted at 207.5".

Ammonolysis of Dicyandiazide to Dicyanamidazide.—A slow current of ammonia was passed into a cold solution of 0.39 g. of dicyandiazide in about 150 cc. of dry ether. Ammonium azide separated as a white, flocculent precipitate. After filtration and removal of the ether, colorless, plate-like crystals of dicyanamidazide remained, which after recrystallization from ether melted at 151–152° with evolution of a gas; yield, 0.30 g.

Anal. Calcd. for $NCNC(NH_2)N_3$: C, 21.8; H, 1.8; N, 76.3. Found: C, 21.8; H, 1.8; N (Dumas), 76.2.

Dicyanamidazide is sparingly soluble in water and ether and is very soluble in alcohol and acetone. It is only slightly soluble in chloroform and hot benzene and it is insoluble in petroleum ether. When an aqueous solution of dicyanamidazide is boiled, hydrazoic acid is given off gradually. When heated with a concentrated solution of sodium hydroxide, sodium azide, sodium carbonate, cyanamide and ammonia are formed. When heated in a tube it decomposes with a flash leaving a light brown residue (melon).

Dicyanamidazide from Aminotetrazole (the Opening of a Tetrazole Ring).—Aminotetrazole nitrate, 37 g., suspended in 50 cc. of water, was brought into solution and neutralized by adding a concentrated solution of sodium hydroxide, using phenolphthalein as an indicator. After cooling to about zero degrees, 27 g. of pulverized cyanogen bromide was added in small quantities while agitating. In order to increase the solubility of the cyanogen bromide, about 40 cc. of acetone was advantageously added at this point. Some heat was evolved. After standing for several hours, the solution was extracted with ether and the ether solution was dried with anhydrous sodium sulfate. Pure dicyanamidazide was obtained after evaporation and recrystallization from ether.[11] The crystals gave all the reactions characteristic of dicyanamidazide; melting point, 151–152°. A mixed melting point gave 151°.

Anal. Calcd. for $C_2H_2N_6$: C, 21.8; H, 1.8. Found: C, 21.8; H, 2.1.

Reduction of Dicyanamidazide to Dicyandiamide.—One gram of finely powdered dicyanamidazide was suspended in 30 cc. of cold water, and hydrogen sulfide was passed through the solution for half an hour. Nitrogen was evolved and sulfur was precipitated. The solution was heated almost to boiling in order to precipitate the sulfur and was then filtered. The cold solution was evaporated in a current of air to a small volume. After purification by three recrystallizations, the substance melted at 207.5°. When mixed with pure dicyandiamide melting at 207.8°, the mixture melted at 207.7°.

Dicyanamidazide Hydrochloride, $NCNC(NH_2)N_3 \cdot HCl \cdot H_2O$.—One gram of pure powdered dicyanamidazide was dissolved in 5 cc. of concentrated hydrochloric acid. Within a few minutes needle-like crystals separated out. The excess of acid was absorbed on a porous plate and after air-drying the crystals were dried for a short time in a desiccator. The hydrochloride containing one molecule of water gradually decomposes when heated, losing its crystalline appearance above 150°.

Anal. Calcd. for $C_2H_2N_6 \cdot HCl \cdot H_2O$: Cl, 21 6. Found: 21.7.

Dicyanphenylamidazide, $NCNC(N_3)NHC_6H_5$.—To a solution of 0.55 g. of dicyandiazide in 10 cc. of alcohol, a solution of 0.35 g. of aniline in 10 cc. of alcohol was added and thoroughly mixed. Hydrazoic acid was freely evolved and within half an hour needle-like crystals separated from the solution. After filtration the crystals were washed with a little alcohol. They were recrystallized from alcohol.

Anal. Calcd. for $C_8H_6N_6$: C, 51.6; H, 3.2. Found: C, 51.2; H, 3.2.

Dicyanphenylamidazide decomposes suddenly with evolution of a gas when heated above 145°. It is insoluble in most of the common solvents. It dissolves in concentrated hydrochloric acid, but it is reprecipitated upon dilution. When heated with concentrated sodium hydroxide solution, sodium azide and aniline are two of the products formed.

Sodium Dicyanphenylamidazide, $NCNC(N_3)N(Na)C_6H_5$.—Dicyanphenylamidazide, 0.5 g., was suspended in 3 cc. of water and a normal solution of sodium hydroxide was added until most of the azide dissolved. After filtration, the solution was concentrated to a small volume by a current of dry air. The crystals separated as very minute needles. They were dried in a desiccator.

Anal. Calcd. for $C_8H_5N_6Na$: Na, 11.1. Found: 11.0.

Reduction of Dicyanphenylamidazide to Phenyldicyandiamide.—Approximately 0.5 g. of dicyanphenylamidazide was suspended in a mixture of 5 cc. of alcohol and 5 cc. of water. After warming to 70°, hydrogen sulfide was passed into the solution. At the

---

[11] The yield was good (E. C. F.).

end of the reaction the solution was brought to boiling in order to coagulate the sulfur. After filtration, the solution was evaporated to a small volume by dry air. Plate crystals were obtained which after recrystallization from water melted at 195–196°. Phenylcyanguanidine[10] is described as forming needle crystals from water, melting at 190–191°.

Dicyan-α-naphthylamidazide, NCNC(N_3)NHC$_{10}$H$_7$.—One gram of dicyandiazide was dissolved in 15 cc. of alcohol and one gram of a-naphthylamine dissolved in an equal volume of alcohol was added. Hydrazoic acid was freely evolved and after some time beautiful needle crystals separated which were filtered and recrystallized from alcohol. The crystals decomposed slowly when heated. They were found to be insoluble in most of the common solvents. When heated with a concentrated solution of sodium hydroxide, sodium azide was formed and the odor of a-naphthylamine was observed.

Anal. Calcd. for $C_{12}H_8N_6$: C, 61.0; H, 3.4. Found: C, 60.9; H, 3.5.

Sodium Dicyan-a-naphthylamidazide, NCNC(N_3)N(Na)C$_{10}$H$_7$.—Dicyan-α-naphthylamidazide (0.3 g.) was suspended in 10 cc. of water and a little less than the calculated amount of normal sodium hydroxide was added. The solution was heated to boiling and filtered. Upon cooling, the sparingly soluble sodium salt crystallized out as needles.

Anal. Calcd. for $C_{12}H_7N_6Na$: Na, 8.9. Found: 8.9.

Reduction of Cyanurtriazide to Melamine.—Cyanurtriazide[6] (0.6 g.) was suspended in a mixture of 25 cc. of alcohol and 15 cc. of water and hydrogen sulfide was passed into the cold solution for about one-half hour. Nitrogen was evolved and sulfur was precipitated. After boiling and filtering, the solution was evaporated to about 7 or 8 cc. Upon cooling, melamine separated as colorless plate crystals. They were recrystallized once from hot water.

Anal. Calcd. for $C_3H_6N_6$: N, 66.6. Found: 66.2.

Cyanuramiddiazide, $C_3N_3(NH_2)(N_3)_2$.—Two grams of cyanurtriazide were dissolved in 200 cc. of anhydrous ether and a current of ammonia was passed through the solution for one hour. A white precipitate formed consisting of a mixture of ammonium azide and cyanuramiddiazide. After filtration, the mixture was treated with a little water in order to dissolve the ammonium azide. The cyanuramiddiazide remained undissolved as dense, colorless crystals which were recrystallized from a large volume of hot alcohol forming large plate-like crystals.

Anal. Calcd. for $C_3H_2N_{10}$: C, 20.2; H, 1.1. Found: C, 20.1; H, 1.2.

This substance does not melt sharply, but starts to decompose above 200°, gradually turning brown. It decomposes with great violence when heated suddenly to 210°. When treated with a solution of sodium hydroxide it dissolves and is reprecipitated when the solution is acidified. When heated with a strong sodium hydroxide solution, sodium azide, cyanamide and carbon dioxide are formed. It is insoluble in most of the common solvents.

Reduction of Cyanuramiddiazide to Melamine.—Cyanuramiddiazide (0.5 g.) was suspended in a mixture of 10 cc. of alcohol and 10 cc. of water. Hydrogen sulfide was passed into the warm solution. Notwithstanding the slight solubility of the substance the reaction took place with vigorous evolution of nitrogen and deposition of sulfur. After filtration, the solution was evaporated to a small volume, whereupon melamine separated as colorless plate crystals.

Anal. Calcd. for $C_3H_6N_6$: N, 66.6. Found: 66.1.

Cyanurdichloridazide, $C_3N_3(Cl_2)N_3$.—One gram of sodium azide was dissolved in 10 cc. of water and was slowly added to a solution of 3 g. of cyanurtrichloride in 20 cc. of acetone. After shaking for about five minutes, the solvent was allowed to evaporate spontaneously. Plate-like crystals separated which were filtered off, washed with water and recrystallized from a small amount of warm alcohol; m. p. 85°.

Anal. Calcd. for $C_2N_6Cl_2$: Cl, 37.2. Found: 37.7.

Cyanurdichloridazide is sparingly soluble in alcohol and insoluble in water. The usual tests showed the presence of an azide group.

In conclusion, the author wishes to extend his sincere thanks to Dr. Edward Curtis Franklin under whose guidance this work progressed.

Summary

1. The product previously known as cyanogen azide or carbon pernitride is shown to be dicyandiazide.

2. The azides studied are shown to be derived from the ammono carbonic acid, cyanamide and its polymers.

3. Two general tests, which show the distinction between compounds containing azide groups and their isomeric tetrazoles are described and their application demonstrated.

4. The structure of cyanurtriazide containing three azide groups is confirmed, thus eliminating the tetrazole structures which the original investigator considered.

5. A tetrazole ring is opened, revealing the free azide group from which the original tetrazole was derived.

6. The following new compounds are described: (1) dicyanamidazide, (2) dicyanamidazide hydrochloride, (3) dicyanphenylamidazide, (4) sodium dicyanphenylamidazide, (5) phenyldicyandiamide, (6) dicyan-α-naphthylamidazide, (7) sodium dicyan-a-naphthylamidazide, (8) cyanuricamiddiazide and (9) cyanuricdichloridazide.

CATALYSIS IN THE CONVERSION OF ALLYL ALCOHOL AND ACROLEIN INTO PROPIONALDEHYDE

BY PAUL E. WESTON AND HOMER ADKINS

RECEIVED FEBRUARY 16, 1928 PUBLISHED JULY 6, 1928

F. H. Constable[1] concluded from a study of the rates of the reactions at different temperatures that allyl alcohol over copper showed two primary reactions

$$CH_2{=}CHCH_2OH = CH_2{=}CHCHO + H_2 \qquad (1)$$

$$CH_2{=}CHCH_2OH = CH_3CH_2CHO \qquad (2)$$

He demonstrated that propionaldehyde was not formed, as bad previously been assumed, according to the reaction

$$CH_2{=}CHCHO + H_2 = CH_3CH_2CHO \qquad (3)$$

For some time one of us has been greatly interested in those properties of oxide catalysts which determine the proportion of simultaneous and

---

[1] Constable, *Proc. Roy. Soc. (London)*, **A113**, 254 (1926).

competing reactions. In almost all of the cases previously studied in this Laboratory one of the competing reactions involved dehydration of the organic compound. It was therefore a matter of considerable interest to investigate the proportions of two reactions, one of which involved dehydrogenation and the other intramolecular rearrangement, over various catalysts whose characteristics had been previously studied for the reactions of saturated alcohols, esters, etc. The results of this investigation will shortly be submitted for publication, but in this communication we wish to present certain data bearing on the conversion of allyl alcohol and acrolein into propionaldehyde over a zinc oxide and an aluminum oxide catalyst.

The apparatus used in the experimental work is shown in Fig. 1. The method of introducing the alcohol was a modification of that designed by Paul E. Millington in this Laboratory. A constant head of water A, equivalent to **35** cm. of mercury, compressed air in the bottle B. The rate of flow of alcohol from the reservoir, *G*, through the fine capillary, H, could be varied slightly by regulating the pressure of the air by changing the depth of the mercury in *C*. D is a calcium chloride tower to dry the air and E is a manometer. The flow of alcohol could be stopped instantly by releasing the air pressure in the reservoir, G, through the stopcock, F. The limb, J, of the catalyst tube was 2 cm. in diameter and **33** cm. long. The exit tube was a capillary of *2* mm. bore. Six tenths of a cc. of the catalyst in the form of fragments of small pills was placed in a thin layer at L, on top of glass beads which filled the tube to the point J. The catalyst tube was immersed in an electrically heated bath of sodium and potassium nitrates, the temperature of which was kept constant at **330** ± 3° by means of a Leeds and Northrup potentiometer controller. At **400°** considerable charring and side reactions took place but at 330° the amount of side reactions was small, as shown by the composition of the gaseous products.

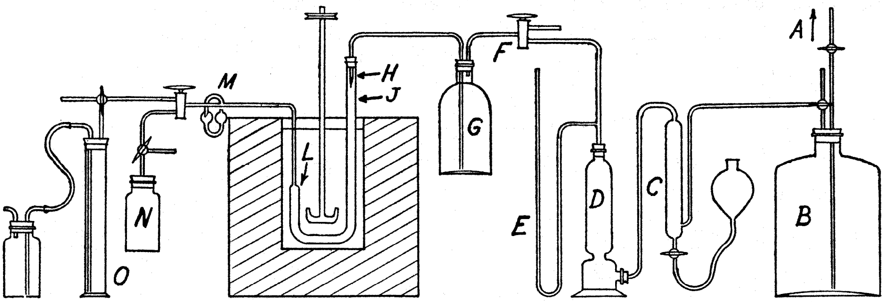

Fig. 1.—Apparatus for the study of the reactions of alcohols over solid catalysts.

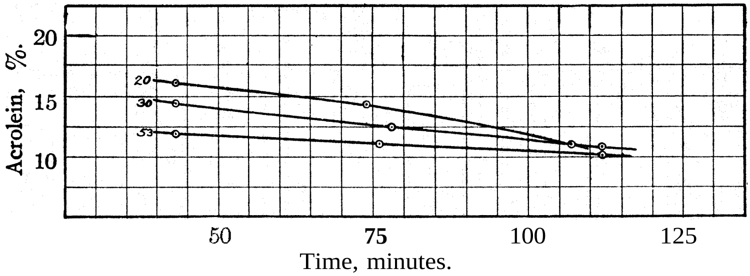
The gaseous products of the reaction were collected over an aqueous solution of sodium bromide in the cylinder, O. Sufficient oxygen was added to make the volume **100** cc., and the gas was analyzed over water in an Orsat apparatus. The portion absorbed by potassium hydroxide is reported as carbon dioxide; that removed by bromine as unsaturated hydrocarbons. The hydrogen and carbon monoxide were determined by exploding the residue and measuring the contraction and subsequent absorption by potassium hydroxide. The composition of the gas was approximately 9% carbon dioxide, 6% unsaturated hydrocarbons, 80% hydrogen and *5%* carbon monoxide.

The aldehydes formed in the reaction were determined by precipitation as the *p*-nitrophenyl hydrazones. Seventy cc. of a saturated solution of p-nitrophenyl hydrazine in normal hydrochloric acid was placed in a 250cc. wide-mouthed bottle, N, closed by a rubber stopper bearing a stopcock. Air was removed from the bottle till a pressure of 30 mm. of mercury was reached. The bottle was then attached to the exit of the catalyst tube and the stopcock opened enough to reduce the pressure in the tube (as indicated by the manometer, M) slightly below atmospheric pressure. After a sample had been collected, the stopcock was closed, the bottle shaken occasionally and allowed to stand for four hours. The hydrazone was collected in a Gooch crucible containing an asbestos mat, dried in a calcium chloride desiccator at 50° under reduced pressure and weighed.

The loaded catalyst tube was put in place in the bath and dry air was allowed to pass through it for one and one-half hours before admitting alcohol. Thirty minutes after the flow of alcohol had begun, an aldehyde sample was collected, then a gas sample which in turn was followed by another aldehyde sample, and so on till three gas samples and four aldehyde samples had been collected. Enough aldehyde was collected to give about **0.3** g. of hydrazone, which took from three to six minutes. Enough gas was collected to give about 15 cc. of hydrogen, which required from fifteen to thirty minutes. The allyl alcohol was prepared from formic acid and glycerin and dried by refluxing with potassium carbonate; b. p. 95.5–96.5° (corr.) at 745 mm.[2]



Pig. 2.—Variation in percentage of acrolein with rate of alcohol flow. The percentage of acrolein (ordinates) in the aldehydes produced is plotted against the time of sampling in minutes (abscissas) lor three rates of allyl alcohol flow, namely, 20, **30** and 53 cc. per hour. The zinc oxide catalyst was formed by the thermal decomposition of zinc oxalate.

From the length of the interval for sampling the aldehyde and the weight of the hydrazone produced, the amount of hydrazone that would be formed per hour was calculated. This was plotted against the mean time during which the sample was collected, giving an activity curve as shown in Fig. **3.** The weight of the hydrogen was calculated from the volume of hydrogen found in the gas analysis. Assuming a 96% conversion of acrolein to the hydrazone,[1] the weight of hydrazone formed was calculated and then the weight per hour. This value divided by the activity (from Fig. **3)** at the mean time of collecting the gas sample gave the percentage of acrolein produced at that time. The three values obtained in one experiment were plotted as in Fig. 2.

It was observed in connection with other experiments that the pro-

---

[2] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1921, Vol. I, p. 15.

portion of acrolein, as compared to propionaldehyde, was increased by decreasing the rate of passage of allyl alcohol over the catalyst. For example, in an experiment where the percentage of acrolein should have been about 14% with 30 cc. of alcohol per hour, the percentage of acrolein found was actually about 19% when the rate of alcohol flow had decreased to perhaps 15 cc. per hour. (A similar effect is of course produced by increasing the volume of the catalyst.) Following this casual observation, experiments were carried out in order to measure this effect. The results of these experiments are summarized in Fig. 2.

The decrease in proportion of acrolein with increased rate of passage of allyl alcohol suggested the possibility that propionaldehyde is formed through the reaction of acrolein and allyl alcohol

$$CH_2{=}CHCHO + CH_2{=}CHCH_2OH = CH_3CH_2CHO + CH_2{=}CHCHO \qquad (4)$$

This possibility was not considered by Constable in his discussion of the reactions of allyl alcohol over copper. It cannot be eliminated as was the possibility that propionaldehyde resulted from the reaction of acrolein and hydrogen, for in this scheme acrolein is reproduced at exactly the same rate that it is consumed.

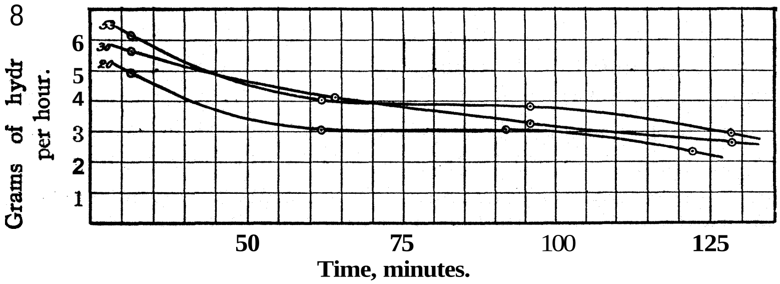


Fig. 3.—Variation of activity with rate of alcohol flow. The rate of hydrazone formation in g. per hour (ordinates) is plotted against the time of sampling expressed in minutes (abscissas) for three rates of alcohol flow.

An increase in the rate of passage of the alcohol over the catalyst would favor reaction (4) because it would increase the probability that an allyl alcohol molecule would be adsorbed by the catalyst on a "point" or area adjacent to an adsorbed acrolein molecule *before* the latter was desorbed.

If propionaldehyde is formed according to reaction (4) then while the *proportion* of acrolein to propionaldehyde decreases with increasing rate of passage of allyl alcohol, the *amount* should remain constant and there should be an increased formation of propionaldehyde, that is, there should be an increase in activity as measured by the amount of hydrazone formation. This is seen to be true from a consideration of Fig. 3, where the highest rate of flow of alcohol gives the highest activity and the lowest rate of flow gives the lowest activity.

That the rate of formation of acrolein is approximately constant and is independent of the rate of flow of alcohol may be readily shown by a consideration of the data given in Figs. 2 and 3. In Fig. 3, the area under the curve between 40 and 110 minutes gives the total weight of hydrazone formed during that time interval at that rate of flow of alcohol. Thus at 53, 30 and 20 cc. per hour, the amounts of hydrazone formed are, respectively, 4.82 g., 4.58 g. and 3.67 g. In like manner the area under a curve in Fig. 2 divided by the length of time gives the mean percentage of acrolein formed during that interval. At rates of flow of allyl alcohol of 53, 30 and 20 cc. per hour, the mean percentages of acrolein are, respectively, 11.0, 12.8 and 14.0%. The product of the weight of hydrazone and the mean percentage of acrolein is the weight of hydrazone equivalent to acrolein. Since 96% of the hydrazone is precipitated, the weights of acrolein formed at rates of flow of alcohol of 53, 30 and 20 cc. per hour are, respectively, 0.16 g., 0.18 g. and 0.16 g. These values are identical within the limit of experimental error.

Furthermore, if reaction (4) takes place, then increasing the concentration of acrolein (as by adding it to the allyl alcohol passed over the catalyst) should increase the amount of propionaldehyde formed and should decrease the amount of acrolein formed over the catalyst. This point was tested experimentally by using allyl alcohol containing 5 cc. of acrolein per 100 cc. of alcohol at a rate of 53 cc. per hour. The weight of hydrazone equivalent to the weight of acrolein already present in the alcohol was subtracted from the total hydrazone found. The remainder was then used in the customary calculations. The percentage of acrolein with pure alcohol would be about 12% at forty-five minutes but with this allyl alcohol–acrolein solution it was only 6.7%. A second determination was made in which the value 6.7% was checked; then over the same catalyst pure alcohol was used and 9.3% of acrolein was obtained. At this time (117 minutes), using pure alcohol throughout, the acrolein would have been 10% of the total aldehyde formed. In another experiment in which a solution of 15 cc. of acrolein in 85 cc. of alcohol was used, 1.5% of acrolein was obtained at the end of forty-five minutes instead of the normal proportion of 12%. The activity in this case was abnormally high, 6.8 g. per hour. This indicated that an abnormally large amount of propionaldehyde was being produced.

The experimental evidence that propionaldehyde is formed through the reaction of acrolein and allyl alcohol would be strengthened if propionaldehyde could be formed under conditions in which the intramolecular rearrangement of reaction (2) could not take place, for example, as in reaction (5)

$$CH_2{=}CHCHO + CH_3CH_2CH_2OH = 2CH_3CH_2CHO \qquad (5)$$

but n-propyl alcohol cannot be used over zinc oxide because it itself is dehydrogenated to propionaldehyde. However, over alumina this latter reaction does not take place. Only traces of aldehyde were formed when n-propyl alcohol was passed over 0.6 cc. of an alumina at 330°. The flow of alcohol was then stopped and in its place over the same catalyst an approximately 10% solution of acrolein in n-propyl alcohol was used. The amount of aldehyde passed over the catalyst was equivalent to 8.7 g. of hydrazone per hour. At the end of seven minutes hydrazone was being produced at the rate of 12.0 g. per hour, at the end of twenty-five minutes the rate was 14.1 g. and at the end of forty-five minutes hydrazone was being produced at the rate of 13.4 g. per hour. There was thus being produced by the reaction of acrolein and n-propyl alcohol, aldehyde equivalent to 3.3 g., 5.4 g. and 4.7 g. of hydrazone per hour. These values correspond to a conversion of acrolein to propionaldehyde of 38, 62 and 54%, respectively. It is thus clearly established that n-propyl as well as allyl alcohol will reduce acrolein to propionaldehyde, and that the reaction takes place over alumina as well as over zinc oxide.

Constable showed that the hydrogenation of acrolein did not occur over copper, so it seems improbable that it should occur over the less active oxide catalysts. In the case of the reaction of acrolein and n-propyl alcohol over alumina there is no possibility of the hydrogenation of acrolein taking place, for alumina does not catalyze the formation of hydrogen from propyl alcohol. It is of course *possible* that a *part* of the propionaldehyde formed over zinc oxide from allyl alcohol results from intramolecular rearrangement or through some other mechanism.

Constable found that sintered copper gave a lower proportion of acrolein than did copper which was not sintered. He suggested that there were two sets of active points, one for each reaction, and that one set was destroyed to a greater extent than the other in the sintering. It is possible that sintering the copper simply reduced its activity, which is similar in effect to increasing the rate of flow of alcohol, and thus reduced the proportion of acrolein.

Summary

The behavior over a zinc oxide catalyst of allyl alcohol and mixtures of it with acrolein has been investigated as has also the reaction over alumina of acrolein and n-propyl alcohol. All of the experimental results indicate that the formation of propionaldehyde from allyl alcohol over zinc oxide results at least in part from the reaction of allyl alcohol with acrolein and not through the hydrogenation of acrolein nor through the intramolecular rearrangement of allyl alcohol.

DIPIPERIDYLS[1]

BY C. R. SMITH[2]

RECEIVED FEBRUARY 20, 1928   PUBLISHED JULY 6, 1928

There are six possible dipiperidyls corresponding to the six dipyridyls. All of the dipyridyls[3] are known, but up to the time of these experiments only three of the dipiperidyls had been prepared. The author has prepared two additional dipiperidyls, p , ~ and p,&, leaving only the α,γ-derivative for further study.

The method of preparation is that of reduction of the dipyridyls by means of hydrogen in the presence of platinum oxide catalyst. The dipiperidyl is produced in a state of purity equal to that of the dipyridyl. Often it can be purified by suitable means when the dipyridyl cannot be easily purified.

The three dipiperidyls previously known were prepared by means of sodium and ethyl or amyl alcohol reduction and required considerable purification. γ,γ-Dipiperidyl[4] was the first dipiperidyl to be prepared by the sodium reduction and presented considerable difficulty in its purification. Ahrens prepared the dipiperidyl in a pure condition by means of the dinitroso derivative. Blau prepared α,β-dipiperidyl[5] with great difficulty, using steam distillation, crystallization of the hydrochloride from alcohol, distillation of the base and repeating the operations until a maximum melting point (68–69°) was obtained. α,α-Dipiperidyl[6] also was prepared in a pure form by Blau and required almost as much manipulation as γ,γ-dipiperidyl.

The author has prepared the dipiperidyls mentioned, together with β,γ- and β,β-dipiperidyls and also certain derivatives useful for characterizing them. All the dipiperidyls are strong bases which absorb carbon dioxide readily from the air. They are very stable to the action of heat and air. The picrates usually melt with decomposition. The bases may be titrated with two molecular equivalents of strong acid to one of base, phenolphthalein being used as indicator. The bases are very soluble in water, slightly soluble in ether and almost insoluble in petroleum ether.

In no instance does a partial reduction of the dipyridyl molecule appear to take place, either in hydrochloric acid solutions of various strengths, acetic acid solution or various solvents. The reduction goes to completion, calculated as for the formation of dipiperidyl, and stops. When

one-half this quantity is used a mixture of dipyridyl and dipiperidyl always results. In alkaline solutions, or solutions without acid, no reduction takes place at all, probably because the catalyst is inactive or rendered so by the production of the alkaline dipiperidyl.

Experimental

The same general procedure was used in the preparation of each of the dipiperidyls. The dipyridyls were usually dissolved in a moderate excess of hydrochloric acid in water or alcoholic solution and reduced at atmospheric or higher pressures. The quantity of hydrogen absorbed agreed with the absorption of twelve hydrogen atoms. The platinum oxide catalyst was prepared by the method of Vorhees and Adams.[7] After reduction the solution was separated from the platinum, evaporated to low volume and precipitated by means of absolute alcohol as the dihydrochloride. (If the original dipyridyls were somewhat impure this precipitation effected a purification but is otherwise unnecessary for the preparation of the bases.)

The bases were freed with caustic potash and extracted with ether. They may be recrystallized from petroleum ether or a mixture of ether and petroleum ether.

The experimental results on five dipiperidyls are given in tabulated form. Only a small amount of crude α,γ-dipyridyl was obtained, boiling at 282–284°, from a large quantity of mixed dipyridyls obtained in the action of sodium on pyridine. The correct quantity of hydrogen was absorbed but the dipiperidyl was too impure to prepare pure derivatives. Further study is required to obtain these α,γ-derivatives.

The phenyl isothiocyanate addition products of the type $C_{10}H_{20}N_2{\cdot}2C_6H_5NCS$ crystallize well from alcohol or alcohol and water mixtures.

of the insecticidal action of these compounds is being made in cooperation with Dr. C. H. Richardson, Deciduous Fruit Insect Investigations, Bureau of Entomology.

Summary

1. α,α-, β,β-, γ,γ-, β,γ- and α,β-dipyridyls were reduced quantitatively to the corresponding dipiperidyls by means of hydrogen in the presence of platinum oxide catalyst. Impure α,γ-dipyridyl was also reduced to the dipiperidyl but proper purification could not be made.

2. Certain physical constants of the bases, their dinitroso and other derivatives were determined to characterize them.

AN ORGANIC TITANOUS COMPOUND AND A NEW METHOD FOR THE PREPARATION OF SOLUTIONS OF TITANOUS SALTS

BY DONALD W. MACCORQUODALE AND HOMER ADKINS

RECEIVED MARCH 5, 1928 PUBLISHED JULY 6, 1928

Bischoff in 1923 observed that a blue colored substance insoluble in organic solvents and containing no sodium resulted from the reaction of an alcoholic solution of tetra-ethyl ortho titanate with metallic sodium. He demonstrated that the compound contained trivalent titanium and was presumably an ethyl titanite.

This crude ethyl titanite is readily prepared by converting titanium tetrachloride into tetra-ethyl ortho titanate.[1] The yield may be increased to 81% of the theoretical by centrifuging the mixture containing the sodium chloride and decanting off the alcoholic solution of the ortho titanate instead of distilling it from the salt mixture. The salt should be shaken and centrifuged twice with alcohol in order to wash out the ester. The titanate is readily purified by distillation so that it is entirely free from all metallic or acid impurities.

The trivalent titanium compound is most easily prepared by adding an alcoholic solution of ethyl titanate as rapidly as possible to a flask containing finely divided sodium, the flask being equipped with an efficient reflux condenser which in turn is equipped with a Bunsen valve. When the reaction becomes too vigorous, it is moderated by immersing the flask in an ice-bath for a moment. However, the more vigorous is the reduction, the better the yield of product, so that the reaction should be allowed to proceed as vigorously as the efficiency of the condenser will permit. The separation of the blue precipitate is best effected by centrifuging, after which the solution can be decanted and the precipitate washed by shaking up with absolute alcohol and centrifuging again. The product should be washed in this manner two or three times, after which it can be dried over concentrated sulfuric acid in an atmosphere of hydrogen or nitrogen. From 30 g. of ethyl titanate dissolved in 200 cc. of absolute alcohol, 20 g. of product may readily be obtained, using 10 g. of sodium for the reduction.

---

[1] Bischoff and Adkins, THIS JOURNAL, 46,257 (1924).

This dark blue amorphous solid contains from 55 to 70% as much trivalent titanium as would an equal weight of ethyl ortho titanite, $(C_2H_5)_3TiO_3$. It reduces aromatic nitro compounds to amines very readily and aromatic aldehydes to alcohols somewhat more slowly, when used in the form of a suspension in absolute alcohol. It dissolves in hydrochloric acid and in dilute sulfuric acid, forming the titanous salts.

When the dry ethyl titanite is exposed to the air it very rapidly turns olive-green and then white, the odor of acetaldehyde being very pronounced. To obtain samples for analysis the material, in alcoholic suspension, was transferred to small glass bulbs which were filled with nitrogen. The alcohol was removed by heating at 100° for one hour under a pressure of 5–10 mm. and the bulbs were then sealed off, filled with nitrogen. The results obtained were as follows. From 0.2287 g. of substance, 0.1736 g. of water and 0.3368 g. of carbon dioxide were obtained: calcd. for $C_6H_{15}O_3Ti$: C, 39.31; H, 8.25. Found: C, 40.18; 8.49.

Trivalent titanium was determined by titrating the ferrous salt formed by the action of the compound on an excess of ferric alum in an atmosphere of carbon dioxide. All values for trivalent titanium were low. A sample which had been boiled with absolute alcohol in a current of hydrogen for several hours showed 21.31 and 20.77% of trivalent titanium instead of the theoretical 26.25%. This would correspond to a mixture of about 80% of ethyl titanite ($(C_2H_5)_3TiO_3$) and 20% of ethyl titanate ($(C_2H_5)_4TiO_4$). Accordingly, a determination of total titanium was made by dissolving the material in concentrated hydrochloric acid with the addition of a few drops of concentrated nitric acid and precipitating the titanium as titanium dioxide.[2] The results were 24.93 and 24.86% of titanium as compared with the theoretical value of 25.21% calculated for this mixture.

From this analysis it seemed probable that the material was a mixture of the two esters and a further effort was made to effect their separation. It was found impossible to wash out the ethyl titanate but a partial separation was accomplished by heating at 156° and 8–10 mm. for one hour. Under these conditions some of the ethyl titanate distilled out and was condensed in the cold part of the tube. A sample treated in this manner was found to contain 22.85% of trivalent titanium, which corresponds to 87.4% of ethyl titanite in the preparation. Increasing the temperature from 156 to 185° had no effect. Probably the remaining impurity was in part titanium dioxide but we were unable to remove this as we found no non-reactive solvent for the ethyl titanite. It appears probable that if the titanites of the higher alcohols were prepared they would be found to be more soluble and so might be more readily purified, but this has not been attempted.

Summary

An organic trivalent titanium compound has been prepared in an impure state by the reduction with sodium of an alcohol solution of tetra-ethyl titanate. This dark blue compound acts as a reducing agent and also dissolves in hydrochloric or dilute sulfuric acid to form titanous salts. The titanous salt solutions so obtained are entirely free from iron or other metallic or acidic impurities. An improvement in the method of preparation of tetra-ethyl titanate has been described.

THE STRUCTURE OF MERCERIZED CELLULOSE. I. THE SPACE LATTICE OF MERCERIZED RAMIE CELLULOSE AS DEVELOPED FROM X-RAY DATA[1]

BY O. L. SPONSLER AND W. H. DORE

RECEIVED MARCH 5, 1928 PUBLISHED JULY 6, 1928

It has been noted by Herzog[2] and by Katz and Mark[3] that mercerized cellulose gives a diffraction pattern with x-rays which differs somewhat from that of untreated cellulose, but no clearly defined space lattice for mercerized cellulose has been heretofore worked out.[3a] Based upon new x-ray data that we have obtained for mercerized ramie fibers, we have developed a space lattice which appears to agree with all of the observed facts. In the present paper this structure is described and suggestions are made in regard to the probable mechanism of mercerization.

Several lots of ramie fibers were extracted with a mixture of alcohol and benzene and then mercerized by treating for thirty minutes with solutions containing **1**, 8, **14**, **17.5** and 28%, respectively, of sodium hydroxide. The alkali was removed by washing for a long time with distilled water, then digesting for a few minutes in very dilute acetic acid and again washing thoroughly with water. Finally the samples were dried in an oven. In order to keep the fibers from becoming tangled during these treatments, each sample was wound on a glass frame and tied in position, where it remained during all of the operations.

After mercerization the fibers were cut from the frames, laid parallel and cemented with dilute celloidin into tablets from which small blocks were cut. These blocks were used for obtaining the diffraction patterns. A molybdenum Coolidge tube was used as the source of radiation, and a monochromatic beam of x-rays was obtained by using screens of zirconium oxide. The procedure is described in greater detail in an earlier paper.[4]

By revolving the block of fibers through known angles, it is possible to determine the position of the atomic planes with reference to the long axis of the fibers. When that axis, designated here as the *c* axis, is parallel to the line of propagation of the x-ray beam,

[2] Herzog, *J. Phys. Chem.*, **30**, **460** (**1926**).

[3] Katz and Mark, *Z. Elektrochem.*, **31**, **105** (**1925**).

[3a] Since this paper was written, **a** paper by Meyer and Mark. *Ber.*, 61, 593–614 (1928), has appeared in which is proposed a structure for native cellulose resembling in many ways the structure proposed by the present authors in **1926** (see ref. **6**), but differing in several respects from the earlier structure. Based partly upon the data of Herzog, and partly upon new data of their own, Meyer and Mark have calculated lattice dimensions for mercerized cellulose and have made suggestions as to the probable orientation changes accompanying mercerization. The lattice dimensions given by these authors as well as their conclusions are at variance with those of the present paper. Additional data will probably be required before it will be possible to show how far these conflicting views are capable of being reconciled.

[4] Sponsler, *J. Gen. Physiol.*, **9**, **221–233** (**1925**); **9**, 677–695 (**1926**).

the position is called the 0° position; when the beam cuts the fibers at right angles, the position of the c axis is referred to as the 90° position. The interplanar spacings calculated from the diffraction lines obtained from the 0° position are the spacings between planes of atoms which are parallel to the fiber length; when obtained from the 90° position, they are the spacings between planes which are perpendicular to the fiber length.

In Table I the interplanar values obtained from the 0° position for the various mercerization treatments are listed for comparison.

TABLE I

INTERPLANAR VALUES FROM 0° POSITION RAMIE FIBERS

Untreated, Å.	8% NaOH, Å.	14% NaOH, Å	17.5 NaOH, Å.	28% NaOH. Å.
6.10	6.08	7.55	7.53	7.64
5.40	5 45	4.49	4.48	4.51
3.98	3.98	4.10	4.10	4 09
2.65	2.64	2.22	2.22	2.24
1.98	1.96	..	..	..
1.93	1.88	..	..	..

The first and second columns are practically identical; similarly, the third, fourth and fifth columns. Apparently no change had taken place in the first two; while in the remaining three columns the change produced by the alkali was the same regardless of the concentrations used. A critical concentration is indicated between 8 and 14%. From data which we are not presenting completely at this time, that critical point was found to be very close to 13%. For convenience we are using the term "unmercerized" as associated with treatments below the critical concentration, and "mercerized" for all above that. We found that fibers which have been subjected to concentrations near 13% may produce lines of both groups. The significance of that observation is as yet uncertain, but studies now under way may determine whether indvidual fibers have slightly different critical points or whether the same fiber wall may contain both mercerized and unmercerized cellulose.

In Table II values from Table I are summarized into the two groups which we have called "unmercerized" and "mercerized." Instead of tak-

TABLE II

INTERPLANAR VALUES FOR MERCERIZED AND UNMERCERIZED RAMIE FIBERS FROM 0° POSITION

Unmercerized. Treated with 1 or 8% NaOH or untreated		Mercerized. Treated with 14, 17½ or 28% NaOH	
Spacing, Å.	Density of line	Spacing, Å.	Density of line
6.10	Strong	7.55	Medium
5.40	Medium	4.50	Strong
3.98	Very strong	4.10	Strong
2.65	Weak	2.23	Weak
1.98	Very weak		
1.93	Very weak		

ing the averages, however, we have used the values for the strongest clean-cut lines which were obtained, on the assumption that they are most nearly correct.

It may not be out of place to assume at this time that the various planes of atoms producing the diffraction lines have shifted from the spacings given in the first column to those given on the same line in the third column. This assumption will be amply justified later by the facts. In the table it will be noted that with the shift in positions, changes also occur in the densities of some of the lines. Especially significant is the change in density of the line corresponding to the 5.40 spacing into a stronger 4.50, and that of the 3.98 to a weaker 4.10. These density changes are of considerable importance in determining the orientation of the constituent C_6 units in the structure for mercerized cellulose, as will be shown further on.

The patterns from the 90° position of the fibers are identical in all cases regardless of the concentration of sodium hydroxide used, so far as the interplanar spacings are concerned. However, there is a very evident difference in the density of at least three lines, between the mercerized and unmercerized groups; the 5.15 line is slightly stronger, the 3.40 considerably weaker and the 2.58 much weaker from the mercerized material.

TABLE III

INTERPLANAR VALUES FOR MERCERIZED AND UNMERCERIZED RAMIE FIBERS FROM 90° POSITION

Unmercerized. Treated with 1 or 8% NaOH or untreated		Mercerized. Treated with 14, 17½ or 28% NaOH	
Spacing, Å.	Density of line	Spacing, Å.	Density of line
5.15	Strong	5.16	Strong
3.40	Medium	3.36	Very weak
2.58	Very strong	2.59	Strong
2.03	Strong	2.02	Strong
1.70	Strong	1.69	Strong

From the intermediate positions, between 0 and 90°, the mercerized fibers produced fewer lines than the unmercerized. Their values and densities are given in Table IV.

TABLE IV

INTERPLANAR VALUES FOR MERCERIZED RAMIE FIBERS FROM POSITIONS BETWEEN 0 AND 90°

Position of fibers	Spacing, Å.	Density of line
70 to 80°	2.46	Weak
60 to 70°	3.15	Strong
60°	2.19	Weak
55°	4.38	Strong
40 to 50°	2.62	Medium
60 to 70°	1.89	Very weak

Development of Space Lattice

The interplanar spacings for mercerized material given in these tables are in agreement with the calculated spacings for a lattice the elementary cell of which is slightly monoclinic and has the axial ratios, $a:b:c$ = 0.595:1:1.352 (a = 4.53 Å., b = 7.61, c = 10.30).

The angle made by the axes, a and b, is approximately 83°. We have departed here from the conventional nomenclature of crystallography, since, consistent with the terms employed in our earlier work on untreated cellulose, we have found it convenient to retain the long axis of the fiber as the c axis.

The volume of this elementary cell is 4.53 X sin 83° X 7.61 × 10.30 = 353 cu. Å. The volume of the cellulose unit, $C_6H_{10}O_5$, assuming that no chemical change has taken place, is 162.1/1.57 X 1/(6.062 X 10^{23}) = 170 X 10^{-24} cm.[3] or 170 cu. Å., where 162.1 is the sum of the atomic weights of $C_6H_{10}O_5$, 1.57 is the value for the specific gravity of mercerized cellulose determined by us by the de Mosenthal method[5] and 6.062 × 10^{23} is Avogadro's number. There are then two of these C_6 units per elementary cell. 353/170 = 2.08 groups per unit cell.

In Table V the data from the previous tables are brought together for

comparison, and the corresponding crystallographic indices and calculated values for the interplanar spacings and for the angular positions have been added. The observed angular position refers to a relationship between the long axis of the fiber and the path of the beam, the calculated position to the angle between the long axis and the diffracting plane as determined from the elementary cell. These two values should agree within a few degrees. The calculated values are based upon the axial dimensions as given above and upon the value of 83° for the angle between the axes *a* and b.

The close agreement between observed and calculated values seems to indicate that the space lattice for mercerized ramie cellulose, which we have described, meets the requirement of the x-ray data.

Discussion

A comparison of the lattice which we have just deduced for mercerized ramie cellulose with our earlier lattice for unmercerized cellulose[4,6] reveals rather definitely, we believe, the rearrangement of the structural units which has taken place during mercerization of the fiber.

In the earlier paper[6] it was shown that untreated ramie cellulose is apparently made up of glucose units arranged in parallel chains of indefinite length running lengthwise of the fiber, the C_6 units of the chain being united throughout by glucosidal linkages. The chains themselves, in a cross section of the fiber, are rectangularly spaced 6.10 by 5.40 Å.

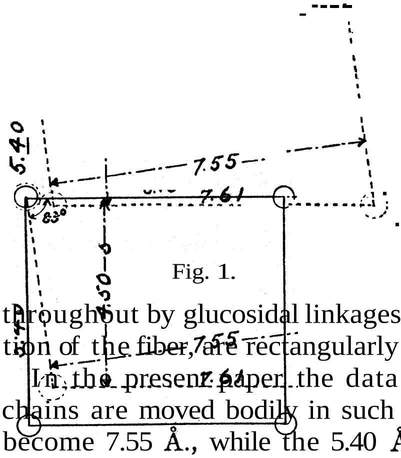

Fig. 1.

In the present paper the data indicate that during mercerization the chains are moved bodily in such a manner that the 6.10 Å. spacing has become 7.55 Å., while the 5.40 Å. spacing has become 4.50 Å. This is illustrated in Fig. 1, which shows a section through the unit cells perpendicular to the *c* axis. The solid circles indicate the centers of the C_6 groups as they occur in the unmercerized fibers; the dotted circles show the new positions after mercerization.

As pointed out in our earlier paper,[6] each of the constituent glucose units of cellulose contained a six-membered ring which gave the unit a flattened structure having a maximum dimension of about 7 Å. at right angles to the *c* axis. In the unmercerized fibers this dimension was regarded as lying along one of the diagonals of the 6.10 by 5.40 rectangle as indicated in Fig. 2.

---

[6] Sponsler and Dore, "Fourth Colloid Symposium Monograph," Chemical Catalog Company, New York, 1926, pp. 174–202.

This view is in agreement with the x-ray data, since the diagonal 3.98 line is much denser than either the 6.10 or the 5.40 lines. The density of the lines from the mercerized fibers, however, forces a different interpretation in regard to the position of the flattened C_6 units. Here the 4.10 line, a diagonal, is of equal density to the 4.50 line, which may correspond to the 5.40 of the unmercerized material. The equality of density of these two lines strongly suggests that in the mercerized material one-half of the number of C_6 groups have their long dimension (7 Å.) along the diagonal and the other half along the 4.50 planes, that is, parallel to the b axis. This may be more clearly seen from Pig. 3, where several possible arrangements are shown, each diagram representing a section through the unit cell perpendicular to the *c* axis. In A and B the long dimensions of all the C_6 units of any one chain lie in the same direction, but all those of two of the chains lie along the 4.50 planes and of the other two chains along the diagonal planes. By either arrangement a given chain would contribute mostly to one line or to the other, but by the arrangement shown in C every chain would contribute equally to each line. Here the dotted circles indicate a level below the solid circles. A study of three-dimensional models seems to indicate the C arrangement as the most probable one.

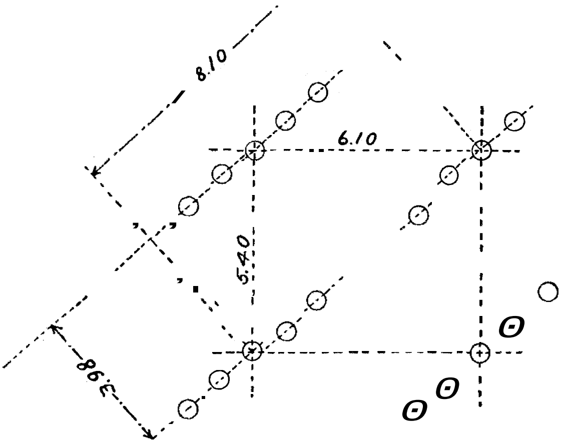

Fig. 2.

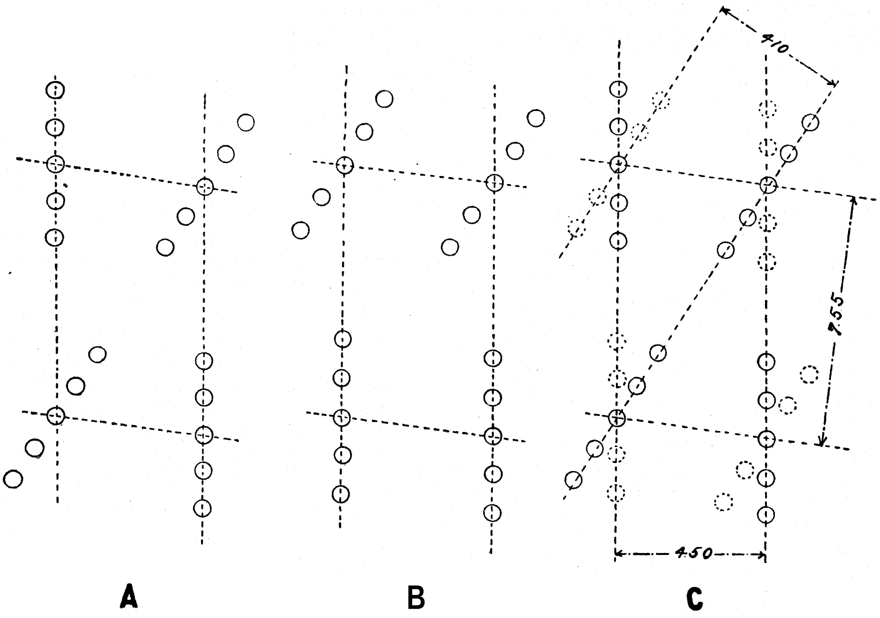
In attempting to fit a three-dimensional model of the glucose unit to our original elementary cell of untreated cellulose, we were forced to place the long dimension of the unit (7 Å.) on a diagonal of the cell because the axial dimensions were too short (6.10 and 5.40). This diagonal position furnished very satisfactory agreement with the densities of the diffraction lines produced. A similar agreement between position of the units and density of lines should occur, of course, with the mercerized cellulose. It is interesting to note that the density of the lines demanded that about half of the units should change their position from the diagonal to the b axis, and then to find that the axial dimension along that axis had actually increased sufficiently (to 7.61 Å.) to allow for the new orientation of the long axis of the glucose unit.

In the above discussion we have attempted to show that the chains of C_6 units have been shifted in their relative positions and that the individual units in each chain have assumed new relative positions with respect to one another. It now remains to be considered whether in addition to these larger shifts there have also occurred internal rearrangements in the structure of the chain and of the C_6 unit.



A B C

Fig. 3.

The fact that identical diffraction lines were obtained from both untreated and from mercerized fibers in the 90° position shows that the planes of atoms at right angles to the *c* axis have not shifted during the mercerization process. Since it has been shown in our earlier paper that the arrangement of these particular planes of atoms is produced by the arrangement of atoms in the amylene oxide ring of the constituent glucose units, the absence of change in the arrangement of the planes would appear to indicate that the ring formation has not been disturbed. Although the same planes of atoms exist after as before mercerization, a distinct change in the intensities of three lines shows that there has been some change in the spacial relationship of some of the constituent atoms of the C_6 group. An adequate explanation may be found in the mobility of the hydroxyl group attached to the sixth carbon atom. An examination of the three-dimensional model[7] will show that while the rest of the atoms in the molecule are in practically fixed positions, this particular hydroxyl is capable of rotation about the axis of the bond joining the fifth and sixth carbon atoms. A rotation from position A to position B, as shown in Fig. **4,** would have a tendency to produce the changes observed, namely, a decrease in the density of the 2.58 and the **3.40** lines and an increase in that of the 5.15 line.

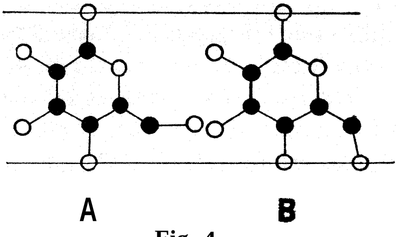


Fig 4

The Nature of the Mercerization Change

From the preceding considerations mercerization appears to be the result of rearrangements in three different ways: (1) a shift in the position of the chain with respect to the neighboring chains, **(2)** a partial rotation of the alternate glucose units in each chain and **(3)** a shift in the position of the hydroxyl attached to the sixth carbon atom. We are not prepared to discuss at present either the time relation or the causal relation of these three events; that is, we do not know whether the movement of the whole chain is due to the partial rotation of the alternate glucose groups nor whether those movements are influenced by the probable shifting of the hydroxyl mentioned.

Regardless of the relationship existing between these three rearrangements, the new positions taken by the chains and by the constituent units and parts seem to dispose of several suggestions which have appeared in the literature concerning the nature of mercerization. It seems extremely unlikely that the mercerization process involves *(a)* a migration of an oxygen bridge,[8] (b) an enolization,[9] (c) an isomeric change,[3] or in fact any type of molecular rearrangement of the constituent glucose, since any such change would almost certainly produce a different diffraction pattern than that which is obtained from the 90° position of the fibers.

It appears also unlikely that mercerization is a progressive change varying in degree with the strength of the alkaline solution employed, as Herzog[2] contended. Herzog recognized three stages of mercerization; the first with 8 to 10% NaOH, the second with about 14% and the third or "total mercerization" with **28%** NaOH.

---

[7] Ref. 6, Fig. 3, p. 179.

[8] Herzog and Londberg, *Ber.*, 57, 329 (1924).

[9] Gebhard, *Chem.-Ztg.*, 37,663 (1913).

Our data indicate that there is a critical concentration of alkali below which the treatment does not produce a permanent effect on the arrangement of the C_6 units. This critical concentration is in the neighborhood of 13% for sodium hydroxide. Material treated with alkali of about that concentration is quite likely to give diffraction lines of both the mercerized and unmercerized fibers, as previously mentioned. It is probable that certain discrepancies between our data and those of Herzog are due to this partially mercerized condition. In his data from the 14% material, the interference points A_1 and A_2 were apparently produced by the parts of the fibers which were unmercerized, since they appeared from the 8% and not from the 28%; while opposed to this the A_3 and A_4 lines were produced by the mercerized parts of the fibers since they appeared from the 28% and not from the 8% treatments. With that explanation his data, but not his conclusions, are in agreement with ours with one further exception. Apparently he has made the error of accepting interference points produced by K_β wave lengths as though they were of K_α origin. His point A_3 from 8% treatment is quite clearly of K_β origin, while A_4 is of K_α origin from the same set of planes. Of course that A_3 point should be discarded and, without that, there is no basis for Herzog's conclusion that mercerization is a progressive change.[10] On the other hand, both his data and ours seem to indicate that only two general types of x-ray diffraction patterns are obtainable, one from unmercerized and the other from mercerized material, and that the spatial rearrangement of the groups of atoms which exist in mercerized material is produced by a definite concentration of the alkali. Although the fibers are swollen to a different extent with different concentrations of alkali, the component chains, upon washing, seem to behave in only two ways: for concentrations below 13% they return to their original position, for those'above that concentration they take on new positions as described above.

We desire to call attention here to the additional support which the observations recorded in the present paper give to the conception of a cellulose structure as being made up of continuous chains of glucose units which are held together by primary valence linkages. As we have shown, mercerization produces a separation of the chains and a partial rotation of the units within the chains. This rotation is definitely a rotation about an axis which is parallel to the long axis of the chain. Throughout these changes the chains as such remain intact; that is, the C_6 units have not become detached from the chain.

If the units were held together by secondary valence forces only,[11] then the alkali treatment should produce a separation of the units lengthwise of the fiber, just as it produces the separation of the chains laterally.

---

[10] Sponsler has discussed this error in greater detail in Nature, 120,767 (1927).

[11] K. Hess and others, Ann., 435, 1–144 (1923); 443, 71–112 (1925).

Our x-ray evidence, however, shows that no separation of the C_6 groups occurs lengthwise of the fiber, but that the chains have become separated, indicating that the forces existing between the units in the chain must be greater than those exerted laterally from chain to chain. We consider that the greater forces holding unit to unit correspond to primary valences and the lesser ones between the chains to secondary valences.

Again, if cellulose were composed of detached C_6 units held in space by secondary valence only, it is scarcely conceivable that the forces which produce mercerization would be exerted so as to produce partial rotation on one axis only and that axis the long axis of the chain. It would seem more likely that rotation would occur on several axes rather than only one which happens to be always the long axis of the chain, and, further, it would seem that the units would be forced out of their linear arrangement unless the forces which hold the units together, and incidentally act as pivots, are stronger than the laterally acting forces.

The x-ray evidence which we have brought forward points very strongly to a linear arrangement of the units and shows that the mercerization process produces rotation of some of the units about the long axis of the chain but does not disturb their linear arrangement. This evidence indicates that the forces holding the units together in a linear chain are too strong to be overcome by the mercerization process and that, on the contrary, the forces acting laterally unquestionably have been overcome. These stronger linear forces correspond to our conception of primary valence forces; the weaker lateral forces, to secondary valences.

We have not yet attempted to correlate the gross changes of swelling, shrinking and twisting which accompany mercerization with the changes observed in the lattice structure.

We have so far been concerned with the structure of mercerized cellulose rather than with the mercerization process. Accordingly, we have as yet no insight into the mechanism by which treatment of cellulose fibers with strong sodium hydroxide solution is able to produce the changes we have been discussing., but studies are now under way with swollen fibers which may give some suggestion as to the mechanism involved in mercerization.

Summary

1. X-ray diffraction data are given for ramie cellulose which has been subjected to mercerization processes with various strengths of sodium hydroxide solutions. The evidence shows that there is a critical concentration of the alkali at about 13%, above which the fibers are mercerized, below which they remain unmercerized.

2. From the diffraction patterns of mercerized ramie cellulose a space lattice has been developed, When compared with the unmercerized lattice the *c* axis is seen to be unchanged while the a and *b* axes have been

changed from $a = 5.40$ in the unmercerized to $a = 4.53$ in the mercerized and from $b = 6.10$, to $b = 7.61$ Å. The angle between axes a and b has been changed from 90 to 83°.

3. As a result of mercerization the chains of glucose units have been shifted laterally in the wall of the fiber and have remained unbroken.

4. Within the chain the original glucose unit has remained unchanged except for a shift of the hydroxyl of the sixth carbon atom. The x-ray diffraction patterns indicate that there has been a partial rotation of some of the glucose units about the long axis of the chain.

5. A comparative study of the structures of mercerized and unmercerized cellulose has produced additional support to the view that the constituent units of cellulose are united in chains by primary valence linkages.

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XIV. POLYMERIZATION OF ALDEHYDES

BY HAROLD HIBBERT, W. F. GILLESPIE[1] AND R. E. MONTONNA[2]

RECEIVED MARCH 8, 1928 PUBLISHED JULY 6, 1928

The nature of polymerization, aggregation and disaggregation is one of peculiar importance in relation to the valence, surface tension, crystal and absorption forces which come into play in the formation of large crystalline and colloidal aggregates in plant and animal life, since "permanence of form" and "capacity to exist" are both dependent on the ability of specific substances to exhibit the pheonomenon of "aggregation." The nature of the forces through which this increased permanence and stability are attained is, as yet, quite unknown, as is evident from the work of Bergmann,[3] R. O. Herzog,[4]

H. Mark,[5] Hess,[6] Pringsheim,[7] Staudinger,[8] Karrer,[9] Waldschmidt-Leitz[10] and others.[11]

As illustrating the complexity of the problem involved, the recent work of Bergmann,[12] on cellobiose anhydride and of Hess[6d] on cellulose may be cited. In the Form of their acetates these substances are present in solution as monomolecular derivatives which, however, on saponification yield the original, highly polymerized, hydroxy compounds.

There seems to be little doubt, as suggested by Bergmann,[13] that in the case of the polysaccharides the factors responsible for the polymerization are concerned with the entire molecule (a) the hydroxyl groups, (b) latent aldehyde groups and (c) oxygen bridge rings.

In order to throw some light on the subject, work has been carried out for some considerable time by the author and his co-workers on the properties of the carbonyl group.

In connection with an investigation carried out several years ago on the mechanism of the formation of esters from aldehydes by the catalytic action of an aluminum alkylate (Tischtschenko)[14] it seemed possible that the function of the catalyst might be explained by the formation of an intermediate, unstable four-membered oxygen ring (A) which, through

$$2RCHO + 2Al(OC_2H_5)_3 = 2RCH(OC_2H_5)[OAl(OC_2H_5)_2] \qquad (1)$$

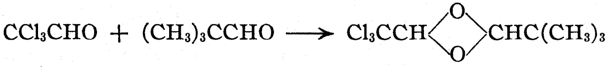
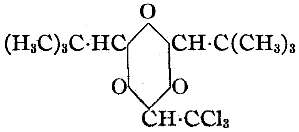
the wandering of a hydrogen atom would be capable of yielding the corresponding ester.'[5]

An attempt to prepare such a ring by the interaction of chloral with trimethylacetaldehyde



yielded instead a mixed paraldehyde, formed from the union of two moles of trimethylacetaldehyde with one of chloral



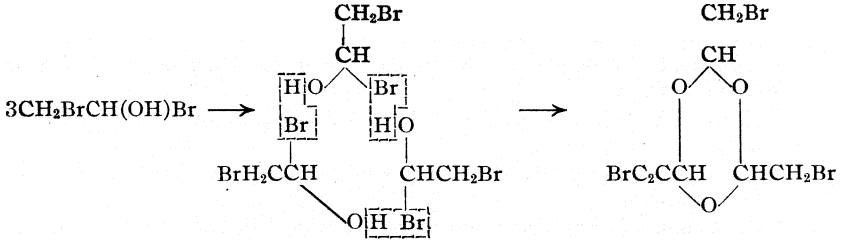
The substance[16] is a crystalline product, remarkably stable toward aqueous and alcoholic alkali. Owing to a temporary interruption in the work it was not possible to carry it further and in the meantime two other interesting communications on the same subject have appeared.

Helferich[17] has shown that mixed paraldehydes can be obtained readily from acetaldehyde and both the halogenated butyraldehydes and chloral in which two moles of acetaldehyde are united with one mole each of the chlorinated aldehydes.

These products are oils which possess a strong paraldehyde odor, are difficultly soluble in water and decompose slowly into their component parts on standing, more rapidly under the influence of acids.

Stepanow and co-workers[18] in an interesting re-investigation of the work of Hibbert and Hill[19] on the synthesis of bromo-acetaldehyde from paracetaldehyde were able to prepare mono-, di- and tribromoparacetaldehydes.

They also were able to isolate α,β-dibromo-ethyl alcohol [$CH_2BrCH(OH)Br$] and to show that the product readily loses hydrobromic acid to give tribromoparacetaldehyde, thus indicating the mechanism by which the acid probably functions as a catalyst in paraldehyde formation.



---

[15] A review of this and similar reactions is to be given in a series of forthcoming papers on "The Mechanism of Organic Reactions."

[16] This product was first prepared by R. E. Montonna in February, 1924.

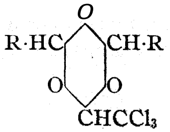
[17] Helferich, *Ber.*, 59, 1276 (1924).

[18] Stepanow, *Ber.*, 58, 1718 (1925); 59, 2533 (1926).

[19] Hibbert and Hill, THIS JOURNAL, 45, 734 (1923).

The action of other catalysts such as sulfuric acid, zinc chloride, etc., may thus be satisfactorily explained.

In the present investigation the work of Stepanow and co-workers on the bromoparaldehydes was confirmed and in addition new paraldehyde derivatives were prepared from both propionaldehyde and *iso*butyraldehyde with chloral in which two moles of each of the former are combined with one of chloral. Each of the members of a series of substituted acetaldehydes, namely, $H{-}CH_2CHO$, $CH_3{-}CH_2CHO$, $(CH_3)_2{=}CHCHO$, $(CH_3)_3{\equiv}CCHO$, is thus found to condense readily with chloral **to give** a mixed paraldehyde of the general type:



These paraldehydes are stable crystalline products which are insoluble in water and show no tendency to alter on standing. They decompose on continued boiling with sulfuric acid but are very stable toward alkali.

All attempts to prepare mixed paraldehydes involving three different aldehydes were unsuccessful. Thus with molecular proportions of *iso*butyraldehyde (A), propionaldehyde (B) and chloral (C), instead of the expected A B C paraldehyde derivative, there was obtained a mixture of two paraldehydes, the one being formed from two moles of propionaldehyde, the other from two moles of di-isobutyraldehyde with one mole of chloral.

Similar attempts using bromo-acetaldehyde in place of chloral were also unsuccessful.[20] It is of interest that a paraldehyde of hydroxypyruvic aldehyde has been isolated[21] and that the recent work of Klason[22] assigns to lignin the role of a paraldehyde derivative of coniferyl aldehyde.

Practical Part

Paraldehyde Formation from Trimethylacetaldehyde and Chloral, $CCl_3CHO + 2(CH_3)_3C{\cdot}CHO$.—14.75 g. of chloral (1 mole) was mixed with 8.6 g. of trimethylacetaldehyde[23] (1 mole) (b. p. 74–78°) at room temperature. There was an increase in tem-

---

[20] The explanation apparently lies in the different reaction velocities with which the components unite. From this standpoint it might be of interest to see whether acetol, dioxyacetone and glyceric aldehyde are capable of forming a mixed paraldehyde of the A B C type, since there is the possibility that abnormal biochemical changes possibly may be due in certain cases to the formation of the relatively stable paraldehyde derivatives, thus interrupting the normal course of oxidation, etc.

[22] Klason, *Ber.*, 58, 1761 (1925); 61, 171 (1928).

[23] This was prepared by Richard's method, Ann. *chim. phys.*, [8] 21, 360 (1910), by first decomposing the trimethylpyruvic acid with aniline. It was found better to hydrolyze this reaction product by refluxing with 20% sulfuric acid for two hours instead of attempting to distil it as he recommends. After washing the bisulfite compound with ether and drying, it should then be decomposed with sulfuric acid and steam distilled, since sodium carbonate tends to cause polymerization.

perature of about 6°. After standing for two days the product had become almost solid. The crystals were separated from the small amount of mother liquor and recrystallized from hot, absolute alcohol, m. p. 114–115°; yield, 16 g.

Anal. Subs., 0.2700, 0.2548: H_2O, 0.1570, 0.1510; CO_2, 0.4436, 0.4222. Subs., 0.1149, 0.2183: AgCl, 0.1537, 0.2908. Calcd. for $C_{12}H_{21}O_3Cl_3$: H, 6.62; C, 45.06; Cl, 33.29. Found: H, 6.51, 6.63; C, 44.75, 45.17; Cl, 33.09, 32.96.

Mol. wt. Subs., 0.2564, 0.2817, 0.2982: benzene, 17.543. ΔT, 0.241, 0.259, 0.280. Calcd.: 319. Found: 311, 333, 311.

The substance is insoluble in hot and cold water and in dilute alcohol, readily soluble in hot absolute alcohol and cold benzene. It is very stable toward aqueous and alcoholic alkali.

The product may be obtained more readily by using a trace of concentrated sulfuric acid as a catalyst and warming until solution occurs. After standing for two hours at room temperature the semi-solid, crystalline mass is filtered and the product recrystallized.

Propionaldehyde and Chloral ($CCl_3CHO + 2CH_3CH_2CHO$).—Fourteen and one-half grams of propionaldehyde (2 moles) was mixed with 18.4 g. (1 mole) of chloral, the flask placed in a freezing mixture (–10°) and a few bubbles of dry hydrogen chloride gas passed into the mixture. The contents were allowed to stand at 0° for about twelve hours, the crystals formed removed by suction filtration, washed with a small quantity of 50% alcohol and then dissolved in absolute alcohol. The solution was diluted by adding one-fifth its volume of water and the oil separating out redissolved by warming. It was filtered hot and allowed to crystallize slowly. The crystals, after filtering, washing with alcohol (50%) and drying, melted sharply at 62.5°; yield, 35–40%.

The same product was also obtained without the use of a catalyst (HCl).

Anal. Subs., 0.1804, 0.1760: H_2O, 0.0798, 0.0791; CO_2, 0.2387, 0.2391. Subs., 0.1287: AgCl, 0.2097. Calcd. for $C_8H_{13}O_3Cl_3$: H, 4.93; C, 36.43; Cl, 40.39. Pound: H, 4.92, 4.98; C, 36.40, 37.00; Cl, 40.27.

*Iso*butyraldehyde and Chloral ($CCl_3CHO + 2(CH_3)_2CHCHO$).—This compound was prepared similarly, both with and without a catalyst; needle crystals from 80% alcohol; m. p. 68.5–69°; yield, 39%.

Anal. Subs., 0.1674, 0.1718: H_2O, 0.0896, 0.0891; CO_2, 0.2565, 0.2601. Subs., 0.1123, 0.1061: AgCl, 0.1680, 0.1569. Calcd. for $C_{10}H_{17}O_3Cl_3$: H, 5.83; C, 41.30; Cl, 36.58. Found: H, 5.93, 5.78; C, 41.80, 41.30; Cl, 36.84, 36.60.

Mol. wt. Subs., 0.3057, 0.8806: benzene, 17.60. ΔT, 0.310, 0.890. Calcd.: 291.5. Found: 287, 289.6.

All three paraldehydes are very insoluble in hot and cold water but are readily soluble in organic solvents. They show no sign of decomposition on standing for several months; are stable toward alkalies, but decompose on boiling with dilute sulfuric acid.

All attempts to prepare paraldehydes involving three different aldehydes (propionaldehyde, *iso*butyraldehyde and chloral; acetaldehyde, *iso*butyraldehyde and chloral, etc.) were unsuccessful, only mixtures of paraldehydes containing two moles of the aldehyde to one mole of chloral being obtained. Negative results were also obtained using bromoacetaldehyde in place of chloral.

It was not found possible to condense acetaldol with chloral to give a mixed paraldehyde.

Summary

1. Chloral either alone or, better, in the presence of a trace of hydrogen chloride, combines with acetaldehyde,'' propionaldehyde, *iso*butyraldehyde and trimethylacetaldehyde to give paraldehydes corresponding to the general type ($2RCHO + CCl_3CHO$).

2. It apparently does not combine with acetaldol under similar conditions.

3. Attempts to prepare a mixed paraldehyde containing three different aldehydes were unsuccessful.

4. The possible role played by such derivatives in plant and animal life would seem to call for some consideration.

ALPHA-FURFURYL CHLORIDE (FURYL-2-METHYL CHLORIDE) AND ITS DERIVATIVES.

I. THE PREPARATION AND PROPERTIES OF ALPHA-FURFURYL CHLORIDE AND A FEW ALPHA-FURFURYL ETHERS[1]

BY W. R. KIRNER

RECEIVED MARCH 12, 1928 PUBLISHED JULY 6, 1928

The synthesis of many relatively simple derivatives of furan has hitherto been impossible or, at best, extremely difficult and complicated, due to the fact that reactive starting materials such as the ω-halogen derivatives of furan homologs have been practically unknown. A halogen in the side chain of a furan ring corresponds in reactivity to that possessed by a halogen in the side chain of a benzene ring.

Fenton and co-workers[1a] were the first to prepare a reactive halogen derivative of methylfuran when they succeeded in isolating 2-chloromethyl- and 2-bromomethyl-5-furfuraldehyde from a large variety of carbohydrates using a non-aqueous solvent (for example, ether, chloroform or carbon tetrachloride) saturated, respectively, with hydrogen chloride and hydrogen bromide. They pointed out the high order of reactivity of the halogen and prepared a number of derivatives in which the halogen was substituted by groups such as H, OH, $OCOCH_3$, $OCOC_6H_5$, C_6H_5 and $CH_2C_4H_2OCOH$, while subsequent workers[2] extended the list of sub-

stitutions to include the OCH_3 and OC_2H_5 groups. Rill and Jennings[3] obtained the 2-bromomethylpyromucic acid by direct bromination under specific conditions and noted the easy hydrolysis to form the hydroxy compound.

Only recently has the preparation of the parent w-halogen methylfuran been successful. Zanetti[4] has succeeded in preparing ethereal solutions of both the a-furfuryl bromide and iodide from a-furfuryl alcohol by simple procedures. In the case of the iodide at least 40% of the alcohol is transformed and 70% in case of the bromide. Using these reactive agents, Zanetti prepared five ethers which had previously been unknown. Zanetti did not isolate the bromide or iodide in a pure condition but merely obtained them in an ethereal solution. Von Braun and Kohler were the first to have prepared an ethereal solution of the bromide[6] by the treatment of a-furfurylethylmethylamine with cyanogen bromide, which resulted in an 80% conversion of the base (by weight) to the bromide. This method is not as convenient, however, as that of Zanetti. Von Braun and Kohler describe the properties of the ethereal solution, particularly its gradual decomposition on standing, and add that when an attempt was made to distil it, it completely decomposed. They consider it a surprisingly satisfactory result that a-furfuryl bromide is stable even for several hours. They also predicted that the same ease of decomposition would probably be found in the chloride.

Von Braun and Kohler attempted to make a-furfuryl chloride by the well known Von Braun reaction which, in this case, consisted in the treatment of the benzoyl derivative of a-furfurylmethylamine with phosphorus pentachloride. The reaction resulted only in the complete resinification of the substances present, the same result being obtained with phosphorus pentabromide. Gilman and Vernon[6] also attempted to prepare the chloride by treatment of an ethereal solution of a-furfuryl alcohol with thionyl chloride at low temperature and by passing dry hydrogen chloride into an ethereal solution of the alcohol in the presence of a dehydrating agent (calcium carbide), The yield in the first case was 10% (based on the amount of a-furfuryl ethyl ether obtained) and 5% in the second case. Both of these methods are therefore decidedly unsatisfactory and impractical. Gilman and Vernon state that "all efforts to distil the chloride were futile. After some 80–90% of the ether had been distilled at reduced pressure, the contents of the flask suddenly and violently decomposed into a hard, intractable tar. The temperature of the water-bath in which the flask was immersed did not exceed 30°."

It is the purpose of this paper to demonstrate that *under certain conditions it is possible to prepare the chloride and isolate it in a pure state by vacuum distillation, to obtain a satisfactory analysis, determine its physical properties and prepare derivatives of it.* Zanetti has shown that the bromide is more stable than the iodide toward potassium hydroxide[7] and in this work it is proved that the chloride is more stable toward potassium hydroxide than the bromide The relative stabilities of these furfuryl halides thus coincide with the order usually given for organic halides, namely, chloride > bromide > iodide. Although the chloride is a relatively unstable substance it is of a much higher order of stability than the statements of previous investigators would lead one to believe.

Since the furan nucleus is sensitive to halogen acids, it is imperative in the successful preparation of the furfuryl halides to avoid so far as possible the presence of halogen acids in an uncombined state. The Darzens method for the preparation of chlorides from alcohols,[8] which consists in the treatment of the alcohol in a solution of a tertiary amine (pyridine was used in this work) with thionyl chloride, is ideal in this case since the hydrogen chloride which is liberated from the alcohol and thionyl chloride is immediately taken up by the base and therefore causes no decomposition of the sensitive alcohol. By this method *α-furfuryl alcohol has been converted into α-furfuryl chloride with a 63% yield of distilled material.* The boiling point observed was 49.6–50° at 27 mm. The substance distils as a water-white liquid which is sufficiently stable, in the absence of moisture, to permit its analysis and the determination of its density and refractive index. It is insoluble in water but soluble in the common organic solvents. It possesses a characteristic odor and is a weak lachrymator. On standing it gradually turns yellow, then green and finally black and deposits a black, resinous precipitate. An ethereal solution remains nearly colorless for several days at room temperature and gradually turns yellow with the formation of a black, gummy precipitate. There is no difficulty whatsoever in preparing and keeping the substance long enough for use in any reaction.

From the pure chloride a number of ethers were prepared using the procedure given by Zanetti.[4] The ethers were chosen as the first derivatives to be prepared since Zanetti has recently prepared a considerable number of them by a convenient procedure and in good yield. They are listed below together with their boiling point, density, yield, refractive index and calculated and observed molecular refraction. It is interesting to note that Zanetti was unable to prepare the allyl ether by treatment of the a-furfuryl bromide with allyl alcohol; he states "the heat of formation was so great as to decompose the α-furfuryl bromide, giving only resinous

---

[8] Darzens, *Compt. rend.*, **152, 1314 (1911).**

products." Using the chloride no difficulty whatsoever was experienced; in fact, the highest yield of the eight ethers prepared was obtained in this *case.*

[a] Some material was lost accidentally.

Experiments are already under way in this Laboratory using the chloride for the preparation of a large number of other furan derivatives such as the amines, acetoacetic and malonic ester derivatives, those obtained from the Grignard reagent, etc.

I wish to thank my friend, Dr. John R. Johnson of Cornell University, for the first generous sample of furfuryl alcohol used in this work.

Experimental

A. Preparation of α-Furfuryl Chloride

The a-furfuryl alcohol was always freshly distilled just before using; it boiled at 84.5–85.0° at 26 mm. The pyridine was obtained from the Eastman Kodak Company, and was thoroughly dried over solid potassium hydroxide and distilled. The thionyl chloride was distilled from cotton seed oil through a Glinsky column and then re-distilled; it was practically water white.

The following procedure is typical of a number of experiments which were made: 46.2 g. (0.47 mole) of freshly distilled furfuryl alcohol was placed in a 500cc. three-necked Pyrex round-bottomed flask, the center neck being fitted with a stirrer, one side neck with a 50cc. dropping funnel and the other with a loosely stoppered thermometer; 44.7 g. (0.565 mole, 20% excess) of pyridine was added, which caused a slight evolution of heat, and then 50 cc. of dry ether (prepared in the same way as one prepares Grignard ether). The flask was immersed in an ice-bath and the stirrer started. When the temperature fell to about 2–3°, 61.7 g. (0.52 mole, 10% excess) of thionyl chloride dissolved in 50 cc. of dry ether was added from the dropping funnel, dropwise, in 10cc. portions, to the mixture in the flask, each 10cc. portion being added over a period of about twenty minutes. In this way the temperature of the reaction mixture remained at 7–9° during practically the entire reaction. The reaction was very vigorous, each drop of thionyl chloride producing a hissing noise and a spattering of the liquid.

During the addition of the second 10cc. portion, each drop of thionyl chloride produced a local turbidity and after about half of this portion had been added a heavy, oily layer started to separate. During the addition of the seventh portion the lower layer crystallized and the temperature rose rapidly to about 15° and then gradually fell again. After this portion was all added the thermometer was temporarily removed while a bent glass rod was inserted to break up the crystalline lumps as much as possible. The last portions of the thionyl chloride caused the crystalline material, which was originally a light brown color, to turn greenish-black. After all of the thionyl chloride had been added the mixture was stirred for an additional twenty-five minutes.

Darzens recommends that, after the addition of the thionyl chloride to the alcohol-pyridine mixture, the mixture be heated until evolution of sulfur dioxide ceases. In this case such a procedure was not possible for it was found that the heating resulted in nothing but a black tar; presumably the furan ring was destroyed or else polymerization occurred, Since heating was not required in this case to give a fair yield it may not be necessary in other cases in which, following Darzens, heating is usually carried out. The removal of the ethereal solution from the flask fortunately was extremely easy since the brownish lumps were rather large and pasty. The thermometer was removed and in its place a glass siphon tube was tightly stoppered, the short end of which reached to the very bottom of the flask. By having an electric light bulb behind the flask so as to be able to see through the ethereal solution the siphon tube could be placed in a space cleared up by the stirrer. Slight air pressure was then applied through the dropping funnel and the ethereal solution completely siphoned off into an Erlenmeyer flask. The ethereal solution was light yellow in color and transparent. The siphon tube was removed, 50 cc. of dry ether added to the reaction flask and the mixture stirred for five minutes after again breaking up the lumps with a bent glass rod. Then the ethereal solution was again siphoned off. This extraction was repeated three times, the last time the flask being removed from the ice-bath to permit it to warm up slightly. The total ethereal solution, which reacted acid to litmus paper, was thoroughly extracted with 50 cc. of 50% potassium hydroxide solution, everything being kept very cold and the potassium hydroxide solution being added in small portions in order not to cause undue heating. The ethereal solution was then removed and dried over anhydrous sodium carbonate.

In the distillation of the furfuryl chloride 75cc. portions of the ethereal solution were used and the distilled product was converted into the various ethers described later. The ether solution was added in portions to a 25cc. Claissen fractionating flask the side arm of which was fitted with a short water condenser, a 50cc. distilling flask being used as the receiver. The air entering the flask during the distillation was dried with a soda lime tube and a similar large soda lime tube was placed between the receiver and manometer; a water pump furnished the suction. It is the custom in this Laboratory to clean glass apparatus by immersion in a bath of very hot sulfuric acid. It was found that unless certain precautions were taken some of the acid remained adsorbed on the walls of the apparatus and that when the furfuryl chloride was distilled decomposition occurred in the side arm and receiver. This difficulty was overcome by carefully washing all apparatus a large number of times in tap water followed by washing with distilled water, then allowing the apparatus to soak in a large bath of distilled water overnight and subsequently re-washing with distilled water. The distilling flask was also steamed to remove completely any acid from the side arm and indentations of the fractionating column. The apparatus was then dried in an oven at 130°.

After removal of the ether in vacuum in the apparatus described above, a yellowish-brown, oily residue remained. On distilling this from a water-bath the liquid distilled very readily and yielded a water-white distillate. Various boiling points observed were: 49.1–49.4° (26 mm.); 49.6–50.0' (27 mm.); 54.0–54.4° (33 mm.), $d_{20}^{20} = 1.1804$; $d_4^{20} = 1.1783$; $N_D^{20} = 1.4941$ (Abbé). M_D, calcd. = 28.666; M_D, obs., = 28.788.

Anal. Subs., 0.2072, 0.2253; AgCl, 0.2538, 0.2747 Calcd. for C_5H_5OCl: Cl, 30.436. Found: 30.299, 30.16.

The analyses are slightly low due to the fact that during the time necessarily required to weigh out the sample and introduce it into the Carius tube some decomposition was taking place. This was evident from the fact that the sample gradually turned yellow.

B. Preparation of α-Furfuryl Ethers

The ethers were prepared by treating a given weight of the distilled chloride in 75 cc. of dry ether with 100% excess of dry, pulverized potassium hydroxide and with 200% excess of the desired alcohol, the alcohol being added in portions. In the case of methyl and α-furfuryl alcohol the reactions were vigorous enough to cause the ether to boil, so that cooling was necessary; large amounts of a flocculent precipitate of potassium chloride formed. In the case of the other alcohols the reaction proceeded more slowly and only small quantities of heat were evolved and small amounts of potassium chloride deposited. The reaction mixtures were allowed to stand overnight. Then the ether was evaporated on a hot-plate until the temperature of the flask contents reached 75°. The flask was then heated in a water-bath at 75–80° for a half hour, cooled, 100 cc. of distilled water added and the oily layer which separated removed with a separatory funnel. The aqueous layer was extracted four times with 25cc. portions of ether and the total oily layer–ether extract was dried over anhydrous sodium carbonate.

The ether was removed in vacuum and the residue subjected to fractional distillation, either at atmospheric pressure or in vacuum, depending on the boiling point of the furfuryl ether. The boiling points and densities, in general, agree quite well with those given by Zanetti except in the case of the a-furfuryl and benzyl ethers. In these cases the boilng points observed were about 10" lower than reported by Zanetti; his distillations were made at 2 mm., while in this work the pressure was 1 mm. The fact that the boiling points of the cinnamyl ethers agree even though distilled at two slightly different pressures makes it probable that the 10° difference in the boiling points in these two instances does not correspond to the decrease occasioned by a 1mm. change in pressure. Both of these ethers were systematically fractionated twice and they boiled very uniformly over the small range of temperature indicated. The close agreement between the calculated and observed molecular refractions indicates that the substances were pure. The value obtained for the refractive index of the ethyl ether does not agree with the value ($N^{20} = 1.4316$) given by Gilman and Vernon. They do not state their light source, but assuming that they used the D line their observed molecular refraction is 33.046, which is quite far from the calculated value of 34 678. It thus appears that their value for the refractive index is incorrect or their substance was impure. . The agreement between the observed and calculated values for the molecular refraction of the substances listed is good in all cases except the cinnamyl ether. In this case there is the usual exaltation due to the conjugated system present in the cinnamyl group. It is also interesting that the refractive indices of the ethyl, *n*-propyl and *n*-butyl ethers are almost identical.

Using the iodide for the preparation of ethers Zanetti obtained a mixture of ethers which contained as much as 30% of the di-α,α′-furfuryl ether formed by the reaction of the iodide with furfuryl alcohol. The latter was present, either because it was not reacted upon during the preparation of the iodide, or was formed by the hydrolysis of the iodide. Using the bromide practically no di-α,α′-furfuryl ether appeared to be formed. This is also true in the case of the synthesis using the choride. The crude ethers are nearly pure and leave practically no residue when distilled.

The remarks of Zanetti concerning the instability of the furfuryl ethers have been confirmed. When placed in tubes at atmospheric pressure they gradually darken, but if sealed off in tubes at about 1 mm. pressure with a trace of hydroquinone, they remain nearly colorless for a considerable length of time.

Summary

1. α-Furfuryl chloride has been isolated in a pure state, analyzed and its physical properties have been determined. It is a relatively unstable substance but of sufficient stability to be distilled in a vacuum and used in a variety of reactions. It seems obviously more stable than the corresponding bromide and iodide. This is the first time the parent w-halogen methyl furan has been obtained in a pure, free condition, having previously been known only in solution.

2. The chlorine atom possesses a high order of reactivity, comparable to that of the chlorine in benzyl chloride. Eight ethers have been prepared from the α-furfuryl chloride and their physical properties determined. The allyl-α-furfuryl ether has been prepared by the direct reaction between the chloride and allyl alcohol.

3. The synthesis of this reactive chloride has opened up new possibilities in the furan series and investigations of other reactions using a-furfuryl chloride are being continued.

A METHOD FOR THE MEASUREMENT OF INTERFACIAL TENSION OF LIQUID–LIQUID SYSTEMS[1]

BY F. E. BARTELL[2] AND F. L. MILLER[3]

RECEIVED MARCH 17, 1928 PUBLISHED JULY 6, 1928

Recently the authors were confronted with the problem of measuring the interfacial tension between water and a series of crude petroleum oils. Some of these oils were very dark, practically black; consequently, the methods most generally used for interfacial tension measurements were not satisfactory. With the more transparent oils the Reynolds capillary tube method[4] was used, but with the darker oils the liquid interface within the capillary could not be seen. After considerable experimentation a method was developed by means of which it was possible to determine the interfacial tension between the dark oils and water and subsequently it was found that this method gave results which checked well with what

---

[1] This paper contains preliminary results obtained in an investigation on the "Displacement of Petroleum Oils from Oil Bearing Sands by Means of Selected Aqueous Solutions," listed as Project No. 27 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by The Universal Oil Products Company. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

[4] Reynolds, Trans. Chem. *Soc.*, **119**, 460–466 (1921).

we believe to be some of the most reliable values to be found in the literature. The apparatus is simple in construction, is easy to operate and measurements can be quickly carried out.

Ferguson[5] has presented discussions covering the different methods which have been used for interfacial tension measurements; accordingly, no comprehensive discussion will be presented in this paper. It is well known that the most generally used methods have involved either the principles of the drop weight or the capillary rise method. The capillary rise method has been used with modification by Lerch,[6] Clark,[7] Reynolds,[7] Harkins and Humphery[8] and others, and not always with agreement in results. It is believed that the results reported by Harkins and Humpherys represent about the most accurate values obtained to date with a method based upon capillary rise.

The result of our experience with a number of the existing methods led first to the construction of an exceptionally simple apparatus with which apparently very satisfactory results were obtained (Fig. 1). The apparatus consists of a glass cup, A, about 4 cm. in diameter and 8 cm. in depth to the bottom of which is sealed a capillary tube outlet of about 0.3mm. radius. The remainder of the apparatus consists only of an open dish, B, which is large enough to eliminate effects due to capillarity.

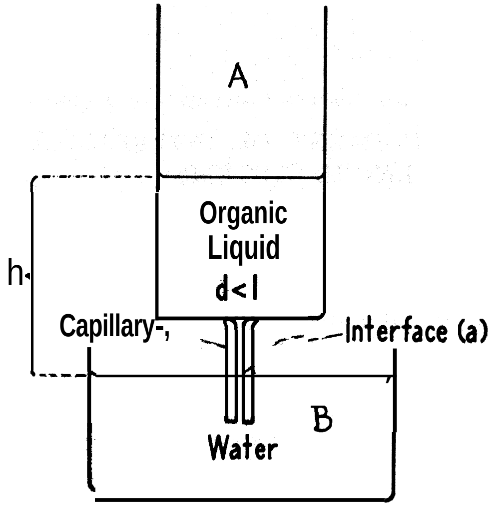

Fig. 1.

For the determination of interfacial tension, one immerses the capillary in the dish of water (B) until the calibration mark (a) is exactly level with the surface. Water will rise in the capillary to the bottom of the cup, thereby wetting the capillary throughout its length. The organic liquid (or oil) to be used is then slowly added from a buret, at the later stages drop by drop, until the water-organic–liquid interface is forced downward to the calibrated mark (a). The height of the organic liquid is then readily measured by means of a cathetometer. Knowing the density of the organic liquid, the interfacial tension, S_{23}, is calculated from the formulation

$$S_{23} = \frac{rhdg}{2} \qquad (1)$$

The results obtained with this apparatus for different organic liquids

[8] Harkins and Humphery, THIS **JOURNAL,** 38,242 (1916).

against water showed close agreement with those obtained by Harkins and co-workers.[9]

The advantages of this apparatus are that it can be constructed from the materials to be found in almost any chemical laboratory and by one not expert in the art of glass blowing. The only precaution to be observed in construction is that excessive constriction or enlargement of the capillary at any point must be avoided; otherwise, difficulty will be encountered in bringing about a gradual descent of the liquid–liquid interface to the mark of calibration. Although this apparatus appeared to give good results, certain disadvantages were encountered such, for example, as the impracticability of using liquids denser than water, as also difficulty in obtaining exact temperature control.

A detailed description of this simple apparatus is given herewith, inasmuch as it is felt that this apparatus may prove to be well suited to the needs of some investigators and, further, it has been found to be satisfactory when placed in the hands of students in the regular laboratory courses.

An apparatus was next constructed which could be used with liquids of any density and which could be placed in a water thermostat and held at any desired temperature. In our experiments a thermostat with plane glass sides was used and readings were made through this glass.

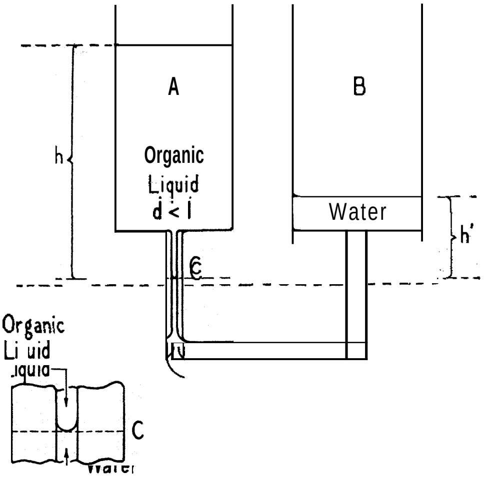

Fig 2

The apparatus is shown in Pig. 2. It consists of two cups, A and B about 4 cm. in diameter and 8 cm. in height. These are connected by glass tubing, one arm of which is a capillary tube of approximately 0.3-mm. radius. The operation of this apparatus is similar in principle to that previously described. In case the organic liquid to be used is less dense than water, the latter (about 10 cc. or more) is put into cup B. It will completely fill the glass tube and will mount to the top of the capillary tube. Immediately the organic liquid is introduced at A so that a liquid–liquid interface is formed at the upper end of the capillary. More liquid is added, finally drop by drop, until the interfacial meniscus is forced down even with the calibration mark at C. Readings h and *h'*, the heights of the organic liquid and water, respectively, above this meniscus, are now taken by means of a cathetometer.

In case the organic liquid is denser than water, the operation is somewhat different. Water (about 10 cc.) is put into cup A until it mounts just to the top of the tube in the

---

[9] Numerous papers on interfacial tension.

bottom of cup B (Fig. 3). The organic liquid (as chloroform, etc.) is now added slowly to cup B, so that the water is forced back until the liquid interface enters the lower end of the capillary and finally reaches the mark C. Readings are taken with the cathetometer as before.

In either of the above cases the procedure is simple and the time required for a determination is not over ten to fifteen minutes. The formulation used in this case is as follows

$$S_{23} = \frac{rg}{2}(hd - h'd') \qquad (2)$$

in which h and d are the height and density of the organic liquid and h' and d' are the height and density of water, respectively.

The radius of the capillaries in both types of apparatus is determined by suspending the inverted cup at a given temperature in a pure liquid (as benzene) of known surface tension (S for benzene is taken as 28.25) for this temperature (25°). By carefully adjusting the apparatus the meniscus is brought to the etched mark on the capillary. The height of this meniscus above the level of the liquid in the container is measured with a cathetometer. The radius, r, is thus determined from the formula

$$S = \frac{rhdg}{2} \qquad (3)$$

or

$$r = \frac{2S}{hdg} \qquad (4)$$

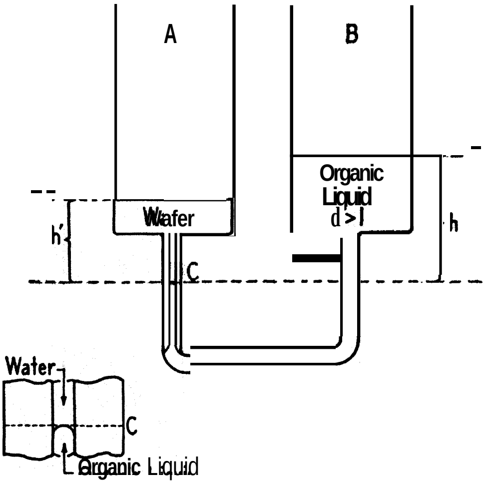

Fig. 3.

Meniscus Corrections.—In the determination of surface tension of a liquid by the capillary rise method, the height of the liquid is measured only to the lowest point of the meniscus. This leaves a small quantity of liquid above this point which should be considered and for which a correction in the reading should be made. In order to determine the height representative of the true mass of the liquid column supported by the force of surface tension, a correction must be added. The actual value in terms of height of liquid which should be considered in this correction is approximately one-third that of the height of the meniscus itself. Different investigators[10] have employed somewhat different meth-

---

[10] Laplace, "Mécanique Celeste," Supp. au livre 10, 1805; Poisson, "Nouvelle Theor. de l'Action Capill.," 1831; Mathieu, "Théorie de la Capillarité," Ch. II, Ch. IV, 1883; Lohnstein, *Wied. Ann.*, 54, *713* (1895); Rayleigh, *Proc. Roy. Soc.*, 92A, *184* (1915); Schrodinger, *Ann. Physik.*, 46, *111, 413* (1916).

ods in making this correction. A generally accepted correction is that given by Poisson,[11] who expressed the correction as a function of the radius of the capillary. The equation follows (h_0 represents the observed height of the liquid column)

$$h = h_0 + {}^1/_3\, r - 0.12\% \frac{r^2}{h_0} \tag{5}$$

accordingly, substituting for the value of h in equation (3)

$$S = \frac{rh_0dg}{2} + \frac{r^2dg}{6} - 0.1288 \frac{r^3dg}{h_0} \tag{6}$$

This correction may be used for small capillaries, that is, those with radius less than 1 mm., but does not hold strictly for larger ones.

Richards and Coombs[12] have justified a simple treatment which involves only a correction for the measurement of the height of the meniscus itself. Letting h_0 represent the observed height and h_m equal the height of the meniscus

$$h = h_0 + {}^1/_3\, h_m \tag{7}$$

from which

$$S = rdg/2\,(h_0 + {}^1/_3\, h_m) \tag{8}$$

They have measured h_m directly and the values obtained by them show satisfactory agreement with those calculated with the Poisson formulation.

The radius of the capillaries used by us came well within the limits demanded by these formulations; accordingly, the Poisson equation was applied to our data for the calculation of capillary radius and comparisons were made between the values obtained when such meniscus corrections were applied and results obtained when no meniscus corrections were made.

Results.—Data will be given which were obtained with two different sets of apparatus (double cylinder type), designated as apparatus No. 1, and apparatus No. 2. The diameter of the capillary in No. 1 was uncorrected, 0.2530, corrected, 0.2522; in No. 2 it was uncorrected 0.3551, corrected 0.3329. In the first case there was an apparent error due to meniscus reading of −0.3%, in the second an error of −0.6%.

In the measurement of interfacial tension a meniscus is also involved, and again when water forms a zero contact angle the general shape of the meniscus is the same as that encountered in the determination of pore radius. Similar theoretical treatment was applied and similar corrections were made. It was found that in the case of liquids whose interfacial tension values ranged between 25 and 40 dynes, the corrections were well within the limits of experimental error. For example, results for the interfacial tension of benzene and water were almost identical when calculated, first, making no meniscus corrections whatsoever and, secondly, making meniscus corrections, that is, making meniscus height corrections

[11] Poisson, "Nouvelle Theor. de l'Act. Capill.," 1831, pp. 112.

[12] Richards and Coombs, THIS JOURNAL, 37, 1656 (1916).

both in the calculation of radius of the capillary tube and in the subsequent calculation of the interfacial tension using this corrected radius value. It happens that in each of these cases in which the interfacial values are within the range indicated, the magnitude of the corrections for the interfacial tension values and for the capillary radius bear the same percentage relationships. In other systems having interfacial tension values outside the range indicated, the corrections for these values do not bear the same percentage relationships to the capillary radius corrections, and failure to apply the meniscus corrections in these cases does involve a perceptible error; even in these cases, however, the error is not great and the deviation still comes within the limits encountered in almost any one of the methods in present use. In fact, as shown in the table below, the deviation is not greater than errors involved in the calibration and use of different apparatus. It may be found that when liquids of an exceptional degree of purity are used and when further refinements are made and precautions are observed in the use of the apparatus, results even more consistent may be obtained.

The following table contains the results obtained with apparatus No. 1 and apparatus No. 2 (each of the double cylinder type) with six different liquids. Both corrected and uncorrected results are given.

TABLE I

INTERFACIAL TENSION VALUES OBTAINED WITH APPARATUS

Summary

1. A method based upon the capillary tube principle was developed for the determination of the interfacial tension of liquid-liquid systems.

2. Two somewhat different types of apparatus were designed. Both types were constructed and used in the experimental work described herein. Both gave satisfactory results.

3. The method is rapid. The apparatus can be cleaned easily. Non-transparent liquids can be used, likewise liquids of any density. The apparatus can be placed in a water thermostat and kept at constant temperature while readings are being made.

4. In constructing this apparatus, it is not essential that the diameter of the capillary be strictly uniform throughout. Calibration of capillary radius is necessary only for a given point on the capillary tube; also for work of ordinary accuracy no capillary corrections for meniscus height readings are necessary.

5. Results which have been obtained show a close agreement with what are believed to be the most accurate interfacial tension data available in the literature.

SYNTHESIS OF HEPTANE DICARBOXYLIC ACID-1,5[1]

BY ALBERT S. CARTER

RECEIVED MARCH 19, 1928 PUBLISHED JULY 6, 1928

Perkin[2] attempted to prepare heptane dicarboxylic acid-1,5 through the condensation of diethyl ethyl malonate with trimethylene bromide and subsequent condensation with diethyl malonate to yield heptane tetracarboxylic ester-1,1,5,5. This was hydrolyzed and partially decarboxylated with the formation of an acid which seemed to be ethyl pimelic acid (heptane dicarboxylic acid-1,5). This product could not be purified to yield a solid acid, such as might be expected from the melting points of the other isomers of azelaic acid, consequently Perkin expressed doubt as to the purity of his product. This work was repeated with the utmost care and it was found that the results duplicated those obtained by Perkin. It was found, however, that small amounts of nonane tetracarboxylic ester-3,3,7,7 could be isolated from the reaction product and it was thought probable that the corresponding diethyl pimelic acid might be the impurity which inhibited the crystallization of the product.

The use of trimethylene chlorobromide or the addition of the sodium derivative of ethyl malonic ester to trimethylene bromide instead of the addition of the bromide to the sodium derivative would decrease the tendency to form the nonane tetracarboxylic acid (the former was tried by Perkin), but neither of these methods would insure that none of the second-

[2] Perkin, J. Chem. *Soc.*, *65*, 991 (1894).

ary product would be formed. The idea of adding the sodium derivative to the bromide in order to have constantly an excess of the bromide present was tried without success.

To avoid completely the condensation of two molecules of the malonic ester with trimethylene bromide, a synthesis involving the use of phenoxypropyl bromide was carried out to yield phenoxypropylmalonic ester and phenoxyvaleric acid. This was hydrolyzed to form iodovaleric acid, esterified and condensed with diethyl malonate.

$$C_6H_5O(CH_2)_3Br \xrightarrow[C_2H_5ONa]{CH_2(COOC_2H_5)_2} C_6H_5O(CH_2)_3CH(COOC_2H_5)_2 \xrightarrow{H_2O}$$

$$C_6H_5O(CH_2)_3CH(COOH)_2 \longrightarrow C_6H_5O(CH_2)_4COOH \xrightarrow{HI} I(CH_2)_4COOH \xrightarrow[HCl]{C_2H_5OH}$$

$$I(CH_2)_4COOC_2H_5 \xrightarrow[NaOC_2H_5]{HCC_2H_5(COOC_2H_5)_2} C_2H_5OOC(CH_2)_4CC_2H_5(COOC_2H_5)_2 \xrightarrow{H_2O} \xrightarrow{Heat}$$

$$HOOC(CH_2)_4CH(C_2H_5)COOH$$

Experimental Part

8-Phenoxypropyl Malonic Ester.—Following the general course of some work by Marvel and MacCorquodale,[3] phenoxypropyl malonic ester was prepared as follows: 32 g. of sodium was added to 500 cc. of absolute alcohol and to this was added 225 g. of diethyl malonate through a dropping funnel, with frequent shaking. During a period of about one hour, 325 g. of phenoxypropyl bromide was added to the reaction mixture, which was then refluxed for four hours. Most of the alcohol was distilled from the neutral product and it was shaken with water to remove the sodium bromide. The ester layer was collected in a little ether, separated from the water and dried over sodium sulfate. From this ether solution, phenoxypropyl malonic ester was obtained by fractionation under diminished pressure. The fraction containing the ester was collected at 228–235° (26 mm.); yield, 310 g. or 76%.

Anal. Subs., 0.2000: CO_2, 0.4770; H_2O, 0.1334. Calcd. for $C_{16}H_{22}O_5$: C, 65.30; H, 7.48. Found: C, 65.05; H, 7.41.

8-Phenoxypropyl Malonic Acid.—One liter of 20% sodium hydroxide and 300 g. of phenoxypropyl malonic ester were refluxed for about five hours. The resulting solution was cooled and acidified with dilute sulfuric acid. The precipitated phenoxypropyl malonic acid was filtered off and recrystallized from hot water; yield, 218 g. or 90%; m. p. 72–78' with some decomposition. The melting point is given in the literature[4] as 75–80°.

δ-Phenoxypropyl Valeric Acid.—Two hundred g. of the malonic acid derivative was decarboxylated by heating in a 2-liter flask in an oil-bath at 175° until the evolution of carbon dioxide was complete. The product was cooled and recrystallized from petroleum ether, giving 147 g. (90%) of the phenoxypropyl valeric acid; m. p. 55–56° (Gabriel gives 65–66"). The silver salt of this acid was prepared by crystallization from a hot solution of the ammonium salt by the addition of silver nitrate.

Anal. Subs., 0.2000: AgCl, 0.0957. Calcd. for $C_{11}H_{13}O_3Ag$: Ag, 35.85. Found: Ag, 36.01.

8-Iodovaleric Acid.—One hundred g. of phenoxyvaleric acid was refluxed for four

---

[3] Marvel and MacCorquodale, THIS JOURNAL, 46, 2838 (1924).

[4] Gabriel, Ber., 25, 418 (1892).

hours with 400 cc. of hydriodic acid (sp. gr. 1.70) and the mixture was diluted with several times its volume of water and extracted with ether. To separate the iodovaleric acid from phenol, the ether solution was extracted with saturated sodium carbonate from which the acid was precipitated with hydrochloric acid, filtered and dried. This crude product was partly purified by dissolving in 75% alcohol and pouring over ice. After drying and recrystallization from warm petroleum ether, white needles were obtained, melting at 54–56°, which agrees with the melting point previously reported;[5] yield, 80 g. or 68%. An attempt to prepare bromovaleric acid in a similar manner using 48% hydrobromic acid gave poor yields.

Ethyl **δ-Iodovalerate.**—A mixture containing 100 g. of the iodovaleric acid in 500 g. of a 5% solution of dry hydrogen chloride in absolute alcohol was refluxed for four hours and then the greater part of the alcohol and hydrogen chloride was removed by distillation. The solution was diluted with an equal volume of water, the ester layer extracted with ether and the ether solution washed with saturated sodium carbonate to remove free acid. The ether solution of the ester was dried over sodium sulfate and distilled under diminished pressure; the ester was collected in the fraction boiling from 108 to 118° (20 mm.); yield, 68 g., representing 61% of the theoretical (this is almost 90% if corrected for the acid reclaimed from the carbonate extract of the reaction product).

Anal. Subs., 0.5000: AgI, 0.4490. Calcd. for $C_7H_{13}O_2I$: I, 49.61. Found: I, 48.54.

Triethyl Ester of Heptane Tricarboxylic **Acid-1,5,5.**—Four g. of sodium was dissolved in 50 cc. of absolute alcohol and to this was added 34 g. of diethyl ethylmalonate followed by 44.1 g. of ethyl iodovalerate. The reaction mixture was worked up in the same manner as in the preparation of phenoxypropyl malonic ester, the product being obtained in a fraction boiling between 195 and 200" at 20 mm.

Heptane Tricarboxylic **Acid-1,5,5.**—As in the case of phenoxypropyl malonic acid, 31.5 g. of the tricarboxylic acid ester was hydrolyzed with 150 cc. of 20% sodium hydroxide to yield a product of oily crystals melting at 86–88' and decomposing with the evolution of carbon dioxide at temperatures above 140°.

Heptane **Dicarboxylic Acid-1,5.**—Decarboxylation of 20 g. of the tricarboxylic acid between 140 and 180° gave 16 g. of yellow oil which was distilled under diminished pressure from a Claisen flask carrying a modified arm. Upon fractionation almost the entire product was collected at 218–223° at 17 mm. (Perkin records 260" at 82 mm.) The fraction was a thick, colorless oil which seemed to resist all attempts to obtain a crystalline product from it, but after standing as a liquid for several days, it suddenly completely crystallized. This crystalline material melted at 41.5–43.0° and was soluble in hot water, alcohol and hot benzene. The silver salt was prepared by dissolving in dilute ammonium hydroxide, boiling out the excess ammonia and precipitating from the cooled solution of the ammonium salt by adding silver nitrate solution.

Anal. Subs., 0.3000: AgCl, 0.2125. Calcd. for $C_9H_{14}O_4Ag_2$: Ag, 53.68. Found: Ag, 53.32.

These analyses, while slightly low for silver, considered with the method of preparation, indicate that the product is heptane dicarboxylic acid-1,5.

Summary

Heptane dicarboxylic acid-1,5 has been synthesized through the following steps: trimethylene bromide, phenoxypropyl bromide, phenoxypropyl malonic ester, phenoxyvaleric acid, iodovaleric acid, heptane tricarboxylic acid-1,5,5 and heptane dicarboxylic acid-1,5.

[5] Cloves, *Ann.*, 319, 367, 388 (1901).

Heptane dicarboxylic acid-1,5 has been obtained as a solid.

In the course of the synthesis, the following new compounds were prepared: ethyl δ-iodovalerate, triethyl ester of heptane tricarboxylic acid-1,5,5, heptane tricarboxylic acid-1,5,5 and the silver salt of heptane dicarboxylic acid-1,5.

THE USE OF PLATINUM-OXIDE PLATINUM BLACK IN THE CATALYTIC REDUCTION OF AROMATIC HYDROCARBONS. XVII[1]

BY ROGER ADAMS AND J. R. MARSHALL[2]

RECEIVED APRIL 2, 1928 PUBLISHED JULY 6, 1928

One of the few classes of reducible compounds which does not lend itself readily to reduction under ordinary laboratory conditions is the aromatic hydrocarbons. These compounds have frequently been reduced at high temperatures, using nickel or other metals as a catalyst, but no satisfactory method is available for their reduction under such conditions as are most conveniently used in a scientific laboratory, namely, room temperature or slightly above, atmospheric pressure or pressures not over two or three atmospheres and readily prepared catalyst. The reactions should be comparatively rapid and it should be possible to reduce large enough quantities to be sufficient for ordinary research purposes. The success of platinum-oxide platinum black as a catalyst for the addition of hydrogen to many unsaturated compounds, as compared with other forms of catalytic platinum, led to a study of its use in the reduction of aromatic hydrocarbons.

Willstatter[3] and his associates report the hydrogenation of benzene and toluene at ordinary pressures and temperatures by means of hydrogen and platinum black prepared by the reduction of chloroplatinic acid and formaldehyde. However, the large amount of catalyst needed compared with the amount of material to be reduced renders the method impractical for ordinary work. For the reduction of 3.0 g. of benzene in 13 cc. of glacial acetic acid with 0.1 g. of platinum black, six hours was required; for 1.8 g. of toluene in 3 g. of acetic acid with 0.5 g. of platinum black, three and one-half hours; for 6 g. of xylene in 4 g. of acetic acid with 0.9 g. of platinum

---

[1] The previous article in this field is by Bray and Adams, THIS JOURNAL, 49, 2101 (1927). Reference to the other work will be found in this article.

[2] This communication is an abstract of a thesis submitted by J. R. Marshall in partial fulfilment of the requirements for the degree of Master of Science in Chemistry at the University of Illinois.

[3] (a) Willstatter and Waldschmidt-Leitz, *Ber.*, 54, 113 (1912); (b) Willstatter and Hatt, *ibid.*, 45, 1471 (1921).

black, twenty-four hours. Other hydrocarbons were reduced under conditions comparable with those cited.

The benzene hydrocarbons have also been reduced by means of colloidal platinum. Skita[4,5] and his associates reduced several, of which may be mentioned as examples, 1 g. of toluene in 120 cc. of acetic acid with 0.41 g. of colloidal platinum in three and one-half hours; 10 g. of xylene in 80 cc. of acetic acid with 1.5 g. of platinum in three to four hours, using in this instance, however, **3** atmospheres' pressure and 80° temperature.

The use of platinum-oxide platinum black has proved to be of value and to be a catalyst far more effective than those mentioned. Although the investigation is not entirely complete, publication of the results at hand is offered since, in an article recently published, Kuhn[6] has noted in the course of an investigation on the addition reactions of conjugated systems that certain compounds such as diphenylbutadiene were reduced by platinum-oxide platinum black not merely to diphenyl substituted saturated hydrocarbons, but even further until the benzene nuclei were saturated. Thus the completely hydrogenated derivatives of diphenylbutane, diphenylhexane and diphenyloctane were prepared. Though alcohol has usually proved to be the most satisfactory solvent for reductions with platinum-oxide black, with ethyl acetate as the second most desirable, in the case of the aromatic hydrocarbons neither is as suitable as glacial acetic acid. The temperature was in practically all cases that of the room and the pressure was varied from two to three atmospheres. The following table indicates how readily various hydrocarbons may be reduced in practically quantitative yields with a small amount of catalyst.

The first seven compounds and the last two in the table could be reduced to completion with 0.2 g. of catalyst. The heavier molecules, however (in general those with more than one phenyl group), required several additions of 0.2 g. of catalyst to obtain complete reduction within a required time.

A few experiments were made with benzene, toluene and xylene, increasing the amount of catalyst and, as might be expected, the time of reduction was very materially decreased. In addition it might be stated that fluorene and α,α-diphenylpropane resisted all attempts at reduction by a similar procedure. It is the opinion of the authors that this difficulty was probably due to slight impurities, even though special precautions were taken to remove them. In general, the rate of reaction of these aromatic compounds seemed to be very dependent on the purity of the compounds and reagents Presence of traces of impurities frequently diminished the rate of reduction markedly.

Skita[4,5] fractionated very carefully 9 g. of reduced m-xylene. From this

he reports that he was able to obtain two constant boiling fractions, one at 119° and the other at 121.5°, which he assumed to be the *trans* and cis forms, respectively. In the reduction with platinum-oxide platinum black the product, even though available in much larger quantities than reported by Skita, could not be fractionated into two constant boiling compounds. It appears that the largest proportion of the product was probably the *trans* form. In the same way, at least the greater proportion of the reduction product of cymene was a single compound.

Experimental

Platinum Black.—The platinum oxide was prepared from C. P. chloroplatinic acid in the manner described previously.[18] The apparatus was the same as has been used in the previous investigations.

---

[18] Adams and Shriner, THIS JOURNAL, 45,2171 (1923); *Org. Syn.*, 8, 92 (1925).

Purification of Substances to be Reduced.—Commercial C. P. products were obtained and further purified. Thiophene-free benzene, toluene, ethylbenzene, xylene. mesitylene, cymene and diphenylmethane were refluxed for three hours over sodium and then distilled. Only the constant boiling fraction was used for the reduction. Triphenylmethane, α,α-diphenylethane, dibenzyl, phenylacetic acid and β-phenylpropionic acid were crystallized alternately from alcohol and glacial acetic acid. After several recrystallizations the compounds were used for reduction.

Method of Isolation of Products.—After filtration and evaporation of the solvent, the reduced compounds, with the exception of the two acids, were treated several times with a mixture of 10 cc. of concd. nitric acid and 25 cc. of sulfuric acid at 0–5° for five to ten minutes. After each treatment the compound was washed with water. When the acid mixture no longer turned yellow, the compound was considered to be pure and was washed, dried and distilled.

The cyclohexylacetic acid and the β-cyclohexylpropionic acid were merely distilled from the acetic acid in order to purify them.

Summary

It has been found that platinum-oxide platinum black is an excellent catalyst in the reduction with hydrogen of various types of aromatic hydrocarbons in glacial acetic acid as a solvent.

THE EFFECT OF THE CYANIDE GROUP ON THE BASICITY OF ALIPHATIC AMINES AS DETERMINED IN WATER AND ALCOHOL SOLUTIONS

BY T. D. STEWART AND VIVIEN COOK

RECEIVED APRIL 16, 1928 PUBLISHED JULY 6, 1928

Stewart and Aston[1] studied the influence of alkoxyl substitution upon the basicity of tertiary aliphatic amines, using derivatives of the type $ROCH_2N(C_2H_5)_2$. They found that methoxy, ethoxy and isobutoxy substitution lowered the base strength and gave to the basic dissociation constants of the amino ethers the values 3.6×10^{-9}, 1.8×10^{-8} and 4×10^{-7}, respectively. The comparisons were made colorimetrically in alcohol, using methylaniline and benzylamine as standards. By assuming that the relative base strengths in water and alcohol solution would be the same, the above figures were assigned as for an aqueous solution. The work of Goldschmidt and Mathiesen[2] indicates that in general amines are stronger bases in alcohol than in water, but with notable exceptions, so that comparisons of basicity in alcohol cannot be considered to offer a similar comparison in water. The above values, then, must be considered not as absolute but as relative to themselves and to methylaniline in alcohol solution only. It is, nevertheless, apparent that alkoxyl sub-

---

[2] Goldschmidt and Mathiesen, *Z. physik. Chem.*, **119**, 439 (1926).

stitution upon the α-carbon of an amine causes a marked decrease in the tendency of the nitrogen atom to attach a proton, and particularly interesting to observe that the effects of different alkoxyl groups are considerably different in magnitude.

The present paper deals with the effect upon the base strength of substituting a cyanide group for a hydrogen atom upon a carbon in the a-position to the nitrogen in methyldiethylamine, triethylamine, benzyldiethylamine and isopropyldiethylamine. The comparisons are made both in alcohol and water solutions in the first and third cases, but only in alcohol in the other two because of the rapid decomposition of these bases in aqueous acid.

Experimental Results

The electrometric titrations of α-diethylamino-acetonitrile and of α-diethylaminophenylacetonitrile were carried out in water as described in the Experimental Part. The results indicate basic dissociation constants,

K_B, of 1.0×10^{-10} and 1.7×10^{-11}, respectively, and are summarized in Tables I and II and Fig. 1. The method of calculation is described in the later section.

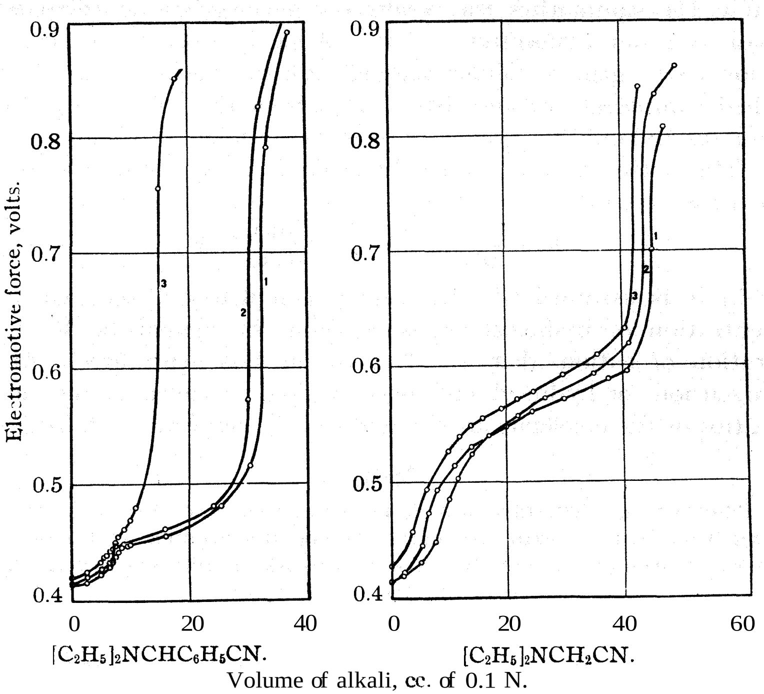

Fig. 1.—Titration curves of salts of α-aminonitriles in water.

In each of the three titrations of a-diethylamino-acetonitrile (Table I, Part B) consistent values of K_B are obtained, but the three do not agree well among themselves, perhaps due to constant small errors in the electrode condition. Still greater difficulty was experienced in attempting to get reproducible results when the base was titrated directly with acid, probably due to poisoning of the electrodes in the alkaline solution. The numerical average given may be considered accurate within 30%.

Since the α-diethylaminophenylacetonitrile is sparingly soluble in water and upon titration of its acid solution started to precipitate before the excess acid was neutralized, the inflection point of the titration curve did not signify the point of equivalency of acid and base present. Moreover, the substance decomposes more or less rapidly in dilute acid, presumably according to the equation

$$C_6H_5CHCNN(C_2H_5)_2 + H_2O \longrightarrow C_6H_5CHOHCN + (C_2H_5)_2NH$$

The net result is the transformation of a weak base to a stronger base, so that the concentration of the salt present (Table II, Part B, Col. 4) **was** corrected for this reaction (see Experimental Part). Curve III, Fig. 1, for this substance was for an acid solution which had stood for two hours before titration. The weak base had almost disappeared.

Table III summarizes the results of the colorimetric comparison in alcohol at room temperature. An alcoholic hydrogen chloride solution of known strength, containing the indicator in question, was added to a weighed sample of the pure base. Details of the color comparison are given later and only the average of several determinations is given in Table III. The ratios of the various basic dissociation constants are taken from the expression

$$K = \frac{(\text{Cation})}{(\text{Base})}(\text{OH}^-) = \frac{(\text{Salt})}{(\text{Base})}(\text{OH}^-)$$

wherein it is assumed that the acid is completely dissociated and the concentration of hydrogen ion is negligible in comparison to the concentration of cation, that is, all of the acid is neutralized. At equal hydrogen ion (or hydroxyl ion) concentration, as shown by the indicator, the ratios of the constants are the ratios of the respective salt/base ratios.

The trend in the ratio of the constants in the case of the phenylated derivative may be due to experimental error, although there is no suggestion in the actual data of an uncertainty of this magnitude.

The fact that the trend is less marked in the experiment using Propyl Red than it is in those with Methyl Red, suggests some specific action of the base upon the indicator, or it may involve the assumptions used in the comparison of the constants.[3] It is doubtful whether the numerical average should be taken rather than an extrapolation toward higher fractional neutralization. Since the averages agree in the two series better than the extrapolations, they are taken as more nearly approaching the correct value and a final value of 8.5 assumed for the ratio of the constants of m-chloro-aniline to a-diethylaminophenylacetonitrile in alcohol. It is believed that this is correct within 20%.

Table IV gives a résumé of the results. The values for aniline and m-chloro-aniline in water are taken from Landolt-Bornstein's "Physikalische-Tabellen." K_B is the basic dissociation constant in water, K_A, the acidic dissociation constant of the cation, obtained for water solution from the relation $K_A = K_W/K_B$, where $K_W = 1.0 \times 10^{-14}$. K_A in alcohol solution is taken in the case of aniline, methylaniline and *m*-chloro-aniline from the work of Goldschmidt and Mathiesen,[2] and in the other cases calculated from these and from the above determined ratios.[4]

---

[3] Goldschmidt and Mathiesen, ref. 2, give the dissociation constant of *m*-chloro-anilonium ion ($ClC_6H_4NH_3^+$) in alcohol as 6.1×10^{-5}, and of anilonium ion ($C_6H_5NH_3^+$) as 2×10^{-6}. A solution of aniline hydrochloride which is 0.05 M would then contain about 3×10^{-4} *N* hydrogen ion, since hydrogen chloride is a strong acid, even in alcohol. A solution of chloro-aniline and its hydrochloride, in equivalent amounts, would contain about 6×10^{-5} *N* hydrogen ion, and at the same point our data show aniline to be about 98% titrated, whereas calculated from the above figures it should be 97%. We are, then, in substantial agreement and are apparently justified in the assumption of our simplified formula.

[4] In addition to the results of Table IV, we have made measurements on a base prepared from acetone, and which is presumably α-diethylamino-*iso*butyronitrile. It had the correct equivalent weight and is a new preparation so far as we know. The yield was small and the preparation has not been duplicated, hence we have not detailed the results at this time. In alcohol solution the substance titrated precisely as does aniline. If this is true, it means that whereas the introduction of one methyl

Discussion of Results

We may record in Table V for reference[5] the dissociation constants in water of the parent compounds of the cyano and alkoxyl amines and the data for a similar series of substitutions in acetic acid.

TABLE V

BASIC AND ACIDIC DISSOCIATION CONSTANTS IN WATER

Bases	K_B	Acids	K_A
Methyldiethylamine	2.7×10^{-4}	Acetic	1.8×10^{-5}
Diethylbenzylamine	3.6×10^{-5}	Phenylacetic	5.3×10^{-5}
Triethylamine	6.4×10^{-4}	Cyanoacetic	3.7×10^{-3}
		Methoxyacetic	3.3×10^{-4}
		Ethoxyacetic	2.3×10^{-4}

From a comparison of Tables IV and V, using either the ratios of the dissociation constants or the logarithms of such ratios, it is seen that the cyano and alkoxyl groups substituted in amines reduce the basicity to a much greater extent than they increase the strength of acetic acid when substituted upon the a-carbon atom. The two systems are not strictly comparable, since that of the amines is a 1,3-substitution from the affected atom (nitrogen) whereas in acids the substitution is 1,4. The effect of substituting a methyl or phenyl group in a cyano-amine is the same as for the same substitution in the simple amine. The logarithm of the dissociation constant of methyldiethylamine (in water) is decreased

---

group into the acetonitrile derivative causes no change in the base strength, a second methyl group produces a 17–18 fold increase in base strength. Mr. A. J. Alstrom, to whom we are indebted for this provisional result, is repeating the preparation.

[5] Landolt-Börnstein, "Physikalische-Chemische Tabellen," Berlin, 1923.

about 0.85 by phenyl substitution in the α-position, and about 6.4 by cyano substitution. Similarly substitution of hydrogen by phenyl in diethylamino-acetonitrile decreases the logarithm of the dissociation constant by 0.77. The increase of the logarithm of the dissociation constant of acetic acid is 0.47 for phenyl substitution, 2.32 for cyano substitution and 1.27 for methoxy substitution. Methoxy substitution in the amines likewise produces a smaller effect than cyano substitution, at least in alcohol solution. From the data now available, it would not be safe to assume that the effect of change of solvent from water to alcohol would produce in the amino nitriles and in the amino ethers the same change or even a similar change in the basic dissociation constants of the respective bases. It is, however, probable that the two classes of amines closely maintain in water the same relative basicities as in alcohol.

It so happens that the bases studied here maintain the same order in base strength in alcohol and in water, although the ratios of the dissociation constants differ widely in the two solvents. The series of bases studied by Goldschmidt and Mathiesen[2] differed even in order. The reasons for this will not be discussed fully at this time. It is evident, however, that in the expression

$$Kg = \frac{(\text{Cation})}{(\text{Base})}(\text{OH}^-)$$

the parentheses denote the activities of the respective substances. Since normally it is the concentration and not the activity that is measured, and since in the present work solutions of equal hydrogen ion activity are compared, we may substitute for the above activities the product of the concentration by a factor γ and write for two different bases in a given solvent

$$\frac{K'_B}{K''_B} = \frac{\dfrac{\gamma_1 C'_{\text{Cation}}}{\gamma_2 C'_{\text{Base}}}}{\dfrac{\gamma_3 C''_{\text{Cation}}}{\gamma_4 C''_{\text{Base}}}}$$

A similar expression could be written for a second solvent. It is then seen that the ratio of the constants, K'_B and K''_B, as calculated only from the concentrations, can be the same in two solvents only in case the ratio of the four γ factors remains constant with change of solvent. The γ factors involve deviations from the laws of perfect solutions and may, in addition, not be constant with respect to changes in concentration. It is not surprising that numerical constancy of the above ratios is not found. The question is further complicated by the assumption of infinitely dilute solutions in each solvent as the standard state of a given molecular species in that solvent. There would be a difference in the energy contents of the hypothetical molal solution of a given solute in two different solvents which should be included in a strict comparison of the basic dissociation constants of a substance in those solvents.

Finally, if a base is composed of two or more tautomers, the net base strength is determined in part by the relative amounts of the tautomers present. A change of solvent may change these relative proportions and in a manner unrelated to the relative base strengths of the individual tautomers. Then the comparison of a base which may tautomerize with one which may not, in different solvents, might lead to results which would be difficult of interpretation in terms of their respective structures.

Experimental Part

Preparation of Materials.—The following amino nitriles were prepared using the method of Knoevenagel and Mercklin.[6]

a-Diethylamino-acetonitrile from formaldehyde, sodium bisulfite, diethylamine and potassium cyanide; colorless oil, soluble in water; b. p. 35–40° (6 mm.) and 62–63° (14 mm.); yield, 85% based on diethylamine.

a-Diethylaminopropionitrile from acetaldehyde and other reagents as above; colorless oil, soluble in water; rapidly hydrolyzes in aqueous acid; b. p. 47–49° (7 mm.) and 67–68' (17 mm.); yield, 65% based on diethylamine.

a-Diethylaminophenylacetonitrile from benzaldehyde and other reagents as above; slightly soluble in water, soluble in dilute acid, usually light yellow or greenish yellow after distillation; b. p. 112° (7 mm.) and 130–131° (11 mm.); yield, 83% based on diethylamine. The base decomposes more or less rapidly in acid solution, most rapidly in dilute acid, but even then the reaction requires some hours. It may be dissolved in acid and be reprecipitated with base unchanged. The equivalent weight may be accurately determined by dissolving a weighed sample in a known excess of 0.1 *N* acid and back-titrating immediately with 0.1 N base, using the difference between the precipitation end-point and the phenolphthalein end-point as a measure of the base present. The latter end-point should coincide with that of an equal amount of acid to which no base has been added.

α-Diethylamino-*iso*butyronitrile, from acetone and the other reagents as above. The yield was very poor and the preparation could not be duplicated after several trials; b. p. 75–77° (23 mm.); equivalent weight to methyl orange titration, 140 g.; colorless oil, soluble in water, rapidly hydrolyzed in aqueous acid.

Aniline.—A redistilled sample of a commercial preparation was used. It was colorless and remained so, in the dark, for several days.

***m*-Chloro-aniline.**—A redistilled sample of Kahlbaum's preparation was used. It distilled within a range of one degree and was colorless.

Alcoholic Hydrogen Chloride was prepared by generating hydrogen chloride from pure concentrated hydrochloric and sulfuric acids, drying the gas by passage through sulfuric acid and collecting it in cooled commercial absolute alcohol of good grade. It was then diluted to the desired normality with the same alcohol and the indicator added to the stock solution in the following concentrations, respectively: methyl red, 0.0083 g. per liter; propyl red, 0.012 g. per liter; thymol blue (acid), 10 cc. of a saturated solution in alcohol, per liter. The normality of the alcoholic acid was determined by diluting a measured volume of the solution with water and titrating with standard alkali, using the contained indicator. One series of experiments was made using 0.1 N acid and several using about 0.05 *N* acid.

Solubility of a-Diethylaminophenylacetonitrile in Water.—This was determined at 20° as follows. A 0.4580-g. sample (0.002349 equiv.) was dissolved in 30.0 cc. of 0.1 N

---

[6] Knoevenagel and Mercklin, Ber., 37, 4087 (1904).

acid and 2.00 cc. portions of this solution were added to known volumes of water. Excess akali in known volume was then added to the mixture and the presence or absence of a turbidity noted. In one experiment, a final volume of 97.0 cc. allowed no turbidity; in another a final volume of 91 cc. allowed a very slight turbidity which cleared on the addition of 1.0 cc. of water. Since a high degree of accuracy was not desired, this volume of 92.0 cc. was taken as accurate and represents a solubility of 0.00176 ± 2% equivalents per liter. At 30° the solubility is about 0.00185 ± 2% equivalents per liter.

Electrometric Titration Procedure.—The side arm of an ordinary decinormal potassium chloride calomel electrode was dipped directly into the solution prepared for the titration. In this was immersed an apron type foil platinum electrode. No attempt was made to exclude liquid junction potentials because of other uncertainties involving poisoning of the electrode which could be of much greater magnitude. A Leeds and Northrup type K potentiometer, a calibrated standard cell and electrolytic hydrogen generator completed the equipment. The hydrogen electrode was first brought in equilibrium with a known amount of 0.1 *N* standard acid and then an amount of organic base added which was not quite equivalent to this acid. The solution was then titrated with 0.1 N alkali as usual.

The titration curves are given in Fig. 1 and the data for the calculations given in Tables I and II (see previous section). The hydrogen ion concentration was calculated from the equation

$$\log \frac{1}{(H^+)} = \frac{E - 0.3358}{0.00019844T}$$

In the case of a-diethylamino-acetonitrile, the constant of hydrolysis of the salt and the basic dissociation constant of the base were calculated from the expressions

$$K_H = \frac{(H^+)^2}{(\text{concn. of salt}) - (H^+)};\quad K_B = \frac{K_W}{(K_H)}$$

The concentration of salt was determined from the total volume (volume of acid plus volume of alkali) at the true end-point, and the amount of base used. The other calculations were based on the simplified expression

$$K_B = \frac{(\text{Salt})\ K_W}{(\text{Base})\ (H^+)}$$

In the case of the phenylacetonitrile derivative the last equation given was used. The concentration of the base was constant and equal to that in a saturated solution; that of the salt (cation) was calculated from: (e) total volume of the solution and (b) total equivalents of salt present (base used minus base decomposed minus salt neutralized and hydrolyzed). The amount of base decomposed was given by the difference between the acid started with and acid found, as shown by the second inflection of the titration curve. Most of the reaction of decomposition took place before the back-titration started and used up acid by the formation of a strong base, presumably diethylamine.

Colorimetric Determination of Relative Base Strengths in Alcohol.—A wedge type colorimeter was used. The two wedges were fitted with the stock alcoholic acid–indicator solution, and one of them was then made alkaline with a few drops of diethylamine. They were each mounted separately on movable frames provided with a scale reading from 0 to 100. The comparator cup was of such dimensions as to give the same depth of solution as that provided by the wedges when their combined scale readings were 100. Careful calibration of the colorimeter was not necessary because it was used in a purely empirical way. A daylight lamp furnished illumination, reflected from a frosted glass background. Manipulation of the wedges permitted variation of the color shades and intensity, and the recorded scale readings allowed reproduction at will of any previously used color standard. In practice it was found that the alkaline wedge could be shifted appreciably without sensible alterations of the color shade. Readings of the acid wedge scale only were used.

The organic bases to be compared were weighed into a small flask provided with glass tubing attachments similar to those of a wash bottle. The stock acid–indicator solution was added in desired quantity from a buret the tip of which passed through the stopper of the flask. At any given time some of the solution could be forced over into the comparator cup, the color comparison made, withdrawn back into the flask, more acid added and the operation repeated until the possible range of color comparison was covered. Small amounts of water caused no appreciable change in the color of the solutions, and in the system employed there was no exposure of the solution to the air except through calcium chloride filled tubes, and except that the comparator cup had a small opening for the insertion of a glass tube through which the liquid was introduced and withdrawn. The acid wedge reading was plotted for each base against its percentage titration and smooth curves were drawn through the points. A given wedge reading then represented a corresponding hydrogen ion activity for each of the various solutions. A summary of the data is given in Table III. By the above method, using the same stock solution for all the bases, the comparisons are made at equal cation, hydrogen ion and anion concentrations (assuming complete ionization of acid and salts). The ratio of the dissociation constants is then very closely the inverse ratio of the concentrations of the free bases under these conditions. Moreover, the total ionic strength of the solution changes but very little during the whole course of the titration.

Summary

The basic dissociation constants of a-diethylamino-acetonitrile and of a-diethylaminophenylacetonitrile in water are 1.0×10^{-10} and 1.7×10^{-11}, respectively. In alcohol solution, the acidic dissociation constants of their salts (chlorides) are 3.4×10^{-5} and 5.2×10^{-4}, respectively, while those of a-diethylaminopropionitrile and of α-diethyl*iso*butyronitrile in alcohol are 3.4×10^{-5} and 2×10^{-6}, respectively. The base strengths of some

amino ethers in alcohol have been recalculated. Some of the factors which determine the apparent change in relative base strength with change of solvent are discussed.

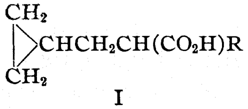
CYCLOPROPYLMETHYL ALKYL ACETIC ACIDS AND THEIR BACTERICIDAL ACTION TOWARD B. LEPRAE. XIII[1]

BY J. A. ARVIN[2] AND ROGER ADAMS

RECEIVED APRIL 17, 1928 PUBLISHED JULY 6, 1928

The various synthetic acids which have been studied for their bactericidal action have so far contained either a five or six membered ring. The present investigation has covered the synthesis of a series of acids containing a three-membered ring, namely, the cyclopropylmethyl alkyl acetic acids, (I) where the R varies from n-amyl to n-myristyl. These acids are of interest because they lead to the possibility of determining whether the significant factor for the bactericidal action in the many acids that have been studied is the character of the ring or is the molecular weight of the whole molecule, or merely that part of the molecule outside of the ring structure.



$(CH_2)_2>CHCH_2CH(CO_2H)R$

I

In Table I are given the bacteriological results.

TABLE I

CYCLOPROPYLMETHYL ALKYL ACETIC ACIDS, $C_3H_5CH_2CH(CO_2H)R$

n-$C_{14}H_{29}$										+	+	+	+	+	+	+	+	+	+

It is noticeable that practically no bactericidal effect appears until the R group is n-octyl or larger. The two most effective acids were those containing the decyl and the undecyl groups. It appears, then, that in this as in other series, at least sixteen carbon atoms in the molecule must

---

[1] Paper XII in this series, THIS JOURNAL, 50, 1790 (1928).

[2] This communication is an abstract of a portion of a thesis submitted by J. A. Arvin in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

be present before the bactericidal effect approaches the maximum. In Table II are the most effective acids of four series.

	n-$C_{10}H_{21}$	C_6H_{11}	176	$C_{18}H_{34}O_2$
$C_6H_{11}(CH_2)_2CH(CO_2H)R$	n-C_7H_{15}	C_8H_{15}	220	$C_{17}H_{32}O_2$
	n-C_8H_{17}	C_8H_{15}	320	$C_{18}H_{34}O_2$

It appears that there is no marked difference between the molecules containing different rings provided the molecular weight of the whole molecule is sufficiently large. It is interesting to note also that in those compounds of proper molecular weight, there seems to be a greater bactericidal effect where the two groups which are substituted in the acetic acid have approximately the same number of carbon atoms.

The acids were prepared by condensing cyclopropylmethyl bromide with malonic ester. The diethyl cyclopropylmethyl malonate was then condensed with the various alkyl bromides, the esters were saponified and carbon dioxide was eliminated.

Experimental

Cyclopropylmethyl Bromide.—This was made by the method of J. von Braun.[3] The last step in the procedure was not described in detail and was observed by the authors to require rather definite conditions if the best results were to be obtained.

In a 500-cc. Claisen flask, 135 g. of phosphorus tribromide was converted to pentabromide by the slow addition of 80 g. of bromine. The mixture was cooled during the addition and then allowed to stand for a few hours. The side arm of the Claisen flask was bent downward and extended through the neck well into the bulb of a 500-cc. distilling flask used as a receiver. The side arm of this receiving flask was also bent downward and connected in the same way to another distilling flask. The phosphorus pentabromide was heated in an oil-bath at 85–90° for a few minutes and then 79 g. of molten cyclopropylmethyl benzamide was added. When the contents of the flask were homogeneous, the system was evacuated and the receiving flasks were cooled by ice and salt mixtures. The reaction mixture was distilled until the temperature of the distilling vapors reached 150° at 18 mm. The distillate was poured into ice water and allowed to stand at 0–5° with occasional stirring for two hours. The product was separated, the aqueous layer extracted with a little ether and the whole washed with water. The crude material made in this way from three runs was fractionated and 87–91 g. (46–48%) of cyclopropylmethyl bromide was obtained: b. p. 104–110°.

---

[3] J. von Braun. Ann., 445, 201 (1925).

Diethyl Cyclopropylmethyl Malonate.—Cyclopropylmethyl bromide was condensed with malonic ester in the usual way, though the mixture was heated for forty hours before the reaction was complete. The yields were 66–70% of the theoretical.

Diethyl Cyclopropylmethyl Alkyl Malonates.—These were prepared by a method previously described, by the condensation of alkyl bromides with diethyl cyclopropylmethyl malonate.[4] The yields were 60–66% of the theoretical.

Cyclopropylmethyl Alkyl Acetic Acids.—These were prepared from the malonic acids by a method previously described.' The yields were 86–94% of the theoretical.

Summary

A series of cyclopropylniethyl acetic acids has been prepared and tested for bactericidal action toward B. Leprae.

No appreciable bactericidal effect appeared until the alkyl group was n-octyl or larger, thus indicating as in previous researches that molecular weight of the whole molecule plays an important role. No marked difference was found between molecules containing 5-, 6- or 3-membered rings provided the molecular weight was approximately the same.

THE CHEMISTRY OF LIGNIN.
II. FRACTIONAL EXTRACTION OF LIGNIN FROM CORN COBS

BY MAX PHILLIPS

RECEIVED APRIL 20, 1928 PUBLISHED JULY 6, 1928

In a previous communication,[1] a description was given of a lignin fraction obtained by treating corn cobs with alcoholic sodium hydroxide solution at room temperature. The analytical data presented agreed with those required for the dissected formula $C_{37}H_{33}O_9(OH)_4(OCH_3)_3$. The yield of this fraction amounted to 3.49% of the weight of the corn cobs treated. This yield represents only a part of the total lignin in corn cobs as determined for example by the Dore[2] modification of the Konig and Becker[3] method. The question arose whether all the lignin could be removed by prolonged and repeated extraction with alcoholic sodium hydroxide solution. If all the lignin were similarly combined with the carbohydrates, such a result might reasonably be expected. It was found, however, that only a part of the total lignin could be obtained even after exhaustive extraction with this reagent. The residual lignin could be obtained only by subjecting the extracted corn cobs to the action of sodium hydroxide solution at successively higher-temperatures.

The experimental procedure employed consisted in subjecting corn cobs that had previously been extracted with a 1:1 alcohol–benzene solution to exhaustive extraction with alcoholic sodium hydroxide solution at room temperature until a test sample upon removal of the alcohol and subsequent acidulation no longer gave any precipitate of lignin. The residual material, which still contained some combined lignin, was successively extracted with a 2% aqueous sodium hydroxide solution at 100° until the extract was free from lignin. The residue from this treatment was similarly extracted with a 2% aqueous sodium hydroxide solution at 135° and finally with a 4% sodium hydroxide solution at 180°. The residue obtained from the final treatment was entirely free from lignin.

Among chemists who have accepted the view that lignin is chemically combined with the cellulose or with other carbohydrate material, much difference of opinion prevails regarding the manner in which this combination occurs. Erdmann[4] and Lange[5] assume that an ester-like union exists

between an acid group in the lignin and an hydroxyl of the carbohydrate. On the other hand Hoppe-Seyler,[6] Grafe,[7] and Mehta[8] are inclined to the view that there exists an ether-like linkage between the lignin and the cellulose or other carbohydrate, Data obtained on the fractional extraction of the lignin from corn cobs indicate that the lignin is dissimilarly combined with the carbohydrates. The assumption that *all* of the lignin is combined with the carbohydrates either as an ester or an ether is unwarranted as far as the lignin from corn cobs is concerned. It is believed that both types of linkage are present, which explanation would account for the fact that only a part of the lignin may be removed from corn cobs with alcoholic sodium hydroxide solution even after exhaustive extraction. The analyses made on the lignin fractions do not justify the conclusion that there is more than one kind of lignin present in corn cobs. There is apparently no alkali lignin present in corn cobs in the free state, for extraction with a solvent such as a 2:1 acetone–ethanol solution, which is an excellent solvent for free alkali lignin, fails to yield any lignin.

Experimental

Five hundred grams of ground corn cobs which had previously been extracted with boiling 1:1 alcohol–benzene solution was digested at room temperature with 1000 cc. of alcoholic sodium hydroxide solution (20 g. of sodium hydroxide, 400 cc. of water and 600 cc. of 95% ethanol) for forty-eight hours. The yellow liquor was decanted, the cobs were pressed and the liquor was combined with that obtained by decantation. This solution was neutralized with hydrochloric acid and the alcohol was removed by distillation under reduced pressure. After the residual solution had been made distinctly acid with hydrochloric acid, the precipitated lignin was filtered off, washed free from hydrochloric acid and dried at 80°. This digestion with alcoholic sodium hydroxide solution and subsequent isolation of the lignin was continued until no more lignin was obtained. Six extractions were required. The six lignin fractions were combined and purified by dissolving in 2:1 acetone–alcohol solution (200 cc. of acetone, 100 cc. of 95% ethanol) filtering and pouring the filtrate into 1.5 liters of boiling water containing 50 cc. of concentrated hydrochloric acid. This was allowed to cool to room temperature, filtered, washed with water until the washings gave no test for chlorine with silver nitrate and dried at 80°. A light yellow, amorphous powder was obtained (Fraction "A," Table I).

The residue from the digestion with alcoholic sodium hydroxide solution was refluxed with 2% aqueous sodium hydroxide solution for lour hours. It was then filtered, the filtrate acidified with hydrochloric acid and the lignin filtered off. The refluxing with 2% aqueous sodium hydroxide solution was continued until no more lignin was obtained. The several lignin fractions were combined and purified by dissolving in acetone and alcohol as already described (Fraction "B," Table I).

The residue obtained after the extraction of lignin fraction "B" was digested with a 2% aqueous sodium hydroxide solution for four hours in an autoclave at 135°. The alkaline liquor was filtered off and the digestion with 2% sodium hydroxide was repeated

until no more lignin was obtained. The lignin was isolated from the alkaline solution and purified from acetone and alcohol as already described (Fraction "C," Table I).

The residue from the foregoing treatment was heated for two hours with 4% aqueous sodium hydroxide in an autoclave at 180°. The alkaline extract was acidified with hydrochloric acid and the precipitated lignin was filtered off. The residue from this operation when similarly treated gave no lignin. The cellulose residue was nearly colorless and gave no color reaction with phloroglucinol and hydrochloric acid. When it was bleached with sodium hypochlorite, a pure white product was obtained. The yield of cellulose amounted to 35% of the weight of the moisture free corn cobs.

The results of this experiment are given in Table I.

TABLE I

LIGNIN FRACTIONS EXTRACTED FROM CORN COBS

Lignin fraction	Lignin (calcd. on corn cobs treated), %	Total lignin, %	Ash in lignin, %	Methoxy (calcd. on ash-free lignin), %	Pentosans in lignin Before purification with acetone and alcohol, %	Pentosans in lignin After purification with acetone and alcohol, %	Cellulose (calcd. on corn cobs treated). %
A[a]	4.4	48.4	0.37	16.45	0	0	35.8
B[b]	3.7	40.7	0.43	15.31	2.16	0	
C[c]	0.84	9.2	.19	15.05	0.79	0	
D[d]	.14	1.5	. .	7.50[e]	. .	.	

[a] "A"—Corn cobs extracted with 2% alcoholic sodium hydroxide at room temperature.

[b] "B"—Residue from "A" refluxed with 2% aqueous sodium hydroxide solution.

[c] "C"—Residue from "B" heated with 2% aqueous sodium hydroxide at 135°.

[d] "D"—Residue from "C" heated with 4% aqueous sodium hydroxide at 180°.

[e] No ash determined in this lignin fraction.

The percentage of methoxyl in the various lignin fractions was determined by the method of Zeisel and Fanto.[9] The pentosans in the lignin fractions were determined by the A. O. A. C. method.[10]

Table I shows that 48.4% of the total lignin in the corn cobs was obtained in the first fraction, 40.7% in the second, 9.2% in the third and 1.5% in the fourth. All of the lignin fractions after purification with alcohol and acetone were free from pentosans. Fraction "A" contained no pentosans or furfural yielding compounds even before purification, owing to the insolubility of the pentosans in the alcoholic sodium hydroxide solution. The statements in the literature that pentosan or some furfural yielding body forms an integral part of the lignin molecule must be considered as erroneous, especially as applied to the lignin from corn cobs. Attention is called particularly to the progressive decrease in the percentage of methoxyl in the lignin fraction with the increase in the temperature used for the extraction of the lignin.

Anal. (Fraction D.) Subs., 0.0857, 0.1039: CO_2, 0.2139, 0.2597; H_2O, 0.0487, 0.0603. Found: C, 68.06, 68.16; H, 6.36, 6.49.

Summary

Lignin was fractionally extracted from corn cobs by a 2% alcoholic sodium hydroxide solution at room temperature, by 2% aqueous sodium hydroxide at 100° and at 135°, and finally by 4% aqueous sodium hydroxide at 180". Each method of extraction was continued until no further lignin was obtained, before the next method in the series was employed. The results justify the conclusion that the lignin in corn cobs is unequally combined with the carbohydrates, part of it being loosely bound, possibly in the form of an ester, and the remainder being more firmly held, probably in the form of an ether-like combination.

THE TAUTOMERISM OF BRILLIANT CRESYL BLUE

BY WALTER C. HOLMES

RECEIVED APRIL 21, 1928 PUBLISHED JULY 6, 1928

Brilliant cresyl blue is an oxazine dye having metachromatic properties which finds important application in biological staining. The stain sold by the National Aniline and Chemical Company is the dimethyl homolog of the dye illustrated under No. 877 in the Colour Index.

With variation in concentration in aqueous solutions this dye undergoes a striking modification in color of the same type that all metachromatic dyes and the majority of aminated triphenylmethane and quinone-imide coloring matters in general undergo.[1] In relatively concentrated aqueous solutions it is present principally in a violet form, with maximum absorption at about 575mμ. The dilution of these solutions is accompanied by a progressive transition to a second dye form, which is blue, with maximum absorption at about 625mμ. Representative absorption curves are recorded in Fig. 1.

Considerable evidence has been obtained which indicates that color modification of this type does not arise from electrolytic or hydrolytic

---

[1] Holmes, Ind. *Eng. Chem.*, *16*, 35 (1924).

dissociation, solvation or alteration in the state of molecular aggregation of the solute. It constitutes evidence of tautomerism in the dye, in which the modification in the dye molecule is probably the result of a rearrangement of affinities, brought about by the interplay of residual affinities of solute and solvent.[2,3]

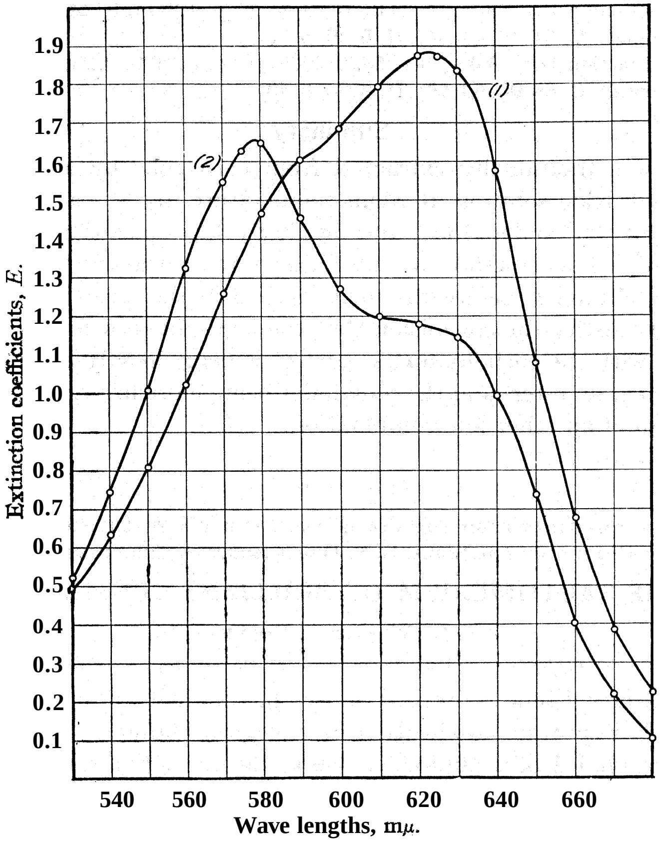

Fig. 1.—Brilliant cresyl blue. (1) Approximately 40 mg. of dye per liter of distilled water in a 1-cm. layer. (2) Approximately 1000 mg. of dye per liter of distilled water in a 0.0432-cm. layer.

Means have been found of obtaining the violet form of brilliant cresyl blue in a medium in which its properties may be investigated to better advantage than is possible in aqueous solutions. The writer is indebted to Dr. Marian Irwin of the Rockefeller Institute for suggestions which led to this discovery.

Holmes, THIS JOURNAL, 46, 2118 (1924).

[3] Holmes, *Am. Dyestuff Reporter*, 16,429 (1927).

A 0.1% solution of the dye is prepared in a $M/15$ acetate buffer solution of 0.6 M sodium chloride content, having a PH value of 3.42. (The solution should be distinctly acid, but the precise degree of acidity is relatively immaterial.) The solution is shaken thoroughly with an equal volume of chloroform and the chloroform is diluted 1:5 to obtain a suitable intensity of color for spectrophotometric measurements in 1-centimeter cells. The absorption curve of such a solution is recorded in Fig. 2, Curve 1.

In this solution most of the dye is present in its violet form. The curve gives evidence, however, of a small proportion of dye in its blue form. The modification of this solution upon saturation with ammonia is illustrated by Fig. 2, Curve 2.

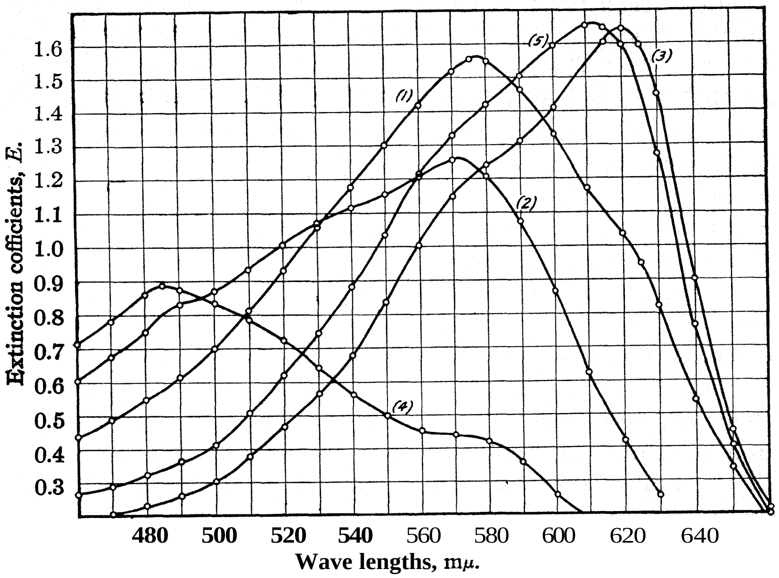

Fig. 2.—Brilliant cresyl blue.

By direct solution of the solid dye in chloroform a solution which gives the absorption represented by Fig. 2, Curve 3, may be obtained. In this solution the greater part of the dye is present in its blue form, although there is definite evidence of the presence of a small proportion of the violet form. The modification of this solution upon saturation with ammonia is recorded in Fig. 2, Curve 4, and the subsequent modification of the ammoniacal solution upon the addition of 2% glacial acetic acid is shown in Fig. 2, Curve 5.

The principal interest of these data lies in the evidence which they supply respecting the relative reactivity of the various forms of the dye.

The saturation of the solution of the violet form of the dye with ammonia results in only a minor degree of conversion to the orange dye-base (see Curves 1 and 2, Fig. *2)*. The actual degree of conversion of violet dye to base is much less than the apparent degree, owing to the presence in the original solution of appreciable quantities of the blue form of the dye, which undergoes complete conversion to base. On the other hand, the saturation of the solution of the blue form of the dye with ammonia results in its immediate and complete conversion to the dye-base (see Curves **3** and 4, Fig. *2)*. The resulting solution still contains the dye originally present in the violet form, apparently in an unaltered state. The blue form of the dye is very reactive to alkali, whereas the violet form of the dye is highly inactive.

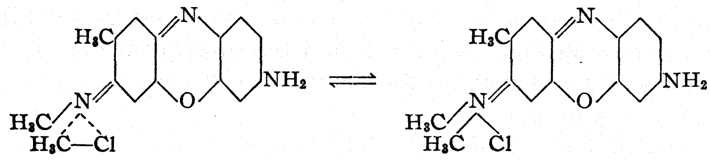
When the blue form of the dye is converted to dye-base and the dye is subsequently regenerated, the absorption curve of the recovered dye does not coincide in spectral location with that of the original dye (see Curves **3** and 5, Fig. *2)*. The recovered dye is not brilliant cresyl blue but its monomethyl homolog, as indicated by the agreement between its absorption and that of the monomethyl homolog prepared by direct synthesis at this Laboratory. It is well known that various quinone-imide dyes, such as methylene blue, are so susceptible to alkaline oxidation that their conversion to the dye-base may be attended by the loss of an alkyl substituent group. The blue form of brilliant cresyl blue is so readily oxidized in ammoniacal chloroform solutions that the reaction is practically instantaneous.

The orange dye-base is readily and completely converted into the dye by acids (see Curves 4 and 5, Fig. 2). The dye-base is so reactive, in fact, that the mere exposure of its unprotected chloroform solutions to air results in a comparatively rapid conversion into dye carbonate.

Both the orange dye-base and the blue form of the dye, accordingly, are highly reactive, whereas the violet form of the dye is relatively inert.

In accordance with the hypothesis recently advanced by the writer[4] to account for the tautomerism observed with variation in concentration of aminated dyes in aqueous solution, the transition concerned is one between structure of addition product type, in which the amino nitrogen atom involved is essentially trivalent, and structure of the ammonium salt type in which it is pentavalent. In the instance of brilliant cresyl blue the two color forms may be represented in the following manner

I



II

(violet) (blue)

---

[4] **Holmes, Stain *Technology*, 1, 116 (1926).**

This hypothesis was based upon color considerations and apparently affords a thoroughly adequate explanation of the observed differences in color in tautonieric forms of aminated dyes. Direct evidence of structure of the type illustrated in Formula I is lacking, although a closely analogous structure has been demonstrated in the complexes which basic dyes form with cyclic derivatives containing phenolic groups.[5]

A compound of the structural type represented by Formula I would be expected to be relatively inert. The writer's hypothesis, accordingly, supplies an explanation of the observed lack of chemical reactivity in the violet form of brilliant cresyl blue, and this inactivity, in turn, supports the validity of the hypothesis.

Summary

The violet and blue forms of brilliant cresyl blue, which exist in tautomeric equilibrium in aqueous solutions of the dye, have been isolated. The former tautomer is chemically inert whereas the latter is reactive. These facts are held to support the author's hypothesis that the tautomerism is one between structure of addition product type and structure of ammonium salt type.

THE WURTZ REACTION. FACTORS INVOLVED IN THE PREPARATION OF OCTANE

BY HARRY F. LEWIS, ROBERT HENDRICKS AND G. ROBERT YOHE

RECEIVED APRIL 23, 1928 PUBLISHED JULY 6, 1928

The work herein described is concerned with an attempt to determine the factors which govern the successful carrying out of a Wurtz reaction. The preparation of octane from butyl bromide offers such an opportunity.

The preparation of 2,5-dimethylhexane from *iso*butyl iodide and sodium as described by Würtz[1] opened up to the organic chemist a valuable method for the preparation of the higher aliphatic hydrocarbons. Fittig and others soon adapted the reaction for use in the synthesis of mixed aromatic aliphatic and higher aromatic hydrocarbons.

Schorlemmer,[2] using butyl iodide and sodium, was the first to use the reaction in the preparation of normal octane. He compared his product with those octanes formed through the hydrogenation of methylhexylcarbinol and suberic acid and proved their identity.

The mechanism of the Wurtz-Fittig reaction has received much study

---

[5] Holmes and Hann (awaiting publication). This paper will probably be published in the October, 1928, issue of *Stain* Technology.

[1] Wurtz, *Ann.*, 96, 365 (1855).

[2] Schorlemmer, Ann., 161, 280 (1872).

within the last few years and a good picture of the situation will be found in a recent article by Bachmann and Clarke.[3]

Discussion of Experimental Work

In order to determine the importance of the various factors which govern the formation of octane, a number of variables have been studied in connection with a standard procedure; these include the relative masses of sodium and butyl bromide, the amount of solvent (diethyl ether), temperature, time, area and diameter of the sodium, dryness of reagents, agitation, influence of methyl cyanide and the method of recovery of octane from the reaction mass.

As the result of this study, a method has been developed for the preparation of large amounts of octane, with yields of 65–70% based upon butyl bromide. Octane thus prepared has the following physical constants: b. p., 124.2–124.8°; $n_D^{20} = 1.3961$; $d_4^{20} = 0.7044$.

The data tabulated on the following pages indicate that: 1. optimum yields of octane are obtained when the sodium is used in excess; the excess need not be greater than 50 mole per cent. This holds for sodium used either as 2 mm. wire, shot or thin shavings.

2. A volume of ether two and a half times the volume of butyl bromide is necessary for keeping the reaction mixture sufficiently fluid to agitate. More is unnecessary and less may result in a loss of octane due to local overheating.

3. Low temperatures appear to favor the production of octane; higher temperatures give greater quantities of unsaturated hydrocarbons. At 0° high yields of octane result. At this temperature the blue intermediate compound is not formed. An accurate temperature study is hard to make without changing more than one variable at a time. An attempt was made to use the higher ethers as solvents, but was not successful because of the difficulty of separating those ethers from the octane. It should be stated here that the ethers up to the iso-amyl ether are stable to the action of sodium for several hours at the reflux temperature.

4. Each set of operating conditions has a maximum time for optimum yield. Too long operation may even cause a loss of octane for there is some evidence that octane is slowly acted upon by sodium at its reflux temperature.

5. The finer the sodium wire, and consequently the greater the area, the more rapid is the formation of octane. Wire finer than 0.5 mm. is difficult to prepare with the ordinary sodium press. Wire of 2 mm. diameter is easily prepared and satisfactory for most uses.

6. Traces of water present in the reaction mixture cut down the yields far more than would be predicted on the basis of the primary reaction

---

[3] Bachmann and Clarke, THIS JOURNAL, 49, 2089 (1927).

between sodium and water. On the other hand, ether prepared by washing with water, drying over phosphorus pentoxide and distilling over sodium does not yield as much octane as does ether dried over calcium chloride and distilled over sodium.

7. Agitation speeds up materially the octane-producing reaction.

8. Methyl cyanide has no positive action in the formation of octane. In fact, octane was not obtained from the reaction mixture containing five drops of the cyanide. This is somewhat different from the experience of Michael.[4] In the preparation of butyl and *iso*-amyl benzene on the other hand, methyl cyanide has no effect on the yield of hydrocarbon.

9. Small amounts of octane are easily recovered from the reaction mixture by distillation at the conclusion of the experiment. Larger amounts are best obtained after the sodium is first destroyed, either with dilute alcohol or with water, as recommended by Bartow and Sellards.[5]

Chemicals Used

Butyl Bromide.—Butyl bromide was prepared from *n*-butanol according to the method described in "Organic Syntheses," Vol. I, p. 5; $d_4^{20} = 1.2740$; $n_D^{20} = 1.4381$.

Sodium.—J. T. Baker metal, used as **2** mm. wire.

Diethyl Ether.—U. S. P. dried over calcium chloride and distilled and kept over sodium.

Procedure

The solvent ether, **50** cc. (**0.472** mole), is placed in a 500-cc. round-bottomed flask equipped with a double neck addition tube and a reflux condenser, and the sodium, **6.9** g. (**0.3** mole), added. The butyl bromide, **21.9** cc. (**0.202** mole), is run in over a period of two minutes. In a short time, the mixture is at the reflux temperature where it is maintained during the required time. If the mixture is to be agitated, a special three-necked addition tube bearing a mercury seal replaces the two-necked tube. At the end of the time set for the reaction, the condenser is turned down and volatile materials distilled. These are separated by fractional distillation, two fractionations being sufficient. The fraction coming over between **110** and 130° is collected as crude octane and the octane content estimated by the refractive index. Reference is made to an octane–butyl bromide refractive index curve drawn from values obtained on mixtures of known composition and tested in an Abbé refractometer, using the sodium light and at a tempera-

Separation of Octane from Reaction Mixture.—No great difference is noted in the yield of octane in runs which have come to an end, when the octane is recovered by distillation on the one hand and by destruction of excess sodium by water and separation of the water insoluble layer on the other. The latter method is much safer when working with large quantities of materials. It has been the experience in this Laboratory that a rapid evolution of octane may occur in the distillation process when the temperature of the sodium mass reaches a certain point. Under such conditions fires may be expected.

Discussion

Constant yields of octane have not been obtained when the solvent ether is completely omitted from the reaction mixture. At times, however, 70% yields of octane have been reached by adding the butyl bromide slowly to the sodium in the standard set-up or by adding sodium in small amounts to the bromide and allowing the mixture to reflux. When the apparatus is fixed for distilling rather than for refluxing, octane mixed with some unchanged bromide may be distilled from the sodium as fast as butyl bromide is added. The octane yield under these conditions is between 50 and 70%.

Large quantities of octane may be prepared in the following way. Twenty moles (1480 g.) of ether, dried over calcium chloride and distilled over sodium, is placed in a five liter round-bottomed flask equipped with an addition tube, a four foot reflux condenser and an agitator. Sodium cut thin with a sodium knife is added to the amount of 12.1 moles (278 g.) and then 8.3 moles (1137 g.) of dry butyl bromide run in over fifteen minutes. The mixture is refluxed with agitation for ten hours and then the excess sodium destroyed by slowly adding water to the contents of the flask. The layers are separated; the ether layer is dried with calcium chloride and fractionally distilled.

Fractions are collected up to 55, 55–110, 110–130, 130–180, 180–210, 210–250 and 250–300°. After a second fractionation, a yield of 450 cc. of octane is obtained. This is 68% on the basis of butyl bromide. The ether recovery is better than 75%.

Butene is also formed and this is recovered by bubbling the reaction gases through bromine. Dibromobutane is recovered; this boils between 160 and 170° and has a refractive index of 1.5151 at 20°. A typical run gave 26 g. of dibromobutane. The literature gives 166° for 1,2-dibromobutane.

A saturated hydrocarbon boiling at 295–300° is recovered to the extent of about one gram. This may be a hexadecane. Three grams of another saturated hydrocarbon, boiling point 210–215°, is also found. The dodecanes boil at that point.

Sodium bromide is recovered from the aqueous layer by crystallization.

The recovery is practically quantitative and the quality of the product satisfactory for use in making butyl bromide.

Conclusions

1. A study has been made of the factors influencing the formation of octane from butyl bromide by the Wurtz reaction.
2. Based upon this study, a method has been developed for the formation of octane in rather large amounts and with yields of 65–70% based upon butyl bromide.
3. Butene and at least two higher saturated hydrocarbons are also formed. The boiling points of the hydrocarbons suggest dodecane and hexadecane.

CAROTIN: A PIGMENT OF HONEY[1]

BY H. A. SCHUETTE AND PHYLLIS A. BOTT

RECEIVED APRIL 23, 1928 PUBLISHED JULY 6, 1928

Color and quality in honey have from time immemorial borne an inverse relationship to each other in the minds of the average consumer, the more deeply pigmented honeys, as a rule, commanding a lesser price. As a result of this, the practice of designating its color has become universal in the grading of honey to the end that certain loosely defined names for these colors have come into use. It is only within recent years, however, that these colors have been defined with the aid of a spectrophotometer.[2]

Since these color designations are but an attempt to describe the pigmentation of a particular honey, and since this pigmentation is due wholly if not in part to red, orange or yellow coloring matters, it seemed but reasonable to assume that the latter are of the carotinoid type. To harmonize this assumption with factual evidence was the purpose of the study herein recorded.

Experimental

A highly pigmented buckwheat honey, described in trade parlance as amber colored, was selected for study since it seemed to offer the greater promise for the recovery of the necessary quantity of pigment for identification.

Attempts at removal of the coloring matter by precipitation with those clarifying agents which are commonly used in "purifying" a sugar con-

[2] E. L. Sechrist, U. S. Dept. Agr., *Dept. Circ.* 364, 1925, p. 3.

taining solution preliminary to analysis, followed by drying and extraction of the resulting precipitate, were abandoned after repeated trials during the course of which numerous variables centering around the dilution of the honey, the nature of the precipitant and the character of the solvent were introduced. Clarification was never complete because of the colloidal nature of the non-sugars; the extraction of the coloring matter from the dried precipitate was not quantitative because of what appeared to be a physico-chemical combination between pigment and sugars or albuminous matter of the honey; and finally the pigment in part was invariably lost by oxidation because the whole operation is time consuming.

An adaptation, with slight modifications to suit the material in question, of the method developed by Palmer and Eckles[3] for the extraction of carotin from blood serum proved to be successful in this case. The procedure is as follows.

One kg. of honey was intimately mixed with an equal weight of plaster of Paris in an ordinary one-gallon ice-cream freezer. To the resulting plastic mass 150 cc. of 95% ethyl alcohol was added and, when this had been thoroughly incorporated in the mass, 500 cc. of petroleum ether (b. p. 60–70°). The contents of the freezer were then stirred for about twenty minutes, the solvent was removed and the extraction continued with successive, but smaller, quantities of the ether until fresh portions were no longer colored. Approximately 800 cc. of solvent was used per kilo of honey.

The residue from 15 kg. of honey represented a yield of 0.01% of a crude pigment which in petroleum ether solution was of a yellowish-orange color and in carbon disulfide an intense orange-red. The colors of these solutions were similar to those prepared from the carotin which had been extracted from carrots by the procedure of Euler and Nordenson.[4]

Purification of the crude carotin was effected by fractional precipitation with absolute ethyl alcohol from carbon disulfide solution. The pigment so obtained was subsequently qualitatively identified[5] as carotin by its resistance to the action of alkalies. by the fact that it was not adsorbed from carbon disulfide solution by finely divided calcium carbonate, and that with ferric chloride it produced a green coloration but none that was characteristic with concentrated sulfuric acid.

Final proof of identity was established by a determination of its adsorption spectrum in carbon disulfide solution. By means of a Hilger constant deviation prism spectroscope illuminated by an iron arc, spectrophotographs were made of solutions of the carotin when placed in I-inch cells provided with quartz ends. Carotin solutions[4] prepared from the pigments of carrots served as controls. It was observed that absorption of light occurred in the region of 4700–5250 Å. and that a portion of the visible violet rays and all of the rays in the region of the ultraviolet were absorbed. This is a characteristic function of carotin.

Summary

It has been shown that at least one of the pigments of buckwheat honey can be isolated with petroleum ether in the presence of ethyl alcohol

PARA-CYMENE STUDIES.

X. PARA-CYMYLENE-2,5-DIAMINE AND CERTAIN NEW DYES

BY ALVIN S. WHEELER AND R. W. BOST[1]

RECEIVED APRIL 25, 1928 PUBLISHED JULY 6, 1928

Of the four possible p-cymylenediamines two are known, the 2,6-diamine described by Alfthan[2] and the 2,5-diamine, the latter only in the form of its hydrochloride as described by Liebermann and Ilinski.[3] The free base was apparently isolated by Kehrmann and Messinger[4] for they state that it was so easily oxidized in the air that it could only be kept as the hydrochloride. Wallach and Schrader[5] prepared the diacetate, melting at 260°. Wheeler and Brooks[6] obtained the same diacetate on reducing 2-acetoamido-5-nitrocymene,followed by acetylation. A method superior to all others was found in the reduction of an azo derivative of 2-aminocymene, a method first used by Martius and Griess.[7] The aminocymene was coupled with diazotized sulfanilic acid, the resulting dye being reduced with stannous chloride. A poor yield is obtained if aniline is substituted for sulfanilic acid.

We locate the second amino group in position 5 for several reasons. This position is para to the amino group already present and is the point where coupling should take place according to analogous reactions. Secondly, the melting point of the diacetate is 260°, which is the same as that of the diacetate obtained from the reduction product of thymoquinonedioxime. Further proof was obtained by converting the diamine into thymoquinone, melting at 45° and described by Carstanjen,[8] and its monoxime, melting at 154–6°, and finally into hydrothymoquinone, melting at 139.5°.

p-Cymylene-2,5-diamine is so unstable in the air that no description of it has appeared in the literature. We isolated it in an atmosphere of nitrogen and at reduced pressure in a specially constructed apparatus.

[8] Carstanjen, J. *prakt. Chem.*, [2] 3, 53 (1871).

It is a light yellow solid which on exposure to the air changes color within a few minutes, passing through deep red and green to blue. Oxidizing agents readily convert it into the quinone, ferric chloride in the cold giving a quantitative yield in less than fifteen minutes. Neither *p*-phenylenediamine nor *p*-toluylenediamine is oxidized to a quinone under like conditions. The diamine forms salts with great readiness, the picrate and benzoate forming almost instantaneously, whereas an ether solution of aniline, o-toluidine or aminocymene gives no apparent reaction with benzoic acid in twenty-four hours.

The diamine was characterized by its conversion into the following new compounds: 2,5-*bis*-(thioureido)-1-methyl-4-*iso*propylbenzene, 2,5-diureido-1-methyl-4-*iso*propylbenzene and p-aminocymyloxamido acid.

Two series of dyes were prepared: first, a group of diazo dyes by coupling with certain naphthols and amino acids; second, a group of azine dyes of the Eurhodine class. The first group gave blue, yellow and red colors while the second gave brown and purple shades. The dye obtained with 2-naphthol colors wool a blackish violet, whereas the thionaphthol dyes wool a light buff; thus the sulfur shows a strong hypsochromic effect. The dye obtained with the naphthol disulfonic acid possesses a very high tinctorial power and the dye-bath exhausts completely.

The isopropyl group in the diamine is very sensitive, for in bromination and nitration reactions it is largely destroyed.

Experimental Part

Reduction of 5-(4-Sulfobenzeneazo)-carvacrylamine Hydrochloride.—This compound was prepared as described by Wheeler and Cutlar,[9] who coupled 2-aminocymene with diazotized sulfanilic acid. Its reduction was carried out as follows: 47 g. of the hydrochloride was slowly added to a boiling solution of 75 g. of stannous chloride, 65 cc. of concd. hydrochloric acid and 500 cc. of water. When the last trace of color had disappeared, the solution was cooled and treated with an excess of sodium hydroxide. The diamine was extracted with ether and converted into the hydrochloride by passing hydrogen chloride gas into the solution; yield, 26 g. or 77.9% of the theoretical.

_p_-Cymylene-2,5-diamine, $C_6H_2CH_3C_3H_7(NH_2)_2$.—The free base was isolated by distillation in an atmosphere of nitrogen and at reduced pressure in an apparatus shown in the accompanying diagram. The air in the system ABIDJR was displaced by nitrogen from a cylinder connected with A. Stopcock B was then turned so that the nitrogen displaced the air in the system ABGC. An aqueous solution of the diamine and 200 cc. of ether was admitted through buret E into funnel G and the solution saturated with nitrogen. In the meantime the system IDJR was evacuated by a pump connected to R. A 15% solution of sodium hydroxide was added to the diamine salt solution in G through buret E until the phenolphthalein present showed excess thereof. The stream of nitrogen passing through the solution served to stir the diamine so that it readily dissolved in the ether layer. The water layer was drawn off through F. The path of the nitrogen stream was changed so as to pass from A through C into G. Stopcock B was opened into the evacuated system IDJR, whereupon the ether solution was drawn from G into flask I. A gentle stream of nitrogen was then passed through the

---

[9] Wheeler and Cutlar, THIS JOURNAL, 49, 2819 (1927).

system ABIDJR and the ether distilled off spontaneously from flask I at a pressure around 120 mm. A light yellow solid remained in the flask into which 200 cc. of methyl alcohol, previously saturated with nitrogen, was admitted in a manner similar to that in which the ether was admitted. The alcohol took up the few droplets of moisture present and also dissolved the diamine. The alcohol was distilled at 120–130 mm. and a temperature around 30°. The diamine remained as a yellow, solid mass, apparently consisting of needles though not well defined.

The diamine in I was dissolved in ether saturated with nitrogen and admitted through the same channel as the alcohol. A partial vacuum was produced in G by evacuating the system ACGBIDJR. C was closed and a rapid stream of nitrogen was passed through ABIDJR until the pressure was one atmosphere. D was closed and B opened into the partial vacuum G whereupon the ether solution of the diamine in I was drawn over into G. Nitrogen was then bubbled through ABGC and the diamine precipitated by the addition of petroleum ether to G through buret E. Then F was connected with L by rubber tubing and the finely divided precipitate of the diamine filtered by suction into the nitrogen filled desiccator P.

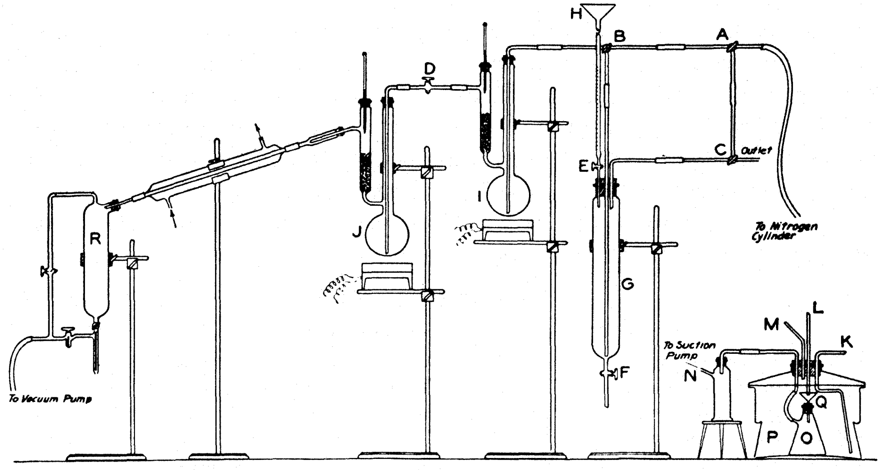

Fig. 1.—Apparatus.

Dibenzoate, $C_6H_2CH_3C_3H_7(NHCOC_6H_5)_2$.—The benzoate was prepared in the usual way in alkaline solution with benzoyl chloride. The product was recrystallized from hot alcohol giving fine, white needles, soluble in acetone and alcohol; m. p. 280°; yield, quantitative.

Anal. Subs., 0.2082: 7.27 cc. of 0.1524 N HCl required for NH_3. Calcd. for $C_{24}H_{24}N_2O_2$: N_2, 7.52. Found: 7.45.

Quinones

The 2,5-cymo-*p*-quinone, its oxime and the corresponding hydroquinone were prepared for orientation purposes. They have been described by Carstanjen.[8]

2,5-Cymo-*p*-quinone.—Four g. of the diamine salt was dissolved in 200 cc. of 2% acetic acid. To this solution was added 5 g. of chromic acid in 200 cc. of water. After stirring for thirty minutes, the brownish black precipitate was filtered off, dried and purified by sublimation to give long, slender, glistening yellow needles; m. p. 45.5°.

Its **monoxime** was prepared by heating the quinone with hydroxylamine hydrochloride for five hours on the water-bath. The product was recrystallized by dissolving in ether and adding petroleum ether, yielding fine, brownish-yellow needles, m. p. 154–156°.

2,5-Cymo-*p*-hydroquinone.—The quinone was dissolved in the least possible amount of acetone and a 2% solution of titanium chloride added until reduction was complete. The product was extracted with ether; fine, white needles; m. p. 139".

Salts

The salts indicated in the table were made by mixing the constituents in the cold. To obtain the hydrochloride dry hydrogen chloride was passed into an ether solution of the diamine. For the hydrobromide and nitrate the corresponding acids were used with gentle heating. These three salts were recrystallized from absolute alcohol. The other salts were prepared by mixing ether solutions of the constituents and washing the salt with ether. All are soluble in water, alcohol and acetone but difficultly soluble in ether. Analyses were made by titrating with sodium hydroxide, using phenolphthalein as indicator.

TABLE I

DATA ON THE SALTS

Salt	Crystal form	M. p., ° C.	Analysis, acid Calcd., %	Found, %
Hydrochloride (di)	Fine granules	323 (decomp.)	30.75	30.77

Condensation Products

2,5-Bis-(thio-ureido)-1-methyl-4-*iso*propylbenzene, $C_{10}H_{12}(NHCSNH_2)_2$.—A solution of 2.0 g. of the diamine salt was poured into a solution of 1.64 g. of potassium sulfocyanate. The solution was evaporated to dryness and the residue kept on the steam-bath for two hours. The material was then washed several times with boiling water, filtered and recrystallized from hot methyl alcohol; white, granular substance; m. p. 235–237°. It is soluble in alcohol but insoluble in water, ether and benzene; yield, 1.2 g.

And. Subs., 0.2024: 18.69 cc. of 0.1524 N HCl required for NH_3. Calcd. for $C_{12}H_{18}N_4S_2$: N2, 19.85. Found: 19.70.

2,5-Diureido-1-methyl-4-*iso*propylbenzene, $C_{10}H_{12}(NHCONH_2)_2$.—To a solution of 0.5 g. of the diamine salt dissolved in 10 cc. of water was added dropwise a solution of 1 g. of potassium cyanate in 5 cc. of water. The mixture was heated on the steam-bath for one hour, the product filtered off, washed with hot water, then with alcohol and finally with ether. It consisted of a white powder insoluble in water and rather difficultly soluble in alcohol and ether. It did not melt under 350°; yield, 0.6 g.

Anal. Subs., 0.1076: 11.37 cc. of 0.1524 *N* HCl required for NH_3. Calcd. for $C_{12}H_{18}O_2N_4$: N_2, 22.39. Found: 22.54.

p-Aminocymyloxamido Acid, $C_{12}H_{16}O_3N_2$.—1.44 g. of the diamine salt was dissolved in 50 cc. of water and the base set free by the addition of sodium hydroxide. The diamine was shaken out with ether and the ether solution carefully dried. To this solution was added an ether solution of 0.55 g. of anhydrous oxalic acid. A precipitate formed immediately but the mixture was refluxed for two hours, the ether distilled off and replaced with 75 cc. of absolute alcohol and then refluxed for fifteen hours. The crystals melt at 210–211°. The product is rather soluble in water but difficultly soluble in alcohol and ether; yield, 0.21 g. The success of the reaction depends upon having the ether solution of the diamine dry before adding the oxalic acid.

Anal. Subs., 0.2040: 11.10 cc. of 0.1524 N HCl required for NH_3. Calcd. for $C_{12}H_{16}O_3N_2$: N_2, 11.86. Found: 11.60.

Diazo Dyes

These dyes were prepared by diazotizing p-cymylene-2,5-diamine at 0°, adding the phenol dissolved in alkali, precipitating the dye with acetic acid and recrystallizing the product from a suitable solvent.

TABLE II

DISAZO DYE DATA

Azine (Eurhodine) Dyes

Three Eurhodine dyes were prepared by dissolving the nitroso compound in 100 cc. of hot methyl alcohol and adding to this solution the diamine salt dissolved in 50 cc. of methyl alcohol. The mixture was refluxed for thirty minutes when the alcohol was distilled off and replaced with water. The dye was set free on the addition of weak ammonia. The product was recrystallized from dilute alcohol.

Summary

1. *p*-Cymylenediamine prepared by reducing the dye obtained by coupling 2-amino-*p*-cymene with diazotized sulfanilic acid is shown to be the 2,5-diamine.
2. A series of thirteen salts with inorganic and organic acids was prepared.
3. Condensation products were obtained with potassium sulfocyanate, potassium cpanate and oxalic acid.
4. A series of disazo dyes was prepared by coupling the diamine with certain naphthols and amino acids.
5. Two azine dyes of the Eurhodine class were prepared.

THE ACIDS OF MAPLE SIRUP

BY E. K. NELSON

RECEIVED APRIL 26, 1928 PUBLISHED JULY 6, 1928

It has long been known that *l*-malic acid is the chief acid in maple products. In an examination of maple sugar "sand," the deposit of the calcium salts of organic acids which forms in the evaporating kettles, v. Lippmann[1] found, in addition to much l-malic acid, considerable d-tartaric acid and a small quantity of tricarballylic acid. E. O. v. Lippmann gives very little information regarding his methods of separating these acids. He states, however, that tricarballylic acid was extracted from the acid mixture by means of ether. A sample of maple sugar sand, obtained in Vermont, was examined in the Food Research Laboratory. In addition to *l*-malic a number of acids not mentioned by E. O. v. Lippmann were identified, but only a trace of tartaric acid and of tricarballylic acid was found.

The material used in the investigation reported in this paper consisted of two 10-gallon lots of maple sirup, one from a producer in Vermont, and the other from a producer at Belleville, Michigan. Both manufacturers were reliable, and the sirups were guaranteed to be genuine and free from adulteration.

The alkalinity of the ash in the Vermont sirup was equivalent to 140 cc. of $N/10$ acid per 100 cc., and in the Michigan sirup it was equivalent to 103 cc. of $N/10$ acid per 100 cc.

The free acidity in the Vermont sirup was 4 cc. of $N/10$ acid per 100 cc.; in the Michigan sirup it was 4.5 cc. of $N/10$ acid per 100 cc. Most of the organic acids in maple sirup are, therefore, in the form of salts.

The general course of procedure consisted of three steps: (1) extracting the ether soluble acids after the addition of a quantity of hydrochloric acid equivalent to the alkalinity of the ash; (2) distilling volatile acids in a vacuum pan and precipitating the non-volatile acids as lead salts; (3) recovering the acids, and esterifying and fractionating the esters.

Experimental

Thirty-eight liters of each sirup were acidified with a quantity of hydrochloric acid equivalent to the alkalinity of the ash, diluted with an equal volume of water and twice shaken out with ether in 4-liter lots. The ether was concentrated on the steam-bath, and the concentrated ether solution was reserved until the entire quantity of sirup had been extracted. The ether extracts were shaken with a dilute solution of sodium bicarbonate to remove ether soluble acids, and the ether solution was reserved for a later investigation of the flavoring substances of maple sirup. The bicarbonate solution was acidified and the acids were recovered by extraction with ether. The residue from the

---

[1] E. O. v. Lippmann, *Ber.*, 47, 3094 (1914).

ether, sharp in odor and dark in color, was dissolved in boiling water and filtered with a little norite.

On standing, the concentrated solution formed crystals. Of this sparingly soluble acid, 0.22 g. was obtained from the Vermont sirup and 0.24 g. from the Michigan sirup. It was unsaturated to potassium permanganate and melted at 286° in a sealed tube. An optical crystallographic examination[2] confirmed its identity with fumaric acid. The further concentration of the filtrate from fumaric acid yielded a small quantity of an unidentified acid having a high melting point but different in optical properties from fumaric acid and not corresponding to aconitic, tricarballylic or succinic acid.

An examination for succinic acid by optical methods established its presence in very small quantity in the Michigan sirup. Proof of its presence in the Vermont sirup was lacking.

After extraction with ether, the solution was concentrated in a vacuum pan to a thick sirup, and the distillates, neutralized with caustic soda, were evaporated to dryness. The residue of sodium salts was dissolved in water, an excess of sulfuric acid was added and the volatile acids were distilled. The distillate was exactly neutralized with barium hydroxide, concentrated to small volume and fractionally crystallized.

The total weight of barium salts from the Vermont sirup was 26.4 g. and from the Michigan sirup, 15.7 g.

The barium salt of volatile acids from the Vermont sirup yielded the following fractions: 1, 4.45 g. = 60.18% of barium (calcd. for barium formate, barium = 60.35%); 2, 2.47 g. = 58.60% of barium; 3, 3.97 g. = 57.09% of barium; 4, 9.23 g. = 56.52% of barium; 5, 4.40 g. = 54.63% of barium (calcd. for barium acetate, barium = 53.72%).

After the formic acid was removed from Fraction 5, the silver salt was prepared and analyzed. It gave 64.01% of silver (calcd. for silver acetate, 64.45%). Optical examination showed that Fraction 1 was pure barium formate and the barium salts were a mixture of nearly equal parts of barium formate and barium acetate.

The barium salts of the volatile acids from Michigan sirup yielded the following fractions: 1, 3.74 g. = 60.58% of barium; 2, 4.98 g. = 59.45% of barium; 3, 2.48 g. = 56.28% of barium; 4, 7.03 g. = 55.95% of barium.

The formic acid was removed from Fraction 4 by potassium permanganate and the silver salt was prepared and found to contain 64.25% silver (calcd. for silver acetate, 64.45% of silver). Fraction 1 was found on optical examination to be nearly pure barium formate, and calculation showed the barium salts to be a mixture of 11.3 g. of barium formate and 6.9 g. of barium acetate.

The concentrated sirup, from which the volatile acids had been distilled, was diluted with water and precipitated with a moderate excess of lead subacetate. The lead precipitate was filtered and washed. Carbon dioxide was passed through its suspension in water to break up lead sugar compounds, after which it was again filtered, dried and weighed. It was then decomposed with an excess of sulfuric acid and the lead sulfate was removed by filtration.

The sulfuric acid was determined in an aliquot of the measured filtrate and its equivalent of barium hydroxide was added to remove it. After filtering barium sulfate, the solution of acids was evaporated to dryness on' the steam-bath. The organic acids were refluxed for five hours with 500 cc. of absolute alcohol containing 2.5% of hydrochloric acid and, after the alcohol was distilled off, this operation was repeated with a fresh portion of alcoholic hydrochloric acid.

The esters, after removal of the alcohol, were dissolved in ether. The ether solu-

---

[2] The optical examinations were kindly made by G. L. Keenan of the Food, Drug and Insecticide Administration.

tion was washed with dilute sodium hydroxide solution until neutral, dried with anhydrous sodium sulfate and evaporated, leaving the crude esters. The esters were then fractionated at **10** mm.

The crude esters from the Vermont sirup weighed **70** g. and after three distillations gave the following fractions: **1,** 115–125°, **0.3 g.; 2,** 125–130°, **52.3** g., α_D = **−11.62"; 3,** 130–135°, **1.7** g.; **4,** 135–145°, **1.8** g.; **5,** 145–165°, **0.4** g.; **6,** 165–170°, **4.8** g.; total, **61.3 g.**

The hydrazides were prepared from these fractions, **0.7** g. of ester, **5** cc. of absolute alcohol and **1** cc. of hydrazine hydrate (42%) being used. Fraction **1** afforded a hydrazide melting at 173–175°, identified as *l*-malic hydrazide. Fraction **2** gave a hydrazide melting at **177–179°,** *l*-malic hydrazide. Nothing but *l*-malic hydrazide in impure form was obtained from Fractions **3** and **4,** whereas Fractions **5** and 6 gave citric trihydrazide, identified by its melting in the hydrated form at 105–107° and in its anhydrous form at **147°** and also by optical crystallographic comparison with pure citric trihydrazide.

Michigan sirup afforded **53.5** g. of crude esters, yielding the following fractions on being distilled twice at **10** mm.: **1,** 125–130°, **41.4** g.; **2, 130–140°, 2.1** g.; **3,** 140–150°, 0.5 g.; **4,** 150–165°, 1.3 g.; **5,** 165–170°, **4.7** g.; total, **50.0** g.

Fractions **1,2** and **3** afforded *l*-malic hydrazide and Fraction **5** gave citric hydrazide, melting (hydrated form) at 105–107°. The identity of the fractions was further checked by optical crystallographic examination.

Fraction **4** was tested for tartaric acid in the following manner. The fraction was saponified with alcoholic potassium hydroxide, made acid with acetic acid and diluted to **150** cc. Then **0.25** g. of ammonium I-tartrate and an excess of calcium acetate were added, the mixture being well stirred. It was allowed to stand for some time but no precipitate of calcium racemate was obtained, establishing the absence of d-tartaric acid.

The approximate quantities of the respective acids in these maple sirups, calculated in grams per liter, are as follows.

Acids	Formic	Acetic	*l*-Malic	Citric	Fumaric	Succinic
Vermont, g.	0.134	0.150	1.04	0.095	0.0056	None identified
Michigan, g.	.121	.085	0.81	.11	.0063	Small quantity present

Summary

The acids in maple sirup from two localities were investigated. In addition to malic acid, which predominates, formic, acetic and citric acids were identified. Also, a small quantity of fumaric acid and a trace of succinic acid were found. There was evidence of the presence of a small quantity of an unidentified acid having a high melting point. Neither d-tartaric acid nor tricarballylic acid could be found.

THE FLAVOR OF MAPLE SIRUP

BY E. K. NELSON

RECEIVED APRIL 26, 1928 PUBLISHED JULY 6, 1928

The pleasant and characteristic flavor of maple sirup and maple sugar has been imitated by mixtures of such things as lovage, fenugreek, hickory bark, vanillin and coumarin. The true character of the Aavor seems never to have been investigated. The investigation reported in this paper was undertaken with the object of throwing some light on the nature of maple flavor.

Experimental

The first attempt to isolate the flavoring material was by the barium process devised by Sale and Wilson[1] of the Food, Drug and Insecticide Administration, a process which consists in removing most of the sugar by means of barium hydroxide. Five liters of Vermont sirup were treated. The product, a concentrated solution of the flavoring material containing sugar and coloring matter, was thoroughly extracted with ether. The ether solution was shaken out with dilute ammonia, 1:10, and then the ammonia solution was acidified and extracted with ether. After the ether had been carefully evaporated, the residue was stirred with 100 cc. of water and 25 cc. of 10% lead acetate solution and filtered, and the filtrate was extracted with ether. On evaporation of the ether, a reddish oil remained which did not crystallize. It has a sharp, acid odor. It was therefore dissolved in dilute sodium carbonate and extracted with ether. The ether residue had a peculiar (phenolic?) odor, and with ferric chloride gave a green color reaction. Vanillin was not identified.

The ether solution left after extraction with dilute ammonia was evaporated, the residue was dissolved in water, lead acetate solution added and the mixture filtered. The filtrate was extracted with ether and the ether was evaporated. The residue became partly crystalline. The crystals were separated on a porous plate and recrystallized from ethyl acetate. White, spindle-shaped crystals, which gradually turned brown in the air, were obtained. The substance melted exactly at 212° but darkened at a lower temperature. It was insoluble in water but dissolved in sodium hydroxide solution and, on shaking, this solution became red.

The substance reduced copper acetate and silver nitrate solutions; on boiling it with ferric chloride a pungent, chlorine-like odor was evolved, and a crystalline substance condensed in the upper part of the tube. These reactions indicate a quinone derivative. Hydrophlorone, which melts at 212°, was prepared and compared crystallographically with the unknown material, but the two were found to be different.

---

[1] United States Patent 1,642,789.

An optical examination[2] showed that the material consisted of spindle-shaped crystals with straight extinction and invariably showing n = 1.560 (approximately) lengthwise, the n crosswise being higher than 1.690.

The oil absorbed by the porous plate was recovered. Most of it was soluble in water to a clear, yellow solution. Ferric chloride turned it red and caused turbidity. Nothing definite was obtained from it.

As it was assumed that the barium treatment may have caused changes in the flavoring substances of maple, a direct extraction of 1 gallon of sirup with ether was undertaken. The ether extract was washed with water, concentrated in a still, and finally evaporated in a vacuum desiccator. The residue was small and had an intense odor of maple. When it was dissolved in dilute sodium hydroxide, the maple odor disappeared, and acidifying the solution did not restore it. This shows that the flavoring material is very sensitive to caustic alkalies.

It was found that the flavor of maple sirup can be removed with norite. One liter of sirup diluted with 1 liter of water was stirred for twenty minutes with 50 g. of norite and filtered. The norite was washed with three 100-cc. portions of water, drained on a Biichner funnel and exhausted with ether in a Soxhlet extractor. On evaporating the ether a red oil remained in which the maple flavor was indistinct. The sirup filtered from the norite, however, had lost its maple flavor. Evidently the flavor, although adsorbed by the norite, had either not been recovered from it or had become changed and lost its identity.

These preliminary experiments having shown that a direct ether extraction is perhaps the best method of isolating the flavoring material, which is a very unstable substance, the use of fixed caustic alkalies and adsorbents was avoided in the further study of the problem.

In the investigation of the organic acids[3] of maple sirup, ether extractions were made and the ether solutions, after being washed with dilute sodium bicarbonate for the recovery of ether soluble acids, were reserved for the investigation of the flavor. These solutions, which represent the ether extracts from **38** liters of Vermont maple sirup and from an equal quantity of Michigan sirup, were shaken with a strong solution of sodium bisulfite and kept in an ice box with occasional shaking for twenty-four hours. The bisulfite solutions were separated and acidified with dilute sulfuric acid, and a stream of carbon dioxide was allowed to bubble through for some time to remove the sulfur dioxide. They were then extracted with ether and the ether carefully evaporated. The residues were boiled out several times with petroleum ether and after this was evaporated the residues had a distinct vanillin-like odor.

The substance obtained from the Vermont sirup showed a tendency to crystallize, but was not sufficiently pure for examination, though it gave a blue color reaction with ferric chloride.

---

[2] Optical examinations were kindly made by G. L. Keenan of the Food, Drug and Insecticide Administration.

[3] Reported in a previous paper on "The Acids of Maple Sirup," THIS JOURNAL, *50, 2006* **(1928).**

The substance from the Michigan sirup, however, was obtained in crystalline form. The entire quantity of material was only 127 mg., of which one-half was dissolved by petroleum ether. The substance gave a blue color reaction with ferric chloride and responded to the resorcinol and phloroglucin tests for vanillin. It crystallized from petroleum ether in plates instead of needles. Crystallographic examination showed that it was neither vanillin nor the ethyl homolog of vanillin. It melted at 74–76°. The odor was intense and very much like that of vanillin.

On boiling with dilute ferric chloride and cooling, a crystalline precipitate corresponding to dehydrodivanillin was obtained. This crystallized in tufts and was found to be different from dehydrodivanillin in optical properties.

The residues left after boiling with petroleum ether were not crystalline and had an odor like maple. The residue insoluble in petroleum ether from the Michigan sirup had a particularly agreeable odor, somewhat like heliotrope (piperonal).

After extraction with bisulfite the ether solutions were shaken out twice with ammonium hydroxide, 1:10, 50 cc. being used for each extraction. The dilute ammonia solutions were separated, poured into dilute sulfuric acid and shaken with ether.

On careful evaporation of the ether, reddish-yellow residues, which were resinous and had an intense odor of maple, remained. The residue from Vermont sirup weighed 0.4 g. and that from Michigan sirup, 0.5 g.

All efforts to induce crystallization failed. Methylation and acetylization also failed to afford crystalline derivatives. A hydro-alcoholic solution treated with a few drops of dilute ferric chloride was colored red, which changed to greenish yellow. The substance changed easily to a darker colored resin, at the same time losing its characteristic maple odor. This change seems to take place to some extent on evaporating its etheral solutions, but whether it is owing to polymerization or oxidation is undetermined.

Boiling with ferric chloride failed to give a volatile, quinone-like substance such as was observed in the crystalline material isolated from the products of the experiment in which the Sale-Wilson process was used.

The maple flavor, therefore, appears to depend to a great extent on an unstable, phenolic substance, or substances, the exact nature of which remains undetermined. It seems a reasonable hypothesis, however, that it may be related to the vanillin-like substance associated with it, and possibly also to the phlorone-like substance which gave a volatile, pungent, crystalline derivative on boiling with ferric chloride. That it may be closely allied with the vanillin-like substance is indicated by the fact that the latter appears to be more unstable than vanillin, easily turning yellow in the air and on heating.

The ether solution remaining after the removal of acids, aldehydes and phenols was evaporated. The residue was very small and did not have a maple odor. It was reddish and became partly crystalline. Recrystallized from alcohol, spindle-shaped crystals which melted at 210–212° were formed. It was thought that this must be the same as the quinone-like substance previously obtained, but when it was boiled with ferric chloride no pungent, volatile substance resulted. On boiling it with ferric chloride a faint odor of vanillin was observed. The residue from the Vermont sirup contained a small quantity of a saponifiable oil. This was not found in the corresponding residue from the Michigan sirup, and it is very probably an oil used in the kettles to stop foaming.

Conclusion

Investigation of the flavor of maple sirup showed that it depends to a great extent on an unstable phenolic substance which is associated with a crystalline aldehyde melting at 74–76' and similar in odor and properties to vanillin. Maple sirup may contain minute quantities of other aldehydic substances which influence the flavor.

THE ACIDS OF FIGS

BY E. K. NELSON

RECEIVED APRIL 26, 1928 PUBLISHED JULY 6, 1928

No record has been found in the literature regarding the identity of the acids of figs. Bigelow and Dunbar[1] in their review of the literature on fruit acids do not mention the fig. Condit and Creuss[2] state that fresh Kadota figs contain from 19 to 24% of sugar and from 0.1 to 0.44% of acid, calculated as citric.

In an investigation of sour figs and figs affected with internal rot, B. J. Howard, of this Bureau, collected samples of normal and diseased figs near Fresno, California, during the summer of 1927. They included Adriatic "black necks," normal Adriatics, Calimyrna figs affected with internal rot and normal Calimyrnas. Part of these samples, when dried, afforded the material for an investigation of the acids in figs.

Experimental

Approximately two kilograms of each kind of figs was ground to a paste. The paste was disintegrated in 1 gallon of water at 60°, digested on a steam-bath for an hour, diluted with an equal volume of alcohol and strained through a linen bag. The residue was pressed dry, soaked in hot dilute alcohol and re-pressed. The fig extract was concentrated to a sirup in a vacuum pan, the distillate being collected for the determination of volatile acids. After being diluted with water and acidified with sulfuric acid, the sirup was extracted with ether to recover ether soluble acids. Only fig fat and small quantities of stearic and oleic acids were found in this ether extract.

The diluted sirup was then precipitated with a moderate excess of lead subacetate. After filtration, the lead precipitate was suspended in water and a stream of carbon dioxide was allowed to bubble through it for some time in order to break up lead sugar compounds. After it was filtered and washed, the lead precipitate was decomposed with sulfuric acid and the excess of acid was removed with the equivalent quantity of barium hydroxide. The acid solution was evaporated to dryness on the steam-bath

---

[1] Bigelow and Dunbar, *J. Ind. Eng. Chem.*, 9, 767 (1912).

[2] Condit and Creuss, Calif. Agr. Expt. Sta., Bull., 436, 1-45 (1927).

and esterified by being refluxed for five hours with absolute alcohol containing 2.5% of hydrochloric acid. After distilling off the alcohol, the esterification process was repeated. The crude esters, in ether solution, were washed with sodium hydroxide solution, the ether was evaporated and the esters, after being weighed, were subjected to fractional distillation at 10 mm.

The hydrazides prepared from the fractions were used for the identification of the respective acids.

The barium salt of the volatile acids from 2282 g. of Adriatic black necks weighed 15.71 g. It was fractionally crystallized and the barium in each fraction was determined. Fraction 1 contained 53.9% of barium; Fraction 2, 53.89%; Fraction 3, 53.95%; and Fraction 4, 53.87%; calcd. for barium acetate, barium = 53.72%. The volatile acid is therefore acetic acid. No ether soluble acids other than small quantities of stearic and oleic from the fig fat were identified.

The crude ester of the non-volatile acid, 9.75 g., when distilled at 10 mm. at 170–171° afforded 8.1 g. of pure ester. It had the boiling point of triethyl citrate and gave the characteristic hydrazide, melting at 104–106° in its hydrated form and at 147° when seeded and in the anhydrous form.

In the tests with normal Adriatic figs, 1925 g. of fruit yielded 1.11 g. of barium salt of volatile acids, corresponding to 0.27 g. of acetic acid per kilo. The silver salt was analyzed and 64.44% of silver was found; calcd. for silver acetate, 64.45%. The ethyl citrate, boiling at 170–171° at 10 mm., weighed 8.93 g., corresponding to 3.2 g. of citric acid per kilo, and afforded the characteristic hydrazide.

Two kilos of Calimyrna figs affected with internal rot yielded 2.4 g. of the barium salt of volatile acids, corresponding to 0.56 g. of acetic acid per kilo. It was shown to be acetic acid by the analysis of the silver salt (64.15% of silver). From the ester of the non-volatile acids a small quantity was obtained distilling under 170° at 10 mm., and from the hydrazide of this, several times recrystallized, a small quantity of malic acid hydrazide which melted at 177–179° was separated; a mixture of this with pure malic hydrazide showed no lower melting point. The main portion of the ester, 9.51 g., distilled at 170–171°, corresponding to 3.3 g. citric acid per kilo and affording the characteristic hydrazide.

Normal Calimyrnas, 2.066 kilos, afforded 1.15 g. of the barium salt of volatile acids, corresponding to 0.26 g. of acetic acid per kilo. The silver salt contained 64.6% of silver.

In the esters of the non-volatile acids, a small quantity of malic acid was identified by the hydrazide. Nine and five-tenths grams boiling at 170–171° at 10 mm. corresponded to citric acid, 3.5 g. per kilo.

Conclusion

Acetic and citric acids were found in Adriatic figs, and acetic, citric and a small quantity of malic acids were identified in Calimyrna figs.

It was found that Adriatic black neck figs contained more than 10 times as much free acetic acid as the normal Adriatic figs. Less citric acid was found than in the normal figs.

Normal Calimyrna figs contained 0.26 g. per kilo of free acetic acid and 3.5 g. of citric acid, besides a small quantity of malic acid.

In Calimyrna figs affected with internal rot the free acetic acid amounted to 0.56 g. per kilo, and the citric acid amounted to 3.3 g. per kilo.

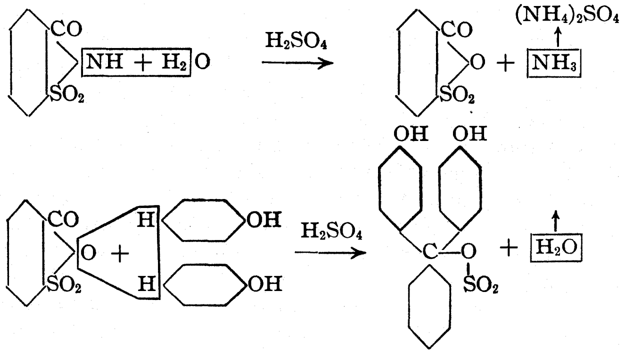
A NEW METHOD FOR THE PREPARATION OF PHENOLSULFONEPHTHALEIN AND BROMOSULFONEPHTHALEIN

BY R. FREAS AND E. A. PROVING

RECEIVED APRIL 27, 1928 PUBLISHED JULY 6, 1928

Introduction

The method used today for the preparation of phenolsulfonephthalein remains in principle the same as that originally employed by Sohon. An observation made by one of us in this Laboratory that saccharin, heated with phenol and sulfuric acid, gave fair quantities of phenol red led to the present study. This reaction probably proceeds according to the following equations



Experimental

Preliminary work indicated the importance of a study of the effect of temperature, which seemed quite a critical factor. High temperatures up to 180° yielded a dye in good quantity, but it was very dark in color, quite readily assumed a tarry condition and was precipitated with difficulty from solution. Lower temperatures gave far superior products but lower percentage yields.

The effect of temperature was studied by heating ten grams of saccharin with phenol and sulfuric acid for seventeen hours at temperatures ranging from 116 to 135°. The results of five such runs are tabulated in Table I.

TABLE I

EXPERIMENTAL RESULTS

Temp., °C.	Molar ratios, phenol	Saccharin to sulfuric acid	Yield, % of theoretical	Quality of product
116	1:4.9	1:3.9	1.0	Excellent
120	1:4.9	1:3.9	1.0	Excellent
125	1:4.9	1:3.9	1.5	Excellent
130	1:4.9	1:3.9	4.6	Fair
135	1:4.9	1:3.9	10.9	Poor

It appears that increase in temperature increases the yield progressively but with accompanying deterioration of the product. The maximum temperature yielding a good product was found to be 125°.

The dye obtained by heating from 130° upwards to 150° was increasingly worse. When isolated it was very dark and inclined to be tarry, rather than the bright red, dry product sought. Examination of some of those samples obtained at temperatures above 135° gave us reason to believe that considerable sulfonation had occurred. They exhibited the typical phenol red color changes but were not tested for their PH range.

The next factor studied was the effect of time upon yield. The optimum temperature which gave a dye of good quality, as previously determined, was 125°, for which reason this was chosen as the constant temperature for the following four runs.

The quantities of the reagents were the same as those used in the study of temperature effect, that is, 10 g. of saccharin in the molar ratio of 1:4.9 of phenol, and 1:3.9 of sulfuric acid. The results for four different intervals of time expressed in per cent. of theoretical yield are tabulated below.

TABLE II

VARIATION OF YIELD WITH TIME

Time in hours	17	35	48	86
Theoretical yield, %	1.5	12.9	24.8	27.0

These results indicate that the best yields may be expected when the experiment reaction mixture is heated for at least forty-eight hours.

Variations of the proportions of saccharin to phenol was next tried. In the five tests, the mixtures were heated for eighty-six hours at a constant temperature of 125". The molar ratio of saccharin to sulfuric acid was 1:3.9 in each case. The five runs are tabulated below.

TABLE III

VARIATION OF YIELD WITH VARIOUS PROPORTIONS OF SACCHARIN

Molar ratio of saccharin to phenol	1:2	1:4	1:4.9	1:5.3	1:9.7
Theoretical yield, %	1.7	10.0	27.0	22.5	20.0

These yields point to a desirable molar ratio of about 1:5.

The next study considered the proper proportions of saccharin to sulfuric acid. The molar ratio of saccharin to phenol previously employed, 1:4.9, was used and the heating was conducted for eighty-six hours at 125°. The variation in the molar ratio of saccharin to acid is tabulated below.

TABLE IV

RESULTS WITH VARIOUS PROPORTIONS OF SULFURIC ACID

Molar ratio of saccharin to sulfuric acid	1:2.5	1:3 9	1:6.4
Theoretical yield, %	10.4	24.8	2.0

The molar ratio of 1:3.9 seemed to be the most desirable.

A study of Tables I, II, III and IV led to the belief that the following are the optimum conditions: time, 48 hours; temperature, 120°; molar ratios, saccharin 1, phenol 5, sulfuric acid, 4.

Certain metal sulfates were next tested as to their catalytic power of accelerating the reaction. To each of a number of test-tubes was added 1 *g.* of the metal salt along with the proportions of reagents just given. These tubes were again heated at 120° for forty-eight hours. A check tube containing no added metal sulfate was included for comparison of color development. This was the means of judging the efficiency as a catalyst of the added salt. The findings are tabulated below.

TABLE V

RESULTS WITH METALLIC SULFATES

Metal sulfate, 1 g.	Intensity of color development as compared to check tube containing no metal salt	Metal sulfate, 1 g.	Intensity of color development as compared to check tube containing no metal salt
Copper	Slight decrease	Cerium	Decrease
Zinc	Slight decrease	Cobalt	Decrease
Mercuric	No difference	Ferric	Marked decrease
Aluminum	Decrease	Manganese	Marked decrease
Chromium	Decrease	Nickel	Marked decrease
Bismuth	Decrease	Silver	No color at all
Thorium	Decrease		

Observations on color intensity were first made on the melt in tubes immediately after heating. These melts were then dissolved, neutralized and diluted, and comparisons of color made with the check tube. In no case was any catalytic action observed.

Experiments were conducted on the effect of various other substances ordinarily used as condensing agents, as possible substitutes for the sulfuric acid. There is always a danger of sulfonation when sulfuric acid is used, which makes necessary a lower temperature with consequent lowering of yield.

The first experiment consisted of heating the optimum proportions of saccharin and phenol with the condensing agents, with the inclusion of one blank. The substances tested were: anhydrous aluminum chloride, anhydrous zinc chloride, anhydrous ferric chloride and phosphoric acid (85%). In all cases the development of color was slight after the tubes were heated for seventeen hours at 120° except with the check tube containing sulfuric acid, in which the deep red color developed as usual. The superiority of sulfuric acid as condensing agent was obvious.

The second experiment consisted of heating saccharin, phenol and sulfuric acid together in tubes with the addition of the four condensing agents used in the last test. Comparison with the fifth check tube again showed no improvement due to the extra condensing agent.

A method based upon the foregoing studies which gives the best yield of the highest quality product is given in detail below.

Procedure

A small balloon flask is charged with 10 g. of saccharin, 25 g. of phenol and 21 g. (12 cc.) of ordinary concentrated sulfuric acid. The contents are warmed until all of the solid is dissolved, then heated in an electric oven at 120° for forty-eight hours. An extra day of heating will increase the yield somewhat. The deep red, tarry looking reaction product is treated while still hot with warm water until solution is nearly complete. Sodium carbonate (a 30% solution is convenient) is added to neutrality, the change of color is the best guide, and the contents are subjected to steam distillation until all traces of phenol are removed. The solution is made faintly acid with hydrochloric acid and allowed to stand. The precipitated dye is filtered off with suction, washed with a minimum of ice water and dried. The dye should be of a bright reb color and but slightly soluble in water.

A few comments on the method outlined adove may be added. Sodium carbonate solution is used in the neutralization of the sulfuric acid present because it will not bind any considerable quantity of phenol, the latter seeming to prevent the dye from precipitating finally as a fine red powder.

Repeated solution of crude products in sodium carbonate and reprecipitation by addition of hydrochloric acid almost to the neutral point rendered the final product a much brighter red and much easier to precipitate.

The vreparation of **tetrabromophenolsulfonephthalein** offered no difficulty. The method used is given here in brief.

Five grams of phenol red was dissolved in 100 cc. of absolute alcohol and the cooled solution was treated with the calculated quantity of bromine. It was found desirable to use a calibrated 10cc. buret to deliver the bromine, basing the weight upon the accurately determined density at room temperature. Mechanical stirring during the slow addition of the bromine and for a short time after the addition was complete was sufficient to complete reaction.

The brom phenol blue was recovered by diluting, dissolving the dye in sodium carbonate solution and finally precipitating it with hydrochloric acid.

Conclusions

A simple method for making phenol red has been given. The product is obtained from cheap materials and after the simplest of manipulative operations.

The preparation of brom phenol blue from phenol red is described and offers no new procedure.

The products obtained checked perfectly with the PH ranges given in the literature for those substances. They were both further tested by the absorption spectrometric method and were pronounced very pure.

The application of the above method of preparation was found practicable in the condensation of many other phenols yielding useful sulfonethaleins and work is now in progress on a simple method of preparation for each of those used in colorimetric hydrogen ion estimation.

THE ACTION OF THIOCYANOGEN UPON O,N-DISUBSTITUTED HYDROXYLAMINES AND PRIMARY AMINES[1]

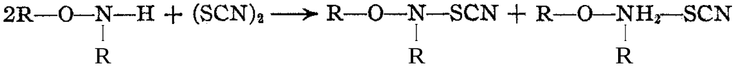
BY LAUDER W. JONES AND ELMER E. FLECK

RECEIVED MAY 12, 1928 PUBLISHED JULY 6, 1928

The action of thiocyanogen upon amines has been investigated by Soderback[2] and by Lecher, Wittwer and Speer.[3] Soderback studied the reaction with phenyl-, diphenyl- and dimethylphenylamine and, in each case, found that the thiocyanogen group entered the benzene ring para to the amino group. Lecher, Wittwer and Speer showed that in the case of the products formed with ammonia and with diethylamine, the thiocyanogen group attaches itself directly to the nitrogen atom. The purpose of this work was to extend the study of these reactions of thiocyanogen by investigation of the behavior of thiocyanogen with O,N-disubstituted hydroxylamines and with certain primary amines.

O,N-Disubstituted N-Thiocyanohydroxylamines

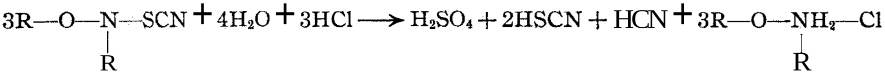
The action of thiocyanogen on O,N-disubstituted hydroxylamines corresponded to the action of thiocyanogen upon ammonia and diethylamine. Hydroxylamines with ethyl and benzyl groups were used for this purpose. They reacted with thiocyanogen as follows



$$2R{-}O{-}\underset{\substack{|\\ R}}{N}{-}H + (SCN)_2 \longrightarrow R{-}O{-}\underset{\substack{|\\ R}}{N}{-}SCN + R{-}O{-}\underset{\substack{|\\ R}}{NH_2}{-}SCN$$

The thiocyanohydroxylamines formed in this manner are not very stable compounds. O,N-diethyl-N-thiocyanohydroxylamine distilled from 45 to 46" at 2 mm. but decomposed rapidly when exposed to the air at room temperature. At 0° this substance showed no signs of decomposition after several hours. The corresponding O,N-dibenzyl compound was a white crystalline solid; m. p. 50–52°. At room temperature it could be kept for about forty-eight hours without signs of decomposition.

Hydrolysis of O,N-Disubstituted N-Thiocyanohydroxylamines.—The structure of these compounds was established by acid and by alkaline hydrolysis. Acid hydrolysis gave results which corresponded closely in form with those observed by Lecher, Wittwer and Speer in their investigations of similar amine derivatives.



$$3R{-}O{-}\underset{\substack{|\\ R}}{N}{-}SCN + 4H_2O + 3HCl \longrightarrow H_2SO_4 + 2HSCN + HCN + 3R{-}O{-}\underset{\substack{|\\ R}}{NH_2}{-}Cl$$

---

[1] This paper is based upon a thesis submitted by Elmer E. Fleck to the Faculty of the Graduate School of Princeton University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Soderback, *Ann.*, 419, 270 (1919).

[3] Lecher, Wittwer and Speer, *Ber.*, **56B,** 1104 (1923).

Bjerrum and Kirschner[4] have shown that the first step in the hydrolysis of thiocyanogen proceeded as follows

$$(SCN)_2 + HOH \longrightarrow HSCN + HOSCN$$

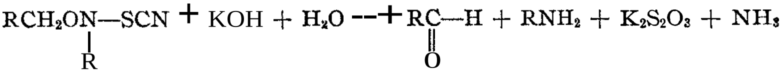
The hypothiocyanic acid then underwent auto-oxidation according to the following reaction

$$3HOSCN + HOH \longrightarrow 2HSCN + HCN + H_2SO_4$$

Since thiocyanic, hydrocyanic and sulfuric acids were also obtained by the hydrolysis of O,N-disubstituted N-thiocyanohydroxylamines, it seemed certain that the first step in the latter hydrolysis must yield O,N-disubstituted hydroxylamine and hypothiocyanic acid. The production of hypothiocyanic acid indicates that the thiocyan group in O,N-disubstituted N-thiocyanohydroxylamine may be regarded as "positive," since it reacts in a manner similar to the "positive" halogen of the halogen amines[5]

$$R_2NCl + HOH \longrightarrow R_2NH + HOCl$$

On the other hand, alkaline hydrolysis of O,N-disubstituted N-thiocyanohydroxylamines gave products quite unlike those obtained in the alkaline hydrolysis of diethylthiocyanamine. Thus, the alkaline hydrolysis of the hydroxylamine derivatives proceeds according to the following reaction



$$RCH_2O\underset{\displaystyle R}{\underset{|}{N}}{-}SCN + KOH + H_2O \longrightarrow R\underset{\displaystyle O}{\underset{\|}{C}}{-}H + RNH_2 + K_2S_2O_3 + NH_3$$

while the alkaline hydrolysis of diethylthiocyanamine gave the following results[3]

$$(C_2H_5)_2N{-}SCN + KOH + H_2O \longrightarrow (C_2H_5)_2NH + KOCN + S$$

The presence of ammonia among the products of hydrolysis of hydroxylamine derivative may be explained by hydrolysis of potassium cyanate. The formation of potassium thiosulfate instead of sulfur may be explained since it has been shown by Lecher and co-workers that sulfur and potassium hydroxide react even in the cold to give thiosulfate and polysulfide. Taking into account these variations in the two reactions, it can be shown that the hydrolysis of O,N-disubstituted N-thiocyanohydroxylamines not only agrees with the theory of Lecher, Wittwer and Speer, but serves to support the mechanism of the hydrolysis advanced by them for thiocyanamine. They postulate, first, the formation of N,N-diethylthiohydroxylamine and then a chain splitting to give diethylamine and sulfur. If a similar reaction occurs in the case of O,N-disubstituted N-thiocyanohydroxylamine, the O,N-disubstituted thiohydroxylamine formed during the first step

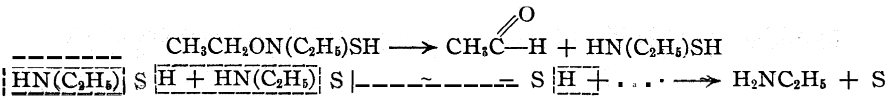
[5] Seliwanow, *Ber.*, **25**, 2621 (1892), Berg, *Ann. chim.*, [7] **3**, 341 (1894); W. A. Noyes, THIS JOURNAL, 23, 460 (1901); Stieglitz, *ibid.*, **23**, 797 (1901); Jones, *ibid.*, **36**, 1268 (1914).

of the hydrolysis would certainly be unstable by virtue of the linking of the ethoxy group and the group SH to the same nitrogen atom. Since the ethoxy group is already in the state of oxidation comparable to an aldehyde,[6] it separates as aldehyde, leaving N-ethylthiohydroxylamine, and this, in turn, decomposes to give sulfur and ethylamine in accordance with the explanation of Lecher, Wittwer and Speer.

$$CH_3CH_2ON(C_2H_5)SCN + KOH \longrightarrow CH_3CH_2ON(C_2H_5)SH + KOCN$$



$$CH_3CH_2ON(C_2H_5)SH \longrightarrow CH_3C(=O)-H + HN(C_2H_5)SH$$

$$\boxed{HN(C_2H_5)}S\ \boxed{H + HN(C_2H_5)}S \cdots S\boxed{H} + \cdots \longrightarrow H_2NC_2H_5 + S$$

In order to show that the formation of aldehyde could not be accounted for by the action of alkali upon the disubstituted hydroxylamine under the conditions of the experiment, sealed tubes containing the disubstituted hydroxylamine and 2% potassium hydroxide were heated at temperatures varying from 100 to 180° for periods of eight hours. In the case of O,N-diethylhydroxylamine no acetaldehyde or ethylamine could be detected below 150°. At 180° considerable quantities of acetaldehyde and ethylamine were formed. O,N-dibenzylhydroxylamine was not affected at 100°, but at 150° almost complete decomposition into benzaldehyde and benzylamine occurred.

Thiocyanamines

The only mention of the action of thiocyanogen upon primary amines,[7] other than the case of aniline already cited, was made by Söderbäck.[2] He stated that such reactions lead only to ill-defined products. In the present work, benzylamine and triphenylmethylamine were found to react with thiocyanogen to produce the corresponding thiocyanamine. The reaction proceeded as follows

$$2RNH_2 + (SCN)_2 \longrightarrow RNHSCN + RNH_3SCN$$

Pure triphenylmethylthiocyanamine was isolated by the action of triphenylmethylamine with thiocyanogen. Triphenylmethylthiocyanamine is a white, crystalline solid; m. p. 142°. It may be allowed to stand at room temperature for a week without serious decomposition. Benzylthiocyanamine, formed by the action of benzylamine with thiocyanogen, could not be isolated in the pure condition. It could neither be crystallized nor distilled. Analysis for nitrogen and sulfur gave values too low by 1–2% for benzylthiocyanamine, but its reactions with acids confirmed its structure.

[7] Attention was directed to this type of reaction by what seemed to be a decomposition of O,N-dibenzyl-N-thiocyanohydroxylamine into benzaldehyde and benzylthiocyanamine. When O,N-dibenzyl-N-thiocyanohydroxylamine was first made considerable difficulty was experienced in crystallizing it. The oil possessed an odor not unlike that of benzaldehyde. Accordingly an attempt was made to prepare benzylthiocyanamine from benzylamine and thiocyanogen in order that the products of this suspected decomposition might be studied.

The reaction of thiocyanogen with primary amines to form thiocyanamines is of particular interest because it corresponds to the production of a monohalogen amine by the action of the halogen upon the amine in an inert solvent.

Action of Acids upon Thiocyanamines.—If the thiocyanamines are related to the monohalogen amines in this fashion, they should react with acids according to the following equation

$$RNHSCN + 2HX \longrightarrow RNH_3X + XSCN$$

The corresponding reaction of the monohalogen amines may be represented[8]

$$RNHX + 2HX' \longrightarrow RNH_3X' + X—X'$$

Thiocyanamines were found to undergo this reaction. When triphenylmethylthiocyanamine was dissolved in dry ether and treated with hydrochloric acid gas, triphenylmethylammonium chloride was precipitated. The ether filtrate, separated from the salt, was evaporated in a current of air and a heavy oil, which possessed a pungent odor, remained. This oil may be the monomolecular form of chlorothiocyanogen which Kaufmann and Lecher[10] have been seeking, as it evaporated slowly and gave an intense red color when treated with a solution of ferric chloride.

Picric acid also reacts with triphenylmethylthiocyanamine to give triphenylmethylammonium picrate, but in this case the second product of the reaction is a yellow, amorphous substance which did not melt but gradually decomposed when heated.

Benzylthiocyanamine reacted similarly with hydrochloric and picric acids. The hydrochloride and the picrate were formed, respectively. In both these reactions the yellow, amorphous substance referred to above was obtained.

Rearrangement of Triphenylmethylthiocyanamine.—Further evidence that the thiocyanamines are related to the monohalogen amines may be had from the fact that triphenylmethylthiocyanamine undergoes the Stieglitz rearrangement.[11] Stieglitz and co-workers have succeeded in causing triphenylmethylbromo-amine, triphenylmethylhydroxylamine, triphenylmethylazide and *bis*-triphenylmethylhydrazine to rearrange; they obtained phenylimidobenzophenone from the rearrangement products. According to the theory advanced by Stieglitz, rearrangement in compounds of this type will be brought about by a reagent which removes a molecule of hydrobromic acid, water, nitrogen or ammonia, as the case may be, and gives rise to an intermediate, monovalent nitrogen compound. It is assumed that two electrons then shift from the methyl carbon atom

[10] Lecher and Joseph, *Ber.*, 59B, 2603 (1926).

[11] Stieglitz and Leech, This Journal, 36, 272 (1914); Vosburgh, *ibid.*, 38, 2081 (1916); Senior, *ibid.*, 38, 2718 (1916); Stieglitz and Senior, *ibid.*, 38, 2727 (1916); Stieglitz and Brown, *ibid.*, 44, 1270 (1922); Stieglitz, *ibid.*, 44, 1293 (1922).

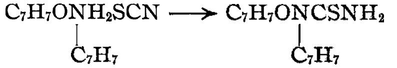
of the triphenylmethyl radical to the nitrogen atom, followed by a migration of a phenyl group from the carbon atom to the nitrogen atom; the final product of the rearrangement is phenylimidobenzophenone. This reaction may be represented in the case of triphenylmethylthiocyanamine as follows

$$(C_6H_5)_3CNHSCN \xrightarrow{—HSCN} (C_6H_5)_3C—N \longrightarrow (C_6H_5)_2C{=}N(C_6H_5)$$

Triphenylmethylthiocyanamine was found to undergo this rearrangement when it was mixed with calcium oxide and heated at a temperature between 440 and 450° for a very short time. The phenylimidobenzophenone produced by this rearrangement was identified by the products of its acid hydrolysis, namely, aniline and benzophenone.

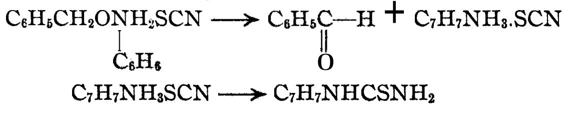
Attempts to use other reagents to produce this rearrangement did not succeed. Soda lime converted triphenylmethylthiocyanamine almost quantitatively into triphenylmethylamine. Mercuric oxide, lead oxide and sodium methylate were also tried.

Formation of Ureas from Substituted Ammonium **Thiocyanates.**—The O,N-dibenzylhydroxylammonium thiocyanate formed in the preparation of O,N-dibenzyl-N-thiocyanohydroxylamine was found to undergo two interesting transformations. When this salt was suspended in water and the water removed by evaporation, the usual transformaton occurred and α,α'-benzylbenzyloxythiourea was the product.



$$C_7H_7O\underset{\displaystyle C_7H_7}{\underset{|}{N}}H_2SCN \longrightarrow C_7H_7O\underset{\displaystyle C_7H_7}{\underset{|}{N}}CSNH_2$$

This compound was found to be the same as that prepared by evaporation of a suspension of O,N-dibenzylhydroxylamine hydrochloride and potassium thiocyanate; but when O,N-dibenzylhydroxylammonium thiocyanate was heated for fifteen minutes at 150° previous to its treatment with water, no α,α'-benzylbenzyloxythiourea could be obtained; the products isolated were benzylthiourea and benzaldehyde. The following reaction represents these changes



$$C_6H_5CH_2O\underset{\displaystyle C_6H_6}{\underset{|}{N}}H_2SCN \longrightarrow C_6H_5\underset{\displaystyle O}{\underset{\|}{C}}—H + C_7H_7NH_3.SCN$$

$$C_7H_7NH_3SCN \longrightarrow C_7H_7NHCSNH_2$$

Efforts to convert triphenylmethylammonium thiocyanate into the corresponding thiourea by this method failed. Heat brought about decomposition and evaporation with water caused hydrolysis of the salt. Triphenylmethylcarbinol was isolated from the products of hydrolysis.

Experimental Part

O,N-Diethyl-N-thiocyanohydroxylamine, $(C_2H_5O)(C_2H_5)NSCN$

Preparation of **O,N-Diethyl-N-thiocyanohydroxylamine.**—A suspension of 11.3 g. of lead thiocyanate in 50 cc. of absolute ether was treated with 4.8 g. of bromine. The mixture was shaken until the color of bromine disappeared and then filtered into an ice-cooled ether (50 cc.) solution of 9.2 g. of O,N-diethylhydroxylamine, prepared by the method of Hecker[12] as modified by Major and Fleck.[13] Reaction took place at once and 4.0 g. of O,N-diethylhydroxylammonium thiocyanate separated as an oil. The ether was removed rapidly by means of diminished pressure. During this operation the temperature of the flask was not allowed to rise above 0°. The oil which remained distilled at 45–46° under 2 mm. A liquid air trap interposed between the receiver and the oil pump greatly facilitated the maintenance of this pressure; yield, 40%.

Anal. Subs., 0.0988: $BaSO_4$, 0.1559. Subs., 0.0536: N_2, 9.0 cc. (20°, 759.6 mm.). Calcd. for $C_5H_{10}ON_2S$: S, 21.92; N, 19.15. Found: S, 21.87; N, 19.5.

Acid Hydrolysis of O,N-Diethyl-N-thiocyanohydroxylamine.—One g. of O,N-diethyl-N-thiocyanohydroxylamine was added to 100 cc. of ice-cooled 2% hydrochloric acid and the mixture kept in the ice box until the oil dissolved. The solution was then distilled and hydrocyanic acid and thiocyanic acid were found in the distillate. A test for sulfate was obtained from the residue of the distillation. The remainder of this residue was made alkaline and distilled. The distillate was extracted with benzene and treated with phenylisocyanate. The crystals which separated melted at 63°. When mixed with α-phenyl β,β'-ethylethoxyurea, $(C_2H_5O)(C_2H_5)N{\cdot}CONH(C_6H_5)$, prepared by the method of Jones and Major,[14] the melting point was unchanged.

Alkaline Hydrolysis of O,N-Diethyl-N-thiocyanohydroxylamine.—One g. of O,N-diethyl-N-thiocyanohydroxylamine was added to 100 cc. of an ice-cooled 2% solution of potassium hydroxide and the mixture allowed to stand in an ice box for two days. The solution was then distilled. The distillate contained acetaldehyde and ethylamine.

The residual liquid of this distillation contained no free sulfur but gave the ordinary tests for thiosulfate. To precipitate lead thiosulfate, calcium nitrate was added to the remainder of the residue, the solution filtered, the color of phenolphthalein in the filtrate discharged by acetic acid and the salt obtained by the addition of lead nitrate.

Anal. Subs., 0.1272: $PbSO_4$, 0.1220. Subs., 0.0606: 19.0 cc. of 0.01 N I_2 solution. Calcd. for PbS_2O_3: Pb, 64.99; S, 20.06. Found: Pb, 65.5; S, 20.0.

The distillate, which contained acetaldehyde and ethylamine, was acidified with hydrochloric acid and the acetaldehyde removed by distillation. This distillate was treated with an acetic acid solution of *p*-nitrophenylhydrazine. The yellow plates which separated melted at 127.5°. Mixing with acetaldehyde-*p*-nitrophenylhydrazone[15] did not alter this melting point. This established the formation of acetaldehyde.

The residual liquid, which contained the hydrochloride of ethylamine, was made alkaline and distilled. Addition of ethyl oxalate to a portion of the distillate yielded colorless needles which melted at 178°. The melting point was not changed when mixed with diethyloxamide.[16] This established the presence of ethylamine. The remainder of this distillate was acidified with hydrochloric acid and evaporated to dryness. Ammonium chloride was found to be present.[17]

O,N-Dibenzyl-N-thiocyanohydroxylamine, $(C_7H_7O)(C_7H_7)NSCN$

Preparation of O,N-Dibenzylcarbethoxyhydroxamic Ester.—To 59 g. of carbethoxy-

hydroxamic acid, prepared by the method of **Jones**,[18] 151 g. of benzyl chloride and 66 g. of potassium hydroxide, dissolved in alcohol, were added. The solution grew warm at once and potassium chloride separated. After twenty-four hours, the mixture was refluxed for one hour, then cooled and filtered. The alcohol was distilled and the residue diluted with water and extracted with ether. The ether solution was washed with dilute sodium hydroxide to remove any O-benzylcarbethoxyhydroxamic ester. Five g. of this substance, b. p. 171–172° under 7 mm., was recovered. The neutral portion remaining with the ether was dried with sodium sulfate. Distillation of the ether left a colorless oil which was fractionated. The fraction boiling between 200 and 203" under 7 mm. was collected; yield, 90 g.

Anal. Subs., 0.2652: N_2, 11.3 cc. (21°, 761.2 mm.). Calcd. for $C_{17}H_{19}O_3N$: N, 4.91. Found: 4.95.

Preparation of **O,N-Dibenzylhydroxylamine.**—A solution of 63 g. of O,N-dibenzylcarbethoxyhydroxamic ester was added to 25 g. of sodium hydroxide dissolved in 200 cc. of 50% alcohol and the mixture refluxed for one hour. After distillation of the alcohol, the O,N-dibenzylhydroxylamine was extracted with ether and the extract dried with sodium sulfate. The colorless oil which remained after removal of the ether distilled at 145–146' under 3 mm.; yield, 41 g.

Preparation of **O,N-Dibenzyl-N-thiocyanohydroxylamine.**—A suspension of 8.0 g. of lead thiocyanate in 50 cc. of absolute ether was treated with 3.8 g. of bromine. The mixture was shaken until the color of bromine disappeared and then filtered into an ice-cooled solution of 10 g. of O,N-dibenzylhydroxylamine in ether. Reaction took place at once and 5.9 g. of O,N-dibenzylhydroxylammonium thiocyanate crystallized. This salt was collected on a filter and recrystallized by dissolving it in a large amount of absolute ether and evaporating the ether under diminished pressure; m. p. 91°.

Anal. Subs., 0.1190: $BaSO_4$, 0.0988. Subs., 0.1450: N_2, 13.4 cc. (25°, 753.0). Calcd. for $C_{15}H_{16}ON_2S$: S, 11.75; N, 10.33. Found: S, 11.43; N, 10.48.

The ether filtrate, separated from the salt, was evaporated under diminished pressure to 10 cc. The second crop of O,N-dibenzylhydroxylammonium thiocyanate which separated during this process was removed by filtration and the filtrate was kept under a high vacuum at room temperature for three hours. The product remained as an oil but it finally crystallized when cooled in ice. Scratching the side of the containing vessel greatly facilitated this crystallization. The crystals were triturated with 5 cc. of absolute alcohol, filtered and washed with a small amount of cold dry ether; m. p. 50–52°; yield, 47%.

Anal. Subs., 0.2098: $BaSO_4$, 0.1746. Subs., 0.1422: N_2, 12.6 cc. (18°, 752.7). Calcd. for $C_{15}H_{14}ON_2S$: S, 11.85; N, 10.37. Found: S, 11.4; N, 10.3.

Acid Hydrolysis of **O,N-Dibenzyl-N-thiocyanohydroxylamine.**—One g. of O,N-dibenzyl-N-thiocyanohydroxylamine was dissolved in 100 cc. of a solution of 2% hydrochloric acid in 75% alcohol. The mixture grew warm and was distilled at once. Hydrocyanic and thiocyanic acids were found in the distillate. When the residue from this distillation was cooled, O,N-dibenzylhydroxylamine hydrochloride precipitated. Evaporation of the filtrate, separated from the salt, yielded more of this salt. A total of 0.95 g. of O,N-dibenzylhydroxylamine hydrochloride was obtained from this hydrolysis. The base was freed with sodium hydroxide, extracted with benzene and treated with phenylisocyanate. The benzene was removed by a current of air and the product purified by dissolving in alcohol and precipitating with water; m. p. 107'. The melting point remained unaltered when mixed with α-phenyl-β,β'-benzylbenzyloxyurea.[19]

---

[18] Jones, *Am.* Chem. J., **20**, 39 (1898).

[19] Beckmann, J. prakt. *Chem.*, [2] 56, 77 (1897).

Sulfate was found in the filtrate from which O,N-dibenzylhydroxylamine hydrochloride had been removed.

Alkaline Hydrolysis of **O,N-Dibenzyl-N-thiocyanohydroxylamine.**—One g. of O,N-dibenzyl-N-thiocyanhydroxylamine was refluxed with 100 cc. of a 2% solution of potassium hydroxide for half an hour. A reddish solid formed. The products of hydrolysis were separated by the method used in the case of the corresponding ethyl compound. Benzaldehyde was identified by conversion into benzalphenylhydrazone and determination of the melting point when mixed with benzalphenylhydrazone prepared by the method of Behrend and Leuchs.[20]

Benzylamine was identified by extraction of the free base with benzene and conversion into α,β-phenylbenzylurea; m. p. 165°. When mixed with a,@-phenylbenzylurea prepared by the method of Ley and Kraft,[21] the melting point was not lowered. Thiosulfate was shown to be present by the usual qualitative tests.

Alkaline Decomposition of O,N-Disubstituted Hydroxylamines

Decomposition of **O,N-diethylhydroxylamine.**—One g. of O,N-diethylhydroxylamine was heated in a sealed tube with 100 cc. of a 2% solution of potassium hydroxide for eight hours. The contents of the tube were then distilled and the distillate was tested for aldehyde with Schiff's reagent. A negative test was obtained from a tube heated at 100°. At 150" only a slight amount of aldehyde was found, while at 180° almost complete decomposition took place. The contents of the tube heated at 180° was acidified with hydrochloric acid and the acetaldehyde removed by distillation. Yellow plates m. p. 127.5°, separated when the distillate was treated with *p*-nitrophenylhydrazine. When mixed with acetaldehyde-p-nitrophenylhydrazone it melted at 127.5°.

The residual liquid from this distillation was made alkaline and the ethylamine removed by distillation. Treatment of this distillate with ethyl oxalate gave white needles; m. p. 178". Mixing with diethyloxamide produced no change in the melting point.

Decomposition of **O,N-Dibenzylhydroxylamine.**—One g. of O,N-dibenzylhydroxylamine was sealed in a tube with 100 cc. of a 2% solution of potassium hydroxide. This solution heated for eight hours at 100° showed no change. When it was heated at 150° for a similar time, almost complete decomposition ensued. The products of this decomposition were separated as in the case of the diethyl compound. Benzaldehyde was identified by conversion into benzalphenylhydrazone; m. p. 155°. When mixed with benzalphenylhydrazone[20] it melted at 155–156°.

The residual liquid, which contained benzylamine hydrochloride, was made alkaline, extracted with benzene and the benzene solution treated with phenylisocyanate. The white crystals which separated melted at 169°. A mixture with α,β-phenylbenzylurea[21] showed no lowering of melting point.

Triphenylmethylthiocyanamine, $(C_6H_5)_3CNHSCN$

Preparation of **Triphenylmethylthiocyanamine.**—A suspension of 6.6 g. of lead thiocyanate in 50 cc. of absolute ether was treated with 3.2 g. of bromine. The mixture was shaken until the color of bromine disappeared and then filtered into a solution of 10.4 g. of triphenylmethylamine in 150 cc. of dry ether. The amine was prepared by the method of Elbs,[22] as modified by Vosburgh.[23] Immediate reaction, accompanied by the separation of 5.6 g. of triphenylmethylammonium thiocyanate, took place. This salt was collected on a filter and recrystallized from benzene by addition of ligroin; m. p. 173°.

Anal. Subs., 0.1630: $BaSO_4$, 0.1174. Subs., 0.1596: N_2, 12.2 cc. (23°, 750.5). Calcd. for $C_{20}H_{18}N_2S$: S, 10.06; N, 8.80. Found: S, 9.89; N, 8.76.

The ether filtrate, separated from the salt, was evaporated to dryness. The sticky solid which resulted was triturated with 10 cc. of carbon tetrachloride and the solution filtered. Triphenylmethylthiocyanamine was recrystallized from absolute ether by addition of ligroin (b. p. 30–60°); m. p. 142°; yield, 55%.

Anal. Subs., 0.1378: $BaSO_4$, 0.1038. Subs., 0.1446: N_2, 11.7 cc. (26°, 743.9). Calcd. for $C_{20}H_{16}N_2S$: S, 10.13; N, 8.86. Found: S, 10.36; N, 9.05.

Rearrangement of Triphenylmethylthiocyanamine.—A mixture of 0.5 g. of triphenylmethylthiocyanamine and 1.0 g. of freshly ignited calcium oxide was heated in a dry 60cc. Pyrex Erlenmeyer flask immersed in a metal-bath at 440–450° for one minute. Considerable decomposition occurred at this temperature and the odor of ammonia was apparent. The product was dissolved in ether, the solution filtered from the lime and the ether filtrate refluxed with an excess of dilute hydrochloric acid for half an hour. The two layers were separated, the water solution was extracted three times with ether and each ether extract washed with dilute hydrochloric acid. The original ether solution was washed twice with dilute hydrochloric acid. The acid portions were united (A) as were also the ether portions (B).

The acid solution (A) was made strongly alkaline and distilled with steam into dilute hydrochloric acid. This solution was evaporated to dryness on a water-bath. The resulting solid, 0.042 g., was treated with a few drops of a strong solution of sodium hydroxide and the aniline extracted with benzene. Addition of a-naphthylisocyanate caused *sym.*-α-naphthylphenylurea to separate m. p. 221–223°. No lowering in melting point was observed when this product was mixed with *sym.*-α-naphthylphenylurea prepared by the method of Dixon.[24]

Most of the ether was distilled from the ether solution (B) and the remainder was distilled with steam. The distillate was extracted with ether and the ether removed *in vacuo.* By this method 0.082 g. of benzophenone, m. p. 25–30°, was obtained. This benzophenone was converted into the corresponding oxime by the method given in Mulliken;[25] m. p. 141–142°. The melting point was not changed when mixed with benzophenone-oxime prepared from pure benzophenone.

Benzylthiocyanamine, $C_6H_5CH_2NHSCN$

Preparation of Benzylthiocyanamine.—A suspension of 6.6 g. of lead thiocyanate in 25 cc. of absolute ether was treated with 3.2 g. of bromine. The mixture was shaken until the color of bromine disappeared and then filtered into a solution of 4.3 g. of benzylamine dissolved in 25 cc. of dry ether. Reaction took place at once and 3.5 g. of benzylammonium thiocyanate separated. This salt was recrystallized from ethyl acetate by addition of ligroin; m. p. 100–101'. No lowering of the melting point of this salt could be detected when it was mixed with benzylammonium thiocyanate prepared by the method of Dixon.[26]

The filtrate, separated from the salt, was evaporated under diminished pressure. When practically all of the ether was removed, the heavy oil was subjected to a high vacuum for five hours. Crystallization could not be brought about and complete decomposition accompanied any attempt to distil this oil. Analysis for nitrogen and sulfur gave results too low by 1–2% for the calculated values. Change of reaction

solvent, washing the reaction products with ice water, etc., did not improve the purity of the benzylthiocyanamine materially.

Action of Acids upon Benzylthiocyanamine.—One g. of benzylthiocyanamine was dissolved in absolute ether and dry hydrochloric acid gas passed into the solution. Benzylammonium chloride separated at once along with a yellow, amorphous substance. The benzylammonium chloride was converted into α,β-phenylbenzylurea and identified by mixed melting point determinations.

One g. of benzylthiocyanamine was dissolved in absolute ether and an absolute ether solution of picric acid added. The reaction proceeded slowly but was complete within one hour. A yellow, amorphous substance also separated from the solution. The benzylammonium picrate was freed from this substance by recrystallization from ethyl acetate by addition of ligroin; m. p. 200–201°. Mixed melting points proved this compound to be identical with benzylamine picrate prepared by addition of an absolute ether solution of picric acid to an absolute ether solution of benzylamine.

α,α'-Benzylbenzyloxyureas, $(C_7H_7O)(C_7H_7)N\cdot CONH_2$

Preparation of α,α'-benzylbenzyloxyurea.—A solution containing 2 g. of O,N-dibenzylhydroxylamine hydrochloride and 0.7 g. of potassium cyanate in 50 cc. of water was evaporated to dryness. The heavy oil which resulted was dissolved in alcohol and precipitated with water. The urea formed as an oil which solidified in long needles after several days. It was recrystallized from ligroin; m. p. 98-99°; yield, 30%.

Anal. Subs., 0.1134: N_2, 10.6 cc. (21°, 741.8). Calcd. for $C_{15}H_{16}O_2N_2$: N, 10.93. Found: 10.6.

Preparation of α,α'-benzylbenzyloxythiourea, $(C_7H_7O)(C_7H_7)N\cdot CS\cdot NH_2$.—To prepare this thiourea, the calculated amount of O,N-dibenzylhydroxylamine hydrochloride and potassium thiocyanate, dissolved in water, was treated as outlined in the previous experiment. The thiourea crystallized in plates; m. p. 94–95"; yield, 24%.

Anal. Subs., 0.1132: N_2, 10.8 cc. (24°, 753.3). Calcd. for $C_{15}H_{16}ON_2S$: N, 10.63. Found: 10.88.

Formation of Ureas from Substituted Ammonium Thiocyanates.—Two g. of O,N-dibenzylhydroxylammonium thiocyanate was suspended in 50 cc. water and the suspension evaporated to dryness. The oil which remained was dissolved in alcohol and precipitated by water. The α,α'-benzylbenzyloxythiourea was recrystallized from ligroin; m. p. 94–95°; yield, 31%. The melting point was not changed when this substance was mixed with α,α'-benzylbenzyloxythiourea prepared from O,N-dibenzylhydroxylamine hydrochloride.

One-half g. of O,N-dibenzylhydroxylammonium thiocyanate was subjected to dry distillation. The pressure was maintained at 20 mm. and the temperature of the metal-bath surrounding the distilling flask was kept between 150 and 160°. The distillate contained benzaldehyde which was identified by conversion into benzalphenylhydrazone and determination of the melting point when mixed with synthetic benzalphenylhydrazone.

The residue from the above distillation was dissolved in alcohol and precipitated carefully with water. The resulting solid was recrystallized from a large amount of boiling water. The benzylthiourea prepared in this manner melted at 147–148°. When mixed with benzylthiourea, prepared by the method of Dixon,[26] no lowering of melting point could be detected.

Summary

1. O,N-diethyl-N-thiocyanohydroxylamine and O,N-dibenzyl-N-thiocyanohydroxylamine have been prepared by the action of thiocyanogen on

the corresponding O,N-disubstituted hydroxylamines. The structure of these compounds has been proven by hydrolysis.

2. O,N-dibenzylhydroxylammonium thiocyanate was found to transform into α,α'-benzylbenzyloxythiourea when a solution of it in water was evaporated. When O,N-dibenzylhydroxylammonium thiocyanate was heated in the absence of water, benzylthiourea and benzaldehyde were the products.

3. Triphenylmethylthiocyanamine and benzylthiocyanamine have been prepared by the action of thiocyanogen on triphenylmethylamine and benzylamine, respectively. These compounds have been shown to resemble monohalogen amines in their chemical behavior.

4. Triphenylmethylthiocyanamine was found to undergo the Stieglitz rearrangement when heated with calcium oxide. Phenylimidobenzophenone was shown to be a product of rearrangement.

THE ACIDS OF MAPLE SUGAR "SAND"

BY E. K. NELSON

RECEIVED MAY 14, 1928 PUBLISHED JULY 6, 1928

Maple sugar "sand" is the deposit of the calcium salts of organic acids, chiefly calcium malate, which forms in the evaporating kettle during the concentration of maple sap. The acids of maple sugar "sand" have been investigated by v. Lippmann,[1] who found, in addition to *l*-malic acid, considerable d-tartaric acid and a small quantity of tricarballylic acid. V. Lippmann gives very little information regarding his method of procedure in separating these acids except that tricarballylic acid was extracted from the acid mixture by means of ether.

Van Zoeren,[2] attempting to confirm v. Lippmann's results, obtained sufficient tartaric acid to identify microscopically as acid potassium salt but was unable to isolate tricarballylic acid.

An investigation of a sample of maple "sand was made in the Food Research Division. The volatile acids were identified as a mixture of formic and acetic acids. In addition to *l*-malic acid, fumaric, succinic and citric acids were separated in small quantities. Traces of d-tartaric acid and tricarballylic acid were identified by crystallographic[3] examination of the proper fractions, though it was impossible to separate these acids in a state of purity sufficient for the determination of melting points.

[2] Van Zoeren, *Trans. Roy. Soc. Canada* (3) *13*, 222 (1919).

[3] Crystallographic examinations were made by G. L. Keenan of the Food, Drug and Insecticide Administration.

Experimental

Five kilos of maple sugar "sand" from Vermont were used in this investigation. The material contained a considerable quantity of inert matter (clay) and 51% of mineral constituents. To neutralize the alkalinity of the ash required 150 g. of sulfuric acid per kilo of "sand."

To each kilo of sand, suspended in water, 150 g. of sulfuric acid was added, and the mixture was stirred well and filtered from calcium sulfate and insoluble matter. The filtrate was concentrated in a vacuum pan, the distillate was neutralized with sodium hydroxide and evaporated to dryness and the residue was reserved for the separation of volatile acids.

The concentrated solution left after the distillation of volatile acids was thoroughly extracted with ether to remove ether soluble acids, after which the non-volatile acids not removed by the ether were precipitated with a moderate excess of lead subacetate. The precipitate of lead salts was decomposed with sulfuric acid, and the lead sulfate was removed by filtration.

The excess of sulfuric acid, determined in a small aliquot of the measured filtrate, was removed with its equivalent of barium hydroxide and the filtrate from the barium sulfate was evaporated to dryness and esterified by refluxing for five hours with absolute alcohol containing 2.5% of hydrochloric acid. The alcohol was evaporated and the esterification was repeated. After removal of the alcohol, the ester mixture was dissolved in ether and washed with sodium hydroxide solution until neutral. The crude esters left after evaporating the ether were then submitted to repeated fractional distillation at 10 mm.

Volatile Acids.—The residue of sodium salts of volatile acids from five kilos of "sand" was acidified with phosphoric acid and the volatile acids were distilled from the concentrated solution in a current of steam. The distillate was neutralized with barium hydroxide and evaporated to dryness, yielding 2.7 g. of barium salts. This was dissolved in water and made up to a volume of 250 cc. An aliquot was tested for formic acid. Mercuric chloride was reduced to mercurous chloride and potassium permanganate solution was reduced. Silver nitrate was instantly reduced to metallic silver.

An aliquot of 200 cc. was warmed and treated with potassium permanganate in slight excess, the excess being removed with sodium sulfite. The filtrate from manganese dioxide was concentrated and slightly acidified with nitric acid. When an excess of silver nitrate was added, a small quantity of silver salt was obtained. On further concentration a second small quantity of silver salt was separated. Fraction 1 contained 63.49% of silver, Fraction 2, 63.66% of silver; calculated for silver acetate, silver = 64.45%. When this fraction was boiled with sulfuric acid and alcohol, the characteristic odor of ethyl acetate was noted. The volatile acids consist, therefore, of formic and acetic acids, the former predominating.

Ether Soluble Acids.—The combined ether extracts from five kilos of "sand" were evaporated and the residue was fractionally crystallized from water. A difficultly soluble acid, amounting to 0.4 g., melted at 286° and corresponded in optical properties with fumaric acid.

About 0.3 g. of a rather sparingly soluble acid melted at 185°, a mixture with succinic acid showing no depression in melting point. Optical crystallographic examination confirmed its identity with succinic acid.

The more soluble fractions were carefully examined for tricarballylic acid. A few crystals of that acid were identified by optical methods but attempts to isolate the acid in order to obtain a melting point were unsuccessful. Some malic acid, which had been removed by the ether extraction, was found in the soluble fractions, and a little succinic acid, which had remained in solution, was separated, but nothing else was identified. A separation of the barium salts of the more soluble fractions by means of 67% alcohol, in which barium lactate is soluble, was made. The acid recovered from the soluble barium salt did not respond to the Germuth[4] test for lactic acid.

Non–Volatile Acids.—The crude esters from five kilos of "sand" were fractionated six times at 10 mm. and the following fractions were obtained: 1, 127–132° = 384 g. (α_D = −10.6"); 2, 150–160° = 0.9 g.; 3, 170–180° = 2.0 g.; 4, 180–205° = 0.7 g.; 5, 205–210° = 3.0 g.; 6, residue = 6.0 g.; total = 396.6 g.

The hydrazides were prepared from these fractions by adding 1 cc. of hydrazine hydrate to a mixture of 0.7 g. of the ester and 5 cc. of absolute alcohol.

Fraction 1 gave pure I-malic dihydrazide, melting at 179–180°.

Fraction 2 gave an immediate precipitate of a small quantity of hydrazide melting at 173–175" which was not *l*-malic hydrazide as a mixture with that substance gave a sharply depressed melting point. The quantity was very small and no identification was made. Optically it did not correspond with any of the hydrazides available.

On further standing, the filtrate from this fraction deposited a further quantity of hydrazide which did not have a sharp melting point and which could not be purified.

A portion of this fraction, which may contain ethyl tartrate, was saponified, acetic acid was added in slight excess and then 0.2 g. of ammonium I-tartrate and an excess of calcium acetate were added. A small precipitate came down after some time. This was dissolved in hydrochloric acid and a solution of calcium acetate and sodium acetate was added. The precipitate formed, which was very small, was identified by optical methods as calcium racemate, proving the presence of a trace of d-tartaric acid.

Fraction 3 gave an immediate precipitate of a small quantity of the unknown hydrazide melting at 173–175°. On standing overnight the main portion of the hydrazide separated from the filtrate which had been seeded with citric hydrazide, crystals having the appearance of citric trihydrazide forming in clusters on the sides of the tube. The substance melted at 103–105". A mixture with citric trihydrazide (hydrated form) showed no depression in melting point and optical crystallographic examination confirmed its identity.

Fractions 4 and 5 afforded a hydrazide melting at 176–178° and a mixture with malic hydrazide showed no depression. The finding of malic acid in this fraction is anomalous. These higher boiling fractions undoubtedly consist of ethyl acid malate as a result of the incomplete neutralization of a portion of the crude ester with sodium hydroxide.

On saponifying these fractions malic acid was obtained, its identity being proved by its decomposition on heating into maleic acid melting at 130°, and fumaric acid.

Conclusion

The acids of maple sugar "sand" were separated and identified. In addition to 1-malic acid, formic, acetic, fumaric, succinic and citric acids were found. There was evidence of the presence of traces of d-tartaric

---

[4] Germuth, *Ind. Eng. Chem.*, 19,852 (1927).

and tricarballylic acids. A small quantity of an unknown acid represented by a hydrazide melting at 173–175° was found.

ALPHA-FURFURYL AMINES

By J. E. Zanetti and C. O. Beckmann

Received May 15, 1928 Published July 6, 1928

The furfuryl amines have been but little investigated. Wallach[1] was the first to prepare a-furfuryl amine by the reduction of a-furoylnitrile with zinc and sulfuric acid. Tafel[2] prepared it also by the reduction of phenylfurfurazide with sodium amalgam in alcohol solution and Goldschmidt[3] by the reduction of furfuraldoxime. Since then but little work has been done upon them[4] until recently Williams6 prepared the hydrochloride of di-a-furfuryl amine by reducing furfuraldoxime with palladinized animal charcoal and hydrogen.

One of the reasons which has held back synthetic work in this field has been the absence of a convenient method of preparing the 2-methyl halogen furans. Since one of us[6] developed recently a convenient method of preparing a-furfuryl bromide in its ether solution, the ordinary methods of preparing these amines have become applicable.

The synthesis of the mono-, di- and tri-α-furfuryl amines was accomplished by a method similar to that employed in preparing the benzyl amines,[7] namely, by adding a solution of α-furfuryl bromide in ether to absolute alcohol saturated with dry ammonia gas (for details see experimental part). On allowing to stand for several days, a mixture of the three amines was obtained which was then fractionated.

The yields were very poor and considerable amounts of tarry material were obtained. We have been able, however, to prepare the three amines in a pure condition and have identified them by preparing some of their derivatives.

The amines when freshly distilled are colorless, oily liquids with an ammoniacal odor but rapidly turn yellow. They do not crystallize even when cooled in liquid air, passing through stages of increasing thickening

until they finally solidify to a glassy mass with no trace of crystallization. They show the ordinary properties of amines, giving well defined salts and addition compounds with gold and platinum chlorides.

Williams[6] obtained the hydrochloride of di-a-furfuryl amine in what appears to us to be an impure condition. He gives a melting point of 170–172°, whereas we have prepared a product melting at 186–187°. The salt prepared by him was yellow in color whereas ours is pure white. Our chlorine determinations give us a higher chlorine content and a further determination of nitrogen leaves no doubt that our compound was quite pure. We had, moreover, no difficulty in preparing the gold and platinum chloride salts, whereas he states that his hydrochloride reduced the platinum chloride to platinum.

Since a-furfuryl amine has already received considerable attention, we have confined ourselves to the preparation of derivatives of the di- and tri-α-furfuryl amines and merely report the synthesis of the mono-a-furfuryl amine by the new method.

Experimental

Preparation of the Amines.—An ether solution of α-furfuryl bromide was prepared from 80 g. of a-furfuryl alcohol and 80 g. of phosphorus tribromide by the method of Zanetti. The best results were obtained when this was made in two parts. This ether solution was added in small portions with cooling to 1 liter of absolute alcohol saturated with ammonia at 0° (about 100–110 g. of NH_3). The mixture was allowed to stand in the cold for one week. The alcohol and excess ammonia were evaporated under reduced pressure and the residue, consisting of the amine hydrobromides and ammonium bromide and probably some α-furfuryl ethers, was treated with dilute sodium hydroxide in the cold. The mixture was extracted with ether, dried and distilled. α-Furfuryl amine distilled over at 144–146° at 760 mm. Distillation was continued under reduced pressure. During this distillation no attempt was made to separate the secondary and tertiary amines. The distillate, consisting of the two amines with some furfuryl ethers, was dissolved in anhydrous ethyl ether. Dry hydrogen chloride was passed through this solution to precipitate the amine hydrochlorides. These were filtered off and washed with ether; yield about 15 g.

The amine hydrochlorides were dissolved in water, dilute sodium hydroxide added in the cold, the mixture extracted with ether, dried and distilled. The amines were separated by fractional distillation under vacuum. Di-a-furfurylamine boils at 102–103° at 1 mm., tri-α-furfurylamine at 136–138' at 1 mm. The amines are colorless oils which turn yellow on standing. Analyses are recorded in Table I.

TABLE I

ANALYSES

	Amine Calcd.	Amine Found	Hydrochloride Calcd.	Hydrochloride Found	Chloroplatinate Calcd.	Chloroplatinate Found	Chloro-aurate Calcd.	Chloro-aurate Found
Difurfuryl amine	C, 67.80	67.35	Cl, 16.62	16.49	$C_{20}H_{24}O_4N_2PtCl_6$		$C_{10}H_{12}O_2NAuCl_4$	
$C_{10}H_{11}O_2N$		67.37		16.54	Pt, 25.55	25.45	Au, 38.11	37.99
	H, 6.21	6.38	N, 6.56	6.75				
		6.30	M. p., 186–187°					
Trifurfuryl amine	C, 70.04	69.83	Cl, 12.08	12.01	$C_{30}H_{32}O_6N_2PtCl_6$		$C_{15}H_{16}O_3NAuCl_4$	
$C_{15}H_{15}O_3N$		69.98		12.06	Pt, 21.20	21.18	Au, 33.00	33.24
	H, 5.84	6.04	N, 4.77	4.81				
		5.78	M. p., 156–157°					

Preparation of the hydrochlorides.—The amines were dissolved in anhydrous ethyl ether and dry hydrogen chloride was passed through the solution. White crystals precipitated; these were filtered off and washed with ether. They were recrystallized by dissolving in the least amount of absolute alcohol possible and precipitating with anhydrous ether. They are white crystalline compounds. Analyses are recorded in Table I.

Preparation of the **Chloroplatinates.**—The amines were dissolved in small amounts of concd. hydrochloric acid and the theoretical amount of chloroplatinic acid added. Upon stirring and scratching the glass dish, the chloroplatinates crystallized out. The chloroplatinate of the di-a-furfuryl amine crystallized in red crystals, while that of the tri-a-furfuryl amine formed orange crystals. Analyses are recorded in Table I.

Preparation of the **Chloro-aurate.**—The method is the same as for the chloroplatinates. Both chloro-aurates are yellow, crystalline solids.

Summary

1. The mono-, di- and tri-a-furfuryl amines have been prepared in a pure condition and their properties, as well as those of some of their salts, are reported.

NEW YORK CITY

[CONTRIBUTION NO. 44 FROM THE DEPARTMENT OF CHEMICAL RESEARCH, PARKE, DAVIS AND COMPANY]

NEW DERIVATIVES OF BARBITURIC ACID

BY ARTHUR W. DOX AND EDWARD G. JONES

RECEIVED MAY 16, 1928 PUBLISHED JULY 6, 1928

Although more than sixty 5,5-dialkyl and 5,5-arylalkyl derivatives of barbituric acid, exclusive of homologs with further substitution on the nitrogen or substitution of oxygen or halogen in one or both of the alkyls, have been described, their variations in hypnotic potency and type of action are sufficient to warrant the preparation of additional members of the series as new alkyl halides become available. Among the alcohols which until very recently have not been obtainable for the preparation of halides required for such syntheses are tetrahydrofurancarbinol and n-amyl alcohol. The present paper describes the preparation of certain 5,5-disubstituted barbituric acids containing a tetrahydrofuranmethyl or a n-amyl group.

Tetrahydrofuranmethyl Bromide.—The alcohol used was a pure preparation supplied by the Miner Laboratories of Chicago. Although this alcohol, in contrast to the non-hydrogenated furancarbinol, is quite stable under ordinary conditions of light, air and moisture, it was found to be unstable to mineral acids, in the presence of which it showed a strong tendency to form tarry products. For this reason the yields of bromide obtained by treatment with hydrobromic acid, with or without sulfuric acid, or with phosphorus tribromide were small. The best yield of bromide thus far obtained was only 25%. It is not improbable that the yield might be much improved by suitable modifications of the usual methods of preparing alkyl bromides. The product was a colorless liquid with the odor characteristic of alkyl bromides and a boiling point of 168–170° at 744 mm.

Anal. (Carius). Subs. 0.2561: AgBr, 0.2943. Calcd. for C_5H_9OBr: Br, 48.48. Found: 48.90.

Ethyl Ethyltetrahydrofuranmethylmalonate.—The ordinary malonic ester synthesis was performed, using molecular proportions of the bromide just described, ethyl ethylmalonate and sodium ethoxide in absolute alcohol. The product was a colorless, oily liquid with faint, fruity odor and boiled at 155–157° at 12 mm.

Anal. Subs., 0.1777: CO_2, 0.4104; H_2O, 0.1426. Calcd. for $C_{14}H_{24}O_5$: C, 61.76; H, 8.82. Found: C, 62.98; H, 8.98.

Ethyltetrahydrofuranmethylbarbituric Acid.—The well-known Fischer and Dilthey synthesis, whereby the ester is condensed with urea in the presence of sodium ethoxide in absolute alcohol under pressure, gave a 75% yield of the disubstituted barbituric acid, which after recrystallization from dilute alcohol melted at 190°. The melting point is very close to that of barbital (191°) but a mixed melting point of the two substances showed a depression of 41°. The substance is rather more soluble in water than barbital and crystallizes in flat needles of much the same appearance.

Anal. (Kjeldahl). Subs., 0.1765: cc. of 0.1 N acid, 14.92. Calcd. for $C_{11}H_{16}O_4N_2$: N, 11.67. Found: 11.80.

Ethyl *n*-Amylmalonate.—The n-amyl bromide required for this synthesis has already been described in the literature. We prepared it from n-amyl alcohol supplied by the Sharples Solvents Corporation, using the hydrobromic–sulfuric acid method and collecting the fraction boiling at 127–131°. The malonic ester synthesis was performed in the usual way. Disregarding intermediate fractions which were not subjected to further fractionation, we obtained a yield of 62% of ethyl a-amylmalonate boiling at 134–136° at 14 mm. The ester is a colorless, oily liquid with a faint, fruity odor.

Anal. Subs., 0.2115: CO_2, 0.4812; H_2O, 0.1822. Calcd. for $C_{12}H_{22}O_4$: C, 62.6; H, 9.5. Found: C, 62.05; H, 9.64.

***n*-Amylmalonamide.**—Like most mono-alkylated malonic esters where the alkyl is primary, the above ester forms an amide when shaken for several days with an excess of concentrated aqueous ammonia. The amide crystallizes from dilute alcohol in very small needles which mat together on the filter into a felt. It is practically insoluble in water and in ether, readily soluble in alcohol and melts at 206°.

Anal. (Kjeldahl). Subs., 0.1799: cc. of 0.1 N acid, 20.70. Calcd. for $C_8H_{16}O_2N_2$: N. 16.28. Found: 16.11.

***n*-Amylchloromalonamide.**—This derivative was of particular interest to the writers because it represents the missing member in an homologous series on which some interesting observations had been made on sweet and bitter taste.[1] n-Amylmalonamide was dissolved in glacial acetic acid and a slow current of chlorine passed in until the solvent had taken on a yellow color. The solvent was then removed by distillation under diminished pressure and the residue treated with water. The white crystals which separated were then washed with water and recrystallized from dilute alcohol. The product resembles in appearance the non-chlorinated amide, but melts at 134–135° and has an intensely sweet taste. A 0.005% aqueous solution showed the same degree of sweetness as a 2% sucrose solution.

Anal. (Carius). Subs., 0.1841: AgCl, 0.1286. (Kjeldahl.) Subs., 0.1793, 0.1949: cc. of 0.1 N acid, 17.21, 18.81. Calcd. for $C_8H_{15}O_2N_2Cl$: Cl, 17.19; N, 13.56. Found: Cl, 17.27; N, 13.44, 13.51.

---

[1] Dox and Houston, THIS JOURNAL, 46, 1278 (1924).

In one preparation in which chlorine was passed in for several hours the product melted at 106° and contained 22.25% of chlorine. Evidently a partial chlorination of the a-carbon of the amyl group had also occurred. The product had, however, approximately the same degree of sweetness as the pure substance on which the correct analysis was obtained.

n-Amylbarbituric Acid.—This was prepared by condensation of ethyl n-amylmalonate with urea in the presence of sodium ethoxide. After recrystallization from dilute alcohol it was obtained in flat, needle-shaped crystals melting at 215°.

Anal. Subs., 0.2027, 0.2086: cc. of 0.1 *N* acid, 20.52, 21.05. Calcd. for $C_9H_{14}O_3N_2$: N, 14.19. Found: 14.17, 14.13.

Ethyl Di-*n*-Amylmalonate.—From the higher boiling residue remaining from the preparation of ethyl n-amylmalonate described above, a small amount of a fraction boiling at 158–161° at 11 mm. was collected. This was a fairly pure di-amyl derivative as shown by analysis and by the preparation of the corresponding barbituric acid described below.

Anal. Subs., 0.2423: CO_2, 0.5948; H_2O, 0.2277. Calcd. for $C_{17}H_{32}O_4$: C, 68.00; H, 10.67. Found: C, 66.95; H, 10.51.

Di-*n*-Amylbarbituric Acid.—The usual method of condensing the ester with urea was employed. The free acid separated first as an oil which gradually solidified. After several recrystallizations from dilute alcohol it showed a constant melting point of 118".

Anal. (Dumas). Subs., 0.1529: N_2, 15.5 cc. at 27° and 740 mm. Calcd. for $C_{24}H_{24}O_3N_2$: N, 10.47. Found: 10.89.

Ethyl *n*-Amylethylmalonate.—This was prepared from ethyl ethylmalonate, n-amyl bromide and sodium ethoxide in absolute alcohol. Without attempting to work up intermediate fractions, the yield of pure product was 56%. The ester boils at 139–141° at 14 mm.

Anal. Subs., 0.2080: CO_2, 0.4922; H_2O, 0.1874. Calcd. for $C_{14}H_{26}O_4$: C, 65.12; H, 10.08. Found: C, 64.54; H, 10.08.

n-Amylethylbarbituric Acid.—This acid was obtained in 93% yield by condensation of the above ester with urea by means of sodium ethoxide in absolute alcohol under pressure. The sodium salt is soluble in alcohol, and when the solution is acidified the free acid separates first as an oil which gradually solidifies to well defined crystals. After recrystallization from dilute alcohol the melting point was 135°.

Anal. (Dumas). Subs., 0.2174: 23.6 cc. of N_2 at 24° and 751 mm. Calcd. for $C_{11}H_{18}O_3N_2$: N, 12.39. Found: 12.03.

The three disubstituted barbituric acids described above were subjected to preliminary tests for hypnotic action by administering the sodium salts intraperitoneally to white mice. The di-n-amyl derivative was found to be practically inert, the ethyltetrahydrofuranmethyl derivative showed some hypnotic action when given in sufficiently large doses, whereas the n-amylethyl derivative appeared to be a very effective hypnotic with a potency several times that of barbital. The n-amylethyl derivative now completes the series of homologous 5,5-ethyl-*n*-alkylbarbituric acids in which the n-alkyl is methyl to n-heptyl, inclusive. The physiological tests were performed by Dr. A. M. Hjort of the Dartmouth Medical School, who will report more in detail elsewhere.

Summary

New 5,5-disubstituted barbituric acids described in this paper are the ethyl-n-amyl, the di-n-amyl and the ethyltetrahydrofuranmethyl derivatives. The first of these is an effective hypnotic with several times the potency of barbital. n-Amylchloromalonamide, prepared from one of the intermediates, is remarkable for its intensely sweet taste, which is estimated to be about 400 times as powerful as that of ordinary sugar.

THE ACTION OF BROMINE ON BETA-PHENYL BENZALACETOPHENONE

BY R. BARRÉ AND E. P. KOHLER

RECEIVED MAY 31, 1928 PUBLISHED JULY 6, 1928

For reasons that need not be specially considered here, it became desirable to secure an unsaturated ketone which has bromine in the α-position and which is too highly substituted to combine readily with other substances. It was decided, therefore, to study anew the action of bromine on β-phenyl benzalacetophenone.

Dilthey and Last[1] seem to be the first to try the action of bromine on this particular ketone and surprisingly enough they stated that no addition took place. The action of chlorine gave them a substance which they thought was a condensation product between the dichloride of phenyl benzalacetophenone and the unchanged ketone. This substance was not analyzed and was not investigated further.

Vorlander, Osterburg and Meye,[2] studying the action of bromine on this same ketone (obtained by the same method employed by Dilthey and Last), observed an evolution of hydrogen bromide and after repeated crystallizations from alcohol obtained a product which when slowly heated melted at 121° and when heated rapidly melted at 165°. This product gave them a percentage of bromine corresponding to α-bromo-β-phenyl benzalacetophenone. An attempt to remove the bromine atom by potassium hydroxide solutions failed and the substance was not further investigated.

Moureau, Dufraisse and Mackall,[3] who had obtained β-phenyl benzalacetophenone by isomerization of triphenylethinyl carbinol, studied the action of bromine on that ketone in their endeavor to identify it.

They found that, upon exposure to light, the chloroform solution of the ketone gave with bromine a colorless compound which melted at 130–

---

[1] Dilthey and Last, J. *prakt. Chem.*, 94, 50 (1916).

[2] Vorlander, Osterburg and Meye, Ber., 56, 1136 (1923).

[3] Moureau, Dufraisse and Mackall, Bull. *soc. chim.*, (4) 33, 937 (1923).

131° and had a bromine percentage corresponding to the mono-bromo derivative. In the dark, they obtained two products: one which melted at 90–96° and which they were unable to obtain in a state of purity sufficient for analysis, and another which melted at 183–184° and which gave a slightly lower percentage of bromine than that required for a monobromo derivative (21.2 instead of 22.0).

While they were engaged in that work they learned through a publication of another author that the ketone with which they were working was β-phenyl benzalacetophenone, and then apparently abandoned the study of its bromination.

It became desirable to investigate anew the action of bromine on this highly substituted ketone, which was prepared by the same method employed by Dilthey and Last.[4] The results published in this paper differ materially from the results obtained by the preceding chemists.

The action of bromine on β-phenyl benzalacetophenone gives chiefly two products, the respective amounts of which vary with the conditions of the bromination. If the chloroform solution of the unsaturated ketone is refluxed immediately after the addition of the bromine so that the hydrogen bromide which is formed is removed, the product is a-bromo-@-phenyl benzalacetophenone, which is obtained in a 90% yield.

$$(C_6H_5)_2C{=}CHCOC_6H_5 + Br_2 \longrightarrow (C_6H_5)_2C{=}CBrCOC_6H_5 + HBr$$

This compound is a colorless solid melting at 88–89'. Reduced by acetic acid and zinc, it gives diphenyl propiophenone—identified by mixed melting point with diphenyl propiophenone obtained by the reduction of β-phenyl benzalacetophenone itself.

$$(C_6H_5)_2C{=}CBrCOC_6H_5 + Hz \text{ --+ } (C_6H_5)_2CH{-}CH_2{-}COC_6H_5 + HBr$$

Along with the α-bromo β-benzalacetophenone, a small quantity of material of higher melting point has been obtained but not in a sufficient quantity to determine its structure. This compound gives on microanalysis percentages of carbon and hydrogen close to those required by the α-monobromo derivative. The investigation of this substance will be continued.

If the bromination is performed by adding the bromine to a solution of the ketone in chloroform or in ethyl bromide and the reagents are allowed to stand at room temperature for a period of at least fifteen hours, a new product is formed together with α-bromo-β-phenyl benzalacetophenone. This new substance separates from petroleum ether in yellow crystals which melt at 104–105°; it dissolves in hot alcohol forming a solution that on cooling deposits colorless crystals which melt at 130–131°. The compound which melts at 104–105° has the formula $C_{21}H_{14}Br_2$ and the compound which melts at 130–131° the formula $C_{23}H_{19}OBr$; it may be seen immediately by the inspection of these formulas that the compound which

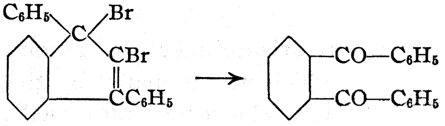
---

[4] Action of phenyl magnesium bromide on dibenzoyl methane and dehydration of the resulting carbinol.

melts at 130–131° is the ethoxy derivative of the compound which melts at 104–105°, and that this in turn is formed by the loss of a molecule of water from α,β-dibromo-β-diphenyl propiophenone.

$$(C_6H_5)_2C{=}CHCOC_6H_5 + Br_2 \longrightarrow (C_6H_5)_2CBrCBrHCOC_6H_5 \xrightarrow{-H_2O} C_{21}H_{14}Br_2$$

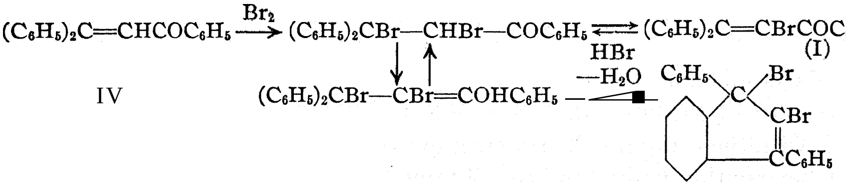
The structure of this particular dibromide was determined by ozonization; the only product obtained was o-dibenzoyl benzene, identified by mixed melting point with an authentic sample. The formation of this diketone leaves no doubt that the dibromide is 1,2-dibromo-1,3-diphenyl indene.



II III

That the substance which melts at 130–131° is the ethoxy derivative of the dibromide was confirmed by the fact that o-dibenzoyl benzene is also found during its ozonization.

It is also possible to obtain 1,2-dibromo-1,3-diphenyl indene from the α-bromo-β-phenyl benzalacetophenone by the action of hydrogen bromide in glacial acetic acid. The fact that the dibromo indene derivative is formed from both the original ketone and its mono-bromo derivative leads to the following supposition concerning the mechanism of the reaction:



VI II

First the unsaturated ketone (IV) would be expected to react with a molecule of bromine to form a dibromide (V). This dibromide (V) which contains a bromine atom linked to a carbon atom which also holds the two phenyl groups is very unstable and loses hydrogen bromide very easily. The loss of hydrogen bromide from the dibromide is reversible as is shown by the fact that the dibromo indene (II) is also obtained from a-bromo-β-phenyl benzalacetophenone by the action of hydrogen bromide. Since hydrogen bromide is also a dehydrating agent, the formation of the indene derivative (II) from the enolic form (VI) of the dibromide (V) is easily explained under the conditions of the reaction.

If hydrogen bromide is removed from the solution as soon as it is formed, the direction of the equilibrium will shift toward the exclusive formation of the a-bromo derivative (I). If hydrogen bromide remains in the solution, its dehydrating effect on the dibromide transforms it into the indene derivative and the equilibrium shifts toward the formation of the dibromide (V), which continues its transformation into the indene derivative (II).

The water formed during the reaction may be seen as a cloud when the bromination is performed in chloroform. In ethyl bromide, the water on standing becomes saturated with hydrogen bromide and collects at the bottom of the flask, then being heavier than the solvent.

The 1,2-dibromo-1,3-diphenyl indene is constituted like 1,2,3-bromo triphenyl indene, which readily forms a free radical.[5] Since it has in addition to the active bromine atom which is common to both these substances a less active bromine in place of the phenyl group on the adjoining carbon atom, its behavior toward metals is peculiarly interesting, and experiments designed to establish this behavior are under way.

Experimental Part

Action of Bromine on β-Phenyl Benzalacetophenone in Boiling Chloroform.—To a solution of 10 g. of β-phenyl benzalacetophenone in chloroform was slowly added 6 g. of bromine. The solution was immediately boiled for five hours. When no more hydrogen bromide was evolved, the chloroform solution, washed with hydrogen sodium sulfite and hydrogen sodium carbonate, was dried and the solvent removed under diminished pressure. The resulting oil was crystallized from petroleum ether after decolorizing with charcoal. The yield of α-bromo-β-phenyl benzalacetophenone was **90%.**

α-Bromo-β-Phenyl Benzalacetophenone (I).—This compound forms nearly colorless crystals which melt instantaneously by projection on a mercury bath at 88–89°. Heated before this point, it melts from 80–85°. The substance has a rather inactive bromine atom; it is not ozonized when submitted to a current of 6% ozone for two hours. It is reduced by boiling in moderately dilute acetic acid with zinc dust and forms β,β-diphenyl propiophenone, identified by mixed melting point. It is soluble in ether, chloroform, ethyl bromide, carbon bisulfide and benzene, sparingly soluble in cold alcohol and petroleum ether.

Anal. Calcd. for $C_{21}H_{15}OBr$: C, 69.4; H, 4.1. Found: C, 68.8; H, 4.1. Molecular weight, calcd.: 363. Found (in benzene): 355.

Action of Bromine on **β-Phenyl** Benzalacetophenone in Chloroform at Room **Tem**peratwe.—To a solution of 10 g. of β-phenyl benzalacetophenone in chloroform was added rapidly a solution of 6 g. of bromine in the same solvent; the solution became warm and hydrogen bromide was evolved. The reaction mixture was set aside for fifteen to twenty hours. The excess of bromine and hydrogen bromide was removed by shaking with a solution of hydrogen sodium sulfite and hydrogen sodium carbonate. The solution dried and evaporated under diminished pressure leaves a yellow oil which separates from petroleum ether (containing a little ether) in yellow and white crystals. These crystals are easily separated mechanically when the crystals are allowed to grow slowly. When a pure yellow crystal is on hand, a solution of white and yellow crystals in petroleum ether seeded by this pure crystal deposits only yellow crystals. From the white compound, α-bromo-β-phenyl benzalacetophenone, the yellow compound was obtained by dissolving the unsaturated bromo compound in a saturated solution of hydrogen bromide in glacial acetic acid. When heated a few minutes at 100°, this solution de-

---

[5] Kohler, *Am.* Chem. J., **40,** 220 (1908).

posited a cloudy precipitate which was redissolved by adding a few drops of glacial acetic acid. The solution, seeded, deposited on standing the dibromo indene derivative.

1,2-Dibromo-1,3-diphenyl Indene **(II).**—This compound separates from petroleum ether in well defined characteristic pyramids which are easily recognized. It melts at 104–105° and is stable. With cold concentrated sulfuric acid, it gives a yellow solution which turns to intense red when heated. It has an active bromine and reacts easily with boiling alcohol, forming the corresponding ethoxy derivative. It is soluble in all organic solvents, less soluble in petroleum ether.

Anal. Calcd. for $C_{21}H_{14}Br_2$: C, 59.1; H, 3.3; Br, 37.6. Found: C, 59.0; H, 3.3; Br. 37.9.

Ozonization of 1,2-Dibromo-1,3-diphenyl Indene.—A solution of 2 g. of the dibromo indene in ethyl bromide was ozonized in a current of ozone for two hours; bromine was evolved and the solution became redder and redder. At the end of this time the solution was treated with cold water and the solvent was removed. The resulting oil was boiled with water to insure the decomposition of the ozonide. The oil was taken up in ether and the ethereal solution, washed with an hydrogen sodium carbonate solution, was dried and evaporated. After decolorizing with charcoal, a colorless, crystalline substance separated from alcohol and melted at 145–146°. The substance is free from bromine.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.9; H, 4.9; molecular weight, 286. Found: C, 83.8; H, 5.2; molecular weight (in benzene), 290.

This compound was found to be o-dibenzoyl benzene, which melts at 146° and was identified by mixed melting point.

1-Ethoxy-2-bromo-1,3-diphenyl Indene,  .—When the dibromo indene is boiled with alcohol, the ethoxy compound separates on cooling into colorless crystals which melt at 130–131°.

Anal. Calcd. for $C_{23}H_{19}OBr$: C, 70.8; H, 4.9. Found: C, 70.4, 70.8, 70.6; H, 5.0, 5.1, 5.1.

This compound gives an intensely red coloration with cold concentrated sulfuric acid. By ozonization it gives the same results obtained by the ozonization of the dibromo indene. The insolubility of this compound in cold alcohol makes it a useful derivative for the characterization of 1,2-dibromo-1,3-diphenyl indene.

Summary

It has been shown that the action of bromine on β-phenyl benzalacetophenone gives chiefly two products: α-bromo-β-phenyl benzalacetophenone and 1,2-dibromo-1,3-diphenyl indene. The yield of the two substances depends upon the presence and the concentration of hydrogen bromide which is formed during the bromination. It has also been shown that the action of hydrogen bromide on α-bromo-β-phenyl benzalacetophenone in glacial acetic acid solution gives 1,2-dibromo-1,3-diphenyl indene. This indene derivative offers special interest because it contains two bromine atoms, one of which is very active, and thus should give free radicals. Investigations on this matter are in progress.

DI-TERTIARY-BUTYLTETRAPHENYLETHANE

BY JAMES B. CONANT AND NEWELL M. BIGELOW

RECEIVED JUNE 1, 1928 PUBLISHED JULY 6, 1928

A study of dialkyl dixanthyls[1] has shown the effectiveness of secondary alkyl groups in promoting the dissociation into free radicals of derivatives of dixanthyl. The close relationship between dixanthyl and tetraphenylethane would lead one to expect that the substitution of secondary and tertiary groups in this hydrocarbon would give rise to compounds with a dissociable carbon to carbon linkage. Only two such compounds have been reported in the literature. One, dicyclohexyltetraphenylethane, was prepared by Ziegler[2] in an impure condition in the course of his extensive study of dialkyl-tetraphenylethanes. Its behavior toward oxygen and halogens indicated that it contained a reactive carbon to carbon linkage. The author reported these results with some reserve because of the difficulty of obtaining an analytically pure sample and because the cleavage with sodium-potassium alloy and carbon dioxide did not result in the formation of the expected diphenylcyclohexylacetic acid. The other compound, di-*tert*.-butyltetraphenylethane was mentioned in a paper by Schlenk,[3] who stated that it did not have the "Dissoziations fahigkeit" of the hexa-aryl ethanes. This statement is surprising both in view of Ziegler's results and those obtained in this Laboratory with dixanthyl derivatives.

Schlenk prepared his compound by the action of molecular silver on a chloride, $(C_6H_5)_2CC_4H_9Cl$, which melted at 103–106°; no description of the ethane was given beyond a statement of its method of preparation.

The identity of Schlenk's hydrocarbon is very questionable. Marvel[4] has shown that the chloride which Schlenk employed is $(C_6H_5)_2C(CH_3)$-$CCl(CH_3)_2$, since it can be prepared by the addition of hydrogen chloride to diphenyl-3,3-methyl-2-butene-1 $(C_6H_5)_2C(CH_3)_2C(CH_3)=CH_2$. The structure of this hydrocarbon was definitely established. Mme. Ramart-Lucas[5] had previously shown that two isomeric chlorides may be obtained from *tert*.-butyldiphenylcarbinol. The lower melting (71–72°) is obtained directly from the carbinol at room temperature by the action of thionyl chloride; the other is obtained by dehydrating the carbinol and adding hydrogen chloride to the unsaturated hydrocarbon. The higher melting chloride may also be obtained by heating the carbinol with acetyl chloride

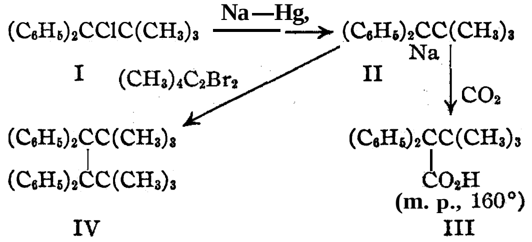
(Schlenk's method); its formation in this case involves a Wagner rearrangement. Marvel attempted the preparation of di-*tert.*-butyltetraphenylethane from the low melting chloride but obtained only diphenyl-3,3-methyl-2-butene-1.

Since *tert.*-butyldiphenylchloromethane (I) (m. p. 71–72") easily undergoes rearrangement to the isomeric chloride, it is obviously necessary to use some reagent to remove the chlorine atom which will act very rapidly at low temperature. Forty per cent. sodium amalgam or a large excess of sodium-potassium alloy are both effective; the former is much more convenient. When a 20% solution of the low melting chloride is shaken in dry ether in nitrogen with either of these reagents at 0–10°, a vigorous reaction ensues and a brick red, metallic derivative (II) is soon formed. This metallic derivative may be isolated in the usual manner. On treatment with carbon dioxide it yields an acid (m. p. 160°) whose analysis and molecular weight (determined with the p-nitrobenzyl ester) correspond to *tert.*-butyldiphenylacetic acid (III). The metallic derivative may be coupled to the corresponding ethane by treating with tetramethylethylene dibromide (Ziegler's procedure). The substance obtained is very sensitive to oxygen and must be manipulated by the procedure employed in handling dissociable ethanes. It is a colorless solid (m. p. 138–141") whose analysis and molecular weight correspond to di-*tert.*-butyltetraphenylethane (IV). On shaking an ethereal solution of this hydrocarbon with 40% sodium amalgam, a brick red metallic derivative was formed which with carbon dioxide yielded *tert.*-butyldiphenylacetic acid (m. p. 160°).



$$\begin{tikzcd}

\end{tikzcd}$$

I II IV III

It is important to establish that the red metallic derivative formed from the low melting chloride is really a primary product of the reaction of this chloride and is not derived from the isomeric chloride which might be the result of a rearrangement. It was found that the high melting chloride when shaken with sodium-potassium alloy in ether yields a metallic derivative which is entirely different from that produced from the low melting isomer. Both the high melting chloride and the corresponding unsaturated hydrocarbon (diphenyl-3,3-methyl-2-butene-1) form the same dark red potassium compound. On treating with carbon dioxide this yields an acid of the same composition as *tert.*-butyldiphenylacetic acid but with entirely different properties (m. p. 217° as compared with 160°). No crystalline esters could be prepared for molecular weight determinations. An amorphous p-nitrobenzyl ester showed a molecular weight double that of the corresponding ester of *tert.*-butyldiphenylacetic acid; this indicates that the acid in question has the formula $C_{36}H_{40}O_4$. On treating with Ziegler's reagent or mercuric chloride, an oil is obtained which is not sensitive to oxygen. On treatment with sodium-potassium alloy, this oil regenerates the dark red metallic derivative as shown by the action of carbon dioxide, which yields the acid melting at 217°.

Thus, in its color and all its reactions, the metallic derivative formed from the high melting chloride or unsaturated hydrocarbon differs from the substance which is formed from the low melting chloride. This fact eliminates the possibility that the product formed by the action of sodium-potassium alloy or sodium amalgam on the true *tert.*-butyldiphenylchloromethane (low melting chloride) may be derived from its rearrangement products. We have not yet completed our study of the action of sodium-potassium alloy on the high melting chloride and will reserve for another paper a further discussion of this interesting reaction.

If an insufficient amount of sodium-potassium alloy is employed in the preparation of potassium *tert.*-butyldiphenylmethyl, the yield is much lowered and about half of the chloride is converted into a hydrocarbon isomeric with di-*tert.*-butyltetraphenylethane. The substance is not sensitive to oxygen and does not react with sodium-potassium alloy in ether after twelve hours' shaking. It seems probable that this hydrocarbon is comparable to Chichibabin's hydrocarbon (*p*-benzhydryltetraphenylmethane) which is formed by the action of metallic sodium on triphenylchloromethane.[6] The use of a 40% sodium amalgam (a liquid) avoids its formation and it is for this reason that this reagent is preferable to sodium-potassium alloy.

Properties of Di-*tert.*-butyltetraphenylethane

The new hydrocarbon is very similar in its reaction to dibenzyldixanthyl and it is clear that it contains a very labile carbon to carbon linkage. Thus, at 20" in bromobenzene it absorbs the theoretical amount of oxygen in four minutes but no peroxide could be isolated. At the same temperature it reacts with 40% sodium amalgam in benzene and ether at an appreciable rate, but not with 1% amalgam in ether; this behavior classes it with the primary alkyl dixanthyls and distinguishes it from ethanes such as hexaphenylethane[7] which are considerably dissociated in solution at room temperature. Even its dilute solutions were only very faintly colored at 25°; the difference between the slight colors of a 0.0125 molar

---

[6] Schlenk and Marcus, ***Ber.***, 47, 1664 (1914).

[7] Conant and Garvey, **THIS** JOURNAL, **49**,**2599** (1927).

solution at 30° and 0" however, was definite. A 0.05 molar solution on warming to 50° became lemon yellow; on cooling the color faded. This could be repeated a number of times. At 100° the color was brighter and seemed to represent the maximum, since a similar experiment at 130° gave no deeper shade. If the solutions are kept at 100° or higher for more than a few minutes they acquire an orange-yellow color which does not fade on cooling. This permanent color is apparently connected with the rapid decomposition of the ethane at elevated temperatures. This decomposition was studied by molecular weight determinations by the freezing point method in *p*-chlorotoluene (in the complete absence of oxygen). Six minutes' heating at 100° of a 5% solution was sufficient to lower the apparent molecular weight from 390 to 266 and twelve minutes at the same temperature lowered it to 227 (theoretical value for complete cleavage 223); further heating was without effect. We have not been able to isolate and identify the products of this thermal decomposition but it is presumably a disproportionation reaction; this reaction seems to be characteristic of free radicals which contain alkyl groups attached to the methyl carbon atom.

A comparison of the facts summarized above with the well-known behavior of hexaphenylethane shows that the tertiary butyl group is somewhat less effective than the phenyl group in promoting dissociation. At room temperature the dilute solutions of di-*tert.*-butyltetraphenylethane must contain less than a few per cent. of the free radical; at 50°, however, the amount of the dissociated form is certainly appreciable. As a rough basis of comparison, we estimate that in a 0.05 molar solution the following substances are just appreciably dissociated (a few per cent.) at the following temperatures: hexaphenylethane, 0"; di-*iso*propyldixanthyl, 0"; di-*tert.*-butyltetraphenylethane, 50"; dibenzyldixanthyl (and di-isobutyl dixanthyl), 75°; dibutyldixanthyl, 130°. If the temperature coefficient of the logarithm of the equilibrium constant is nearly alike for all these substances, these temperatures are a measure of the relative free energy of dissociation in solution.

It has long been known that the xanthyl group is considerably more effective than two phenyl groups in causing dissociation. The fact that di-*iso*propyldixanthyl is appreciably dissociated at 0° and di-tert.-butyltetraphenylethane only at 50° is thus consistent with the idea that secondary and tertiary alkyl groups are approximately equivalent in their dissociating influence. Unfortunately no facts are as yet available which enable us to make a direct comparison of these two classes of alkyl groups. It may be pointed out in conclusion that the somewhat greater influence of the phenyl group as compared to the tertiary butyl group may not reside in the unsaturated nature of the phenyl group. If the presence or absence of hydrogen atoms in the α- and β-positions are a determining factor, one should really compare the phenyl group with such a tertiary group as $C(CH(CH_3)_2)_3$. The accumulation of evidence in recent years certainly points to the conclusion that the lability of a carbon–carbon linkage is to a large extent a function of the branching of the carbon chain with the corresponding elimination of hydrogen atoms in critical positions.

Experimental Part

***Tert.*-butyldiphenylcarbinol** and ***Tert.*-butyldiphenylchloromethane.**—The carbinol was prepared by three different methods: by the reaction of *tert.*-butylmagnesium chloride on benzophenone, by the reaction of phenylmagnesium bromide on trimethylacetophenone and by the reaction of phenylmagnesium bromide on ethyl trimethylacetate.[3,4] The latter method proved the most satisfactory. The preparation of the chloride followed the directions of Mme. Ramart-Lucas.[5] From 10 g. of carbinol and 6.0 g. of thionyl chloride, 8.5 g. of chloride melting at 71° was obtained; at no time in the preparation was the material heated above room temperature.

Preparation of *Tert.*-butyldiphenylmethyl Sodium.—Five grams of the low melting chloride was dissolved in 25 cc. of dry ether in a side-arm test-tube and to this solution was added 10 cc. of 40% sodium amalgam. The air in the test-tube was replaced with pure nitrogen and the tube shaken by hand, with frequent cooling in an ice-bath. The reaction was very brisk, heat was given off and a gray suspension of sodium chloride was rapidly formed. In about five minutes the characteristic brick red color of the sodium derivative appeared. This grew rapidly deeper and the solution became quite thick. The tube was then shaken for about twelve hours on a machine. The sodium derivative is somewhat soluble in ether but is almost insoluble in petroleum ether; it may be partially purified by washing with this solvent.

Tert.-butyldiphenylacetic Acid.—The sodium compound formed from 5 g. of low melting chloride was decomposed with carbon dioxide and the acid isolated in the usual manner. The freshly precipitated, amorphous acid tended to sinter together into a gummy mass; hence the precipitation, washing and filtration were done in chilled solutions and as rapidly as possible. The yield of crude acid was 3 g., about 60%. The acid may be recrystallized from a mixture of methyl alcohol and water. It melts at 160°.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.4. Found: C, 80.6, 80.3; H, 7.5, 7.4.

Combining weight with NaOH. Calcd. for $C_{28}H_{20}O_2$, 268. Found: 271. 264, 268.

***p*-Nitrobenzyl** Ester.—The *tert.*-butyldiphenylacetic acid was converted into the *p*-nitrobenzyl ester by warming for one hour on the steam-bath an alcoholic solution of the sodium salt with *p*-nitrobenzyl bromide. The ester was recrystallized from alcohol; it melted at 77°; 1.6 g. of acid yielded 1.5 g. of ester.

Anal. Calcd. for $C_{25}H_{25}O_4N$: C, 74.4; H, 6.25. Found: C, 74.2; H, 6.5.

Mol. *Wt.* (by the cryoscopic method in benzene). Benzene, 9.39 g.; calculations from the second increment. Subs., 0.1949: $At = 0.274°$, m. w. = 388; subs., 0.1595, $At = 0.222°$, m. w. = 392. Calcd. for $C_{25}H_{25}O_4N$: 403.

Di-*tert.*-butyltetraphenylethane, $C_4H_9(C_6H_5)_2CC(C_6H_5)_2C_4H_9$.—The preparation of the sodium derivative was carried out in a 500-cc. round-bottomed flask to which a side tube and stopcock were attached at right angles to the mouth. The side tube is bent below the stopcock at 45°. In this flask 5 g. of the low melting chloride was dissolved in 50 cc. of dry ether and 15 cc. of 40% sodium amalgam was added. In the mouth of the flask was placed a cloth filter backed by copper gauze, the filter being held in place by a cork ring which fitted tightly into the neck of the flask. The mouth of the tube was closed by a one-holed rubber stopper fitted with a glass stopcock.

The air in the flask was removed by evacuation and replacement with pure, dry nitrogen; the flask was shaken vigorously by hand, with cooling in ice as necessary. In about five minutes the red color of the sodium derivative appeared, the suspension in the flask becoming quite thick. At this point the shaking was carried on in a shaking machine; this was continued for about sixteen hours.

At the end of this time the reaction was considered complete; the excess amalgam was removed by suction through the side arm. Twenty-five cc. of low boiling petroleum ether was added to decrease the solubility of the sodium derivative, the mother liquors were removed by filtration with suction through the cloth filter and the filter cake was washed with petroleum ether. The flask was immersed in an ice-bath with the rubber stopper uppermost and 25 cc. of dry ether sucked in through the filter. Tetramethyl ethylene bromide (1.5–2.5 g.) dissolved in 10 cc. of dry ether was then added in small portions with constant shaking. The course of the reaction was followed by the change of color from red to colorless.

The colorless solution of the ethane was filtered from the sodium bromide in an atmosphere of nitrogen. The solution was concentrated by evaporation under diminished pressure until crystals of the ethane began to form. An equal volume of petroleum ether was added and the crystallization of the ethane made as complete as possible by cooling to $-10°$. The crystals were filtered off in an atmosphere of nitrogen, washed with small quantities of petroleum ether and dried at room temperature in a stream of nitrogen. The apparatus was then opened to the air and the solid transferred to a Fischer pistol in which it was kept in an atmosphere of nitrogen. All the manipulations except the final transfer were carried out in an atmosphere of nitrogen carefully freed from oxygen and moisture. A slight modification of the usual type of apparatus employed in such work made possible the filtration from the sodium bromide and the crystallization of the ethane.

The ethane was recrystallized from a mixture of ether and petroleum ether in an atmosphere of nitrogen. It melted at 138–141° in nitrogen to a red melt; in air it melts at 40–50°. It is stable indefinitely in the dark under pure dry nitrogen and is not affected by subdued daylight. In the air the dry crystals become slightly sticky in about a half hour, and in twelve to eighteen hours it turns into a sticky brown mass. The weight of the sample decreases during this process; in sixteen hours the sample loses about 2% of its original weight. In two instances the crystals, on being removed from the recrystallizing machine, decomposed almost instantaneously to a yellow oil; white fumes smelling something like benzophenone were given off, and the oil became too hot to touch. The whole yield did not undergo this decomposition; the unchanged powder, guarded from contact with the oil, usually, although not always, did not decompose, but if any part of a sample came in contact with the oil, it decomposed in turn. This decomposition may be due to impurities or to moisture. In one of the cases in which the formation of the oil occurred, the sample had been dried for only a half hour; however, a small sample of the pure ethane slightly moistened with petroleum ether did not decompose on short exposure to air.

Anal. Calcd. for $C_{34}H_{38}$: C, 91.4; H, 8.6. Found: C, 90.6, 91.6; H, 8.5, 9.0.

Molecular weight (cryoscopic in an atmosphere of nitrogen). (a) Benzene (8.08 g. of solvent). Subs., 0.0766 g.: $\Delta t = 0.125°$, mol. wt. = 372; subs., 0.1491, $\Delta t = 0.205°$, mol. wt. = 440.

(b) In *p*-chlorotoluene (10.7 g.) (first increment disregarded). Subs., 0.2106 g.: $\Delta t = 0.272°$, mol. wt. = 404; subs., 0.1769 g.; $\Delta t = 0.222°$, mol. wt. = 418. Calcd. for $C_{34}H_{38}$ = 446.

Oxygen Absorptions.—The method used was the same as that employed in the previous work on free radicals in this Laboratory. The bottle containing the bromobenzene solution of the ethane and oxygen was shaken vigorously. The percentage oxygenation was calculated from the weight of the sample and the volume of oxygen corresponding to the formation of a peroxide. A 0.05 molar solution in bromobenzene absorbed oxygen at 14° at the following rate: two minutes, 70%; five minutes, 106%; eight minutes,' 122%; twenty-five minutes, 126%; twenty hours, 165%. These results were reproducible within a few per cent. No peroxide could be isolated from the oxygenation in ether or other solvents.

Cleavage with Alkali Metals,—A determination of the activity of the ethane toward the alkali metals was carried out according to the method previously described." The ethane was rapidly cleaved by sodium-potassium alloy in ether and also in benzene; it was not, however, acted on by 1% amalgam in ether. It was cleaved by 40% sodium amalgam in ether and also in benzene. In all these runs, 0.10 g. (0.00025 moles) of the ethane was placed in a small test-tube with a constricted neck. After the air in the tube had been displaced by pure dry nitrogen, 5 cc. of the solvent and 1 cc. of liquid alloy or amalgam were introduced through a separatory funnel. The tube was then sealed off at the constriction and shaken vigorously by hand for five minutes. In all cases in which color was reported, it developed practically at once; the tube containing the 1% alloy was shaken on a machine for twenty-four hours without the development of color. The metal derivative formed in all these cases, when decomposed with carbon dioxide, yielded the *tert.*-butyldiphenylacetic acid (m. p. 160").

Color Changes on Heating.—A 0.05 molar solution of the ethane in ethyl benzoate in an atmosphere of nitrogen at room temperature showed a faint but definite coloration. When heated for thirty seconds in a water-bath at 50°, a light lemon-yellow color appeared. This color disappeared when the tube was plunged into an ice-bath. This could be repeated several times. A similar solution heated for thirty seconds at 100° was a bright lemon-yellow color; when the tube was immersed in ice and water the color vanished immediately. Heated again at 100" for two and one-half minutes, the color reappeared; on subsequent cooling the color faded but did not entirely disappear, indicating that the latter was due to a different cause. The color at 130° after forty-five seconds was the same shade as at 100". If these solutions are heated to 100° for three hours, the yellow color first formed passes through a brownish-yellow into a bright orange color.

Decomposition of the Ethane in Solution on Heating.—The rate of disproportionation at 100° was measured by the decrease of apparent molecular weight in *p*-chlorotoluene by the cryoscopic method. The apparatus was of special construction and was kept filled with oxygen-free nitrogen. The results are tabulated below; the somewhat low initial molecular weight was probably due to the fact that the sample employed was only crystallized once.

TABLE I

DECOMPOSITION OF THE ETHANE ON HEATING

Sample, g.	Solvent, g.	Heating period Time, min.	Temp., °C.	Freezing point depression, °C.	Apparent mol. wt.
0.4078	10.70	0	20	0.547	390
.5241	10.70	3	100	.880	312
.5241	10.70	6	100	1.032	266
.5241	10.70	9	100	1.146	139
.5241	10.70	12	100	1.208	227
.5241	10.70	17	100	1.221	224
.5241	10.70	22	100	1.212	226

A sample removed at the end of the experiment had no oxygen absorption capacity. When heated to 100" for the first time, a bright yellow color was observed; on cooling this faded slightly but a marked color remained. After the first heating, no variation in color was observed between the hot and cold solutions. No orange color developed.

Isomeric Ethane.—Four and one-half g. of low melting chloride, dissolved in 40 cc. of dry ether, was shaken with 2 g. of sodium-potassium alloy for twenty-four hours. At the end of this time the solution had acquired a light red color. Carbon dioxide was introduced and the *tert.*-butyldiphenylacetic acid obtained in the usual manner. The ethereal layer containing the non-acid material yielded crystals on evaporation. These were washed with a little ether, filtered and recrystallized from alcohol and ether; yield, 1.7 g.; m. p. 145°.

Anal. Calcd. for $C_{34}H_{38}$: C, 91.4; H, 8.6. Found: C, 91.0; H, 8.52.

Mol. wt. by the freezing point method in 9.81 g. of benzene. Subs., 0.2748 g.: $\Delta t = 0.352°$, m. w. = 411; subs., 0.4122 g.: $\Delta t = 0.517°$, m. w. = 419. Calcd. for $C_{34}H_{38}$: m. w. = 446.

The substance did not react with oxygen or with sodium-potassium alloy after twelve hours' shaking in ether.

Potassium Derivative from Isomeric Chloride and from **Diphenyl-3,3-methyl-2-butene-1.**—The unsaturated hydrocarbon (diphenyl-3,3-methyl-2-butene-1) and the corresponding chloride were prepared according to Marvel's directions.[4] When a 20% solution of either of these substances in anhydrous ether was shaken with sodium-potassium alloy (2 g. per 25 cc. of solution), a dark red potassium derivative was formed. This substance was not identical with the red metallic derivative formed from *tert.*-butyldiphenylchloromethane, as the following experiments prove.

(a) Decomposition with Carbon Dioxide.—The suspension of the metallic derivative was treated with carbon dioxide and the acid obtained in the usual manner. It was precipitated from an aqueous solution of its sodium salt by the addition of mineral acid as a white, amorphous solid. The yield was about 32%. It could be recrystallized by solution in methyl alcohol at room temperature, addition of water to incipient turbidity and setting aside; m. p. 218–224° with decomposition.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.5; H, 7.4. Found: C, 80.8, 80.2; H, 7.61, 7.23.

Combining weight with NaOH, calcd. for $C_{18}H_{20}O_2$: 268. Found: 267,258.

The p-nitrobenzyl ester was prepared by the action of p-nitrobenzyl bromide on an aqueous solution of the sodium salt of the acid. The ester was an amorphous yellow powder. All attempts to recrystallize it were unavailing.

Mol. wt. by the micro method in camphor. Subs., 0.0105 g.; camphor, 0.1141 g.: $\Delta t = 5.2°$, m. w. = 705; subs., 0.0273 g.; camphor, 0.1078 g.: $\Delta t = 14.6°$, m. w. = 695. Calcd. for $C_{50}H_{48}O_8N_2$: 804.

Attempts to prepare a crystalline methyl ester and an amide yielded only amorphous, gummy materials.

(b) Decomposition with Tetramethylethylene **Dibromide.**—When the metallic derivative was treated with tetramethylethylene dibromide in the manner described above, the color disappeared. The resulting ether solution on evaporation in nitrogen yielded an oil which failed to crystallize. This oil did not absorb oxygen at any measurable rate in bromobenzene solution. On shaking an ethereal solution of it with sodium-potassium alloy, the dark red metallic derivative was formed. On treating with carbon dioxide, the acid melting at 218–224° was obtained.

Summary

1. Di-*tert.*-butyltetraphenylethane has been prepared from sodium *tert.*-butyldiphenylmethyl. This was formed when the corresponding chloride was treated with a large excess of sodium-potassium alloy or 40%

sodium amalgam. No rearrangement was involved in this reaction since the isomeric chloride was shown to yield an entirely different metallic compound when treated with the alloy.

2. Di-*tert.*-butyltetraphenylethane absorbs oxygen rapidly in solution at 25°. On heating a dilute solution to 55° a reversible color change indicative of dissociation appears. On heating for a few minutes in solution at 100°, in the absence of air, it disproportionates completely. These results show that the effect of the tertiary alkyl group in promoting the dissociation of the carbon linkage is similar to the effect of the secondary groups studied in the dixanthyl series.

RELATIONS BETWEEN ROTATORY POWER AND STRUCTURE IN THE SUGAR GROUP.

XVIII. ALPHA-METHYL d-LYXOSIDE TRIACETATE[1,2]

BY F. P. PHELPS AND C. S. HUDSON

RECEIVED JUNE 8, 1928 PUBLISHED JULY 6, 1928

In Article VII[3] it was assumed that the alpha forms of methyl d-xyloside and d-lyxoside possess the same ring structure and the rotation of the latter was calculated from that of the former by use of the known difference of rotation between the alpha forms of methyl d-glucoside and d-mannoside, which at that time were supposed to have like ring structures. Subsequent results[4] indicated, however, that the glucoside possesses a 1,4-ring and the mannoside a 1,5-ring and consequently in Article XII[5] it was suggested that a-methyl d-lyxoside does not possess the 1,5-ring of methyl d-xyloside but rather a 1,4-ring. The 1,3-ring appeared to be excluded because 1,3-ring glycosides in the mannose and rhamnose series are hydrolyzed very rapidly by dilute acids, whereas a-methyl lyxoside is hydrolyzed far more slowly even by stronger acid solutions. It has now been sought to obtain further evidence on this question of the possibility of a 1,3-ring structure in α-methyl d-lyxoside by examining the behavior of its fully acetylated derivative, a triacetate, toward alkaline saponification. It has been found that the acetates of methyl mannoside[6] and methyl rhamnoside,[7] of the 1,3-ring type, retain one acetyl group (presumably that

attached to carbon atom 2) under conditions of strong alkalinity and it would therefore be supposed that a triacetate of a-methyl lyxoside, of the 1,3-ring type, would behave similarly since the configurations of mannose, rhamnose and lyxose are alike with respect to carbon atoms 1, 2, 3 and 4. The experimental results now to be reported show that the three acetyl groups of a-methyl d-lyxoside triacetate are easily removed by alkali, and we therefore conclude that the ring is not in the 1,3-position. It must, therefore, be a 1,4- or a 1,5-ring if ring 1,2 is excluded as an improbable structure for stable, difficultly hydrolyzable glycosides of the true sugars.

Since the molecular rotation (+ 25,240) of a-methyl d-xyloside of the 1,5-ring type[8] differs from that of a-methyl d-lyxoside ((59.4)(164) = + 9740) by a value (15,500) that is far removed from the "epimeric difference of rotation"[9] (6700) for glycosides, it is concluded that the substances are not epimeric structures and that, therefore, α-methyl d-lyxoside possesses the 1,4-ring. The value now reported ((30.1)(290) = + 8730) for the molecular rotation of the triacetate of this substance leads to the same conclusion, since it differs from that of a-methyl d-xyloside triacetate (+ 34,700) by an amount (25,970) far removed from the epimeric difference of rotation (11,300) for acetylated glycosides.

It becomes possible from the preceding conclusions to calculate the rotations of several members of the d-xylose series of the 1,4-ring type and likewise several of those of the *d*-lyxose series of the 1,5-ring type, by the use of the epimeric difference of rotation. Thus the specific rotation of the unknown a-methyl d-xyloside (*1,4*) is calculated to be (9740 + 6700) ÷ 164 = + 100 in water, and that of its triacetate to be (8730 + 11,300) ÷ 290 = + 69 in chloroform. Likewise the specific rotation of the unknown a-methyl d-lyxoside (*1,5*) is calculated to be (25,240 − 6700) ÷ 164 = + 113 in water, and that of its triacetate to be (34,700—11,300) ÷ 290 = + 80 in chloroform. These calculations can obviously be extended to the a- and β-forms of xylose and lyxose, of both the 1,4- and 1,5-ring types, and to various derivatives of these pentoses other than those just considered. Since the rotation of a-d-lyxose (+ 5.5) differs normally from that of a-methyl *d*-lyxoside,[3,5] it is concluded that this crystalline form of the pentose possesses the 1,4-ring structure.

Experimental

Preparation of α-Methyl d-lyxoside **Triacetate.**—One *g.* of pure α-methyl d-lyxoside ($[\alpha]^{20}_{\mathrm{D}} = +59.4°$ in water) was heated with 6 cc. of acetic anhydride and 3 cc. of dry pyridine for half an hour on the steam-bath. On pouring the solution into ice water a sirup separated and quickly crystallized, yielding 0.9 g. of crystalline triacetate ($[\alpha]_{\mathrm{D}} = +29.2°$ in $CHCl_3$). Extraction of the mother liquor with $CHCl_3$ yielded 0.6

[9] Hudson, THIS JOURNAL, 48, 1439 (1926).

g. of crystals of nearly the same rotation. Three grams of the substance was thus prepared in two experiments. One recrystallization from hot water gave a pure product, the rotation of which was not changed by four subsequent recrystallizations; m. p. 96°. The rotation measurements on the final product are recorded in the table, the tube length being *2* dm. and the solvent being pure chloroform. The angles are in all cases dextro-rotations.

TABLE I

ROTATION OF PURE a-METHYL*d*-LYXOSIDE TRIACETATE IN CHLOROFORM SOLUTION

Concn., g./100 cc. of soln.	Sodium yellow λ = 589		Mercury yellow A = 578		Mercury green λ = 546		Mercury blue X = 436	
	α	$[\alpha]^{20}_{D}$	α	$[\alpha]^{20}_{578}$	α	$[\alpha]^{20}_{546}$	α	$[\alpha]^{20}_{436}$
0.745	+0.438	+29.4	+0.461	+31.0	+0.530	+35.6	+0.705	+61.0
1.307	+ .803	+30.7	+ .838	+32.1	+ .941	+36.0	+1.62	+62.0
1.776	+1.074	**f30.2**	+1.137	+32.0	+1.274	+35.8		
1.908			+1.208	+31.7	+1.358	+35.6	+2.40	**f62.9**
Average		**$30 1**		+31.7		**$35.8**		+62.0

A Zeisel analysis showed **10.4%** of methoxyl **(0.3222 g.** of substance yielded **0.1552** g. of AgCl) in comparison with the value **10.7** required by the formula $C_{11}H_{15}O_7OCH_3$ (m. w., **290).**

An acetyl estimation by the method of Kunz[10] agreed with this formula for a triacetate **(0.2126** g. of substance was equivalent to **21.5** cc. of **0.1** M HCl).

Summary

Pure a-methyl d-lyxoside triacetate has been prepared and it is concluded from a comparison of its rotation with that of a-methyl d-xyloside triacetate that the lyxoside derivative possesses a 1,4-ring structure, and that crystalline a-lyxose ($[\alpha]_D = +5.5$) also has this ring structure since its rotation differs normally from that of a-methyl d-lyxoside.

WASHINGTON, D. C.

NEW BOOKS

A Comprehensive Study of Starch Chemistry. Volume I. Compiled and edited by ROBERT P. WALTON in collaboration with twenty other authors. The Chemical Catalog Company, Inc., **419** Fourth Avenue, New York, **1928. 240** + iv + **360** pp. Illustrated. **18** × **26** cm. Cloth. Price, **$10.00.**

In the introductory paragraph of the Preface the compiler writes: "The most prominent aspects of the subject have been treated by authorities who have contributed significantly to the advancement of the field and who are actively engaged in further investigations or developments." This statement describes adequately the nature of the first part of the book and the material presented in it.

The nineteen papers comprising the symposium and the first *235* pages of the volume range in subject matter from various aspects of the molecular constitution and physical and chemical properties of starches and

---

[10] Kunz and Hudson, THIS JOURNAL, **48,1978 (1926).**

related substances by Pictet, Irvine, Ling, Pringsheim, Samec, Taylor (T. C.), Katz and Sherman, through the role of starch in such industrial processes as bread making and fermentation by Alsberg, again Katz and Fernbach; the manufacture and use of starches, gums and adhesives by Moffett, Preuss, Bloede, Alexander, Nivling and Farrow; and starch-converting enzymes by H. C. Gore and others. The final article is a review of the early development of starch chemistry and manufacture (to 1811) by the editor of the book.

The latter half of the volume comprises an elaborate list of verified references to books and articles on starches, dextrines and amylases that appeared in the period 1811–1925. These are grouped under six general divisions and 46 classifications. Following each reference is a brief "discriminative" abstract or description of the material contained in it, often quoted from abstracts previously published in the literature.

Each of the two parts of this book—the symposium and the bibliography—covers material that is amply sufficient in itself to justify publication. Together they comprise a survey of the field of the starches and their congeners that makes the book of extraordinary value, both to the student and to those trained workers whose activities are concerned with these substances.

WILLIS A. BOUGHTON

Tables of Physical and Chemical Constants and Some Mathematical Functions. By G. W. C. KAYE, D.Sc., Superintendent of the Physics Department, the National Physical Laboratory and T. H. LABY, Sc.D., Professor of Natural Philosophy, University of Melbourne. Sixth edition. Longmans, Green and Company, 55 Fifth Avenue, New York, 1928. iii + 163 pp. 16.5 × 25 cm. Price $4.75.

Except for a table of Isotopes and one of the Thermal Conductivities of Gases, this edition appears to be a reprinting of the fourth and fifth editions (1920 and 1926). The table of atomic weights is that of 1925.

STUDIES OF HYDROGEN ION CONCENTRATION MEASUREMENTS. I. METHODS OF MEASUREMENTS

BY CLARKE E. DAVIS AND GLENN M. DAVIDSON

RECEIVED AUGUST 29, 1927 PUBLISHED AUGUST 4, 1928

Introduction

Beans and Oakes[1] state that their investigation undertaken for the purpose of developing a method of measuring the hydrogen ion concentration of pure water as directly as possible became a problem of developing and applying a new method of measuring potential differences in which the resistance of the circuit would not affect the accuracy of the results, and which at the same time would not require an excessive amount of current for operation. In other words, this new method was to have all the advantages of the potentiometer arrangement with the additional advantage of being independent of the internal resistance of the cell.

It is also stated that the application of such a method would not be limited to the cell mentioned above. This same method could be applied to all concentration cells, finding its greatest use, however, in connection with the measurement of the electromotive force of cells having such a high internal resistance as to render them impossible of measurement so long as the potentiometer method is the only one available. The method so developed consisted of the employment of a high grade condenser, standard cell and ballistic galvanometer. The diagram of the connections is shown in Fig. 1.

A similar method was described by Carhart;[2] Potter,[3] also, describes the condenser method of determining the conductivity of cells of high internal resistance.

Considerable data have been accumulated on acids and bases by Davis, Oakes and Salisbury,[4] where a standard procedure was employed throughout, using the apparatus described by Beans and Oakes.[1]

[2] Carhart and Patterson, "Electrical Measurements," Allyn and Bacon, Boston, 1900, pp. 188–189.

[3] Potter, *Proc. Roy. Soc. London*, 84B, 260–275 (1911–1912).

[4] Davis, Oakes and Salisbury, *Ind. Eng. Chem.*, 15, 182 (1923).

In consideration of the moderate cost of the apparatus as pointed out by Beans and Oakes,[1] a standard Leeds and Northrup condenser, capacity of one microfarad, subdivided into five sections was used by Davis, Oakes and Salisbury.[4] Several anomalies in the data as obtained by Davis, Oakes and Salisbury[4] were noted and reasons suggested for such discrepancies; however, it seemed there were experimental errors in the general ballistic method outlined by Beans and Oakes[1] which have hitherto been overlooked.

The primary purpose, therefore, of this investigation was to test the effectiveness and technique required in electrometrically determining hydrogen ion concentration of a solution by means of the condenser arrangement. It was also our purpose to determine the significance of the individual data obtained by the condenser arrangement and the precision necessary to secure a given accuracy for the resultant electromotive force. In order to secure accuracy of final results, it was necessary to compare directly measurements of electromotive force by the condenser method with those obtained by the standard potentiometer method.

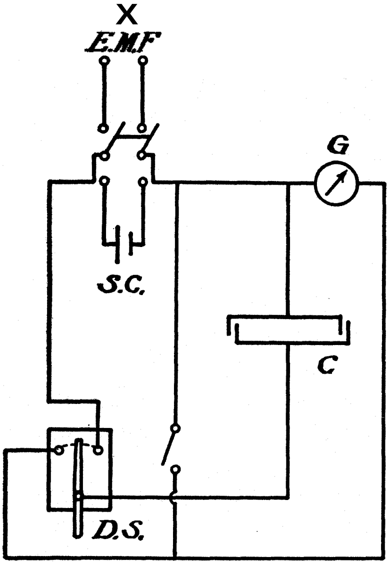

Fig. 1.

Apparatus and Method of Measurement

The investigation was divided into three major parts: (1) the measurement of the inherent errors in the ballistic galvanometer method of hydrogen-ion determinations; (2) the titration of typical acids with sodium hydroxide to point out the significance of such errors as was noted in part one; (3) a mathematical discussion of the formula used in calculating the unknown electromotive force as determined by the ballistic galvanometer method.

Part (1) of this experiment was conducted in the following manner. The condenser was charged with a definite electromotive force obtained from the potentiometer. This charge was then released through the ballistic galvanometer and the swing accurately noted to plus or minus 0.1 mm. A swing as nearly equal as possible was then made with the standard cell using the proper condenser capacity. The agreement of the swings in most cases could be obtained within 2 to 10 mm. Knowing the ratio of the plates used and the voltage of the standard cell, the electromotive force equivalent to this swing can then be calculated. The difference between the calculated electromotive force and the charging electromotive force from the potentiometer was considered an inherent error in the ballistic galvanometer method. The diagram of the connections is shown in Fig. *2*.

The apparatus used consisted of a Leeds and Northrup Type K Precision Potentiometer with Leeds and Northrup Type H highly sensitive galvanometer, Leeds and Northrup standard mica condenser of one microfarad capacity subdivided into five sections having values of 0.5, 0.2 and 0.05 microfarads' capacity, respectively, Type R highly sensitive galvanometer and two Weston Standard cells.

The standard cells used were checked against two Eppley cells, standardized by the U. S. Bureau of Standards, as well as calibrated by means of a Wolff potentiometer in the Ernest Kempton Adams Laboratory, Department of Physics, Columbia University.

Discussion of the Galvanometer and Condenser

Many precautions are to be observed and possible errors guarded against in the operation of the general ballistic galvanometer method.

The individual errors of leakage and inequality of swings have been pointed out to a certain extent while many inherent errors of the ballistic galvanometer and condenser have been omitted. These errors are many in number and may be neutralized one by the other or may be additive. In this respect, Zeleny[5] and White[6] have noted several precautions and possible errors which apply to the ballistic galvanometer method.

In ballistic work the throw that is equal at least to the maximum that is to be used is given to the coil so that a set is affected in the direction of the throw that is to follow.

The coil on returning to the null point must not be allowed to move past, as otherwise part of the set is removed. Subsequent throws in the same direction cause little or no addition to the set.

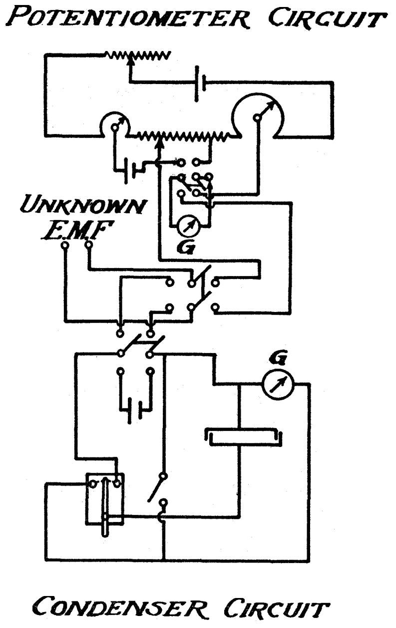

Fig. *2*.

Hysteresis Effects.—The first throw of the galvanometer is generally at least 0.3% more than the following ones and should be discarded.

When a ballistic throw is to be taken while the coil is not entirely at rest, the discharge must be made when the coil is at either turning point of its motion. The throw in either case must be computed from the natural zero point and not from the point at which the throw originated, as is sometimes stated.

In all cases the galvanometer should be used on an open circuit; it is

---

[5] Zeleny, *Phys. **Rev.***, 23, 399 (1906).

[6] White, *ibid.*, 23, 382 (1906).

then more sensitive and the quantities more nearly proportional to the throws. When the circuit is closed an error may be introduced by the thermo-electric current that usually exists in a closed circuit, which itself produces an appreciable deflection.

The ballistic galvanometers for use in the condenser method have a relatively short period and the possibility of reading the throw accurately is very difficult and is generally taken as plus or minus 0.1 millimeter. Calculations show that amount of error in the resultant electromotive force due to this personal error in reading cannot be overlooked.

The zero shift of the ballistic galvanometer amounts to 3.0 to 7.0 mm. during the usual period required in titration work. This effect is due to such factors as change in temperature, lengthening and shortening of the suspensions, hysteresis in the suspensions from magnetic foreign material, possible set in the suspension fiber and other mechanical disturbances in the system.

With this knowledge of the working peculiarities of a ballistic galvanometer, it would be difficult to calibrate the galvanometer deflections and construct a graph so as to read electromotive forces directly. As will be noted, the zero point will change from time to time, and shifting the zero point on the scale to equal the original zero will now create a possible variation in the angular deflection of the galvanometer and thus change its calibration, as the relationship between the electromotive force and deflection of the galvanometer for a given capacity is not a straight line function but curvilinear. It will be seen that such a precaution is eliminated in using the galvanometer as a null instrument because in such a case the deflections when in service are small and do not disturb the zero position.

In the operation of the ballistic galvanometer method, it is necessary to select by trial a set of plates of one capacity for the standard cell and a set of plates of another capacity for the unknown electromotive force in order to secure proper equality of ballistic deflections. The arrangement of the plates in either case to secure the proper capacity may have been either in series or parallel. The guaranteed accuracy as stated by the manufacturers is plus or minus 0.1 to 0.25% for each individual set of plates. With this idea in mind, it is very probable and possible that in such an arrangement of the plates, to secure proper agreement in swings, this error is additive, for instance, positive error for the standard cell and negative error for the unknown electromotive force. Calculations will show these errors to be of primary importance in the resultant electromotive force.

It was noted in a previous paragraph that the errors due to inaccuracy in reading the galvanometer deflections plus or minus 0.1 mm. were of like magnitude, as pointed out above, thus making the total error of significant value. From this standpoint of errors originating from the use of several sets of plates, it would seem only logical to use a fixed condenser of suitable capacity, that is, 0.3 or 0.6 microfarad. This particular idea was pointed out by Beans and Oakes[1] where they suggest the use of a single unit condenser, thus eliminating the capacity factor in the equation $E_1/E_2 = d_1C_2/d_2C_1$. With such an arrangement it is obvious that the capacity value would not appear in the calculations for the unknown electromotive force and the calibrated value of such a fixed condenser need not be accurately known. This method, however, could not be used with any degree of accuracy, as the equality of the swings in such a case would never be possible and errors of such magnitude as shown in Fig. 4 would be encountered.

There is also a serious objection to the condenser method inasmuch as the condenser will maintain with uncertainty the same capacity from time to time. This would invalidate calibration data being used over various periods of time. The condenser plates are held together by the insulating materials only, usually the paraffin in which they are imbedded. If the temperature of the room varies to any great extent, or in case the condenser were placed in such a manner so as to be subjected to external heating, the plates would change their relative positions and thus raise or lower their stated capacity. It is obvious from this consideration that great care should be exercised in preventing such temperature variations and the condenser should be tested from time to time for its accuracy.

In the selection of a condenser for such electromotive force measurements as herein discussed, it is of great importance to secure an instrument which has a very small absorbed charge. The absorption charge in good mica condensers will vary from 0.1 to 1.5%; each condenser or set of plates will have its own characteristic property as to absorption.

Furthermore, and of greater importance, is the adoption of a condenser which can be properly calibrated. Condensers designed for precision measurements are of two general types, namely, fixed single-unit condensers and condensers subdivided into several sections so as to provide various parallel and series combinations.

When considering the use of a condenser subdivided into several sections so as to eliminate errors in the swing of the galvanometer, such as would be encountered when using a fixed condenser, we find there are two general classes of this type of condenser. The first class consists of those with binding posts fastened to the terminals of the condenser and the second class is those of the plug switch type.

With condensers of the latter type the leakage across the exposed metal bars for holding the plugs will be of an appreciable value. Also, it will be noted that each plug switch affords a small air condenser, which will play an important part when calibrating this type of condenser. The value of the error arising from these small air condensers will be directly proportional to the frequency used for calibration.

Experimental

In the discussion of the condenser method by Beans and Oakes,[1] practically no emphasis was placed on the importance of adjusting the swing of the galvanometer for the unknown electromotive force to an equal value as obtained with the standard cell.

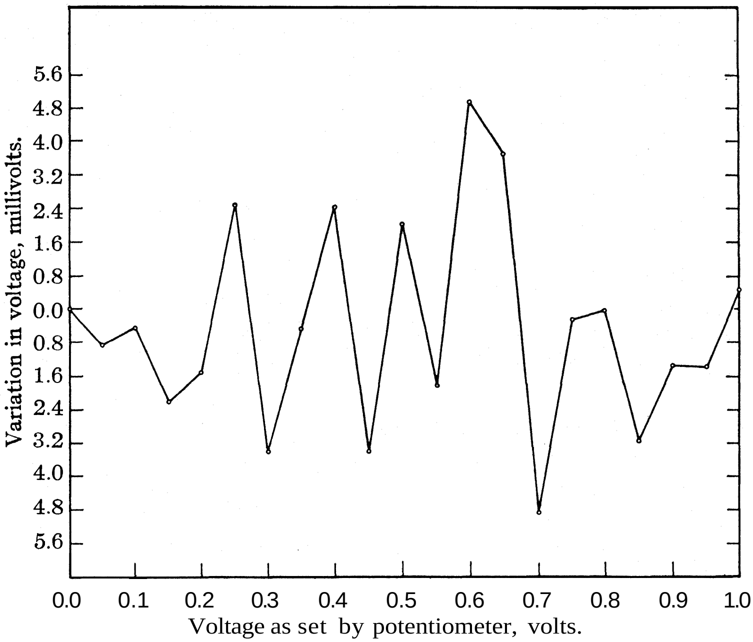

Fig. 3.

"The average deflection for this cell after reaching maximum voltage is 25.0 mm. for one microfarad capacity. Since the standard cell of 1.01823 volts gave a deflection of 50.0 mm. when used with a capacity of one microfarad, the voltage of this cell is 25/50 X 1.01823 volts or 0.5091 volt." Such a method of disregarding the equality of swings leads to extremely large errors in the final calculated electromotive force. With this precaution in mind variations in the resultant electromotive forces were determined with the swing of the galvanometer for the unknown electromotive force adjusted by trial as nearly equal as was possible to that obtained with the standard cell as a source of potential. These results are shown graphically in Fig. 3.

The average of these observations was plus or minus 2.0 millivolts, the error being plus or minus depending on whether the swing of the galvanometer for the unknown electromotive force was greater than the swing obtained with the standard cell. Actually, when the swing of the galvanometer for the unknown electromotive force was greater, the error was in all cases minus, and *vice versa.*

It will be noted from Fig. 3 that the error in 0.50000 volt was plus 2.0 millivolts. Fig. 3 was plotted from data obtained by using a Leeds and Northrup Type 1058 condenser where there are 57 possible direct series and parallel plate combinations, thus affording 57 possible variations of capacity. Actual readings of the galvanometer swings for the above point were 227.0 millimeters for the unknown electromotive force and 229.0 millimeters for the standard cell.

This is a variation of 2.0 millimeters in approximately 230.0 millimeters, the result of which is a difference of less than 0.9%. Even with this small variation in galvanometer swings, the resultant error was large, namely, 2.0 millivolts. This error might have been slightly reduced in case the use was made of a high grade precision condenser where a greater number of plate combinations is possible. It will be readily seen that such a means of decreasing this error as noted above, by a cut and try method of finding the exact combination of plates which would give *a* swing for the unknown electromotive force more nearly approximating that of the standard cell, would result in an excessive waste of time when compared with the potentiometer method for obtaining the same result.

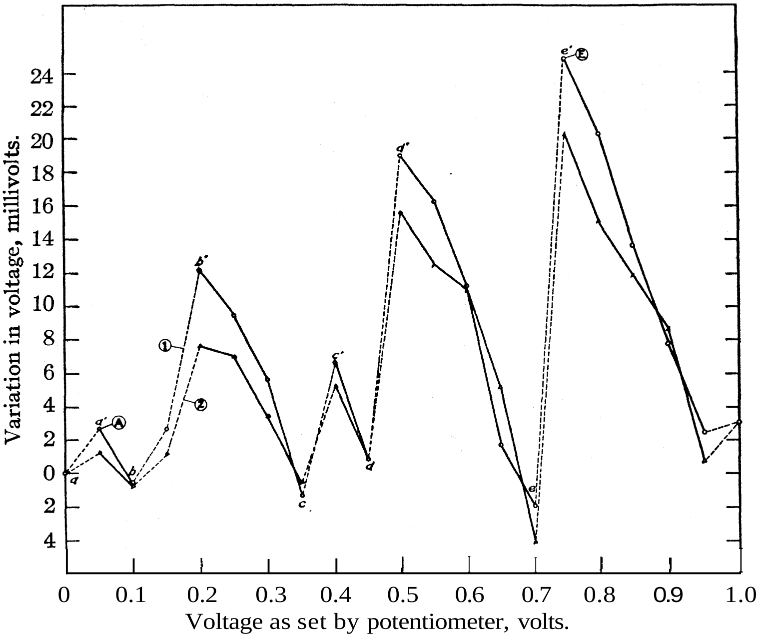

Fig. 4.

Fig. 4 shows several possible sources of error: first, the large error obtained when no account is taken of the equality of the galvanometer swings for the unknown electromotive force and the standard cell. This error is not a fixed one and depends largely on the differences between these two values of swing. This error is also a factor of the voltage, that is, point (A) was obtained with a difference in the swings of 67.0 millimeters, while with point (E) there was 25.0 millimeters' variation. This points out that large differences at low voltages will give less error than small differences at higher voltages. In other words, the best range at which to operate the swing on the galvanometer would be below 100 millimeters' rather than around 200 millimeters' deflection, as is generally assumed. In the next case, the slopes a-a', b-b' and c-c' are significant because they show a decrease in the error with the increase in voltage for each particular slope. The points on the slope a-a' were taken with one definite combination of plates; likewise for b-b' and c-c'. In each case it will be seen that as the voltage increases the deflection differences decrease and the error between the electromotive force for the potentiometer and that calculated from the standard cell with the condenser approaches a small value.

Finally, the error due to a high humidity condition surrounding the apparatus was considered. Curves 1 and 2 of Fig. 4 were plotted from data obtained with relative humidities 39.0 and 66.0%, respectively. Although these observations were made on separate days, care was exercised in order to have approximately all conditions except the humidity the same in each case. In other words, the combination of the plates of the condenser arranged for the proper capacity at each point was made identical, thus eliminating any possible error due to a change in plates or an error which might arise due to a marked difference in the deflection of the galvanometer. It will be seen from these, two graphs that with a high humidity the error is apparently decreased; this is no doubt due to a leakage of the charges from the plates and from the system comprising the condenser apparatus. Humidity will cause a difference in the insulation resistance of the condenser arrangement and consequently a variation in the leakage. This would include leakage across the terminals of the galvanometer, leakage across the terminals of the charge and discharge key and leakage between the leads to and from the various instruments. It will be noted that this is an important factor which might easily be overlooked and give conflicting results in case the atmospheric conditions were disregarded.

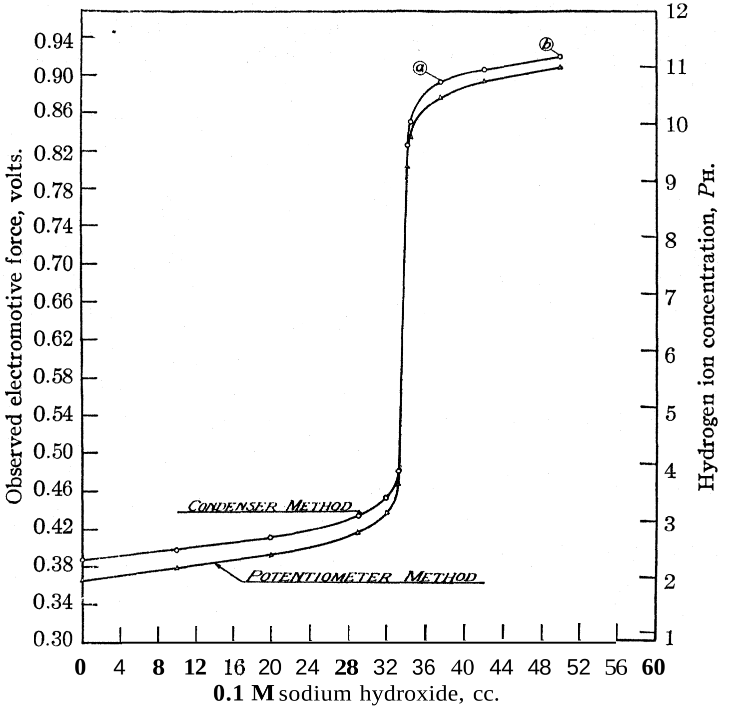

Fig. 5.—Titration of sulfuric acid with 0.1 M sodium hydroxide.

Fig. 5 represents a change in voltage when sulfuric acid was titrated with sodium hydroxide and shows typically the displacement which occurs when the condenser method is used to determine this electromotive force. Considering the irregularities of the errors obtained on different readings, one might assume that the curve obtained with the condenser would be somewhat jagged and not smooth in character. The lower section of the curve up to the beginning of the break does not agree with this view but is quite regular and is a very smooth curve. The reason for this is no doubt the fact that over this region one set of plates was used on the condenser. The accumulated errors on the plates were apparently greater than the errors set up by the inequality of the swings on the ballistic galvanometer. Therefore the displacement was practically constant throughout this region.

It will be seen that the curve obtained with the potentiometer and that with the condenser coincide at the inflection point. This must be so since the points are vertically displaced and the inflections here have assumed a perpendicular touching all the points of the two systems. Where the upper part flattens out again we have another disagreement between the two systems. The amount of this difference is slightly less than in the lower section of the curve. This again is no doubt due to the accumulated errors on the combination of the plates used on the condenser. Another consideration which seems to indicate that the plate error is considerably greater than the error of unequal swings is shown at points (a) and (b). At (a) the difference in the swing between the unknown and the standard electromotive force on the galvanometer was 7.5 mm., and at (b) this difference was practically zero. Even with this equality of swings the displacement for both points is nearly equal, which points out strongly that the error of displacement is from some other source which might well be due to the errors in the calibration of the plates of the condenser.

An important point which must be emphasized here is that the center of the break in the curve as obtained with the potentiometer is equivalent to a *P*H of 6.9, while with the condenser the center is equivalent to 7.2 in PH value. Although this difference may not have significance in a curve of one deflection, it is of vital importance when two deflections occur, such as in the titration of orthophosphoric acid.

What was said of the sulfuric acid curve regarding the displacement of the two systems as being due primarily to the summation of the plate errors, may also apply in the phosphoric acid titration curve. It can readily be appreciated that if the two breaks in the phosphoric acid curve are displaced due to the errors mentioned above, that difficulty might be encountered in showing the true relationship for the first and second end-points.

The purpose of the curve in Fig. 6 is to show the variation in the trend of the curve with a change in the combination of plates of the condenser. The section a-b was obtained by titrating orthophosphoric acid with sodium hydroxide and with the use of one combination of plates arranged for the most suitable capacity. The displacement is in accordance with that found in titrating sulfuric acid. Section b-c was obtained with a second combination of plates. It will be seen that the slope of the curve breaks very sharply at point b-b' due to the difference in the accumulated errors in the two sets of combinations. The smoothness of the curve when using the condenser method depends, therefore, upon the number of times the combinations of plates are changed. If any changes are made, a jagged curve is certain to arise. This is seen in Fig. **3,** where for each point a different set of plates was used.

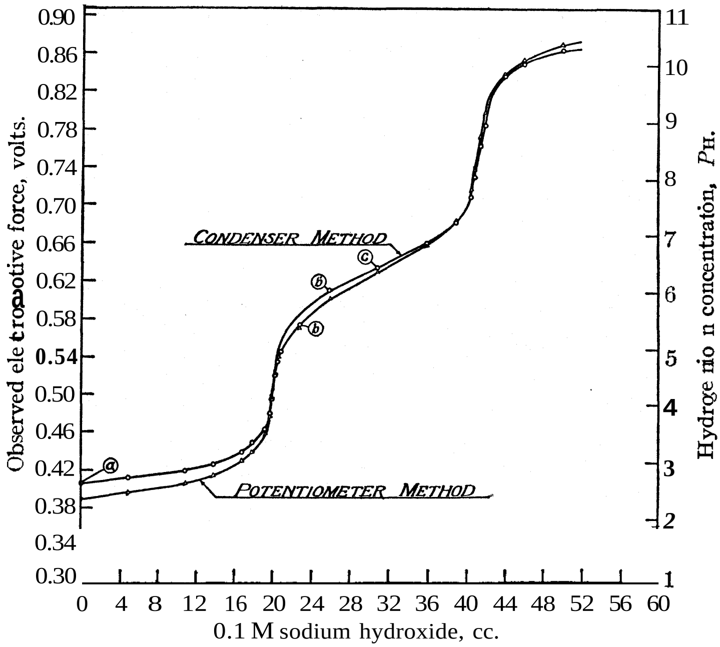

Fig. 6.—Titration of orthophosphoric acid with 0.1 M sodium hydroxide.

Mathematical Discussion of Errors

Since the galvanometer cannot be read to a value closer than plus or minus 0.1 mm., the following calculations will show the magnitude of such errors in the resultant electromotive force due to the personal error in reading the swing of the galvanometer.

$$\text{Electromotive force of the standard cell} \times \frac{\text{Gal. Swing Unknown}}{\text{Gal. Swing Known}} \times \frac{\text{Con. Cap. Known}}{\text{Con. Cap. Unknown}}$$

is equal to the Unknown Electromotive Force.

The following figures are taken from actual data as obtained during these experiments, the condenser arrangement being identical with that used by Davis, Oakes and Salisbury.[4]

$$1.01850 \times \frac{230.3}{229.0} \times \frac{0.183}{0.250} = 0.74979$$

Assuming a plus or minus 0.1 mm. difference of the two readings of the galvanometer, we have

$$1.01850 \times \frac{230.5}{228.8} \times \frac{0.183}{0.250} = 0.75106$$

This gives us an error of 0.00127 volt or 1.27 millivolts.

Since each plate of the standard mica condenser used is only accurate to plus or minus 0.25% and the manipulation to obtain equality of swing necessitates the arrangement of as many as five plates in parallel and series, one can easily see that an extremely large error may result from this cause. Calculating the resultant error due to the percentage variation on the average of three plates used for this point, we have

$$1.01850 \times \frac{230.3}{229.0} \times \frac{0.18346}{0.24937} = 0.75357$$

Here the difference between this value and the original value of 0.74979 volts gives an error of 0.00378 volt or 3.78 millivolts.

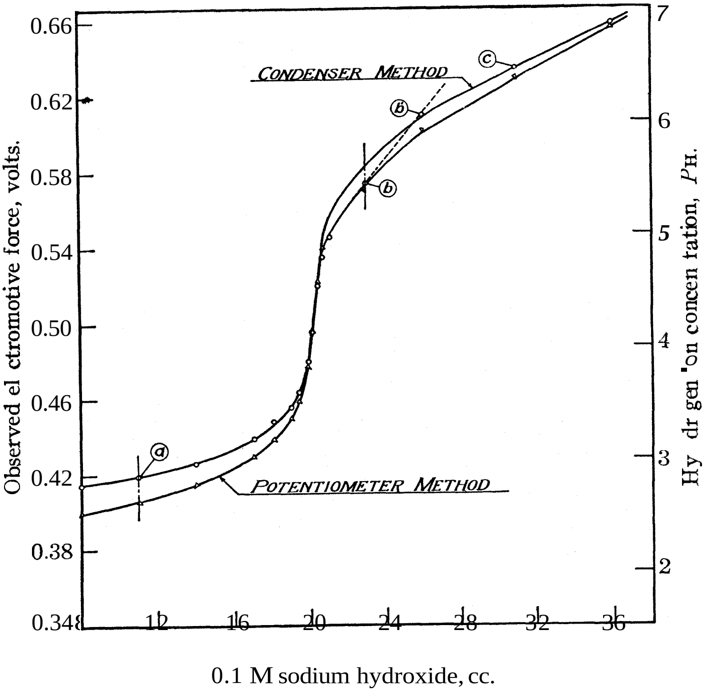

Fig. 7.—Section from Fig. 6 enlarged.

Since it is quite possible that the plate errors and errors due to the reading of the galvanometer swings might occur at the determination of the particular electromotive force stated above, we have a maximum possible error equal to the sum of these two errors, which is 5.05 millivolts.

When considering the use of a precision condenser similar to the type employed by Beans and Oakes[1] (Plug Type Precision Standard Mica Condenser, manufactured by Jas. G. Biddle), we have the values of capacitance accurate to approximately 0.1%. Calculating the resultant error due to this particular percentage variation in capacitance, for the above point in question, we have

$$1.01850 \times \frac{230.3}{229.0} \times \frac{0.18318}{0.24975} = 0.75128 \text{ volt}$$

With this added accuracy in capacitance values, we have still a noticeable error amounting to 0.00149 volt or 1.49 millivolts. Now we will have as a maximum possible error occurring at the determination of the particular electromotive force indicated above, a value equal to 0.00276 volt or 2.76 millivolts. These calculated maximum errors of 5.05 and 2.76 millivolts are equal to more than ten and five times, respectively, that quantity given by Beans and Oakes,[1] which states a precision of plus or minus 0.5 millivolt for the condenser system of measuring potentials.

It might be well to mention here that with small deflections amounting to approximately 70.0 mm., the above errors are greatly reduced because the multiplying factor is of a smaller quantity.

Although this may theoretically give a smaller error it will be apparent to those who have used a ballistic galvanometer that, for small deflections the time period is so much shorter than in higher ranges, it is doubtful whether the readings can be made to as close a value as plus or minus 0.1 mm. as assumed above. It would not be at all surprising if this error approached a value of approximately plus or minus 0.2 mm. It can be seen therefore that it is almost impossible to judge the accuracy of any electromotive force measurement as obtained by the use of the condenser system, and further it seems almost impossible to eliminate one or many of these sources of error.

The above formula as used for these calculations of the unknown electromotive force and, as recommended by Beans and Oakes,[1] requires the use of the electromotive force of the standard cell, which is assumed to be accurate to one or two in the fifth decimal place and multiplies this value by a factor, condenser capacity, which is accurate to only one in the third place.

When several independent sources of error conspire to produce a resultant error, we find that if any term in the operation is in doubt by say 1.0%, the product or quotient will be in doubt by 1.0% on account of that term alone. In other words, the product or quotient cannot therefore be more precise than the percentage precision of the least precise factor entering into the computation.[7] In the case of the example mentioned above, we can calculate the probable resultant error as follows.

---

[7] F. W. Mellor, "Higher Mathematics for Students of Chemistry and Physics," Longmans, Green and Co., London, 1919.

$$Q = \frac{q^1\, q^2\, q^3}{q^4\, q^5}$$

where q^1 = electromotive force of the standard cell; q^2 = ballistic swing of the unknown electromotive force; q^3 = condenser capacity of the known electromotive force; q^4 = ballistic swing of the known electromotive force; q^5 = condenser capacity of the unknown electromotive force.

The percentage deviations are used in these calculations, for in such a function as above the percentage error in any component factor produces the same percentage error in the final quantity, that is

$$100\,\frac{\Delta q_n}{q_n} = 100\,\frac{\frac{\delta Q}{\delta q_n}\,(\Delta q_n)}{Q}$$

The value of Q was found to be equal to 0.74979 volt. Consequently, if E is the actual error in Q caused by errors e_1, e_2, e_3, e_4 and e_5, which arise from errors in the components, the percentage error in Q will be given by

$$100\,\frac{E}{Q} = \sqrt{\left(\frac{100\,\Delta q^1}{q^1}\right)^2 + \left(\frac{100\,\Delta q^2}{q^2}\right)^2 + \left(\frac{100\,\Delta q^3}{q^3}\right)^2 + \left(\frac{100\,\Delta q^4}{q^4}\right)^2 + \left(\frac{100\,\Delta q^5}{q^5}\right)^2}$$

from which the actual error E can be computed.

Using the data of the foregoing calculations, the percentage precision of Q becomes ±0.35%. The actual error E is then 0.74979 × 0.0035, which is 0.00252 volt or 2.52 millivolts.

The percentage precision of Q when using a precision condenser similar to the one employed by Beans and Oakes[1] becomes 0.15%. The actual error E would then be 0.74979 × 0.0015, which is 0.00112 volt or 1.12 millivolts. Here the value of the error is reduced somewhat as the accuracy of the condenser plates is plus or minus 0.1%.

General Summary and Conclusions

1. The use of the condenser and ballistic galvanometer in determining electromotive forces of solutions was employed by Carhart[2] and by Potter.[3]
2. The important errors in this method are due to the accumulation of errors on the plates of the condenser, the throw of the galvanometer, humidity and the formula used in the calculation of the unknown electromotive force.
3. The important errors have been calculated and graphs drawn to show the significance of such errors in the titration of sulfuric acid and orthophosphoric acid.
4. The accumulative error may sometimes reach a value approximating plus or minus 3.0 to 4.0 millivolts.
5. Results seem to indicate that the condenser system of electromotive force measurements cannot be used where precise work is required, such as in the titration of solutions or in the determination of equilibrium constants.

THE NORMAL POTENTIAL OF THE IODINE–IODIDE ELECTRODE

BY GRINNELL JONES AND B. B. KAPLAN

RECEIVED FEBRUARY 23, 1928 PUBLISHED AUGUST 4, 1928

Historical Introduction

There is considerable confusion in the literature because of different definitions of the normal potential of the iodine–iodide electrode by various authors. In the following discussion we shall use the term normal potential of the iodine–iodide electrode to mean the potential of the cell Pt, I_2 (solid), I^- (activity = 1.0); 1.0 *N* KCl, HgCl, Hg containing a platinum electrode immersed in a solution which is in equilibrium with solid iodine and which has the iodide ion present at such a concentration that its activity is unity, measured against a normal (1 mole of KCl per liter) calomel electrode, and with corrections applied for liquid junction potentials. In accordance with the usual convention a positive sign of the potential would mean that the mercury is the positive pole of the cell and the platinum the negative pole. As a matter of fact, in this case the platinum is positive and the mercury negative, which is indicated by using a negative sign.

The other definition used by some authors postulates instead of solid iodine a solution in which the activity or concentration of the dissolved free iodine is unity. The concentration of free iodine (I_2) in water saturated with iodine at 25° is 0.00132.[1] Since this solution is dilute and free from ions the activity of iodine may be taken as equal to its concentration, 0.00132, and this figure may be used for any aqueous solution saturated with iodine. Therefore the difference between these two definitions at 25° is $(RT/2F) \ln 1.0/0.00132 = 0.0851$ volt.

At 0° the activity[2] is 0.000635 and therefore the difference between the two definitions is $(RT/2F) \ln 1.0/0.000635 = 0.0866$ volt. These corrections will be applied if necessary in the following discussion to make the results of the various authors comparable. In case the other authors referred to have omitted liquid junction corrections or defined the normal calomel electrode differently, no correction will be applied for this variation from the definition given above.

The work of Crotogino[3] and of Sammet[4] is similar in technique and the

[3] F. W. Küster and F. Crotogino, Z. anorg. *Chem.*, 23, 87 (1900); F. Crotogino, *ibid.*, 24, 247 (1900).

[4] V. Sammet, Z. *physik. Chem.*, 53, 674 (1905).

results agree within one millivolt. They measured the potential of a platinum electrode immersed in solutions of potassium iodide varying from about 0.001 N to 1.0 *N* saturated with solid iodine against a calomel electrode. Crotogino did not attempt to compute a normal potential from his data. Sammet computes the normal potential on the assumption that exactly one-half of the iodide is converted into tri-iodide and that the concentration can be computed from the conductivity and applies no liquid junction corrections. It is now known that both of these assumptions are only approximately true. These results show an apparent shift in the normal potential with dilution from —0.256 volt in the more concentrated solutions to —0.278 in 0.001 N KI. He regards the value obtained with the more concentrated solutions as the more reliable, which would not be the modern interpretation.

Maitland[5] was the first to use solutions of potassium iodide containing less iodine than is required to saturate the solutions (about $^1/_3$ to $^1/_{30}$ saturated). The amount of free iodine was determined by distribution experiments using carbon tetrachloride. The concentration of the potassium iodide varied from 1.0 N to 0.1 N. The degree of ionization assumed was based on conductivity data. No liquid junction correction was applied. The results show a distinct systematic variation with the degree of saturation of iodine and with the concentration of the potassium iodide but Maitland averages all of the results, obtaining —0.2569 in good agreement with Sammet's result derived from 1.0 N KI saturated with iodine. Unfortunately Maitland's measurements did not extend below 0.1 *N*. All the earlier workers either made no measurements below 0.1 N or rejected their measurements in dilute solutions as unreliable.

Jones and Schumb[6] made measurements with saturated iodine electrodes with 0.1 *N*, 0.05 N and 0.02 N KI, interpreted by the use of data by Bray and MacKay[7] on the tri-iodide formation, obtaining —0.2658, —0.2558 and —0.2549 at these concentrations. They were the first to apply the liquid junction correction. All investigators agree that the more dilute the KI solution the greater is the difficulty in obtaining definite and reproducible experimental results; but the theoretical interpretation of the data on dilute solutions is more reliable. Jones and Schumb also made measurements at 0° which when recomputed with the definition given above give —0.2536, —0.2534 and —0.2528 with 0.1 N, 0.05 N and 0.02 N KI, respectively. The systematic variation of the results with concentration made it desirable to extend the measurements to still greater dilution but Jones and Schumb were unable to obtain definite results with 0.01 N

solution and therefore the results were averaged, giving —0.2555 at 25° and —0.2533 at 0°.

The measurements of Maitland have been recomputed by Lewis and Randall,[8] who were the first to reject the calculation of the concentration of the ions from the conductivity and substitute instead the activity of the iodide ion as determined from thermodynamic considerations. They also use a new conventional definition of the normal calomel electrode as the potential measured against 0.1 N KCl, 1 N KCl, HgCl, Hg, with no correction applied for the liquid junction potential between 0.1 *N* KCl and 1 N KCl. The usual formulas for the computation of liquid junction potentials give 0.0004 volt for this potential, the dilute solution being negative. Therefore to make this result comparable with results against 1 N KCl calomel electrode without the intervention of 0.1 N KCl, a correction of – 0.0004 volt should be applied. Lewis and Randall used Maitland's results with 0.1 N KI only and assumed that the activity coefficient of the iodide ion in this solution is 0.794 (instead of assuming that the degree of dissociation is 0.86 as was done by Maitland), with the following results.

TABLE I

NORMAL POTENTIAL OF IODINE–IODIDE ELECTRODE COMPUTED BY LEWIS AND RANDALL AFTER MAITLAND

KI, KI_3	Degree of saturation	*E*
0.1 *N*	0.3127	–0.2530
.1 *N*	.0881	– .2541
.1 *N*	.0686	– .2542
.1 *N*	.0338	– .2539

The change in the method of calculation thus influences the result by more than 2 millivolts.

The results of a research by Lewis and Faragher (which so far as we know has not been published in detail) are also given by Lewis and Randall. In these experiments several mixtures of potassium chloride and potassium iodide were shaken with a standard solution of iodine in carbon tetrachloride to make them 0.1411 saturated with iodine. The normal potential is computed by the use of the activities of the ions from the tables of Lewis and Randall, giving —0.2539 volt.

By combining measurements by Gerke[9] of an iodine electrode against a lead–lead iodide electrode with measurements by Lewis and Brighton[10] of this lead–lead iodide electrode against a normal calomel electrode (as defined by Lewis and Randall) the result —0.2531 has been computed.

McKeown[11] has carried out experiments similar to those of Crotogino and of Sammet, using solutions saturated with iodine varying from 0.1 N to 0.001 N in potassium iodide. McKeown's results differ greatly from all others. He regards his data obtained with the 0.001 N solutions as the most reliable and concludes that –0.2454 is the normal potential of the iodine electrode. This value is nearly one centivolt different from the value obtained by all other investigators and since McKeown fails to point out any source of error in the earlier work this figure does not deserve serious consideration,

Murray[12] measured the potential of a cell Pt, $xI_2 + yKI$ 0.1 N KCl, HgCl, Hg in which x and y were much less than 0.1 N. The effect of triiodide formation was allowed for by computation. He determined the equilibrium constant 0.001390 by the distribution method for this purpose and uses Lewis and Randall's tables of activities. He gives 0.6204 against the hydrogen electrode for an assumed free iodine of unit activity. If this is reduced to the normal calomel electrode by applying the correction –0.2818 (see pages 2075–2076) and to saturated iodine by the correction –0.0851, it becomes –0.2535.

Experimental

The innovation of Lewis and Randall in using the activity of the iodide as determined thermodynamically is undoubtedly sound but the experimental basis for the values of the activity coefficients of the individual ions at the various concentrations[13] is yet meager and is not fully explained by them except in general terms. The values given in their table for the activity coefficient of the iodide ion at various concentrations are not supported by references to experimental data but are probably mainly based on the assumption that they are the same as the chloride ion at the corresponding concentration. They do not give references to experimental proof of this assumption but it wins some support from the measurements of Pearce and Fortsch.[14]

It therefore seemed desirable to check up the values for the activity coefficient of the iodide ion, f, as given in the table of Lewis and Randall. The change in activity coefficient of the iodide ion with dilution can be computed from measurements of the potential of concentration cells with transference, with silver–silver iodide electrodes. The relative activity coefficients at the two concentrations can then be computed by the well-known formula

$$E_2 - E_1 = -2t_K \frac{RT}{F} \ln \frac{c_2 f_2}{c_1 f_1}$$

Fortunately in this case the mobility of the potassium ion (74.8) and of the iodide ion (76.5) are so nearly alike that the liquid junction potential is small. The factor $2t_K$ (twice the transference number of the potassium ion), which gives the effect of the unequal mobilities of the ions at the liquid junction on the measured potential, is $(2 \times 74.8)/(74.8 + 76.5) = 0.989$. Therefore the liquid junction potential is only 1.1% of the measured potential. We measured the potential of a silver–silver iodide electrode in 0.1 N KI against a similar electrode in various other concentrations of KI at 25°. The ground stopper type of cell was used. An electrostatic condenser was used to increase the sensitiveness as described by us in an earlier paper.[15] Constant and reproducible results were obtained using 0.05 N and 0.02 N KI measured against 0.1 N KI, but variable, non-reproducible, mostly abnormally high values were obtained with the more dilute solutions tried. Unfortunately the work had to be interrupted before the proper technique was developed to overcome this difficulty with the dilute solutions. Only the results which we believe to be reliable are published. The duplicate results given were obtained with

[15] Jones and Kaplan, THIS JOURNAL, 50, 1853 (1928). After the publication of our earlier paper and while this paper was in proof the article by Beans and Oakes, THIS JOURNAL, 42, 2116 (1920), first came to our attention. Beans and Oakes describe the use of a condenser and ballistic galvanometer to measure the voltage of a cell with high internal resistance. In their arrangement the total voltage of the cell is impressed on the condenser, then discharged through the galvanometer and the total voltage inferred from the scale reading of the calibrated galvanometer. An accuracy of 0.5 millivolt was obtained. In our arrangement the condenser and galvanometer are used as null instruments. Only the difference between the setting of potentiometer and the potential of the cell is impressed on the condenser and the potentiometer is adjusted until this difference becomes zero, so that the voltage of the cell is obtained from the setting of the potentiometer, which is an advantage. No calibration of the galvanometer is necessary. With our arrangement a senitiveness of 0.02 millivolt was obtained in measuring a cell having 1,600,000 ohms internal resistance. Moreover, our arrangement is superior to that of Beans and Oakes in avoiding errors due to leakage and dielectric absorption, since the potential impressed on the condenser need never exceed one millivolt.

new electrodes and solutions. The values given remained constant for many hours.

Brönsted[16] found empirically that the activity coefficient, f, varies with the concentration in accordance with the equation

$$\log f = -3\alpha\sqrt{c} + 2\beta c$$

where a and β are constants. This relationship has since been deduced from the Debye-Hückel theory.[17] We may therefore write

$$\log \frac{f_1}{f_2} = -3\alpha(\sqrt{c_1} - \sqrt{c_2}) + 2\beta(c_1 - c_2)$$

or

$$-0.0283 = -3\alpha(\sqrt{0.1} - \sqrt{0.05}) + 2\beta(0.1 - 0.05)$$

and similarly

$$-0.0552 = -3\alpha(\sqrt{0.1} - \sqrt{0.02}) + 2\beta(0.1 - 0.02)$$

From these equations the values of -3α and 2β have been computed and substituted in the general equations, giving

$$\log f = -0.373\sqrt{c} + 0.125\,c$$

From this equation the values of the activity coefficient, f, have been computed at various concentrations and the results are compared in Table III with the values given in the tables of Lewis and Randall and with the degree of dissociation as computed from the conductivity.

TABLE: III

ACTIVITY COEFFICIENTS OF THE IODIDE ION AT VARIOUS CONCENTRATIONS AT 25°

c	f, calcd. from our equation	f, from Lewis and Randall	Dissoc. from conductivity
0.1	0.784	0.79	0.859
.05	.837	.84	.888
.02	.891	.89	.9205
.01	.920	.92	.940
.005	.943	.95	.955
.002	.963	.97	.970
.001	.973	.98	.978
.000	1.000	1.00	1.000

The agreement between our new results and the table of Lewis and Randall is good. The values of the degree of ionization computed in the conventional manner from the conductivity are unmistakably different.

The new equilibrator which we invented for this purpose and have described in a separate article[18] gives a means of avoiding the dilemma which has introduced some uncertainty in the earlier work on the iodine electrode. Some experimenters (Crotogino, Sammet, Jones and Schumb, McKeown) have used solutions saturated with iodine, thereby making

---

liquid junctions and osmotic corrections large and risking errors due to higher polyiodides. Others (Maitland, Lewis and Randall, Lewis and Faragher) have decreased these difficulties by using solutions unsaturated with iodine but have been obliged to fix the iodine concentration by shaking with carbon tetrachloride, thereby risking analytical errors due to emulsified carbon tetrachloride, or a change in the nature of the solvents due to solution of carbon tetrachloride in the water. With the new equilibrator we can use solutions containing only a little iodine and fix this concentration accurately without the use of any other medium. Furthermore, the improvement in potentiometer which we have described[19] has made it possible to work with 0.01 *N* solutions successfully.

In Table IV below, E_s is the measured potential of the cell Pt, I_2 (solid) xN KI; 0.1 *N* KCl, HgCl, Hg, taken from the measurements of Jones and Schumb for the 0.1 N, 0.05 N, and 0.02 N solutions. We made new measurements using 0.01 N KI against 0.1 *N* calomel electrodes, using the cell with liquid junction in a ground stopper. The measured difference between the decinormal and normal calomel electrode is —0.0529 according to Lewis, Brighton and Sebastian[20] and this figure has been exactly confirmed by Jones and Schumb. For the reason explained above the liquid junction of -0.0004 should be added giving -0.0533 as the value to be added to change from decinormal to normal calomel electrode. E_2 is the measured potential of the cell Pt, I_2 (unsat.) xN KI; xN KI, I_2 (solid), Pt, in which the composition of the unsaturated solution was determined by the equilibrator and is shown at the top of the column.[21] E_j is the liquid junction correction, which is the potential between 0.1 *N* KCl and the KI solution unsaturated with iodine shown at the top of the column. It should be noted that by the use of the equilibrator this correction is reduced to a small value. This reduction in magnitude is important because the calculation is relatively uncertain. $E_c = (RT/2F) \ln I_2 \text{ (unsat.)}/0.00132$ makes proper allowance for the unsaturation of the iodine. In order to obtain the potential in a solution of unit activity in iodide ion the quantity $-(RT/F) \ln fI$ must be added. For convenience in computation and analysis, this is split up into two terms $E_0 + E_f = -(RT/F) \ln I - (RT/F) \ln f$. The values of the activity coefficient used are taken from Col. 2 of Table III.

These results show a gratifying concordance with no evidence of systematic variation with the concentration of either potassium iodide or of iodine. If the activity coefficients from the tables of Lewis and Randall are used, the following results will be obtained: 0.1 N KI, —0.25458; 0.05 N KI, —0.25447; 0.02 *N* KI, —0.25447; 0.01 *N* KI, —0.25434.

---

[19] Jones and Kaplan, THIS JOURNAL, 50, 1853 (1928).

[20] G. N. Lewis, T. B. Brighton and R. L. Sebastian, *ibid.*, 39, 2245 (1917).

[21] The method of using the equilibrator with these solutions is explained in more detail in our recent paper, *ibid.*, 50, 1845 (1928).

These results show a slight systematic variation with concentration which disappears when our values for the activity coefficient are used. The difference between our value of the normal potential and the value of Lewis appears to be due chiefly to the fact that Lewis used the measured difference for the potential between decinormal and normal calomel electrode, −0.0529, ignoring the liquid junction potential between decinormal and normal potassium chloride. This potential, like all liquid junction potentials, is somewhat uncertain but it may be computed to be −0.0004 volt. If our data are computed with the Lewis convention, the result would be −0.2540 (compared with his result, −0.2539).

These results are not so concordant or reliable as the results for 25° for two reasons. (1) It is more troublesome to maintain a constant temperature at 0° in the equilibrator for the longer time necesssary to obtain equilibrium with iodine (unfortunately this work had to be done in June and July and there were several very hot nights so that the ice in the tub was nearly gone by morning). (2) Owing to unavoidable interruptions of the work, we have no direct measurements of the activity coefficient of the iodide ion at 0° but are compelled to assume provisionally that the activity coefficients are the same at 0° as at 25°.

The results on the normal potential of the iodine–iodide electrode are summarized in the following table. In this table the figures given by the authors have been changed if necessary to make them applicable to a saturated iodine electrode; but no corrections to the authors figures have been applied on account of liquid junction potential, variations in definition of normal calomel electrode, or to the use of activity instead of concentration.

TABLE VI

It is of some interest to express the normal potential of the iodine–iodide electrode against the hydrogen electrode instead of against the calomel electrode. Unfortunately, there seems to be more uncertainty as to the difference between the hydrogen and calomel electrodes than between the iodine and calomel electrodes. In 1917 Lewis, Brighton and Sebastian found for Hg, HgCl, KCl (1 mole per liter), 0.1 N KCl, H^+ (activity 1.0), H_2, (g); E = −0.2828. In 1923 Lewis and Randall in their book on Thermodynamics, p. 407, changed this figure to −0.2822. The change is caused by revision of the activity coefficients used in the calculations. This value has come into common use. Very recently Randall and Young[22] have cast serious doubt on the reliability of this figure. They find that the presence of air influences the potential of the hydrochloric acid calomel electrodes but not the potassium chloride calomel electrode. They also redetermine the activity coefficients of hydrochloric acid solutions. From these experiments they conclude that the difference between the calomel and hydrogen standards is −0.2812, a value differing by 1 millivolt from the figure of Lewis and Randall. In a matter of this importance independent confirmation is desirable. Pending such confirmation and systematic recomputation on the hydrogen basis of all normal potentials determined by the aid of the calomel electrode, we shall provisionally use the older value of Lewis and Randall, −0.2822. This must be changed by 0.0004 volt on account of the different definitions of the calomel electrode used by Lewis and Randall and the definition adopted in this paper (see page 2066). The result will thus be on the same basis as most other recent values for normal potentials. We may therefore write

[22] M. Randall and L. E. Young, THIS JOURNAL, 50,989 (1928).

Pt, I_2 sat., I^- ($a = 1.0$), 1 *N* KCl, HgCl, Hg	$E = -0.2544$
Hg, HgCl, 1 *N* KCl, 0.1 *N* KCl, H^+ ($\alpha = 1.0$) H_2 (g), Pt	$E = -0.2822$
Liquid junction correction 1 N KCl, 0.1 N KCl	$E = +0.0004$
Pt, I_2 sat., I^- ($a = 1.0$), H ($\alpha = 1.0$) H_2 (g)	$E = -0.5362$

No attempt will be made at this time to compute the normal potential of the iodine–iodide electrode referred to the hydrogen electrode at 0°, owing to inadequate data on the difference between hydrogen and calomel electrodes at this temperature.

Summary

The normal potential of the iodine–iodide electrode has been redetermined, using solutions containing so little free iodine that the effect of formation of tri-iodide is minimized and can be accurately allowed for. The activity of the iodine has been determined by a new device. The activity coefficient of the iodide ion in solutions of potassium iodide has been determined by measurements of the potential of iodide concentration cells with transference containing silver–silver iodide electrodes. The results can be expressed by the formula of the form suggested by Bronsted: $\log f = -373\sqrt{c} + 0.125\,c$. The normal potential of the iodine–iodide electrode against the normal calomel electrode at 25° is found to be —0.2544 volt; and at 0° is found to be —0.2522 volt.

THE EXTRAPOLATION OF ELECTROMOTIVE FORCE MEASUREMENTS TO UNIT IONIC ACTIVITY

BY DAVID I. HITCHCOCK

RECEIVED APRIL 7, 1928 PUBLISHED AUGUST 4, 1928

The relation between the electromotive force, E, of a cell such as Ag, AgCl, HCl, H_2 and the mean activity coefficient, γ, of the ions of the electrolyte is given by the equation

$$E = E_0 - 2k \log m - 2k \log \gamma \qquad (1)$$

Here m is the molality of the acid, k is 2.3026 RT/NF, and E_0 is the electromotive force which the cell would have if the mean activity of the ions, or the product $m\gamma$, were equal to unity. In order to calculate activity coefficients from electromotive force data alone, it is necessary to determine the value of E_0 by extrapolation. This has usually been done, following Lewis and Randall,[1] by plotting the quantity E_0', which is defined as E + 2k log m, against $\sqrt{m}$. Since $\gamma = 1$ when m = 0, it follows from equation (1) that $E_0' = E_0$ when m = 0. Curves which have

---

[1] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 335.

been obtained in this way for aqueous hydrochloric acid[1,2] are straight lines only for the region of extreme dilution (well below 0.01 M), where the scattering of the points makes the position of the line, and hence the extrapolated value, somewhat uncertain.

If the Debye-Huckel equation, in its simplest approximate form

$$-\log \gamma = 0.5\sqrt{m} \tag{2}$$

applies to the data, it follows from Equations (1) and (2) that a plot of E_0' against $\sqrt{m}$ should be a straight line of slope equal to k over the range where the approximate equation holds. Scatchard[2a] found it possible to draw a curve whose slope approached this value asymptotically at $m = 0$, using data obtained by himself, by Linhart,[3] and by Noyes and Ellis.[4] Nonhebel[2b] found that his data when plotted in this way gave points falling around a line having a slope equal to $0.78k$. He concluded, therefore, that his data were not in agreement with the Debye theory.

The method of extrapolation just described lays great weight on the determinations in very dilute solutions, where the measurements are reproducible only with difficulty and where, as Randall and Young[5] have pointed out, all existing data are probably erroneous on account of the solubility of glass. It would therefore be desirable to find a method of extrapolation from the more reliable determinations at somewhat higher concentrations.

If the Debye-Huckel theory holds, any experimental data should agree with the second approximate equation over a wider range than with the first. For the case in question this equation is

$$-\log \gamma = 0.5\sqrt{m} - Bm \tag{3}$$

where B is an additional constant whose value is not known independently. This form of equation has been shown by Brönsted,[6] Scatchard,[7] and others to apply to a number of electrolytes, in some cases up to 0.1 M. The combination of Equations (1) and (3) gives

$$E + 2k\log m - k\sqrt{m} = E_0 - 2kBm \tag{4}$$

or

$$E_0' - k\sqrt{m} = E_0 - 2kBm. \tag{4a}$$

Over the range where Equation (3) holds, it follows that the left member of Equation (4) or (4a), which may be called E_0'', should be a linear function of m.[8] Moreover, if Equation (4) holds, it follows that $E_0'' = E_0$ when $m = 0$.

[4] Noyes and Ellis, *ibid.,* **39,** *2532 (1917).*

[5] Randall and Young, *ibid., 50,989 (1928).*

[6] Bronsted, *ibid., 45,2898 (1923).*

[7] Scatchard, *ibid.,* 47, *648 (1925).*

[8] The quantity E_0'' was used by Nonhebel and Hartley, *Phil. Mag. [6]50,* **729** (1925), who called it E_0 Debye, and found, in the case of hydrogen chloride in methyl alcohol, that it was a linear function not of m but of $\sqrt{m}$.

Hence this furnishes a method of extrapolation for the determination of E_0. If the experimental points fall on a straight line over a range of concentration where the data are reliable, a linear extrapolation to $m = 0$ may be made with considerable confidence.

If the complete equation of Huckel[9] applies to the data, this method of plotting cannot give a truly straight line for more than a limited range. Scatchard[10] has calculated values of γ from this equation for aqueous hydrochloric acid at 25°, using electromotive force data only for the empirical determination of two constants in the equation. By substituting these values of γ in Equation (1), it is possible to calculate values for $E - E_0$ and hence, using the definition of E_0'', values of $E_0 - E_0''$. These calculated values, when plotted against m, appear to deviate slightly from a straight line above 0.02 M. A straight line through the points at 0.02 and 0.05 M makes the extrapolated value 0.2 millivolt too low. Hence the complete theory is not in agreement with an exactly linear plot. The theoretical points, however, deviate so little from a straight line, even up to 0.1 M, that it is possible to make an exact extrapolation from them by the use of a flexible spline which is held on the points at 0.01, 0.02, 0.05 and 0.1 M. Below 0.02 M the curvature is inappreciable. Hence this method of extrapolation, if a spline is used instead of a straight rule, gives a result in full agreement with the complete equation of Hiickel.

The application of this method to the available experimental data[2a,b,3,4,5,11] for aqueous hydrochloric acid up to 0.1 M, at the temperatures 20, 25 and 30° is shown in Fig. 1. The curves were drawn with a spline from the points at 0.01 M and above, before the points for lower concentrations were plotted. The deviation of these curves from straight lines is so slight below 0.05 M that its effect on the extrapolated value is less than 0.1 millivolt. The position of the line for 25° is rather arbitrary on account of the multiplicity of discordant determinations. The values extrapolated from these curves are: for 20°, $E_0 = 0.2253$ volt; for 25°, 0.2223; and for 30°, 0.2193. Previous values are. for 20°, 0.2255 (Güntelberg), 0.2253 (Randall and Young, from Giintelberg's data); for 25°, 0.2234 (Linhart, Lewis and Randall), 0.2226, 0.2224, or 0.2223 (Scatchard, from compiled data), 0.2228 (Nonhebel), 0.2221 (Randall and Young, from compiled data adjusted to agree with freezing point determinations); at 30°, 0.2187 (Randall and Young, from two points of Harned and Brumbaugh, adjusted as above).

The ultimate test of such a method of extrapolation must lie in its application to points at low concentrations. Such determinations should

[10] Scatchard, THIS JOURNAL, 47, 2098 (1925).

[11] (a) Harned and Brumbaugh, ibid., 44, 2729 (1922); (b) Harned and Swindells, *ibid.*, 48, 126 (1926); (c) Giintelberg, *Z. physik. Chem.*, 123, 199 (1926); (d) Hitchcock, *J. Gen. Physiol.*, not yet published.

be made, as suggested by Randall and Young, in quartz vessels. At present the new method seems to apply reasonably well to all the data except those for 25° below 0.003 *M*. The large number of points obtained by Nonhebel in this range made it impossible to show them all in Fig. 1, but their trend is clearly toward a higher value of E_0. This agrees with the smaller slope found by him in using the older method of plotting. If this slope is correct, then neither the new method of extrapolation nor the Debye theory is applicable. The extrapolation as given here, then, must stand or fall with the constant 0.5 of the Debye equation.

Fig. 1.—Extrapolation of e.m.f. data for Ag, AgCl, HCl(aq), H_2.

This method should be of use in the treatment of electrolytes of other valence types. In such cases Equations (1) to (4) will be of correspondingly different form.

Summary

A method is given, based on a partially expanded form of the Debye and Hiickel equation, for an almost linear extrapolation of electromotive force data to unit ionic activity. The method is applied to compiled data for aqueous hydrochloric acid at 20, 25 and 30°. It is pointed out that the method is in agreement with the complete theoretical equation of Hiickel, as well as with experimental data, up to 0.1 M.

SILVER ION CATALYSIS OF PERSULFATE OXIDATIONS. III. THE OXIDATION OF AMMONIUM ION[1]

BY CECIL V. KING

RECEIVED APRIL 20, 1928 PUBLISHED AUGUST 4, 1928

Introduction

It was found by Marshall[2] that ammonium persulfate in solution, in the presence of silver salts, decomposes at a measurable velocity, according to the following equation

$$NH_4^+ + 4S_2O_8^{--} + 3H_2O \xrightarrow{Ag^+} 10H^+ + 8SO_4^{--} + NO_3^- \qquad (1)$$

Presumably, according to the recent work of Yost, the first step in this oxidation will be[3]

$$S_2O_8^{--} + Ag^+ \longrightarrow 2SO_4^{--} + Ag^{+++} \qquad (2)$$

It is difficult to postulate a mechanism for the succeeding reaction; the following occurs, but whether in one step or more, one cannot say

$$4Ag^{+++} + NH_4^+ + 3H_2O \longrightarrow 4Ag^+ + NO_3^- + 10H^+ \qquad (3)$$

In any case, from the preceding work on persulfate oxidations catalyzed by silver ion, it was expected that reaction (2) would be the velocity determining reaction; that is, (3) or its equivalent would be comparatively immeasurably rapid. Then, since the Ag^+ ion is regenerated and its concentration would remain constant, one should obtain a "pseudo-unimolecular" reaction with the velocity independent of the concentration of ammonium ion, *provided the salt concentration is held constant throughout the course of the reaction.* The above two conditions were practically fulfilled in the experiments of Marshall and Inglis, with 0.5 *N* and 1.0 N salt solutions.

These investigators found that with 0.25 molar ammonium persulfate and 0.0005 molar silver nitrate the reaction proceeded practically according to a unimolecular curve; that the acid formed did not interfere much with the reaction—though it appears that there was a little oxidation of water and that this was greater if the solution contained 0.25 molar nitric or sulfuric acid at the start; and that the salt effect was negative. All of this agrees with the above postulated mechanism. However, if one starts with quite dilute solutions, the change in salt concentration during the reaction is comparatively enormous—for instance, if one starts with 0.0005 molar ammonium persulfate and 0.0005 molar silver nitrate, the total equivalent concentration at the beginning will be 0.0015, and at the

---

[1] Sections I and II of this series will be found in THIS JOURNAL, **49,** 2689 (1927).

[2] (a) Marshall, *Proc. Roy. Soc. Edinburgh,* 23, 163 (1900); (b) Marshall and Inglis, *ibid.,* **24,** 88 (1902).

[3] (a) Yost, THIS JOURNAL, 48, 152 (1926); (b) *ibid.,* 48, 374 (1926).

end 0.0026. With such concentrations, the salt effect will be quite pronounced, and in this case we should not expect the velocity to follow the unimolecular scheme, but to fall off from this considerably as the reaction progresses. Then we should expect the velocity to follow the Brönsted scheme

$$\frac{\mathrm{d}C_{S_2O_8^{--}}}{\mathrm{d}t} = kC_{S_2O_8^{--}}C_{Ag^+}f_2^2 \qquad (4)$$

where f_2 is the activity coefficient of the $S_2O_8^{--}$ and is continually decreasing as the reaction proceeds; and C_{Ag^+} is a constant. Now in sufficiently dilute solutions f_2 can be expressed as a function of the concentration, according to the formula

$$-\log f_2 = 0.5 \times 2^2 \sqrt{\mu} \text{ at } 25° \qquad (5)$$

where μ is the ionic strength; whence

$$f_2 = 10^{-2\sqrt{\mu}} \qquad (6)$$

and (4) becomes

$$\frac{\mathrm{d}C_{S_2O_8^{--}}}{\mathrm{d}t} = kC_{S_2O_8^{--}}C_{Ag^+}10^{-2\sqrt{\mu}} \qquad (7)$$

μ can be expressed as a function of $C_{S_2O_8^{--}}$; if we let the initial $C_{S_2O_8^{--}} = a$, at time t, $C_{S_2O_8^{--}} = (a - x) F$ and $C_{Ag^+} = b$, then $\mu = 3a + 3.25x + b$, and (7) becomes

$$\frac{\mathrm{d}x}{\mathrm{d}t} = kb(a - x)\, 10^{-\sqrt{3a \times 3.25x + b}} \qquad (8)$$

It was hoped that this equation might be applied but as will be shown later the correct expression for the velocity of this reaction is probably much more complicated than (8); in fact, (8) could scarcely be used even as a first approximation.

The fact that the ion concentration changes by such a large amount during the reaction makes it possible to find the rate of reaction by following the conductivity of the solution, provided the mechanism above is correct. The conductivity does change enormously, especially since hydrogen ion is formed. The conductivity of a solution containing 0.0005 M ammonium persulfate and 0.0005 *M* silver nitrate was 2.2 X 10^{-4} reciprocal ohms at the start and 6.2 × 10^{-4} reciprocal ohms at the end of the reaction. In other solutions the change was smaller or greater according to the concentrations.

Materials and Measurements

Ammonium persulfate and silver nitrate were prepared by recrystallizing from distilled water. No measurements were made on solutions having a conductivity less than 100 times that of the water and consequently ordinary distilled water was used.

Conductances were measured in cells with constants ranging from 0.3455 to 0.3819, as measured with 0.005 *N* KCl. The electrodes were unplatinized. The source of current for the measurements was a radio tube oscillator adjusted to near 1000 cycles per second.[4] The bridge was a Leeds and Northrup ratio coil bridge and resistance box which had been checked with 1000 cycle current against a standard A. C. bridge. A two-stage radio amplifier was used to make the reading of the null point easy. Air and mica condensers were used across the resistance arm of the bridge to balance capacity effects of the cells. The cells were immersed in a small thermostat electrically controlled to ±0.02°. All errors due to temperature and to conductance measurements were undoubtedly well within the other errors of reaction velocity measurements.

Solutions of ammonium persulfate and silver nitrate were made up of twice the concentration desired for the experiments; 10 cc. of one was placed in the conductivity cell in the thermostat and 10 cc. of the other withdrawn from a bottle standing in the thermostat and allowed to run into the cell, which was then shaken to mix the solutions thoroughly. The first conductivity reading could be taken one minute, or two minutes at the most, after the solutions were mixed. This turned out to be quite important, as it gave valuable information about the first stages of the reaction, showing that it has an autocatalytic character, a fact which is not evident if one discards the measurements of the first hour. This factor is not apparent in the before-mentioned measurements of Marshall and Inglis, since measurements were not made during the first few minutes of the reaction; however, perhaps an effect of it is seen in the fact that their "unimolecular" constants seem to increase steadily by 3–6% throughout the course of the reaction.

Results of the Measurements

Table I gives the details of two typical experiments, and several experiments are shown graphically in Figs. 1 and **3.** Figs. 2 and 4 show the first stages of these same experiments on a much enlarged scale. These figures show that experiments could not be duplicated with certainty. In general, the reaction seemed to be autocatalytic, as shown in Experiments 2, 3, 4, 7 and others not recorded here, but sometimes such effects as shown in Experiments 5 and 6 were present. At any rate, the divergence of the results for duplicate experiments seemed to be due to divergence at the start: this was probably dependent on the exact manner of mixing the solutions, though several experiments failed to show this conclusively. Catalytic effects by the walls of the cell, by the platinum electrodes or by "dust" particles are not ruled out, though rather unlikely.

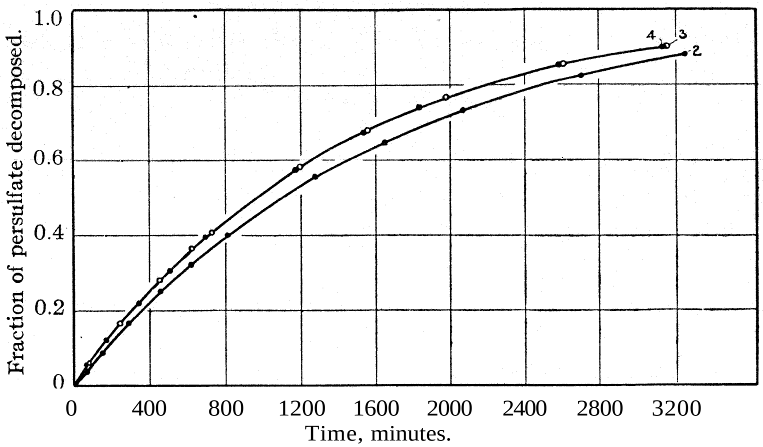

Fig. 1.—Rate of decomposition of 0.0005 M ammonium persulfate with 0.0005 M silver nitrate as catalyst.

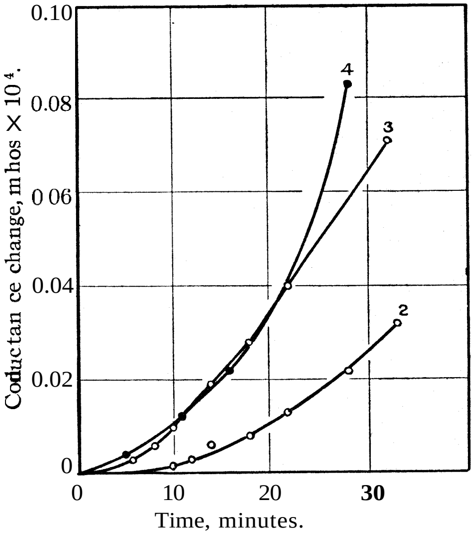

Fig 2.—The initial part of the curves of Fig. **1.**

It has been assumed above that the measured conductivity change is proportional to the amount of persulfate decomposed, an assumption which must be proved. The autocatalytic character of the curves indicates that reaction **(3)** is not immeasurably rapid, and this means that some small concentration of Ag^{+++} ion is built up in the solution.

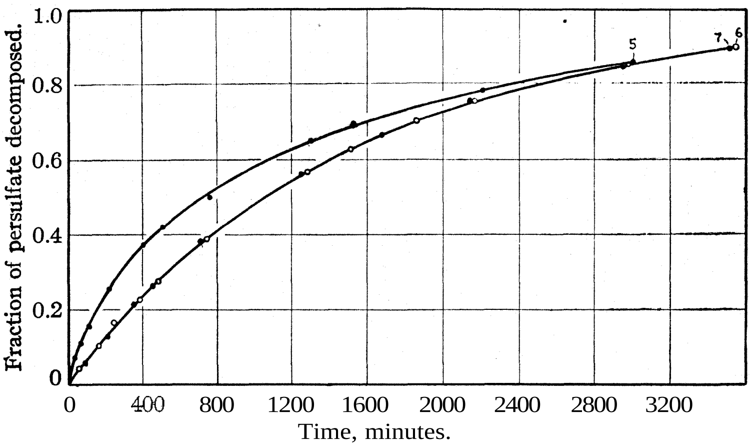

Fig. 3.—The rate of decomposition of 0.001 M ammonium persulfate with 0.0005 M silver nitrate as catalyst.

The conductance of 0.001 M $AgNO_3$ at 25° was 1.360 X 10^{-4} mhos; that of 0.001 *M* $(NH_4)_2S_2O_8$ was 3.042 X 10^{-4} mhos. The mean of these is 2.201 X 10^{-4} mhos. When 10 cc. of each of these solutions were mixed, the conductance was 2.203 X 10^{-4} mhos. This indicates that in this dilute solution the conductances were additive and there was little, if any, immediate compound formation or reaction of any kind. In the experiments recorded in Table II, various proportions of the freshly mixed solution and the same solution after complete decomposition were mixed and the conductance of these mixtures was compared with the points on the conductance curve to which they would be expected to correspond. To make this clear: in Experiment 3, the freshly made solution had the conductance 2.203 × 10^{-4} mhos. The conductivity after the persulfate was

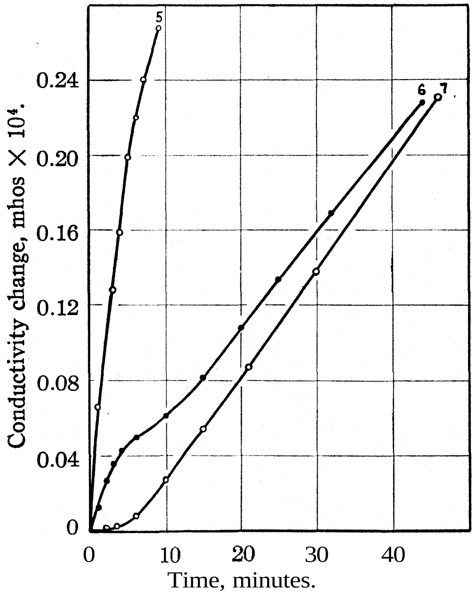

Fig. 4.—The initial **part** of the curves of Fig. **3.**

entirely decomposed was 6.181×10^{-4} mhos. The mean of these is 4.192×10^{-4} mhos. A mixture of 10 cc. each of the fresh solution and the decomposed solution gave 4.108×10^{-4} mhos. Further values are given in Table II.

TABLE II

COMPARISON OF CONDUCTIVITIES OF MIXTURES OF INITIAL AND FINAL SOLUTIONS WITH CORRESPONDING POINTS ON THE VELOCITY CURVE

Solutions of Experiment 3	$\kappa \times 10^4$	Corresponding κ from curve	Solutions of Experiment 6	$\kappa \times 10^4$	Corresponding κ from curve
40 cc. init., 10 cc. final	3.05	3.00	40 cc. init., 10 cc. final	5.20	5.14
20 cc. init., 10 cc. final	3.59	3.53	20 cc. init., 10 cc. final	6.25	6.16
10 cc. init., 10 cc. final	4.20	4.19	10 cc. init., 10 cc. final	7.55	7.43
20 cc. init., 30 cc. final	4.57	4.59	10 cc. init., 20 cc. final	8.88	8.70
10 cc. init., 20 cc. final	4.86	4.85			
10 cc. init., 30 cc. final	5.23	5.19			

This shows that there are no intermediate compounds formed in the solution in concentration high enough to affect the conductance by more than, say, 1% and that the conductance change really corresponds closely to the persulfate changes.

Discussion of Results

The autocatalytic character of the curves indicates that both reaction (2) and reaction (3) are comparatively slow. As (1) proceeds, a higher and higher concentration of the intermediate compound is built up and reaction (3), being dependent on the concentration of this, proceeds faster and faster, though there is never enough of the intermediate to greatly affect the conductance. There must soon be reached an equilibrium concentration of this intermediate compound; otherwise the "induction" period would be longer; or if persulfate were present in excess of the amount required for all the ammonium ion, the velocity would perhaps keep on increasing indefinitely, until all the ammonium ion was used up. Also, if any appreciable concentration of the intermediate compound were built up in the solution, we should expect it to precipitate. No such precipitation occurred in any of the solutions recorded, but if more concentrated solutions are used, this does occur. If equal volumes of 0.05 M solutions of ammonium persulfate and silver nitrate are mixed, the solution becomes discolored at once and there is a slow precipitation of the black compound of trivalent silver. This reaches a maximum amount and if the solution is shaken, all disappears in the course of two hours. This also indicates that the oxidation of the ammonium ion by the trivalent silver is not "instantaneous."

If we were sure that Equation (3) is correct, we could set up an equation for the resultant velocity of the two reactions, However, there are several reasons why this is impracticable. First, we do not know that (3) is the correct expression of the second slow reaction. Second, the equation would be too complicated to test experimentally. Third, the non-reproducibility of the experiments shows the presence of some factor that is as yet unknown. It seems probable that the velocity of the second reaction is of the following form

$$\frac{dC_{NH_4^+}}{dt} = k_2 C^n_{Ag^{+++}} C_{NH_4^+} F \qquad (9)$$

where F is the kinetic activity factor and depends on the value of n, the number of Ag^{+++} ions taking part in the velocity determining reaction. A combination of (4) and (9) would then give the velocity of oxidation of the ammonium ion in terms that could be tested experimentally, were the expression not so complicated. The mathematics of some types of consecutive reactions has been thoroughly worked out and tested by Wegscheider, Skrabal and others,[5] but no case similar to this, where there is both a continually regenerated catalyst and an activity factor in one or both velocity expressions, has been worked out.

If one neglects the short induction period, and calculates "k" in equation (4), considering $f_2 = 1$, it might be expected that "k" will be much higher than the unimolecular constants obtained by Marshall and Inglis for 1 N and 0.5 N solutions; and that "k" will decrease throughout the reaction as the salt concentration increases. That this is true is shown in Table III. The corresponding k for the 1 N solution is 0.218. In these solutions of equivalent salt concentration 0.0015 to 0.0025, the velocity is, at the start of the reaction (after the induction period), about eight times as rapid.

TABLE III

"k" FROM THE UNIMOLECULAR EQUATION FOR EXPERIMENT 3

Time, min.	67	135	228	432	606	1179	1539	1954
"k"	1.86	1.70	1.59	1.51	1.50	1.48	1.49	1.49

It is seen too, in Table III, that the value of "k" does not decrease as much during the course of the reaction as would be expected from the salt concentration change. This is, no doubt, due to the effect of the second reaction.

Discussion of Other Reactions

In the oxidation of ammonia by persulfate, in alkaline solution, catalyzed by silver ion, studied by Yost and by the present author, there was no noticeable autocatalytic effect. The reaction is much faster, however, in the same salt concentration than the present reaction; and the facts

---

[5] Wegscheider and others, *Monatsh.*, 36, 471 (1915); *ibid*, 37, 137 (1916); *ibid*, **39,** 741 (1918), and other papers.

that none of the black compound of trivalent silver is precipitated even from comparatively concentrated solutions, and that this black compound, prepared by mixing potassium persulfate and silver nitrate, dissolves very rapidly in ammonia, with evolution of nitrogen, indicate that in this case the second reaction is very much faster. This undoubtedly makes the autocatalytic character of the curve disappear.

Equation (9) makes the velocity dependent on the concentration of reducing agent. The effect of ammonium ion concentration was not thoroughly studied in this investigation; but while experiments **3** and 4 should be faster than 6 and 7, due to the lower salt concentration, they show about the same velocity. This is probably due to the fact that the ammonium ion concentration was lower in experiments *3* and 4. Some experiments with 0.0001 M ammonium persulfate and 0.0005 M silver nitrate showed a somewhat higher velocity, though again not as much higher as would be expected with the lower salt concentration. This was probably also due to the fact that the ammonium ion concentration was lower, as well as the total salt concentration. Yost[3] found a linear relation between ammonia concentration and reaction velocity; this he explained by assuming that in more concentrated ammonia solutions more of a higher complex with Ag^+ ion than $Ag(NH_3)^+_2$ is formed. The present work makes it seem quite possible that even though the second step of the oxidation is fast compared to the first, it is not so fast that the concentration of the reducing agent does not have some influence on the resultant velocity.[6]

One might suspect that other "catalytic" reactions would show this autocatalytic type of velocity curve. The unimolecularity of the inversion of sugar, catalyzed by acid, has been questioned; it seems that the first part of the curve may be irregular.[7] The measured velocity constants increase as the reaction proceeds, even if correction is made for the "mutarotation lag" of the inversion products. This would be in accord with a slight autocatalytic effect, in a reaction where there is no salt effect due to change in ion concentration during the course of the reaction. It is probable that a hydrated sugar molecule is inverted by hydrogen ion in

---

[6] It should be noted that the oxidation of ammonia and ammonium ion has not been investigated in solutions containing both these ions over a wide range of relative concentrations. Marshall's work indicated that the oxidation to nitrate is quantitative in solutions originally containing only neutral ammonium persulfate and silver salt. An experiment by the present writer showed that no appreciable amount of nitrogen was evolved during twenty-four hours from such a solution. Some of the solutions recorded in section I of this series contained ammonium ion, increasing in concentration as the reaction progressed, but also an excess of free ammonia, and no diminution in the amount of nitrogen evolved was observed. It would be valuable to investigate the nature of the reaction in solutions of intermediate PH.

[7] Fales and Morrell, THIS JOURNAL, 44, 2071 (1922); Pennycuick, *ibid.*, 48, 6 (1926); see, however, Scatchard, *ibid.*, 48, 2259 (1926).

two steps, which we may represent as follows, neglecting hydration of the hydrogen ion and the corresponding complications

$$C_{12}H_{22}O_{11}\cdot nH_2O + H^+ \longrightarrow C_{12}H_{22}O_{11}\cdot nH_2O\cdot H^+ \qquad (10)$$

$$C_{12}H_{22}O_{11}\cdot nH_2O\cdot H^+ \longrightarrow \text{invert sugar} + H^+ \qquad (11)$$

Only if reaction (11) is "instantaneous" would we expect a unimolecular sugar inversion; if (11) is slow enough that the intermediate compound increases in concentration for a time, the curve will have at least some indication of an autocatalytic character.

The hydrogen ion catalysis of ester hydrolysis does not present the irregularities that the sugar inversion does. If the mechanism is similar to that of the sugar inversion, this would mean that the reaction corresponding to (11) is very rapid compared to that corresponding to (10).

The esteracid–water system has been investigated to find if there are any ternary compounds formed immediately on mixing the solution and no conclusive evidence of any appreciable concentration of such compounds was found,[8] although previous work made it seem quite certain that the hydrolysis proceeds through the formation of intermediate compounds.[9] However, the investigation mentioned was not extended to looking for a slow accumulation of such ternary compounds as the reaction proceeds; but as mentioned before, the unimolecularity, or rather "pseudo-unimolecularity" of the hydrolysis makes it unlikely that there is any such accumulation. On the other hand, in the case of the sugar inversion, it is possible that there is a slight accumulation of such an intermediate, and this might be detected experimentally.

Summary

The velocity of oxidation of ammonium ion by persulfate ion, catalyzed by silver ion, has been measured in much more dilute solutions than before.

It is shown that the conductance method used gives a nearly correct measure of the velocity.

The velocity curves are mostly autocatalytic, though not strictly reproducible, showing that the reaction proceeds through at least two steps of comparable velocity. In previous work on persulfate oxidations catalyzed by silver ions it has been assumed that the second step is immeasurably fast.

It is suggested that the irregularities in sugar inversion catalyzed by hydrogen ion may be due to a slight autocatalytic effect similar to the one measured here.

SILVER ION CATALYSIS OF PERSULFATE OXIDATIONS. IV. OXIDATION OF OXALATE ION[1]

BY CECIL V. KING

RECEIVED APRIL 20, 1928 PUBLISHED AUGUST 4, 1928

Introduction

It was found by R. Kempf[2] that oxalic acid is only slowly, if at all, oxidized by persulfates, at room temperature, in the absence of any catalyst, while in the presence of a small amount of a silver salt the oxidation proceeds quite rapidly, and presumably quantitatively, according to the following reaction

$$H_2C_2O_4 + K_2S_2O_8 \longrightarrow 2KHSO_4 + 2CO_2 \qquad (1)$$

This oxidation is given as a quantitative method for estimating persulfates by Treadwell and Hall.[3] A neutral oxalate seems to be oxidized just as completely and rapidly as an acid solution (perhaps more rapidly); silver salts have a much greater catalytic effect than in some of the other persulfate oxidations.[4] The purpose of this investigation was to study the velocity of the reaction quantitatively with a view to the elucidation of its mechanism and its differences from the other reactions mentioned.

Theoretical

This reaction was expected, in accordance with the others, to proceed in two steps, as follows

$$S_2O_8^{--} + Ag^+ \longrightarrow 2SO_4^{--} + Ag^{+++} \text{ (slow)} \qquad (2)$$
$$C_2O_4^{--} + Ag^{+++} \longrightarrow 2CO_2 + Ag^+ \text{ (faster)} \qquad \text{i3)}$$

If reaction (3) were extremely fast, then the net rate should be "pseudo-unimolecular," and independent of the oxalate ion concentration, so long as the oxalate, and not the persulfate, is in excess in the solution; if the persulfate is in excess a modified unimolecular curve will result. On the other hand, if reaction (3) is comparatively slow, trivalent silver ion will increase in concentration as the reaction proceeds and autocatalytic curves may be obtained as in the case of the ammonium ion oxidation.[5] From the complete ionic equation

$$S_2O_8^{--} + \text{GO}\sim - \xrightarrow{Ag} 2SO_4^{--} + 2CO_2 \qquad (4)$$

---

[5] Section III of this series.

it is seen that there is no change in ionic strength in the solution during the course of the reaction (or very little; a small amount of ionized carbonic acid will be formed) and consequently there will be little salt effect during the course of the reaction. Of course, with different initial concentrations or in the presence of a foreign salt the velocity will be changed.

However, the oxidation proceeds, it will be seen, much faster than does reaction (2)—judging from the velocity of the reactions studied before. Consequently, the preceding mechanism is perhaps entirely ruled out as an explanation for this reaction. No complete explanation for the results obtained in this investigation can be offered, but some of the factors involved will be discussed and tentative explanations proposed.

Experimental

Potassium persulfate, sodium oxalate, silver sulfate and nitrate were all prepared by recrystallization and thorough drying of the crystals; the salts were either weighed directly for each experiment or to make standard solutions.

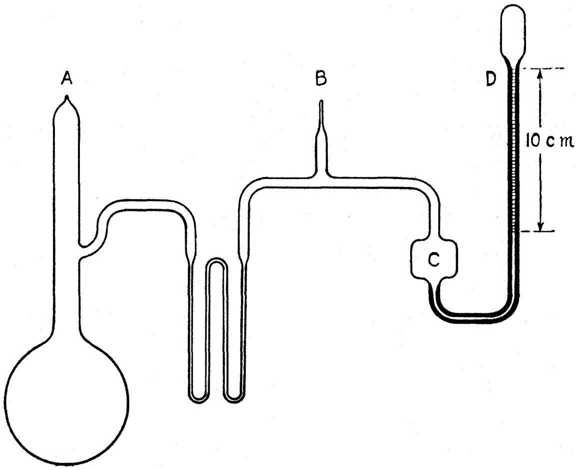

Fig. 1.—The modified apparatus for measuring the rate of gas evolution.

Since carbon dioxide is evolved, the easiest way to follow the reaction is to follow the evolution of this gas. This was done in a modification of the apparatus designed by Brönsted.[6] The modified apparatus is shown in Fig. 1. All stopcocks and ground stoppers were eliminated. The solution, containing (usually) the oxalate and the silver salt, was introduced into the flask and the solid persulfate was suspended in a small glass capsule, from a platinum loop sealed in the side of the neck of the flask. D was a closed manometer, well evacuated and "boiled out," with a 5cc. bulb at the top, to prevent error from any traces of gases remaining above the mercury. The bulb C was made large enough to accommodate this extra mercury. When all was ready for an experiment, A was sealed off, the system evacuated through a capillary at B and this

---

[6] (a) Brönsted and Duus, Z. *physik. Chem.*, **117, 299 (1926)**; (b) Bronsted and King, THIS JOURNAL, **47, 2523** (1925).

then sealed off. At the close of an experiment only the tip of B was broken off at first, so that the air entered the apparatus slowly, otherwise the mercury, rising rapidly in the manometer, might break the bulb D.

This form of the apparatus is somewhat more difficult to manipulate than the older style but if it is made of Pyrex glass the seals are not difficult and it has the advantages that accidental leaks are almost completely eliminated and, besides, it can be used for reactions in which gases are evolved that attack the usual vacuum-tight stopcock lubricants.

Some of the experiments were carried out at 20 ± 0.02°, others at 25 ± 0.02°, as indicated in the tables. During each experiment the room temperature was kept slightly higher than that of the bath to prevent distillation of water from the reaction flask to other parts of the apparatus.

The Measurements

Some preliminary Experiments and Experiments 44, 45, 46 and 47 were made to find whether the reaction between $S_2O_8^{--}$ and $C_2O_4^{--}$ had an appreciable velocity with no silver ion present as catalyst. The velocity is small; the results are not in very good quantitative agreement and it is possible that the reaction is due to traces of "accidental" catalysts. The velocity is negligible compared to that in most of the experiments with silver ion as the catalyst. The results are given in Table I.

TABLE I

THE REACTION BETWEEN $S_2O_8^{--}$ AND $C_2O_4^{--}$ WITH NO CATALYST AT 25°

Concentrations: 0.01 *M* $Na_2C_2O_4$, 0.005 *M* $K_2S_2O_8$

Time. min.	Frac. persulfate decomposed Expt. 44	Expt. 45	Time min.	Frac. persulfate decomposed Expt. 46	Expt. 47
120	0.001	0.000	120	0.007	0.007
240	.007	.007	210	.010	.015
440	.015	.010	360	.019	.030
620	.025	.018	420	.025	.034
1380	.104	.061	1110	.142	.136

In Experiments 34 and 35, which have the same concentrations as the above, with the addition of 0.00002 M silver nitrate, the velocity was nearly unimolecular. Table II gives a part of the experimental figures to illustrate this, and the entire curves are shown graphically in Fig. 2.

TABLE II

VELOCITY "CONSTANTS" WITH A SILVER SALT PRESENT AT 25°

Concentrations: 0.01 M $Na_2C_2O_4$, 0.005 M $K_2S_2O_8$, 0.00002 M $AgNO_3$

$$``k" = \frac{2.3}{t \times C_{Ag^+}} \ln \frac{a}{a - x}$$

Expt. 34	Time, min.	50	70	120	240
	"*k*"	213.2	217.9	208.4	190.7
Expt. 35	Time, min.	50	70	120	240
	"*k*"	263.6	260.5	251.5	237.5

However, the experiments recorded in Table II, although carefully made up duplicates in concentration, do not agree with each other within reasonable experimental error, and this is by no means the worst case of disagreement in the velocity in solutions that duplicated each other in concentration. Further, the velocity was not always as nearly unimolecular as in the above cases. In several instances typical autocatalytic curves were obtained, while in others there was a very short autocatalytic period at the beginning of the reaction, as in the ammonium ion oxidation; sometimes this autocatalytic period was not evident but the velocity curve was flattened at the beginning, no doubt due to the same cause. Table III gives the details of concentration and temperature, and Figs. 3–5 show the data graphically for several experiments carried out with an excess of oxalate present.

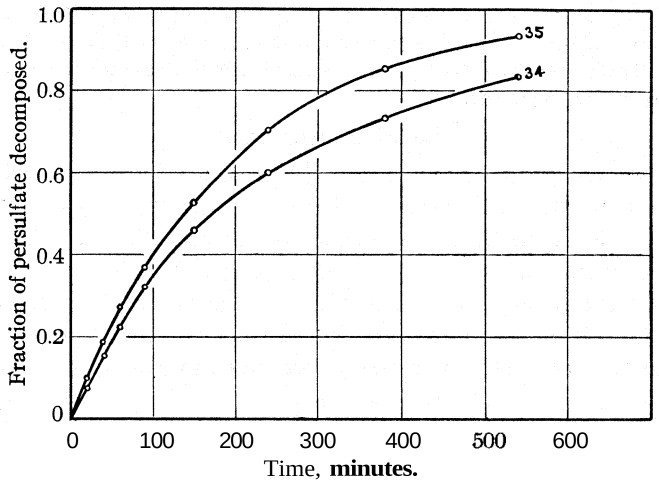

Fig. 2.

TABLE III

CONCENTRATION AND TEMPERATURE FOR EXPERIMENTS PLOTTED IN FIGS. 3–5

Expt. no.	$Na_2C_2O_4$, *M*	$K_2S_2O_8$	$AgNO_3$	Ag_2SO_4, *N*	Temp., °C.
4, 6, 7, 8, 9, 17	0.01	0.005	....	0.00002	20
36, 37	.005	.0025	0.00003	....	25
38, 39	.005	,0025	.00004	....	25
40, 41, 54, 55	.005	.0025	.00002	....	25
42, 43	.005	.0025	.00001	....	25

All of the experiments in Fig. 3 were duplicates and should agree; but their velocity is far different. As a rule, when experiments were run with different concentrations, the velocity was changed in the direction expected, but there was no quantitative agreement. For instance, 43, with 10^{-5} M Ag+ is slower than 38, with 4 X 10^{-5} M Ag^+, but much more than one-fourth as fast. Many other similar discrepancies can be noted. Nevertheless, the order of magnitude of the velocity was always the same. The experiments at 25°, for instance, were run about a year later than those at 20°, with entirely new salts and new reaction flasks, and still are of the same order of magnitude.

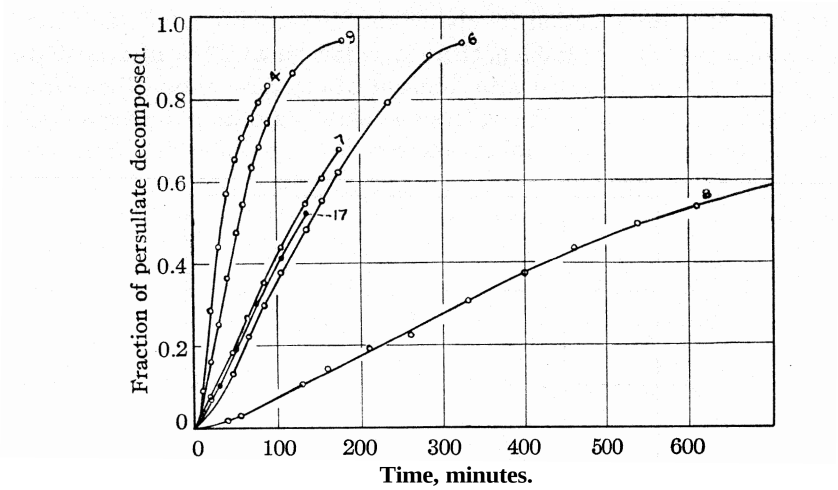

Fig. 3.

When persulfate is present in excess instead of oxalate, conditions are somewhat different. While the velocity may be somewhat dependent on the concentration of oxalate, it is more dependent on the persulfate

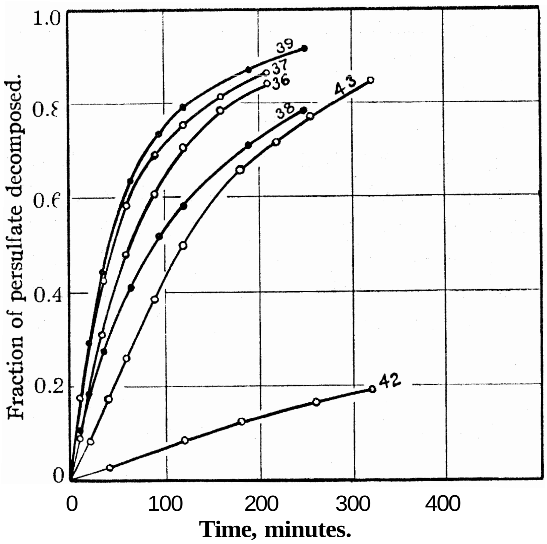

Fig. 4.

concentration, as is shown by the nearly unimolecular nature of some of the above curves. The autocatalytic character of some of these curves indicates, however, that an intermediate, unstable compound is formed, presumably by the interaction of the persulfate and silver ions, and if persulfate is present in sufficient excess, the silver ion concentration is high enough and the reaction involving the decomposition of the intermediate compound is slow enough, there is no reason why this intermediate should not keep on increasing in concentration throughout the entire reaction and consequently the rate of oxalate oxidation increase continuously. Several experimental curves were found to have this character; in Table IV are given the details of concentration and temperature and in Figs. 6–8 are shown graphically several examples, some with twice as much persulfate as oxalate, some with a larger excess. Again, however, it must be noted that experiments could not at all be duplicated, in spite of care in making up the solutions and in cleaning the vessels used, and attempts to trace the cause of these discrepancies were not very successful.

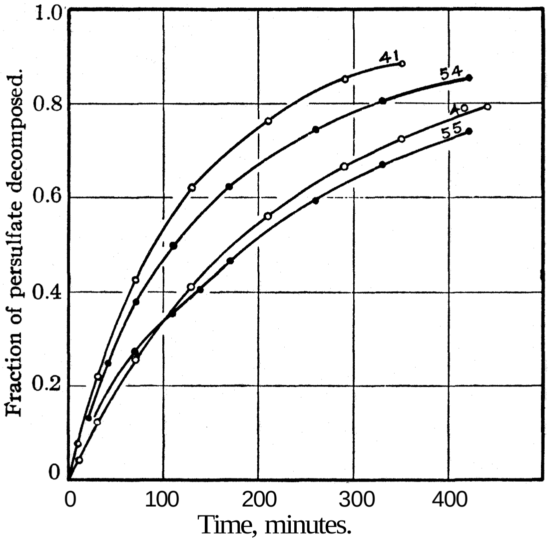

Fig. 5.

51, 52, 53	.0025	..	.01	.00002	....	25

It was suspected that the reaction might be catalyzed by the diffuse daylight or electric light that reached the flasks, but a 200-watt tungsten lamp placed just outside the thermostat quite near one of the reaction flasks had no appreciable effect on one rather slow experiment. Also, the divergences could scarcely be ascribed to a difference in illumination of the two flasks used, or of one flask at different times. It was suspected that the exact manner of mixing the last reagent in the solution caused the velocity to vary. Usually the persulfate was dropped in last, and sometimes it dissolved rapidly (30–40 sec.), sometimes more slowly (2-4 min.)

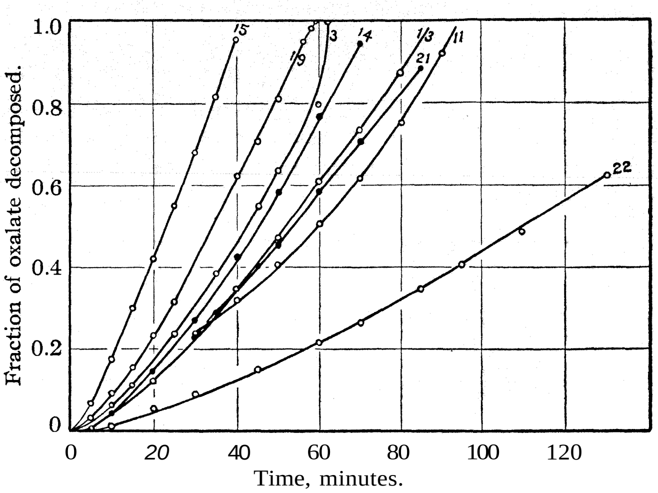

Fig. 6.

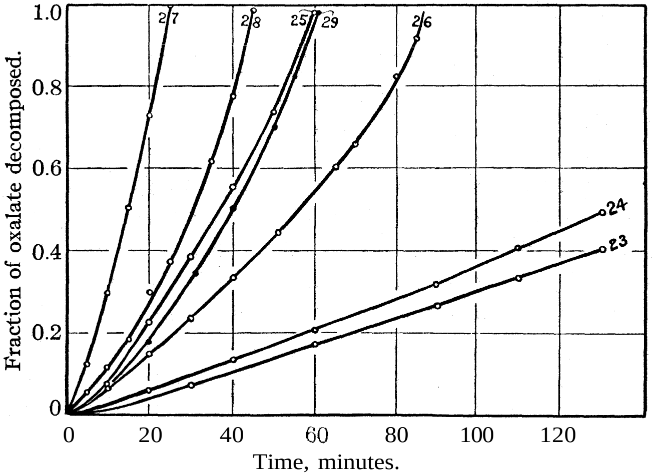

Fig. 7.

depending on the exact manner in which the glass capsule fell into the solution. So in Experiments 38 and 40 the solid persulfate was allowed to dissolve slowly (6 min.) with very little shaking of the flask, while in **39** and 41, run side by side with 38 and 40, the persulfate was dropped in and dissolved in a few seconds. The difference is no greater than in many other experiments in which the rate of solution of the persulfate was approximately the same. In other experiments the silver nitrate was dropped in last, and in general these experiments seemed to have a slightly higher velocity than the others with the same concentrations, but the effect was not pronounced.

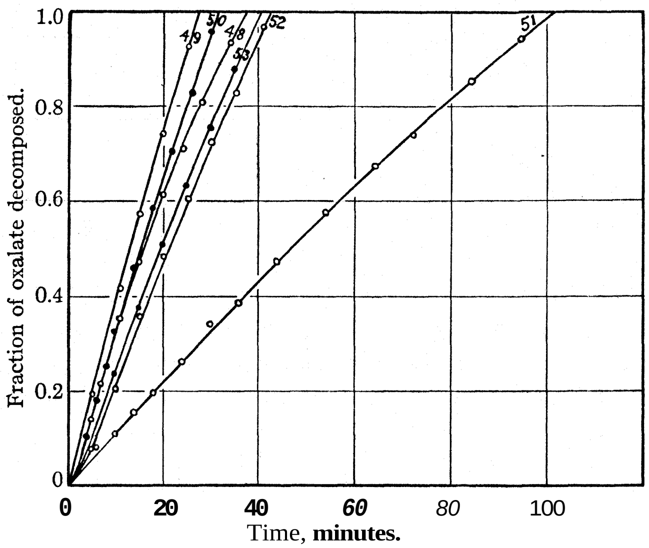

Fig. 8.

If the autocatalytic effect is due to an accumulation of intermediate compound formed by reaction of the persulfate and silver ions, then if these two are mixed and allowed to react until the maximum amount of the intermediate is present, the autocatalytic character should disappear and the curve be either a "zero order" curve—if this maximum concentration of the intermediate is maintained--or a concave curve, if the concentration of the intermediate diminishes after the oxalate is added. For Experiment 15, the persulfate and silver sulfate were mixed, and one hour later the oxalate was added and the experiment started. The autocatalytic character almost disappeared, and the reaction was somewhat faster than the others of the same concentrations. Possibly the reaction between the persulfate and silver ions was not complete in one hour.

Only one consistent discrepancy was noticed in any series of experiments;

for a time, when duplicates were run side by side in the two pieces of apparatus, those in apparatus No. 1 were consistently slower than those in apparatus No. 2. This is shown by Experiments 34, 36, 38, 40, 42 and 48, which were run in apparatus No. 1, and were, respectively, duplicates of and were run beside Experiments 35, 37, 39, 41, 43 and 49 in apparatus No. 2. This suggested catalysis by the flask walls and to see if an increase in the glass surface would change the velocity considerable broken glass was introduced into flask No. 1 while Experiments 42 and 43 were run. If there was any catalytic effect it was negative. Next the wall of flask No. 1 was thoroughly etched with hydrofluoric acid, and Experiments 52 and 54 were run side by side with 53 and 55. Fifty-three in No. 2, was slightly faster than 52, in No. 1; while 54, in No. 1, was faster than 55 in No. 2. Any effect was slight, however, compared to the differences between duplicate solutions run in the same apparatus on different days.

It is possible that there was some catalysis by "dust" in the solutions,[7] though there was probably no large effect from this source. Small amounts of precipitated silver oxalate could scarcely he responsible; in all the solutions reported here, care was taken that the concentrations should be below those at which silver oxalate would precipitate and no precipitation was discernible. Several experiments were run with concentrations high enough to cause a slight visible precipitation, without any pronounced effect that would indicate such a catalysis.

Discussion

The experiments mentioned before make it seem quite likely that there is some wall catalysis. No simple procedure is sufficient to prevent this or make it possible to duplicate its effects except accidentally. The fact that broken glass in the flask, or etching the flask, had no pronounced effect, makes it seem impossible that this wall catalysis could be responsible for the enormous difference in velocity between these experiments and the oxidation of other reducing agents. It is just possible that "dust" or some unknown impurities could be responsible, for many reactions are extremely sensitive to traces of catalysts. For example, the effect of Cu^{++} and Fe^{++} and mixtures of these two on the persulfate oxidation of iodide ion may be cited,[8] also the effect of traces of impurities on some isomeric changes.[9]

If most of the catalysis were heterogeneous, one would expect a zero order or a unimolecular reaction in all cases. This is nearly true in some of the solutions. Expts. 48, 49, 50, 51, 52 and 53 are almost of zero order, and further showed irregularities that might very well attend wall catalysis when the shaking of the flask is not quite uniform, but the auto-

catalytic effect, especially in solutions containing excess persulfate, indicates rather that the phenomenon is at least largely some peculiarity of the reactions between the various ions and intermediate products, and that this makes the reaction *so* much faster than the others, while the wall catalysis probably accounts for the comparatively small differences between the individual experiments.

It should be noted that the irregularities cannot be accounted for by supersaturation of the solution with carbon dioxide and consequent failure of the manometer readings to represent the rate of reaction. This may cause small errors in such velocity measurements (say 1–3%) but not the wide variations found here, especially since precautions were taken to shake the reaction flasks in approximately the best manner.[10]

Various explanations can be advanced for the high velocity of this reaction. As was mentioned before, the oxalate is, apparently, oxidized faster than trivalent silver ion is formed. Dr. R. Livingston[11] has suggested one explanation for this. Assume that the persulfate and silver ions form first a complex ion that is relatively inactive, that is, can oxidize only good reducing agents, as the oxalate ion, but not ammonium or chromic ion. From this is formed a more active silver ion, AgO^+ or Ag^{+++}, which can oxidize the poorer as well as the better reducing agents. To fit all the existing data a series of simultaneous and consecutive reactions can be formulated which will account for the various rates, for the autocatalytic character of some of the curves and for any dependency on the concentration of the reducing agent.

We can scarcely expect the initial reaction to be represented merely by Equation (2)

$$Ag^+ + S_2O_8^{--} \longrightarrow Ag^{+++} + 2SO_4^{--}$$

except perhaps as an approximation under certain conditions. In the thermal decomposition of persulfates in water solution there are at least three reversible steps, before the final product of SO_4^{--} ion is formed from the $S_2O_8^{--}$ ion.[12] In the photochemical decomposition in water solution, sulfate ion is the only detectable product obtained,[13] but it is nevertheless quite likely that there are undetectable intermediate stages. The constitution of the persulfates is not well understood but it is unlikely that sulfate ion can be formed directly by splitting of persulfate ion, that is,

$$S_2O_8^{--} + 2\ominus \longrightarrow 2SO_4^{--}$$

(the silver ion supplying the electrons). So some mechanism similar to that of Livingston's is quite probable.

[13] Morgan and Crist, THIS JOURNAL, 49, 16 (1927).

One might also formulate a mechanism in which the silver ion is oxidized in two steps, first to bivalent and then to trivalent silver. The slower oxidations would be sensitive only to the trivalent silver while the oxalate ion would be oxidized by the bivalent silver. Intermediate reducing agents could be oxidized rapidly by the trivalent, slowly by the bivalent form.

It is unfortunate that the irreproducibility of these experiments makes it quite impossible to tell whether the velocity is proportional to the first or the second power of the silver-ion concentration or to test properly any suggested mechanism for the reaction. Consequently, the chemistry of the persulfate oxidations cannot be much further elucidated.

Summary

The rate of oxidation of oxalate ion by persulfate ion in dilute water solution has been measured, using silver salts as the catalyst, and the following conclusions have been reached.

With no added catalyst the reaction proceeds very slowly, and it is not known whether or not this slow action is due to "accidental" catalysts or the vessel walls.

With silver salts added as a catalyst, the reaction is very much faster than the similar oxidation of ammonia, ammonium ion and chromic ion.

There is undoubtedly some catalytic effect, either positive or negative, by the glass reaction vessel walls and possibly some catalysis by accidental impurities.

However, the major portion of the difference between the velocity in this and the other oxidations is most likely due to some peculiarity in the reaction itself.

The autocatalytic character of some of the curves indicates that some intermediate compound decomposes at a speed comparable with that of its formation and that in certain cases it accumulates in the solution. This cannot be the trivalent silver ion that was postulated as the intermediate substance in the other oxidations.

Possible mechanisms for the main part of the reaction (not the wall catalysis) are discussed.

The extreme irregularity of the velocity even in carefully prepared duplicate solutions makes it impossible to elucidate the mechanism further or to study other aspects of the problem such as "salt effect" on the velocity.

THE THERMAL DECOMPOSITION OF AMMONIA ON TUNGSTEN, MOLYBDENUM AND NICKEL. I

BY C. H. KUNSMAN

RECEIVED APRIL 21, 1928 PUBLISHED AUGUST 4, 1928

The decomposition of ammonia on the surface of hot iron catalysts has been used in experiments to give further information regarding the role played by the catalysts in the ammonia reaction.[1] In order to compare the results of these experiments with the published results of similar tests on tungsten[2] and molybdenum,[3] it was necessary to make tests on drawn tungsten and molybdenum filaments, under the same conditions as for the catalysts. As these tests were made through a wider range in temperature and give results somewhat different from those previously reported, a detailed account of these tests will be given.

The impetus toward this method of studying a heterogeneous or surface reaction and the method of interpreting the experimental result are due primarily to Hinshelwood and his collaborators.[4] They studied the decomposition of ammonia on silica, platinum, tungsten and molybdenum with the view of interpreting the temperature coefficient of the surface reaction as a measure of the heat of activation somewhat as the analogous idea is applied to a homogeneous reaction. They were also interested in the magnitude of this apparent heat of activation in relation to the catalytic activity of the surface.

In some earlier work the homogeneous decomposition of ammonia was sought by Perman and Atkinson[5] and by Bodenstein and Kranendieck[6] in porcelain and quartz vessels, respectively, at temperatures from 677 to 1111°, with the result that all decomposition could be accounted for by a wall, or surface, reaction.

Very recently Schwab[7] has studied the decomposition of ammonia on platinum and tungsten at low pressures with the view to determining the order of the reaction and the effects of the products of the reaction.

The ammonia reaction is a surface reaction of the simpler form where

both the reacting substance, ammonia, and the products, nitrogen and hydrogen, are gases and it lends itself to kinetic treatment.

Apparatus

The apparatus consisted of a decomposition chamber of 1 or 2 liters' capacity made of Pyrex glass with heavy tungsten leads. Fig. 1 shows a late type of the chamber in which the filaments were mounted horizontally. In an earlier design the filaments were mounted vertically. The tungsten, molybdenum and nickel filaments were attached directly at one end to heavy tungsten leads and at the other to a fourth common lead through molybdenum springs and platinum strips The function of the springs was to keep the filaments taut, and of the platinum strips, which shunted the springs, to carry most of the current so that no part of the leads or filament connections became hot when current from the storage battery was used to heat the filaments. The chamber was attached to a high vacuum system and mounted so that it could be surrounded by an electric oven and baked to 500° and thoroughly evacuated to a pressure of 1×10^{-6} mm. of mercury. Ammonia gas from a liquid ammonia reservoir, previously dried in contact with sodium, was admitted into the system shown. The ammonia pressure, about one-third of an atmosphere, was read on a McLeod gage. Tank nitrogen and hydrogen were admitted to the system as desired after having been very thoroughly treated and dried by passing each gas over hot copper filings, calcium chloride, fused potassium hydroxide, a very hot tungsten spiral filament and through a liquid-air trap. A mercury trap, not shown in the figure, separated the decomposition chamber and McLeod gage from the rest of the system when the proper pressure of ammonia or gas mixture was obtained before current was applied to the filament. As the pressure in the chamber doubles when the ammonia is decomposed into N_2 and $3H_2$, the data sought were obtained by observing the rate of increase of pressure on the gage as a function of the temperature of the hot filament.

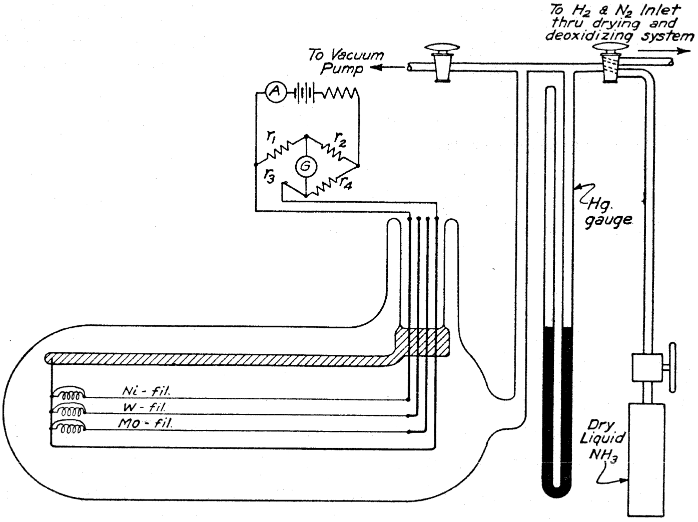

Fig. 1.—Apparatus for the study of the decomposition of ammonia on drawn filaments.

The temperature of the filament was determined by two methods: first, by direct observation with a Leeds and Northrup optical pyrometer, calibrated by the Bureau of Standards, and correcting for the emissivity of the surface and absorption of the glass;[8] second, by employing the temperature coefficient of the resistance of tungsten and molybdenum as determined by Jones[9] and Worthing.[10] These two methods were found to check within about 25° through the range of temperatures employed.

Any discrepancy in temperature was practically constant over the entire range of temperature used, and was therefore not a function of the individual observations or any part of the range.

The fact that the hydrogen formed as a decomposition product is a better conductor of heat than ammonia or nitrogen makes it necessary to increase the current through the filament in order to keep its temperature constant throughout the test or until the greater part of the ammonia is decomposed. The Wheatstone Bridge arrangement shown in Fig. 1 enables this to be done very easily and effectively. The filament is made one arm, r_3 of the bridge, which is comparable to r_4 and quite small in comparison to r_1 and r_2. As the decomposition takes place on the hot filament, the current (A) is increased, keeping r_3 constant. A sensitive galvanometer indicates when this balance is obtained.

The decomposition chamber was cooled by being immersed in a bath of continuously flowing tap water throughout all tests.

As the equilibrium concentration of ammonia with nitrogen and hydrogen at one atmosphere and at this temperature range is less than 1%, all tests were made far from equilibrium and the reaction velocities measured are, therefore, free from the effect of counter reaction.

Experimental Results

The decomposition of ammonia on hot surfaces is a chemical reaction no different from most surface reactions in that it can be expressed by Arrhenius' equation through a limited temperature range at least. Arrhenius stated that the rate of a chemical change = A $e^{-E/RT}$ holds equally well for a homogeneous gas phase, or a heterogeneous surface reaction, where R is the gas constant, 1.987 cal./deg.; T, the absolute temperature; e, the base of the Napieran logarithm, and A and E are constants.[11] In general A has to do with the number of reacting molecules at a given temperature T; E has the form of energy and is expressed in calories per gram molecule and can be obtained from the temperature coefficient of the reaction.

Arrhenius' equation may now be used to study the experimental results in order to see to what extent deductions can be made in regard to the relative significance of the A and E constants for a given reaction for various surfaces under identical experimental conditions; or to see to what extent A and E can be used to study catalysts in a heterogeneous system, rather than entering into a theoretical discussion of these constants.

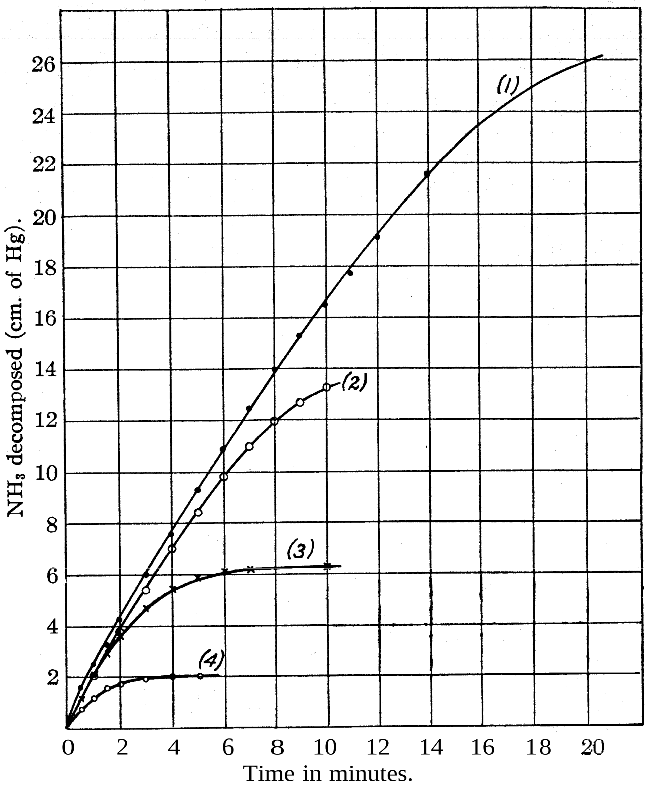
[11] See Hinshelwood, "Kinetics of Chemical Changes in Gaseous Systems," for the meaning of these constants for the various types of reactions.

The Decomposition of Ammonia on Tungsten

The order of the reaction was determined by the usual method and found to be in general as reported by Hinshelwood and Burke, an apparent zero order. The zero order reaction is given by $dx/dt = k$, where x is the number of moles of ammonia per liter which have been changed to the resultants N_2 and $3H_2$ in time t, and k is the velocity constant which is independent of the concentration of the reactants at any time. Hinshelwood pictures the surface in the zero order as being nearly saturated with reacting gas and as molecules react and leave the surface others at once are adsorbed, so that the rate of reaction is constant regardless of the diminishing concentration in the gas phase. However, at sufficiently reduced pressure a point is reached where the surface is no longer saturated and the reaction becomes unimolecular.



Initial pressure: (1) 26.5 cm.; (2) 13 cm.; (3) 5.8 cm.; (4) 1.6 cm.
Fig. 2.—The decomposition of ammonia on a short tungsten filament at 1100°.

Typical examples of the results for tungsten are given in Fig. **2,** where the ammonia decomposed as measured by the increase in total pressure in cm. of mercury is plotted against the time, for initial pressures of ammonia of 26.5, 13.0, 5.8 and 1.6 cm. Each experiment was started with pure ammonia, that is, free from excess of either H_2 or N_2. The time for one-half of the ammonia to decompose, which is a convenient measure of the rate, is 7.6, 3.7, 1.7 and 1.0 minutes for the respective pressures, instead of 7.6, 3.73, 1.66 and 0.46 minutes, which are calculated from the ratio of the initial ammonia pressures. In a unimolecular change all "half times" would be equal. There is a tendency in these data and all tests for the "half time" to become less dependent on pressure at the lower pressures, which may mean that at the lower pressures the reaction is tending toward a unimolecular form.

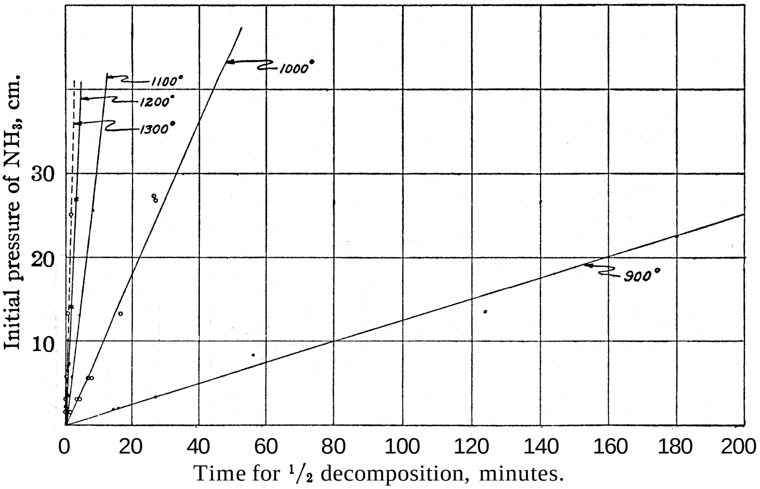


Fig. 3.—The decomposition of ammonia on a short tungsten filament from 900 to 1300°.

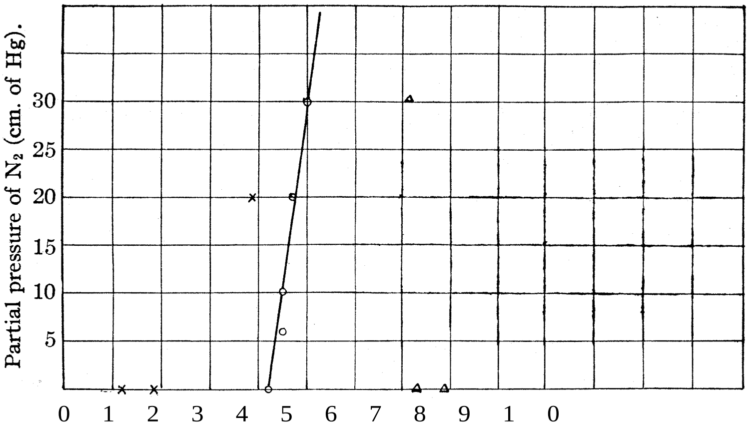
In Fig. 3 we have the results of tests at 900, 1000, 1200 and 1300". The "half time" is here plotted against the initial ammonia pressure. This again shows that the zero order test holds throughout the entire temperature range.

Figs. 2 and 3 are from early data on short filaments and under conditions where the exact temperature was not well enough known to give dependable values of the temperature coefficient, although the temperature was kept constant in the test for the order of the reaction as the gas pressure was varied. The "half time" or relative activity from Figs. 2 and 3 cannot therefore be directly compared with the values obtained later under improved experimental conditions.

The next important point in regard to the reaction system is the extent to which the reaction rate is influenced by the products of the reaction, N_2 and H_2. Fig. 4 gives the times required for the decomposition of one-half of the ammonia where 10 cm. was the initial ammonia pressure. To this initial ammonia pressure of 10 cm. were added, in a series of experiments, varying quantities of very carefully deoxidized and dried nitrogen, representing, respectively, 5, 10, 20 and 30 cm., and the rate of decomposition of ammonia was noted for a given temperature, 950". The pure tungsten filament was 0.18 mm. in diameter and 18 cm. long. We note that the large dilution with nitrogen has relatively little effect on the rate for a given state of activation of the surface. The slope of the curve drawn through the points is a measure of this effect. However, a far greater effect is caused by subjecting the surface to heat treatments. For example, the effect of glowing the tungsten filament in a vacuum at 1600° is to decrease the activity of the surface. This is shown by a doubling of the time for one-half decomposition, while an appreciable activation can be produced by glowing the tungsten filament in nitrogen at 1000°. This variation can best be compared by noting the points on the x-axis corresponding to the decomposition of one-half the ammonia where no nitrogen was present. The average time for the most active surface is 1.5 minutes. A value of 7.6 minutes after heat treatments in a vacuum may have been caused by a removal or modification of the active surface.



Time (min.) required for $^1/_2$ decomposition of NH_3 (initial pressure 10 cm.). OO A constant state of activity. XX Effect of glowing filament in N_2 at 1000". AA Effect of glowing filament in vacuum at 1600°.

Fig. 4.—The effect of heat treatment and nitrogen on the rate of decomposition of ammonia on pure tungsten at 950°.

Fig. 5 shows a similar test on the same filament where the decomposition of ammonia was studied in the presence of hydrogen. In this case, for the given temperature 950°, hydrogen had a larger retarding effect than nitrogen, but the actual retarding effect was small at this temperature, 950°. Preliminary tests on the activation of the tungsten filament in hydrogen gave no change in activation comparable to those observed in nitrogen.

In general, the small retarding effect due to nitrogen or hydrogen decreased and disappeared at higher temperatures and increased at lower temperatures. The observation of a definite retarding effect of hydrogen and nitrogen is qualitatively in agreement with the results of Schwab.

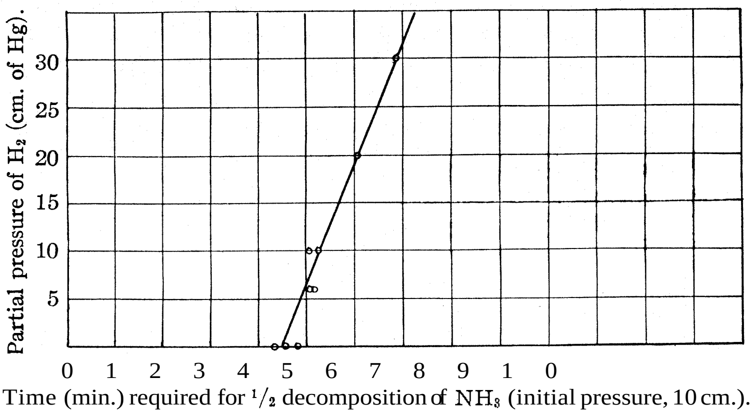


Fig. 5.—The effect of hydrogen on the rate of decomposition of ammonia on pure tungsten at 950°.

Determination of E for Tungsten

A very convenient way of representing the decomposition data is to plot the logarithm of the time for one-half decomposition against the reciprocal of the absolute temperature. Ordinarily in applying Arrhenius' equation, the velocity constant, which is the reciprocal of the time for one-half decomposition, is plotted against the reciprocal of the absolute temperature. Since the data for the entire temperature range can in no case be represented by a single straight line, we will adopt the method of resolving the data for a given filament surface into two straight lines, representing the two extremes of the temperature coefficient of the reaction. A smooth, unbroken curve can be drawn through all the points of a series of tests and is the best representation of the data. In this case E could be expressed as a function of T; then E would show a continuous decrease with increase in temperature. In this way a more accurate comparison of the values of E for the various surfaces could be made. Further studies will no doubt justify this form of presentation.

Fig. 6(a) gives the results from a very pure 7 mil (diam. 0.018, length 18 cm.) tungsten filament furnished by I. Langmuir of the General Electric Company. The total surface is 1.006 sq. cm., calculated from micrometer measurements of the filament. The value of E, which is proportional to the slope of the curve, Fig. 6, is obtained in the following way.

Arrhenius' equation states: rate = $A\, e^{-E/RT}$. Suppose the times for one-half decomposition for temperatures T_1 and T_2 are t_1 and t_2, respectively. Then $1/t_1 = A\, e^{-E/RT_1}$, and $1/t_2 = A\, e^{-E/RT_2}$. Taking logarithms, $\ln t_1 = -\ln A + E/RT_1$, and $\ln t_2 = -\ln A + E/RT_2$; by subtraction

$$\ln t_2 - \ln t_1 = E/R\,(1/T_2 - 1/T_1)$$

whence

$$E = \frac{R(\ln t_2 - \ln t_1)}{1/T_2 - 1/T_1}$$

or

$$E = \frac{2.3026\, R(\log t_2 - \log t_1)}{1/T_2 - 1/T_1}$$

E from the steeper straight line is 45,300, while E_2 from the other line is 36,470 calories.

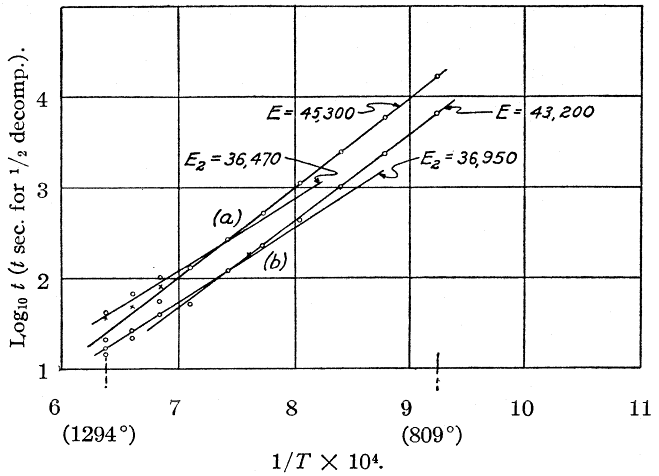

Fig. 6.—The temperature coefficient of the decomposition of ammonia on pure tungsten, for (a) "¹/₂ time" and (b) "¹/₄ time."

In Fig. 6(b) the time for one-fourth decomposition is taken from the original decomposition runs. The variation of E from that for one-half decomposition is comparable to the experimental error. This gives an added check on the method of determining E as to temperature control and effect of the products of the reaction as the reaction progresses. The temperature of the surface was obtained from a pyrometer calibration curve which was found to be 25° higher than, but parallel to, the calibration curve obtained from the temperature coefficient of tungsten by Jones. Since these two methods check so well, we are reasonably sure that although the exact temperature for a given point may not be known to within 25°, this error has no appreciable effect on the slope of the E curves.

The results for a 10 mil (diam. 0.025 cm., length 16.7 cm.) commercial tungsten filament are shown in Fig. 7, E_1 being 47,220 and E_2 34,800 calories. Similar tests were conducted on other grades of commercial tungsten and on a thoriated tungsten filament. Early tests made on the thoriated tungsten furnished by the General Electric Company and activated in a vacuum according to direction[12] showed no appreciable increase in activity over that of commercial tungsten, as was expected. However, no test, as the increase in electron emission of thoriated tungsten over tungsten, was made on the activity of the thoriated tungsten filament. Then again, as the thorium layer is very sensitive to gases, the ammonia

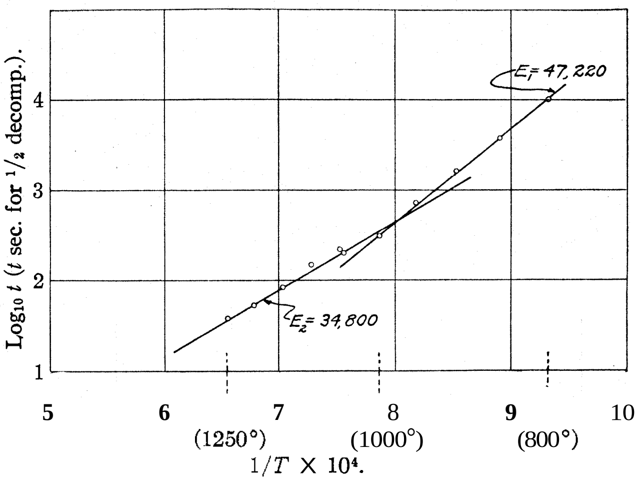

Fig. 7.—The temperature coefficient of the decomposition of ammonia on commercial tungsten.

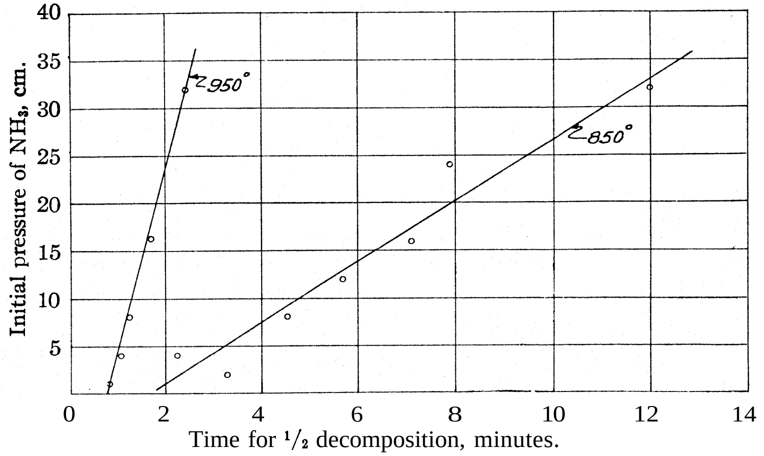

Fig. 8.—The decomposition of ammonia on molybdenum.

---

[12] I. Langmuir, *Phys. Rev.*, 22, 357 (1920).

may have destroyed the added increase in activity expected from the thoriated tungsten. Sufficient tests were not made under the best experimental conditions to say that a properly activated thoriated tungsten surface is not more active than a tungsten surface.

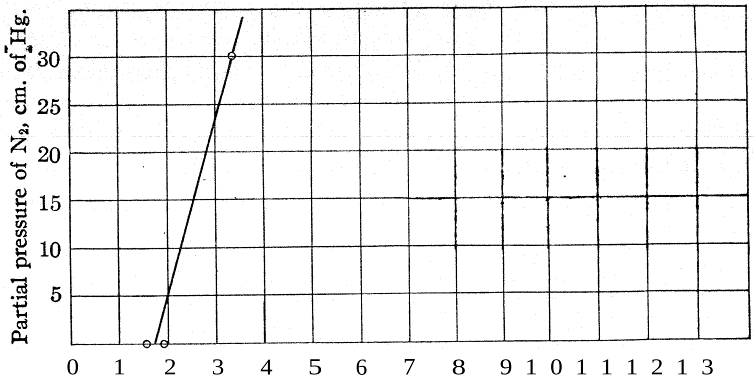

Fig. 9.—The effect of nitrogen on the rate of decomposition of ammonia on molybdenum at 850°.

Decomposition of Ammonia on Molybdenum

A 12 mil (diam. 0.030 cm., length 18 cm.) molybdenum filament from wire furnished by the Fansteel Products Company was used in these tests. Tests on the order of the reaction gave results very similar to those on tungsten, and an apparent zero reaction, Fig. 8. The effect of an initial concentration of nitrogen or hydrogen on the decomposition at 850° is shown in Figs. 9 and 10, respectively. Nitrogen has a much smaller effect than hydrogen. These results do not agree with those recently

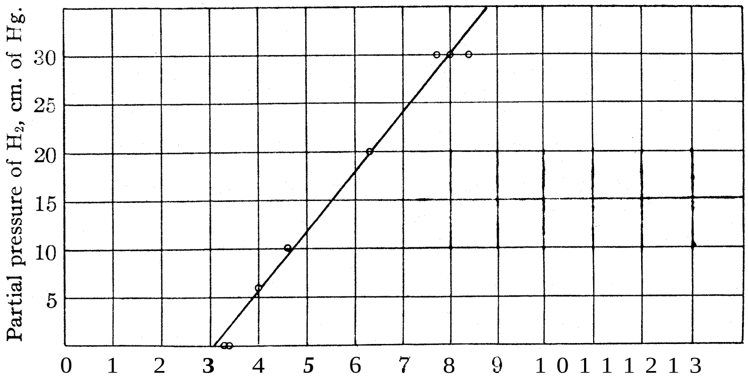

Fig. 10.—The effect of hydrogen on the rate of decomposition of ammonia on molybdenum at 850°.

published by Burke,[3] who finds no retarding effect for hydrogen and a very marked retarding effect for nitrogen. We do not know how to reconcile these two results. Water vapor or oxygen contaminations in the nitrogen used by Burke may have produced the progressive poisoning or retarding effect. Every effort was made to locate the discrepancy, but without success. Another difference has been noted in the value of E, Fig. 11. E_1 for the lower temperatures is 42,700 and at the higher temperature is 31,820 calories, while Burke's value is 53,200 between the temperatures of 824 and 955°. The experimental error is much less than 10,000 calories, the difference between these results and those of Burke.

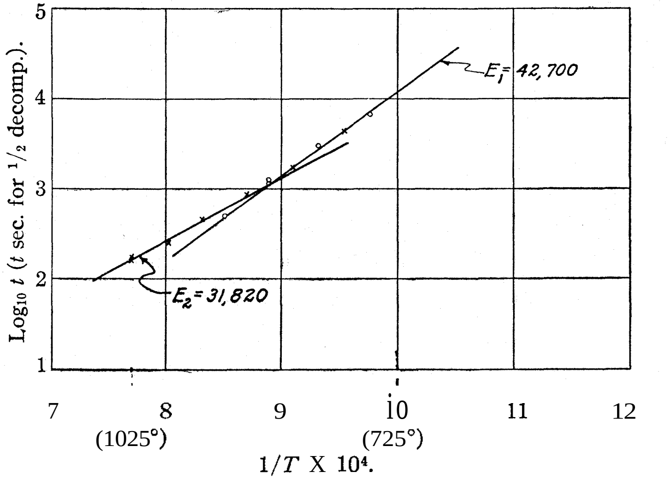

Fig. 11.—The temperature coefficient of the decomposition of ammonia on commercial molybdenum.

The Decomposition of Ammonia on Nickel

Only sufficient tests were made on a good grade of 12 mil commercial nickel wire (diam. 0.030 cm., length 16.5 cm.) to determine the relative position of nickel on a chart, Fig. 12, in respect to tungsten and molybdenum. Again we note a variation of E with temperature, starting at the low rates with values similar to tungsten and molybdenum and falling off with increase in temperature. In Fig. 12 the ordinates are based on one square centimeter of catalyst surface. Attention should be called to the general similarity of all curves and the relative activity of the respective metals for the ammonia reaction.

Discussion of Results

The experimental determinations of E for tungsten and molybdenum are not considered sufficiently reproducible for the lower temperatures to warrant deductions as to the relative values of E/T observed for a given rate of decomposition per square centimeter surface for the two materials. The observed values of E for the tests on tungsten were 45,300, 49,000, 45,250 and 49,750, with an average of 47,320; and for molybdenum, 44,200, 45,750, 44,600, 48,750 and 42,530, with an average of 45,170. Then again, at the lower temperatures, the retarding effects of the products are quite pronounced, so that although the reaction is of apparent zero order, the "true heat of activation" as expressed by Hinshelwood and Burke is not known. Tests are in progress toward a determination of more accurate values of E and a definite evaluation of the effects of the products of the reaction at the lower temperatures. There is no apparent relation between the catalytic activity of tungsten, molybdenum and nickel, and the observed temperature coefficients.

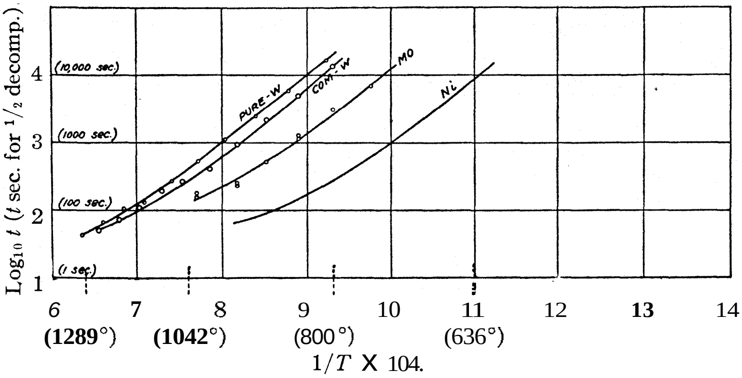

Fig. 12.—The relative activity of metal catalysts per square centimeter of surface for the decomposition of ammonia.

The catalyst surfaces were determined from careful measurements of the diameter and length of the drawn wire filaments in the absence of a better method of obtaining these surfaces. In so far as deductions can be made from the observed temperature coefficient and the measured surfaces, it would seem that the relative catalytic activity depended primarily on the catalyst surface and therefore on A, which is proportional to the number of molecules of ammonia decomposing per unit time per square centimeter surface. All curves, Fig. 12, are of the same general form and can be thought of as a shift to a higher or lower temperature, respectively.

In view of the fact that in general the log t against $1/T$ relation is curved rather than linear, and that the meaning of the heat of activation as applied to surface reactions is not too well understood, we prefer to speak of the results in terms of the temperature coefficient of the surface reaction expressed in terms of E, rather than a heat of activation. The answer to the question as to what extent the catalytic activity of a surface can be expressed in terms of the A or E constants of Arrhenius' equation is also not conclusive. At the lower reaction rates E has the value of about 45,000 calories, independent of the metal surface upon which decomposition takes place. The change of E with increase in temperature is no doubt due to a change of the surface upon which decomposition takes place. This may be due to (1) some change in the metal atoms of the surface with temperature; (2) a change in the amount or nature of the gas adsorbed on the surface with temperature; (3) not to be underestimated, a change of the physical and chemical properties of the composite surface with temperature, where the composite surface is the metal surface atoms in equilibrium with adsorbed gas molecules or atoms at any temperature; (4) a combination of (1), (2) and (3).

In dealing with surface catalysis, where the reactants need to be adsorbed before activation and reaction, the adsorbed gas no doubt has far different properties than in the gas phase. Likewise, the surface metal atoms in contact with gas would be expected to be different from atoms within the solid, so that the combination of the gas or gases on the metal surface presents a problem of the chemistry and physics of a fourth state, as considered by William B. Hardy, where the four states are: gases, liquids, solids and surfaces.

The results in Fig. 4, showing the activation of tungsten and similarly of molybdenum by glowing in an atmosphere of nitrogen, indicate the importance of the activation of a surface.

It seems of prime importance to know more of the physical and chemical properties of the catalyst surface at the temperature and conditions at which the catalyst is operating before much can be said as to the nature of the surface, mechanism of the reaction on the surface and the corresponding meaning of E. Experiments with the view of obtaining this information are now in progress at the Laboratory.

The recently reported work by Davisson and Germer[13] gives us a tool whereby surface phenomena can be investigated, namely, the analysis of diffraction patterns from slow speed electrons produced by potentials of 10 to 400 volts. These results have already shown that a thin film of adsorbed gas at room temperature has a definite solid lattice structure similar to the atoms in a nickel crystal, which lattice completely disappears at about 200° without a removal of the gas from the surface; that is, a solid or frozen lattice structure of adsorbed gas is changed into a 2-dimensional liquid structure by increasing the temperature of the surface from room temperature to 200 degrees or more.

The author wishes to express his appreciation for the interest shown and suggestions received in this work from the Laboratory staff, and especially to Mr. R. A. Nelson for constructing the apparatus and assisting through

these studies; also to Messrs. E. S. Lamar and J. W. Westhaver, for assistance in the experimental work.

Summary

The decomposition of ammonia on tungsten, molybdenum and nickel has been investigated as a part of a program designed to give further information in regard to the ammonia reaction and the role played by the catalyst in this reaction. The results are expressed in terms of the A and E constants of Arrhenius' equation.

The decomposition of ammonia on tungsten and molybdenum was apparently of zero order. The reaction rate was decreased at the lower temperatures by both hydrogen and nitrogen.

The value of E as determined from the temperature coefficient was approximately constant for all surfaces at the lower reaction rates, about 45,000, decreasing for the higher temperatures to 35,000 for tungsten, 32,000 for molybdenum and 26,000 for nickel.

The relative catalytic activity of the surface investigated was not given by the observed temperature coefficient of the reaction expressed in terms of E but was given rather in terms of the surface, that is, in terms of A, in so far as comparisons can be made from the measured dimensions of the hot catalyst surfaces.

In general, the conclusions herein reached agree with the results obtained on promoted iron catalysts, which are to be published soon.

INFRA-RED ABSORPTION BY THE S-H BOND

BY JOSEPH W. ELLIS

RECEIVED APRIL 26, 1928 PUBLISHED AUGUST 4, 1928

The apparent possibility of identifying the carbon–hydrogen[1] and the nitrogen–hydrogen[2] atom pairs as the probable origins of certain series of absorption frequencies in the near infra-red spectra of organic molecules has suggested a search for corresponding frequencies characteristic of the sulfur–hydrogen linkage. The spectra of the mercaptans suggest possible sources in which to look for such absorption bands. Bell[3] has obtained the spectra of several alkyl and aryl mercaptans and sulfides in the spectral region from 1–12μ. The general appearance of these spectra is strikingly similar to that of the corresponding alkyl or aryl amines recorded by Bell.[4]

---

[2] (a) Ellis, THIS JOURNAL, 49, 347 (1927); (b) 50, 685 (1928).

[3] (a) Bell, *Ber.*, 60, 1749 (1927); (b) private communication.

[4] (a) Bell, THIS JOURNAL, 47, 2192 (1925); (b) 47, 3009 (1925); (c) 48, 813 (1926); (d) 48, 818 (1926); (e) 49, 1837 (1927).

This suggests that the main features of the spectra are assignable to origins within the substituted organic radical, some of them doubtless to the C–H linkages.

In the spectrum of a mercaptan, however, there is one band at 3.8–3.9μ which disappears, or practically disappears, in the spectrum of the corresponding sulfide. It was the opinion of the present author that this band might represent a fundamental frequency characteristic of the S–H atom pair, corresponding to the 3.4μ, **3.2–3.3μ** and 2.8–3.0μ band ascribed by him and others to alkyl C–H, aryl C–H and N–H linkages, respectively.

The present investigation was undertaken to search for possible harmonics of this 3.8–3.9μ band. The recording quartz spectrograph used in previous studies was employed here. The compounds studied were ethyl, n-propyl, n-butyl, *iso*-amyl, phenyl (thiophenol) and benzyl mercaptans and the corresponding sulfides. These were supplied by the Eastman Kodak Company.

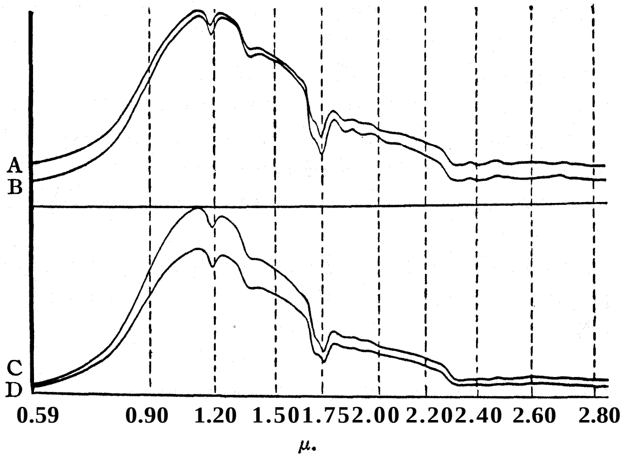

Fig. 1.—A. Ethyl mercaptan, *T* = 1 mm. B. Ethyl sulfide, T = 1 mm. C. n-Propyl mercaptan, T = 1 mm. **D.** n-Propyl sulfide, T = 1 mm.

The records of these spectra are shown in Figs. 1–4. In reproducing these records the plate containing the photographic tracing of the mercaptan was placed over that of the sulfide and these were photographed together by transmitted light. There seems to be but one distinguishing feature in the spectra of the mercaptans, namely, a band at 1.99–2.00μ. This is regarded as the first harmonic of the 3.8–3.9μ band. Both of these bands are strongest in the spectra of thiophenol and benzyl mercaptan. The presence of the overtone band may be considered uncertain in the records of 1-mm. cells of ethyl and n-propyl mercaptans, Fig. 1. However, it appears quite strongly when a 1-cm. cell of the latter substance is used, Fig. 2. An inspection of the original record of n-butyl mercaptan removes any doubt of its presence in that substance, and it is very noticeably present in the record of *iso*-amyl mercaptan in Fig. 3.

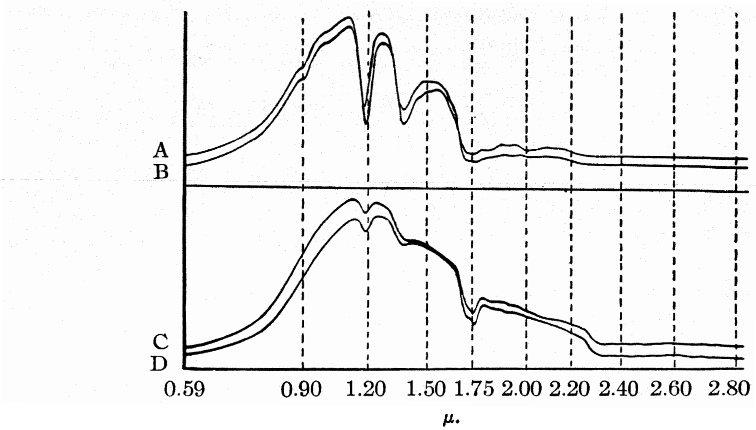

Fig. 2.—A. n-Propyl mercaptan, T = 10 mm. B. *n*-Propyl sulfide, T = 10 mm. C. *n*-Butyl mercaptan, *T* = 1 mm. D. n-Butyl sulfide, T = 1 mm.

A possible second harmonic would be superimposed upon the 1.4μ absorption region characteristic of both the mercaptan and the sulfide and hence could not be expected to be capable of detection.

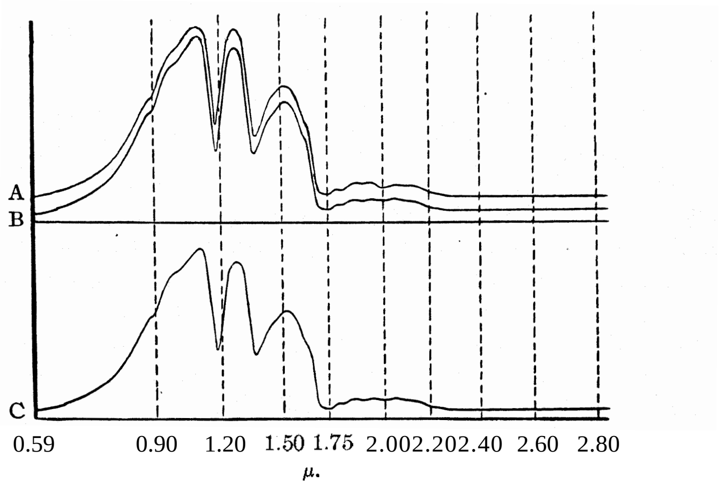

Fig. 3.—A. Iso-amyl mercaptan, T = 10 mm. B. *Iso*-amyl sulfide, T = 10 mm. C. Iso-amyl disulfide, T = 10 mm.

The deviation from true multiple relationship between the 3.8μ and the 1.99μ wave lengths for the alkyl mercaptans seems slightly greater than would be expected from comparisons with the fundamental and first overtone bands assigned to C–H and N–H atom pairs. However, the deviation is quite comparable with these latter cases in the case of the two aryl mercaptans; in these instances Bell's value (unpublished) varies from 3.85μ to 3.90μ and the overtone value from the present investigation is 2.00μ.

The main features of the spectra of the mercaptan and of the corresponding sulfide are quite similar over the whole region in which they have been studied. The main bands which occur are also found in the spectra of the corresponding primary, secondary and tertiary amines.[2,4] Certain of these, which have already been assigned to the C–H linkages, are tabulated, together with the bands assignable to S–H pairs, for the mercaptans and sulfides in Table I. Inspection of the table reveals the fact that the 3.30–3.35μ alkyl C–H value seems to be a trifle low as compared with the integral multiples of the corresponding overtone wave lengths. This fact, taken with the slight discrepancies in the S–H values discussed above, suggests a possible small systematic error in Bell's investigation of the alkyl mercaptans and sulfides.

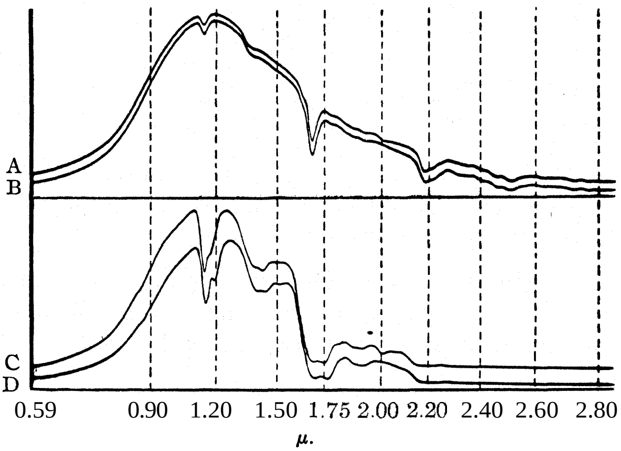

Fig. 4.—A. Thiophenol, T = 1 mm. B. Phenyl sulfide, T = 1 mm. C. Benzyl mercaptan, T = 10 mm. D. Benzyl sulfide, T = 10 mm.

The record of di-iso-amyl sulfide, Fig. 3, reveals nothing not shown by iso-amyl sulfide. Consequently, a study of the disulfides was pursued no further.

The doubling of the 1.145–1.19μ and 1.69–1.76~bands in benzyl mercaptan and benzyl sulfide is probably due, as in the corresponding amines, to the presence of both phenyl and alkyl types of C–H bonds. The doubling of the 1.7μ alkyl band, more noticeable here than in the corresponding records heretofore published by the author, has been brought about by an increase in the resolving power of the spectrograph. This increased resolution has been produced largely by focusing the spectrum upon the slit in front of the thermopile rather than upon the thermo-elements themselves. The possible significance of this revealed doubling here and in other instances will be discussed elsewhere.

All of the compounds examined are liquids at room temperature with the exception of benzyl sulfide. The record shown for this compound in Fig. 4 was taken through a 1-cm. cell of the molten substance maintained at a temperature just above the melting point. Upon cooling in an open dish, benzyl sulfide crystallizes in rhombohedral plates. A record was taken through such a specimen about 2 mm. in thickness. It was found necessary to open the slits considerably to get sufficient intensity, but the positions of the bands were found to be unchanged. This would seem to indicate that the force constants and the energy associated with the C–H bond, at least in this instance, remain unchanged during crystallization.

TABLE I

BANDS CHARACTERISTIC OF MERCAPTANS AND SULFIDES

	Bands assignable to C–H, μ							to S–H, μ	
Ethyl mercaptan			1.18	1.38	1.70, 1.74			2.00	
Ethyl sulfide			1.185	1.38	1.70, 1.74				
n-Propyl mercaptan	0.91	1.01	1.19	1.385	1.71, 1.75	3.3	6.8	1.99	3.80
n-Propyl sulfide	.91	1.01	1.19	1.385	1.71, 1.75	3.35	6.85		
n-Butyl mercaptan			1.19	1.395	1.71, 1.75	3.3	6.8	1.99	3.80
n-Butyl sulfide			1.19	1.385	1.71, 1.75	3.35	6.85		
Iso-amyl mercaptan	.90	1.00	1.18	1.38	1.73	3.3	6.8	1.99	3.80
Iso-amyl sulfide	.90	1.00	1.18	1.37	1.73	3.4	6.85		
Iso-amyl disulfide	.90	1.00	1.18	1.37	1.73				
Thiophenol			1.145	1.39	1.685	3.25	6.8	2.00	3.90
Phenyl sulfide			1.145	1.39	1.685	3.25	6.8		
Benzyl mercaptan			1.145	1.39	1.69, 1.75	3.25	6.6, 6.9	2.00	3.85
Benzyl sulfide			1.145	1.39	1.69, 1.76	3.25	6.7, 6.9		

The spectrum of hydrogen sulfide has been recorded beyond 3μ by Coblentz.[5] Inasmuch as the mercaptans are mono derivatives of hydrogen sulfide, it might be expected that the spectrum of this latter substance would show a band analogous to that at $3.8–3.9\mu$. A band at 4.2μ might

---

[5] Coblentz, *Carnegie Inst. Pub.*, 1905, 35.

be interpreted as such. However, the complexity of the hydrogen sulfide spectrum beyond 4μ tends to make this comparison uncertain.

Summary

1. The infra-red absorption spectra of several alkyl and aryl mercaptans and sulfides have been examined with a recording quartz spectrograph.

2. **A** single band at 1.99–2.00μ differentiates the spectrum of a mercaptan from the corresponding sulfide. This band is regarded as the first harmonic of one found by Bell at 3.8–3.9μ, and both are interpreted as originating in the S–H bond.

GALLIUM. III. QUANTITATIVE SEPARATION OF IRON FROM GALLIUM BY MEANS OF ALPHA-NITROSO-BETA-NAPHTHOL[1]

BY JACOB PAPISH AND L. E. HOAG

RECEIVED APRIL 30, 1928 PUBLISHED AUGUST 4, 1928

The method frequently employed for separating iron from gallium is based on the property of trivalent iron to form a precipitate on the addition of an excess of fixed alkali hydroxide while gallium, being amphoteric, passes into solution as alkali gallate. This method was first used by de Boisbaudran,[2] the discoverer of gallium, and in so far as the preparation of iron-free gallium is concerned it will be found satisfactory; the resulting alkali gallate and the gallium hydroxide and oxide ultimately obtained from it will be found on spectroscopic examination to contain negligible traces of iron, provided care is taken to prevent contamination through reagents and containers. A similar examination of the residual ferric hydroxide will reveal that even after thorough washing, small quantities of gallium are retained. This can be undoubtedly ascribed to the strong adsorptive power of ferric hydroxide, a phenomenon frequently observed in similar cases.

In extracting gallium from a natural mineral or in recovering it from commercial products, iron which is always present will accompany the

---

[1] This article is a corollary of experiments supported by a grant from the Heckscher Foundation for the Advancement of Research, established by August Heckscher at Cornell University. It is respectfully dedicated by the authors to Professor L. M. Dennis, and will be reprinted as article No. 9 in the Louis Munroe Dennis Quarter Century Volume to be published in 1928 in commemoration of the completion by Professor Dennis of twenty-five years of service as Head of the Department of Chemistry at Cornell University.

[2] De Boisbaudran, Compt. *rend.*, 94, **1439,** 1625 (1882).

gallium through the various stages of concentration. Furthermore, in the separation of gallium from aluminum by converting the former to the ferrocyanide, large quantities of iron are unavoidably introduced in the form of the precipitating agent. It may be worth while to remark in passing that the ferrocyanide method is among the best for separating gallium from aluminum.[3] In either case the chemist is confronted with the necessity of separating iron from the gallium. Papish and Holt[4] employed a-nitroso-@-naphtholfor this purpose. An examination of the residual iron salt obtained by this method proved that it was free, even in a spectroscopic sense, from gallium. This at once suggested itself as a suitable method for quantitative analytical work and the following experiments were undertaken to determine its applicability.

A solution of α-nitroso-β-naphthol was prepared by dissolving 1 g. of the reagent in 50 cc. of a 50% solution of acetic acid. It was made up fresh and filtered each time before using.

A solution of ferric chloride of known concentration was prepared by dissolving the salt in a definite volume of water and determining the iron content as ferric oxide by adding ammonium hydroxide to a small portion of the solution and washing, igniting and weighing the precipitate. The ferric chloride, before being dissolved, was examined spectroscopically for gallium and aluminum and was found to be free from both these elements.

Ignited gallium oxide, which on spectroscopic examination was proved to be free from iron,[5] was dissolved in hot aqua regia, boiled with separate portions of hydrochloric acid and the resulting solution of gallium trichloride, freed from the oxides of nitrogen, was diluted with water to a definite volume. The gallium content of this solution was determined in duplicate samples as follows. Two 20cc. portions were transferred to beakers and an excess of ammonium hydroxide was added to each. The solutions were boiled until a moistened piece of red litmus paper did not turn blue on exposure to the vapors evolved from them. On cooling, the precipitates of gallium hydroxide were collected on ashless filter papers and washed with a dilute solution (about 1%) of ammonium nitrate until washings gave no test for chlorides.

If it was noticed or even suspected that some gallium hydroxide adhered to the walls of the beaker, a small amount of hydrochloric acid was added and the gallium was reprecipitated with ammonium hydroxide in the manner just described. While this additional precipitate could have been added to the bulk of gallium hydroxide on the filter, it was found more expedient to collect and wash it on a separate filter paper. The tendency of precipitated gallium hydroxide to adhere to the walls of the container is to be taken into consideration while working with this substance.[6] This tendency is pronounced when the concentration of gallium

---

[3] For details of this method see Crookes' "Select Methods in Chemical Analysis," 3d ed., Longmans, Green and Co., London, 1894, p. 159.

[4] Papish and Holt, *J. Phys. Chem.*, **32,** 142 (1928).

[5] As a matter of fact the small amount of iron was removed from this sample of gallium oxide by a previous treatment with α-nitroso-β-naphthol.

[6] See Dennis and Bridgman, THIS JOURNAL, 40, 1545 (1918).

is high and when the boiling is prolonged, and it becomes negligible in the case of small quantities boiled for a short time.

The filter papers and contents were transferred to previously weighed porcelain crucibles and ignited to constant weight. Freshly ignited gallium oxide is quite hygroscopic and in order to prevent errors from this source the crucible containing the oxide was placed in a stoppered weighing bottle after ignition, allowed to cool in a desiccator and weighed with the bottle.

Measured volumes of solutions of iron chloride and of gallium chloride, each of known concentration, were mixed, and to the mixture ammonium hydroxide was added carefully until a slight, permanent precipitate resulted which dissolved on the addition of a drop of hydrochloric acid. One or two additional drops of hydrochloric acid were added to insure acid reaction and an excess of a 50% solution of acetic acid was added. A very good alternate method consists in using ammonium acetate in place of acetic acid. This will insure the absence of hydrochloric acid as such, though a very small amount of this acid works no hardship with the procedure. The reagent α-nitroso-β-naphthol in acetic acid was next added to insure excess and the whole was allowed to stand for several hours. The precipitated ferric α-nitroso-β-naphtholate was removed by filtration, washed, first with a 50% solution of cold acetic acid and then with water. After drying, the filter paper and contents were transferred to a porcelain crucible and ignited to constant weight over a Méker flame. This ignition must be carried out very carefully so as to prevent mechanical loss which will be caused by too rapid decomposition of the organic compound.[7] The iron was weighed as ferric oxide.

The galliferous filtrate from the ferric α-nitroso-β-naphtholate was evaporated to dryness to expel the acetic acid and ammonium hydroxide was

[7] It was not found necessary to add oxalic acid to the ferric α-nitroso-β-naphthalate before ignition as suggested by Illinski and Knorre in connection with the separation of iron from aluminum, see *Ber.*, 18, 2728 (1885).

added to distinct alkalinity. From this point on the procedure was identical with the one already described in connection with the determination of gallium in the original solution of gallium chloride. The results are recorded in Tables I and II.

At the completion of the determinations the oxides of iron and gallium were examined spectroscopically[8] with the following results. The oxides of iron, as already mentioned, were invariably found to be free from gallium. The oxides of gallium contained negligible quantities of iron, a fact established by the presence only of the more persistent spectral lines of this element, λλ 2382.0, 2395.6, 2596.4 and 2599.4 Å.

Summary

A quantitative method is described for the separation of iron from gallium by means of α-nitroso-β-naphthol.

It is proved spectroscopically that the iron separated by this method is free from gallium.

It is proved spectroscopically that the gallium obtained from such a separation contains negligible traces of iron.

AN ACCURATE METHOD FOR THE DETERMINATION OF IODINE IN MINERAL MIXTURES[1]

BY M. D. KNAPHEIDE AND ALVIN R. LAMB

RECEIVED APRIL 30. 1928 PUBLISHED AUGUST 4, 1928

The addition of potassium or calcium iodide to mineral mixtures to be fed to farm animals has made necessary the accurate estimation of iodine in such mixtures, both by the manufacturer and by the feed control chemist. The volatility of iodine under certain conditions, its probable adsorption upon the charcoal which is commonly found in such mixtures and the very small amounts which are permissible, tend to complicate the situation.

Simple extraction methods, using water, alcohol or alkali, were tried by the authors and found to be entirely inadequate. Except in freshly prepared mixtures, less than half of the iodine was recovered by extraction. Using samples of mixtures containing charcoal, it was found that the sum of the iodine in the alcoholic extract and in the residue approximated the total amount present, 40 to 50% of this amount being found in the extract.

Combustion of the sample in a silica tube and determination of the iodine by the method of McClendon[2] or by a combination of this method with

---

[8] See Papish and Holt, ref. 4, for the arc spectrographic method employed.

[1] Presented at the St. Louis meeting of the American Chemical Society, April 18, 1928.

[2] McClendon, J. *Biol.* Chem., 60, 289–299 (1924).

that of Kendall[3] was laborious and produced rather low results. Fusion of the sample in a special Parr sulfur bomb with sodium peroxide and potassium chlorate, followed by determination of the iodine according to Kendall, gave very low results. Fusion with a mixture of sodium carbonate, potassium carbonate and potassium nitrate in molecular proportions was not satisfactory on account of the high temperature necessary and the short life of the nickel crucible.

Extraction of the sample with sodium hydroxide in aqueous solution, followed by fusion of the evaporated extract with sodium hydroxide in a nickel crucible according to Kendall gave concordant and fairly good but still low results.

Finally the fusion of the original sample with sodium hydroxide and potassium nitrate, followed by a modification of Kendall's procedure was found to yield the most nearly quantitative results. The working out of the proper conditions and the testing of various modifications have involved running several hundred determinations. The method is still rather laborious, but six or eight determinations can easily be completed each day, the entire procedure extending most conveniently over three days. The details of the method and typical results follow.

Twenty grams of sodium hydroxide and 10 g. of potassium nitrate are fused together in a 100cc. nickel crucible. After cooling, a 10g. sample of the mineral mixture is placed evenly on top of the fused alkali and completely moistened with 5 cc. of saturated sodium hydroxide solution and 10 cc. of 80% alcohol. The crucible is then placed on a cold three-heat hot plate and the alcohol evaporated by the low heat. After half an hour the heat is cautiously increased until the crucible has been subjected to the highest temperature of the hot plate for about one and one-half to two hours. Thorough heating at this time prevents most of the trouble from effervescence of the material during the fusion. The crucible is then placed in a crucible furnace or one similar to that used by Kendall and Richardson,[4] which heats evenly both the sides and the bottom of the crucible. An ordinary electric furnace might be used, if it were not necessary to watch and sometimes cool the crucible to avoid bubbling over.

Mineral mixtures containing charcoal will require more attention during the fusion, on account of the violent reaction between the charcoal and the potassium nitrate. There is, however, no loss if the crucible is carefully watched. If the reaction becomes too violent the crucible is lifted from the furnace for a moment, and if necessary the bottom of the crucible is cooled in a beaker of water.

After the mixture is in a quiet state of fusion the crucible is tipped on all

---

[3] *Kendall, J. Biol. Chem.,* **43, 149–159 (1920).**

[4] *Kendall and Richardson, ibid.,* **43, 164 (1920).**

sides in an open flame to wash down the sides of the crucible with the fusion mixture. Next a few small crystals of potassium nitrate are added until no more gas is liberated by further additions and the sides of the crucible are again washed down in the flame.

The melt is then poured out into the clean crucible cover to cool or the crucible is turned while cooling so that the material solidifies on the sides of the crucible. The cooled melt and the crucible are placed in a 600cc. beaker, covered with water and heated below the boiling point for a short time. After standing overnight at room temperature, the crucible and cover are rinsed off and removed. In order to neutralize part of the alkali and facilitate filtering, 10 cc. of sirupy phosphoric acid is added and the beaker placed on a steam-bath for about three or four hours with occasional stirring to break up the mass and insure complete solution of the iodine.

The beaker is cooled[5] and the insoluble residue filtered off in a 10cm. funnel and washed with cold water into an 800cc. beaker, adjusting the volume to about 550 to 600 cc. At this time the solution should be clear and colorless.

In order to destroy nitrites, which interfere with the titration with methyl orange, 10 cc. of 20% sodium bisulfite solution is now added, the solution brought just to the boiling point and then cooled. About 30 cc. of 85% phosphoric acid is run in from a buret, a few drops of methyl orange solution added and the addition of phosphoric acid continued to the neutral color of the methyl orange, after which 1.5 cc. of the phosphoric acid is added in excess. The total amount of phosphoric acid required is generally not over 35 cc., except when the presence of considerable charcoal in the sample has necessitated the use of more potassium nitrate, which is thus mainly reduced to carbonate. Care must be taken not to run appreciably over the end-point, since excess acid gives low results. However, the addition of the acid must be fairly rapid, as the color of the methyl orange has a tendency to fade, due to incomplete destruction of the nitrites.

After neutralization, a small lump of anthracite coal[6] (0.5 cm. in diameter) is put in and the solution is boiled for at least twenty minutes, the volume being reduced to about 400 to 500 cc. This length of time is essential in order to remove all traces of sulfurous acid. The solution is cooled again and bromine water added until a distinct and permanent yellow color is produced. The solution is then boiled until colorless by reflected light and then for exactly five minutes longer. A few crystals of salicylic acid are added to assure the removal of the last traces of brom-

---

[5] A galvanized iron pan with sides about 10 to 12 cm. high and outlets at different levels is a very convenient means of cooling beakers of solution, which is necessary several times during this determination.

[6] Kendall, *J. Biol. Chem.*, **43**, 151 (1920).

ine, and the solution is cooled, after which 5 cc. of 20% reduced phosphoric acid[7] and 0.5–1.0 gram of chemically pure potassium iodide are added. The solution is then titrated in the usual manner with 0.005 N sodium thiosulfate solution, adding starch solution when the brown color of the liberated iodine is nearly gone. The volume of the solution at the final titration should be 400 to 500 cc.

The thiosulfate solution is standardized according to Kendall, by dissolving approximately 1 g. of pure iodine in a liter of 0.5% sodium hydroxide solution. This solution is then diluted ten times, 25 cc. is pipetted into a flask, diluted to 200 cc. and 10 cc. of 30% sodium hydroxide added. The solution is then neutralized with phosphoric acid and the iodine determined as in the method here outlined.

The thiosulfate solution may also be standardized by pipetting into a beaker or flask 25 cc. of a solution containing 0.1308 g. of potassium iodide per liter, adding 200 cc. of water, 5 cc. of 20% sodium bisulfite and 2 or 3 g. of sodium hydroxide. This is neutralized with phosphoric acid, adding 1.0 cc. of the concentrated acid in excess and proceeding further as in the regular determination described above. To calculate the milligrams of iodine to which 1 cc. of the thiosulfate solution is equivalent, the following formula is used

$$\frac{2.5}{\text{cc. of } Na_2S_2O_3 \text{ soln.}} = \text{mg. I equiv. to 1 cc. of } Na_2S_2O_3 \text{ soln.}$$

It is well to keep the volume of the solution used in standardization down to about 200 cc. for better and more comparable end-points in the final titration.

[7] Impurities in the phosphoric acid are reduced according to Kendall's method (*J. Biol. Chem.*, 43, 150 (1920)) by diluting the 85% acid with four volumes of water and boiling for some time with aluminum strips.

The table shows some typical results obtained by this method with samples containing known amounts of iodine. The iodine was added in the form of potassium iodide to samples of mineral mixture containing no iodine or a very slight trace. Blanks were always run on the samples used and on the reagents.

Samples which contain no charcoal or bone meal may be fused with 20 g. of sodium hydroxide alone, omitting the potassium nitrate except for the addition of a few small crystals at the end of the fusion.

Summary

A method is described for the quantitative determination of small amounts of iodine in mixtures of mineral salts, charcoal, spent bone black, etc. The method is a modification of Kendall's and involves fusion with sodium hydroxide and potassium nitrate, removal of interfering substances, oxidation with bromine and determination of the iodine iodimetrically. Necessary conditions are outlined. Other methods were found very unsatisfactory for complex mixtures except when the samples were freshly prepared.

THE ANTIMONY–ANTIMONY TRIOXIDE ELECTRODE AND ITS USE AS A MEASURE OF ACIDITY[1]

BY E. J. ROBERTS[2] AND F. FENWICK

RECEIVED MAY 2, 1928 PUBLISHED AUGUST 4, 1928

Increased realization of the importance of a knowledge of acidity in the control of chemical reactions has aroused a general interest in methods by which the activity of the hydrogen ion may be measured. If we dismiss from consideration the numerous and widely used color indicators, whose applicability rests upon comparative measurements with the hydrogen electrode, the latter at present constitutes by far the most important means of determining acidity. Under strictly defined conditions, it possesses a very high degree of accuracy and reproducibility; the maximum accuracy of the hydrogen electrode is not easy to attain, however, even approximately. The proper functioning of the platinum (or iridium) coating of the electrode is readily affected by traces of many substances not unlikely to be present in the system; reactions catalyzed by the platinum black may affect the hydrogen ion activity of the solution; the necessity of employing a gas phase of known partial pressure of hydrogen is awkward and presents serious difficulties in the investigation of

---

[2] Loomis Fellow, 1926–1927.

solutions in equilibrium with a dissolved gas. In this case the gas surrounding the electrode must be such that the equilibrium conditions of the original solution are not disturbed. Solutions containing carbonates, which are of especial interest to the physiological chemist, are but one example of a case in which the gas phase must consist of a mixture of gases of known partial pressure.

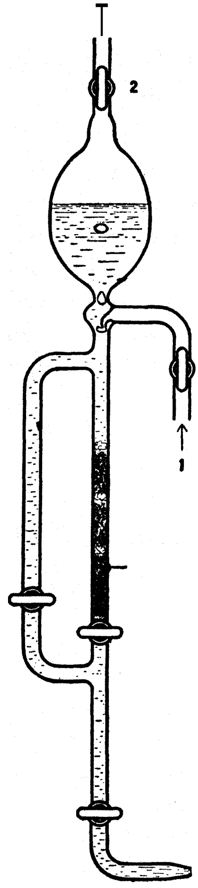

Fig. 1.—Antimony–antimony trioxide electrode for use with nitrogen. 1. Nitrogen inlet. 2. Nitrogen outlet.

The quinhydrone electrode and its several modifications are used quite extensively. The independence of a gas phase is a marked advantage of this electrode but its stability falls far short of that of the hydrogen electrode and it is not usable in solutions of appreciable alkalinity.

Another class of electrodes closely related to the hydrogen in principle but employing no gas phase is the metal oxide electrode, more particularly an electrode made up of a pure metal in contact with a solution saturated with respect to its oxide. Probably the best known example of this type is the mercuric oxide electrode; but, because of the solubility of the oxide, this electrode does not function as a measure of the activity of hydrogen ion except in alkaline solution and in absence of ammonia and of the anions of the slightly soluble mercurous salts, notably the chloride.

The first suggestion for a metal oxide electrode composed of a metal which does not displace hydrogen, whose salts are readily hydrolyzed and whose oxide possesses a low solubility in both acids and bases, was made by Uhl and Kestranek.[3] These authors pointed out that antimony and its amphoteric trivalent oxide meet the requirements over a presumably wide range in acidity. Their working electrode, which was used only as an end-point indicator in acidimetric titrations, was somewhat crude, consisting of a bar of massive antimony standing in the solution in which had been suspended several milligrams of antimony trioxide prepared by treating antimony with nitric acid.

The obvious advantages of such an electrode for measuring acidity led us to make an intensive investigation of the electromotive behavior of antimony and its trivalent oxide. Kolthoff and Hartong[4] have published the results of a brief study of the potential of the antimony–

---

[3] Uhl and Kestranek, Monatsh., 44, 29 (1923).

[4] Kolthoff and Hartong, Rec. *trav. chim.*, 44, 113 (1926).

antimony trioxide electrode in various solutions of known acidity. Their electrode arrangement was that of Uhl and Kestranek; the relation between potential and PH was shown to be nearly linear, although the change in potential for each Sørensen unit was always less than that required by theory, diverging more in acid than in alkaline solution. Similar results were obtained in a rather more detailed research by Vlès and Vellinger.[5] After our work was practically complete, Franke and Willaman[6] described a form of antimony electrode for use in the control of pulp and paper manufacture; their electrodes, bars of metal cast with more care than those of previous authors, gave potentials which, at 25°, differed by only 54 mv. for a tenfold ratio of the hydrogen ion activities over the range 1 to 12 *P*H.

In the following we have attempted to define the conditions under which the behavior of the antimony–antimony trioxide electrode approaches the ideal, and also to describe a practical form of the electrode which may be used as a substitute for the hydrogen electrode with no essential decrease in accuracy and a considerably increased field of applicability over the latter. This has involved a study of the condition of both metal and of oxide stable at ordinary temperatures, the effect of oxygen upon the system, the time required for equilibrium to be established and the direction from which it must be approached. Moreover, it has necessitated a detailed examination of the validity of the accepted *P*H values of certain buffer solutions at 25° and, because of the uncertainty of some of the corrections involved, the direct measurement of some of them at 25°.

The Antimony–Antimony Trioxide Electrode at 25°

Corresponding to the electrode reaction $\mathrm{Sb(s)} \qquad \mathrm{Sb}^{+++} + 3\ \ominus$, the potential of an antimony electrode at 25° may be written

$$E_{\mathrm{Sb}} = E_0' - (0.05915/3) \log (\mathrm{Sb}^{+++}) \qquad (1)$$

In a solution saturated with respect to the trioxide, the following equilibrium may be considered to exist: $\mathrm{Sb_2O_3(s)} + 3\mathrm{H_2O} \qquad 2\mathrm{Sb}^{+++} + 6\mathrm{OH}^-$, wherefore, substituting in Equation (1) the value for the activity of Sb^{+++}, we have

$$\begin{aligned} E_{\mathrm{Sb}} &= E_0 + 0.05915\,[-\log(\mathrm{H}^+) - \log(\mathrm{Sb_2O_3})^{1/6} + \log(\mathrm{H_2O})^{1/2}] \\ &= E_0 + 0.05915\left[\mathrm{P_H} - \frac{1}{6}\log(\mathrm{Sb_2O_3}) + \frac{1}{2}\log(\mathrm{H_2O})\right] \qquad (2) \end{aligned}$$

Thus, if the last two terms in the equation are disregarded, E_0 is the difference in potential between an antimony–antimony trioxide and a hydrogen electrode in solutions of the same acidity. This cell was measured by Schuhmann[7] in three concentrations of perchloric acid ranging from 0.23 to 1.13 M, who demonstrated that in acid solution trivalent

---

[6] Franke and Willaman, *Ind.* Eng. Chem., 20, 87 (1928).

[7] Schuhmann, THIS JOURNAL, 46, 52 (1924).

antimony is present mainly in the form of SbO^+. The ions Sb^{+++}, $SbOH^{++}$, SbO^+, SbO_2^-, SbO_2OH^{--} and SbO_3^{---} may be regarded as capable of existence under different conditions of acidity. However, provided the system is in equilibrium, Equation (2) is independent of the form of the ion in which the antimony may occur; indeed, it may be very simply derived from the reaction expression $2Sb(s) + 3H_2O \quad Sb_2O_3(s) + 6H^+ + 6\ominus$.

The term in Equation (2) which involves the activity of the solid oxide disappears if the oxide is in its standard state (that is, the stable crystalline form), and this condition must hold if the antimony trioxide electrode is to attain its highest accuracy in acidimetric measurements. Other authors have paid no attention to this point, which has proved to be of major importance.

The term involving the activity of water is not altogether desirable from the standpoint of the applicability of the electrode for determining P_H. It is not always easy to evaluate this term with absolute accuracy but, since the activity of water decreases slowly with increasing concentration of dissolved salts, an approximation can usually be made that is within the experimental accuracy. For instance, even with solutions saturated at 25° with potassium chloride, sodium chloride, and potassium sulfate, respectively, the correction for the activity of water[8] amounts to 2.2, 3.7 and 0.4 mv.; in the case of the buffer solutions used in our experiments this term, being of the order of 0.01 mv., may be entirely neglected.

Since E_0 at 25° for the antimony–antimony trioxide electrode is essentially the potential of the electrode in a solution containing hydrogen ions at unit activity referred to a hydrogen electrode under a partial pressure of hydrogen of 1 atmosphere at 25° in a similar solution, the value of E_0 must be determined by making such a measurement either directly or indirectly, the direct measurement being obviously the more reliable method. However, owing to the fact that previous investigators have found that the coefficient of the second term of the right member of Equation (2) may deviate from theory as much as 10%, the indirect method promised distinct advantages in the study of the electrode under varied, but strictly defined, conditions. Accordingly, if the potential of the antimony electrode in a buffer solution, whose P_H has been determined by means of a hydrogen electrode measurement, is measured against reference electrodes corresponding to those used in the standardization of the buffer, the value for E_0 may be determined provided that (a) the conventions adopted with regard to the liquid junction potentials in the two systems correspond, (b) the reference electrodes in the two cases have the same thermodynamic properties. Since the slope of the E vs. P_H curve

---

[8] Leopold and Johnston, THIS JOURNAL, 49, 1974 (1927).

of the antimony electrode is altered by 1 mv. per PH (that is, by almost 2%) by a change of as little as 0.12 in the difference attributed to a pair of buffers of PH 3 and 10, respectively, and since an uncertainty of this magnitude may easily enter when the buffers are used at a temperature other than that at which the values were set, we were forced to consider very carefully the *PH* of the standard buffers which we used. Furthermore, it is necessary to establish that the liquid junction potentials in our reference system correspond to those used in the standardization of the buffers and to choose the proper potentiai of our reference electrode.

The PH of the Standard Buffer Solutions at 25°

The buffers used in this investigation were those described by Clark and Lubs,[9] the PH of which was fixed by means of the hydrogen electrode at 20°, thus rendering a temperature correction to 25° necessary. Table I lists the several buffers with corresponding temperature corrections obtained from a number of sources (Col. 3). In the case of the two potassium chloride–hydrochloric acid buffers, the measurements were made at 25°; the next five were corrected on the basis of the work of Kolthoff and

[9] Clark and Lubs, *J. Biol. Chem.*, 25, 479 (1916).

Tekelenburg[10] on the change of *PH* in buffer mixtures at varying temperatures. Walbaum[11] found the *PH* of the phosphate buffers of the Sørensen series independent of the temperature over a wide interval, therefore the same conclusion was drawn with respect to the similar Clark and Lubs buffers; the corrections adopted for the borate buffers were also taken from Walbaum's work on the Sørensen solutions. The two most alkaline buffers are not from the Clark and Lubs series but were calculated from Ringer's[12] data by Kolthoff. The *PH* at 25° for the supposed *PH* 12.06 buffer is calculated from our own direct measurement on the preceding solution, assuming Kolthoff's difference to be correct. In some instances we determined the *PH* of the buffer directly with a hydrogen electrode; these values, discussed later, are given in the fifth column of the table and are used in subsequent calculations in preference to the computed values (Col. 4), as each of these involves a consideration of the work of more than one author.

Liquid Junction Potentials

Clark and Lubs measured the cells Pt, H_2 | buffer | 1.75 N KCl followed by 3.5 N KCl | KCl (saturated), Hg_2Cl_2 | Hg and Hg | Hg_2Cl_2, KCl (saturated) | 0.1 N KCl, Hg_2Cl_2 | Hg, employing the Bjerrum extrapolation indicated as a correction for the liquid junction potential between the buffer and the saturated potassium chloride, and "neglecting the liquid junction potential between saturated and 0.1 N potassium chloride." However, Scatchard[13] showed that in using a flowing junction apparatus in measuring the cell Hg | Hg_2Cl_2, KCl (saturated) || 0.1 M KCl, AgCl | Ag[14] the electromotive force did not change on stopping the flow, indicating that the junction potential was independent of the nature of the junction in the case of two potassium chloride solutions, and, therefore, that the combination of liquid junctions 3.5 N KCl | KCl (sat.) | 0.1 N KCl is exactly equivalent to the junction 3.5 *N* KCl | 0.1 N KCl; also that the combination 1.75 N KCl | KCl (sat.) | 0.1 N KCl is equivalent to 1.75 N KCl | 0.1 N KCl. This conclusion is still further verified by the fact that Clark found no Bjerrum extrapolation in the measurements on the borate buffers at low sodium ion content, that is, when the ions in the buffers were chiefly potassium and chloride ions. This means that the junction potential 0.1 N KCl | 1.75 N KCl plus 1.75 N KCl | KCl (sat.) equals 0.1 N KCl | 3.5 N KCl plus 3.5 N KCl | KCl (sat.) which may be extrapolated to equal 0.1 N KCl | KCl (sat.). Therefore 3.5 N KCl | 0.1 *N* KCl equals 3.5 N KCl | KCl (sat.) plus KCl (sat.) | 0.1 N KCl.

[13] Scatchard, THIS JOURNAL, 47, 696 (1925).

[14] The symbol || indicates a flowing junction.

If this is the case, Clark's liquid junction train is reduced in effect to Bjerrum's original train, solution | 3.5 N KCl followed by 1.75 N KCl | 0.1 N KCl, and the extrapolation tends to reduce the sum of all the liquid junction potentials to zero rather than merely that between the buffer and the saturated potassium chloride solution.

Our measurements were made with the liquid junction system buffer | 3.5 *N* KCl | 0.1 *N* KCl; since this corresponds to Bjerrum's train, it, in effect, is equivalent to Clark's train; therefore Clark's determined values for the Bjerrum extrapolation on the several buffers (Table I, last column) may be applied to our readings, thus bringing them into concordance with Clark's corrected potentials. It is to be noted that this correlation of our junction potentials with Clark's and our use of his Bjerrum extrapolations are necessary if we are to use his calculated values for the P_H of the solutions; but it must be emphasized that our derived value for E_0 is independent of any theory of the liquid junction since the corrections applied merely cancel those introduced by Clark in calculating the P_H of the solution.

Potential of Reference Calomel Electrodes

Clark used for the value of the decinormal calomel electrode —0.3355 v. referred to a platinized electrode immersed in a solution normal with respect to hydrogen ions and under an atmosphere of water vapor and pure hydrogen gas at a partial pressure of the latter of 760 mm. at 0°. In order to obtain the value of E_0 for the antimony–antimony trioxide electrode at 25° referred to a hydrogen electrode under 1 atmosphere partial pressure of hydrogen at 25°, now the generally accepted standard, by comparison with a 0.1 M calomel electrode, through the medium of a 3.5 N KCl, silver–silver chloride electrode, it is necessary to correct Clark's value for the 0.1 N calomel electrode for (1) the difference in concentration of hydrogen at a partial pressure of 760 mm. at 0° and 760 mm. at 25°, or 0.89 mv.; (2) the temperature coefficient of the electrode, giving rise to a potential change from 20 to 25° of 0.30 mv.;[15] (3) the difference in concentration between 0.1 N and 0.1 M potassium chloride, or —0.15 mv. The resulting value, -0.3374_6 v., refers our measurements to the desired hydrogen standard and to Clark's P_H scale, which, in turn, depends upon the absolute accuracy of his adopted value and his liquid junction corrections. The validity of the scale comes into question later when 0.1 M and 0.01 M hydrochloric acid solutions were used in some of the electrodes and the P_H values calculated on the basis of Scatchard's[13] values for the activity coefficients of hydrogen ion.

On the basis of the activity coefficients for hydrochloric acid[16] from

---

[15] Clark, "The Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, Maryland, 1925, Chap. XIX.

[16] Scatchard, THIS JOURNAL, 47, 641 (1926).

which those for hydrogen ion were derived, Scatchard finds the absolute value of the 0.1 M calomel electrode, including no junction potentials, to be —0.3353 v.[13] This calculation, however, is based on the value 0.3989 v. (average of best existing values in the literature, as judged by Scatchard) for the electromotive force of the cell Pt, H_2 | 0.1 *M* HCl, Hg_2Cl_2 | Hg which leads to 0.0466 v. for the difference between the calomel and the silver–silver chloride electrodes. In view of the fact that our direct measurements of this potential[17] using 0.1 M potassium chloride gave 0.04530 v. ± 0.05 mv. and that the calomel electrode is known to behave erratically in dilute hydrochloric acid solutions, we prefer to calculate the value of the calomel from Scatchard's measurements of the cell Pt, H_2 | HCl, AgCl | Ag[16] and our own value[18] for the difference between the silver chloride and calomel electrodes. Calculation of Scatchard's results to exactly 0.1 M hydrochloric acid gives 0.35230 v.; adding our value of 0.04535 v. we arrive at a result of 0.39765 v. for the potential of the hydrogen–calomel cell in 0.1 M hydrochloric acid. A value almost identical with this may be calculated from measurements presented later in Tables IV and V; that is, the electromotive force of the cell Pt, H_2 | 0.1 M HCl, Sb_2O_3 | Sb is 0.14436 v.; that of the cell Sb | Sb_2O_3, 0.1 M HCl || 3.5 N KCl, AgCl | Ag is 0.1259 v.; and for the cell Ag | AgCl, 3.5 N KCl || 0.1 M KCl, Hg_2Cl_2 | Hg the electromotive force is 0.13135 v.; from this it is evident that the electromotive force of the combination Pt, H_2 | 0.1 M HCl || 3.5 N KCl || 0.1 M KCl, Hg_2Cl_2 | Hg is 0.4016 v. In a paper to be published shortly, we will show that the difference between the two flowing liquid junction potentials indicated is 3.9 mv., which gives 0.3977 v. for the electromotive force of the cell Pt, H_2 | 0.1 M HCl, Hg_2Cl_2 | Hg if the activity of chloride ion in 0.1 M HCl and 0.1 M KCl is the same. Both of these values lead to an E_0 for the electrode Hg | Hg_2Cl_2, Cl^- of —0.2680 v., and —0.3341 v. for the potential of the decimolal calomel electrode, using Scatchard's values for the necessary activity coefficients.[19]

Thus, since the correct value for the potential of the decimolal calomel

---

[17] Roberts and Fenwick, **THIS JOURNAL**, 49, 2787 (1927).

[18] In view of later measurements in connection with liquid junction potentials soon to be published, the highest of the possibilities indicated above, 0.04535 v., is judged to be more nearly accurate.

[19] Randall and Young, in a paper appearing just after the writing of this paper had been completed, **THIS JOURNAL**, 50, 989 (1928), give the following values:

	Randall and Young	Our values
Pt, H_2 | 0.1 M HCl, Hg_2Cl_2 | Hg, E	0.3976 v. (p. 990) 0.3977 v. (p. 993)	0.3977 v.
Hg | Hg_2Cl_2, Cl^-, E_0	—0.2676 v.	—0.2680 v.
Hg | Hg_2Cl_2, 0.1 M KCl, E	—0.3341 v.	—0.3341 v.

The agreement between the two sets of results is remarkable, the difference in the second value in the two cases being due to the use of different activity coefficients in the calculations.

electrode, corresponding to Scatchard's activity coefficients of hydrogen ion, is **–0.3341** v., and we are using -0.3374_6 v., we must either make a special case of the two hydrochloric acid solutions and use **–0.3341** v. for the potential of this cell in our calculations in these two instances, or else modify the calculated PH by an amount equivalent to the difference between the two calomel values, this being 3.3_6 mv. $(0.3374_6-0.3341)$ or **0.0568 PH,** which must be subtracted from the given calculated values **(1.075** and **2.036)** in order to make them conform to Clark's scale and our own working value for the calomel electrode; these computed values for **0.1** M and **0.01** M hydrochloric acid solutions become **1.018** and 1.979 **PH,** respectively, upon applying the above adjustment.

From this it is clear that our value for the E_0 of the antimony–antimony trioxide electrode is independent of any PH scale, since in both cases we have in effect used a value for our reference electrode which corresponds to that of the author from whose work the PH of our solution was derived. The absolute value of the hydrogen ion activity, as derived from measurements with this type of electrode as well as the hydrogen electrode, depends, of course, upon the value attributed to the reference electrode. For this the value **–0.3341** v. for the potential of the **0.1** M calomel seems to be preferable, while if the relative activity of hydrogen ion is desired, the value -0.3374_6 v., corresponding to that used by Clark, may be used as this leads to results in concordance with the generally accepted PH scale.

Preparation of Solutions and Materials

Buffer Solutions.—The standard buffer solutions were made up much as directed by Clark;[20] potassium chloride, potassium acid phthalate, potassium dihydrogen phosphate and boric acid were recrystallized as advised but the buffers were prepared as needed from weighed samples of the salts rather than from stock solutions. A special grade of disodium hydrogen phosphate ($Na_2HPO_4 \cdot 2H_2O$) was purchased ready for use.[21] A solution of constant boiling hydrochloric acid, analyzed gravimetrically, was used in the most acid buffers, and for the standardization of carbonate-free sodium hydroxide obtained by diluting a stronger hydroxide solution prepared by dropping metallic sodium into a deep ether layer above water.[22] All of the water used for the solutions was freshly distilled and collected in a current of escaping steam.

Antimony.—Pure crystalline antimony was prepared by the rapid electrolysis of antimony trifluoride solution, as described by Schuhmann;[7] however, the product was not allowed to dry but was kept under water until needed, treated with hot, dilute hydrofluoric acid and washed. The trifluoride solution was obtained by dissolving specially purified precipitated oxide in pure hydrofluoric acid.

Antimony Trioxide.—The oxide required for the antimony electrode was obtained from the hydrolysis of antimony trichloride, which was prepared in a very high state

[21] From LaMotte Chemical Products Co., Baltimore, Md.

[22] Cornog, THIS JOURNAL, 43, 2573 (1921). The sodium carbonate content of our solution was shown by nephelometric comparison to be less than 0.01% of the sodium hydroxide present; no cloudiness developed on the addition of barium chloride.

of purity by distilling the hydrochloric acid solution of commercial "C. P." antimony trioxide[23] in an all-Pyrex apparatus. The high boiling point of antimony trichloride (above 220°) renders an elaborate still unnecessary; a 1-liter distilling flask with the neck drawn down to about 8 mm. in diameter, stoppered with a flanged rod and a 70–80-cm. length of tubing slipped over the side arm for a condenser serves excellently. The distillate was discarded until a test drop of the dense, highly refractive liquid solidified on striking a cold glass surface. The collected product was melted, poured into about 15 times its volume of water and allowed to stand overnight at 80°. The initial voluminous flocculent precipitate of basic chloride became coarsely crystalline; it was washed with distilled water, digested twice for eighteen hour periods at 80° with a strong solution of carefully recrystallized sodium carbonate and then with hot distilled water for three weeks, the water being changed daily. The resulting very finely divided oxide, which will be termed "precipitated oxide," was filtered and dried at 110°; it was easily and completely soluble in hydrochloric acid and gave no chemical test for pentavalent antimony.

Consideration of the behavior of the electrodes containing this precipitated oxide as a solid phase (Nos. 1 and 2) led us to undertake a study of the allotropy of antimony trioxide with the view of obtaining definitely stable, crystalline material.

The Allotropic Forms and Transition Temperature of Antimony Trioxide

A cubic form of antimony trioxide occurs naturally as Senarmontite, and an orthorhombic form as Valentinite. The literature with regard to the form stable at 25° is indefinite.

Small amounts of our pure precipitated oxide were placed in a platinum boat in a sealed, evacuated Pyrex tube, heated in a small electric furnace, cooled quickly and the products examined under a petrographic microscope. A platinum–platinum-rhodium thermocouple with direct reading galvanometer, calibrated at the sulfur point, was used to measure the temperature of the furnace. A sample heated at 550° for twelve hours gave as a product cubic crystals only, 0.005 mm. to 0.02 mm. in diameter, octahedra and octahedra truncated by the cube, dodecahedron, or both. A sample heated at 590° for twelve hours gave orthorhombic crystals only; the orthorhombic form also separates from the molten material when it is allowed to crystallize. On heating these orthorhombic crystals at 550° for twenty-four hours, no trace of the original crystal form remained, transformation to the cubic being complete. At 380° no crystallization of the original oxide took place in twenty-four hour-, while at 470° cubic crystals were formed from all samples in twenty-four hours. This was chosen as a safe temperature at which to heat the oxide for future use in the electrodes.

The transition point of antimony trioxide, which must lie between 550 and 590°, was found by a series of successive trials. A final run was made

---

[23] Every sample of antimony trioxide that we were able to procure contained considerable quantities of sulfide, which made drastic methods of purification an obvious necessity.

at 573°, as recorded when the thermocouple extended to within 2 cm. of the front of the platinum boat, which did not rest on the bottom of the furnace. At the end of six hours the tube was removed and allowed to cool. The material in the boat was found to consist of orthorhombic crystals only in the rear end, a mixture of orthorhombic and cubic in the middle section and cubic crystals only for the first centimeter. The temperature gradient of the furnace, although not extreme, was positive toward the rear, therefore 570 ± 10° was adopted as the temperature at which cubic and orthorhombic crystals of antimony trioxide are in equilibrium under the pressure of their own vapor, the cubic being the stable form below this temperature.

In order to ascertain the structure of the unheated precipitated oxide, powder photographs were taken of this material, a similar product obtained by treating antimony trichloride over a period of months with water only and which showed a positive orthorhombic structure under the microscope,[24] cubic crystals prepared by heating at 525°, and orthorhombic crystals prepared by sublimation at 600'. The lines from the water hydrolyzed material checked the lines of the orthorhombic control perfectly, while the lines from our oxide prepared by sodium carbonate hydrolysis differed from the orthorhombic control only in that the principal line was broader, extending from 3.14 Å. to 3.21 Å. The principal line of the orthorhombic is 3.13–3.15 Å., of the cubic 3.22 Å., indicating that our precipitated oxide consisted of a mixture of both crystal forms with the orthorhombic greatly predominating.

Preparation of Electrodes and Method of Measurement

Antimony–Antimony Trioxide Electrode.—The electrode vessel used was a modification of the type described by Brönsted[25] in which the solution flows slowly down through a deep layer of the saturating substance, past the electrode proper, to the junction. The modified vessel and the mica-plate flowing junction arrangement have been discussed in an earlier paper.[17] The addition of the by-pass so that there is no flow of electrolyte past the electrode metal while the potentials are being measured is of the utmost importance in this work. In setting up an electrode, the vessel was first filled with water to prevent the entrainment of air bubbles and the main arm was then packed with antimony crystals (or a mixture of metal and oxide) using cotton plugs to prevent clogging of the stopcock and to break the column into several sections. This insures a sufficiently rapid flow of electrolyte for thorough washing when the solution is being changed and also assists in equilibrating the flowing solution with metal or metal and oxide before it reaches the electrode proper.

Hydrogen Electrode.—The hydrogen electrode vessel adopted was of the type described by Lewis, Brighton and Sebastian.[26] The electrode consisted of a section of

gold plated platinum foil coated with a thin layer of platinum black. Tank hydrogen was purified for use by passing through a strong solution of sodium hydroxide, over phosphorus pentoxide and through two 75-watt tungsten filament bulbs before entering the presaturator.[27]

Reference Electrodes.—The antimony-antimony trioxide and hydrogen electrodes were measured against a silver–silver chloride electrode in 3.5 N potassium chloride[28] as a reference; this in turn was checked against a decimolal calomel electrode as the ultimate standard. The silver and calomel electrodes were made up as outlined in the former investigation[17] except that the mercury for the calomel electrodes was even more carefully purified. After spraying many times through dilute nitric acid, it was distilled several times under diminished pressure in air as described by Hulett,[29] followed by a double distillation in *vacuo*.[30]

The electrode system was maintained at 25 ± 0.02° in an air thermostat. A Leeds and Northrup Type K potentiometer was used and the working standard Weston cell was checked at frequent intervals against two newly calibrated cells purchased from well-known makers.

The Measured Electromotive Force of the Cell Sb | Sb_2O_3, Solution || 3.5 N KCl, AgCl | Ag at 25°

A. Precipitated Oxide, Air Substantially Excluded (Electrodes Nos. 1 and 2).—The first measurements of the potential of the antimony–antimony trioxide electrode were made with precipitated oxide. In the preparation of duplicate electrodes (Nos. 1 and 2 of Col. 2, Table 11), the platinum lead-wires were given a very thin electroplate of antimony from a trifluoride solution and the columns filled with antimony alone, the only oxide introduced being that suspended in the saturated solutions. Each electrode solution was saturated with the respective soluble constituents of the electrode by shaking in the thermostat with an excess of the solids over a period of at least twelve hours. In the case of the solutions for the antimony electrodes, both oxide and metal were used, the metal being introduced to reduce any pentavalent antimony that might be present. The equilibrating solutions completely filled the containing bottles to avoid the presence of air; after equilibration, they were siphoned quickly into the electrode vessels until the bulb was completely filled and an Orsat bulb containing hydrogen was connected to the top. Immediately before the introduction of the equilibrated solution, the electrodes were thoroughly washed with a similar unequilibrated solution and, immediately after, thoroughly washed again. Readings were taken at various intervals over a period of from seventy-two to ninety-six hours, at the end of which time the next solution was intro-

---

[28] The electrode solution contained 3.5 moles (air weight) of potassium chloride per liter at 20°; $d_4^{20} = 1.1526_5$, or the solution was 3.927 molal (vacuum weight).

[29] Hulett, *Phys. Rev.*, 33, 307 (1911).

[30] The additional precautions were evidently unnecessary since the electromotive force found for the cell Ag | AgCl, 3.5 N KCl || 0.1 M KCl, Hg_2Cl_2 | Hg checked our former result precisely.

duced. The metal was rinsed with fresh solution from the reservoir bulb after every reading during the first forty-eight hours and occasionally during the rest of the run. The potential difference showed an upward trend with time, the increase during the first twenty-four hours after the introduction of a new solution normally amounting to from 3 to 6 mv., disregarding erratic changes during the first hour or so. After twenty-four hours, further change was very slow. For example, after the first forty-eight hours, the potential with the buffer of PH 1.2 remained constant to within 0.5 mv. for forty-eight hours, at the end of which the experiment was closed. The deviations during this period showed no definite trend.

The observed potentials given in the third column of Table II were read at least twenty-four hours after setting up the cell. The fourth column contains the observed potential difference corrected for the liquid junction potential by means of the Bjerrum extrapolation given in the last column of Table I. These values were plotted against the corrected PH of the buffers (Col. 1) and a straight line with slope 0.05915 was drawn through the points. The line fitted the data within the limit of experimental accuracy from PH 5 to PH 10. The rate of change of potential with *P*H thus being fixed, E_0 was calculated from the equation E_0 =

E_{Sb} – 0.05915 PH (Equation (2) rewritten on the basis of our stated assumptions), where E_{Sb} is the potential of the antimony–antimony trioxide electrode alone, obtained by adding to E' the value for the potential of the reference half cell, –0.2061 v. This was derived from our measured electromotive force of the cell Ag | AgCl, 3.5 N KCl || 0.1 M KCl, Hg_2Cl_2 | Hg, 0.13135 v., and the value for the decimolal electrode at 25° corresponding to that employed by Clark and Lubs in the standardization of their buffer solutions, –0.33746 v. The mean value of E_0 over the range in PH stated was –0.1512 v., with a maximum deviation of 3.1 mv. and a mean deviation of 1.6 mv.; below *PH* 5 and above *PH* 10, the deviation was greater. If the computed values of *PH* (Col. 4, Table I) were used to the exclusion of any of our later determined values, the slope was less than the theoretical, about 0.0586. Schuhmann[7] found 0.1524 v. for the electromotive force of the cell Pt, H_2 | $HClO_4$, aq., Sb_2O_3 | Sb with a maximum deviation from the mean of his three cells of 2.5 mv., a result which compares favorably with our own.

Thus far the antimony–antimony trioxide electrode had exhibited two distinct peculiarities; the "best" E *vs.* *PH* curve is not linear except from *PH* 5 to PH 10, the slope, based on the most reliable published values for the buffers, tending to be rather less than the theoretical, and the approach to a constant potential being very slow, sometimes requiring days. In the case of our measurements the first abnormality is not large, but it is in the same direction as the much larger deviations found by other workers.[4,6] Several explanations for the erratic behavior of the electrode suggest themselves. (1) The assumption that the term in Equation (2) involving the activity of the solid oxide drops out may not be valid because the oxide used was not in its stable state and a virtual supersaturation of the solution with antimony trioxide persisted. This would not only explain the slow change of the potential with time but it is a plausible reason for the departure of the curve from linearity and from the ideal slope, since it is easy to believe that the rate of approach to equilibrium might always be slow and yet vary considerably with the acidity. (2) Extreme precautions to exclude air were not taken. It is possible that the system is more susceptible to oxidation than supposed, pentavalent antimony ions forming so readily that the equilibrium $Sb^{+++++} + Sb \qquad Sb^{+++}$ is attained with difficulty.[31] (3) The derived *PH* values assigned to the buffer solutions may not be actually correct. Although suspicion of the accuracy of the temperature corrections employed for the buffers is justifiable, this last reason for inconsistency will, for the present, be disregarded; in view of the facts that two crystal forms of antimony trioxide are known and the material used showed no definite crystal structure at a magnifi-

---

[31] Franke and Willaman report serious drifts in potential on bubbling air through their solutions.

cation of 1000 diameters, the first explanation seemed most likely. Consequently the study of the allotropy of antimony trioxide was made and a supply of definitely pure cubic oxide prepared.

B. Cubic Oxide, Air not Excluded (Electrodes **Nos.** 3 and 4).—Two new electrodes were made up with cubic antimony trioxide in order to investigate its electromotive behavior and to compare it with the precipitated oxide in electrodes Nos. 1 and 2. In keeping with the precautions with regard to the exclusion of any unstable oxide, the subject of the constant activity of the metal was considered. Although the presence of a large number of unstrained crystals of metal in contact with strained metal is supposed to dissipate the strain, electroplating of the platinum lead-wire was discontinued. Instead, it was pretreated with a strong solution of stannous chloride in hydrochloric acid, washed, and a solution of antimony trifluoride introduced to adjust the potential of the wire to that of antimony,[32] before the electrode column was filled, in this case with an intimate mixture of metal and oxide. Crystals of antimony prepared as described for the first two electrodes were used in electrode No. 3; for No. 4 the metal was annealed by heating to 500° in a vacuum, followed by slow cooling. Before use, the annealed metal was treated with boiling hydrofluoric acid for several minutes and washed thoroughly. No precautions were taken to exclude air beyond a soda-lime guard tube in the top of each electrode to avoid the absorption of carbon dioxide, and the solutions were unequilibrated with either metal or oxide before their introduction into the electrode reservoirs.

The pair of electrodes was read over a period of from forty-eight to ninety-six hours after introduction of the buffers. In most cases, the final value was reached within fifteen or twenty-four hours, the potential thereafter remaining constant within 0.2 mv. or less. Upon rinsing the metal with fresh solution from the bulb, a drop of 2 to 3 mv. occurred; after a lapse of ten hours, the electrode had always returned to constant potential. In all cases in which the change of potential with time at the beginning of an experiment was studied, the readings at the end of the first thirty minutes were never more than 6 mv. lower than the final value. Table III shows the behavior of these electrodes. The column headings are self-explanatory and the calculated values given in the table were arrived at in a manner similar to those in Table II, except for Col. 6, in which the value 0.05835 for the slope was determined analytically on the basis of the values for electrode No. 3. The average value for E_0 was also based on the values for electrode No. 3, excluding the widely divergent value at PH 6.018. The final column indicates the direction

---

[32] A similar procedure was found of great value in the preparation of noble metal electrodes for use in the electrometric determination of silver by precipitation as silver chloride, Van Name and Fenwick, THIS JOURNAL, 47, 9 (1925).

of approach to equilibrium, that is, whether the preceding solution in the electrode had been more alkaline or more acid; *U* signifies that this solution had been more acid and D the reverse. It will be noticed that electrode No. 3 is the more consistent of the two, the mean deviation being but 0.17 mv. if the value at PH 6.018 is excluded, and that in this case the equilibrium was always approached from the more alkaline side; this peculiarity was also noticed in later work. The values for E_0 for electrode No. 4 are in general more negative than those for No. 3 (the mean being —0.1513 v.), indicating greater mobility and therefore less strain; nevertheless, no significance was attached to the fact that the metal was annealed, since the individual deviations from the mean are considerably greater than for No. 3, and since later work showed that approach to equilibrium from the acid side, as was the case with No. 4, always tended to give slightly low and varying readings.

The use of cubic instead of precipitated oxide, therefore, resulted in smaller deviations from a straight line relationship between the potential and PH, over a wider range in PH (2.2–10); but the slope of the straight line was now further from the theoretical than before. Hence only a part of the abnormal behavior of the electrodes could be ascribed to the presence of an unstable solid phase and the effect of complete elimination of dissolved oxygen from the electrolyte was next investigated.

C. Cubic Oxide, Air Completely Eliminated (Electrodes Nos. 3a, 4a and 5).—New reservoir bulbs of 150-cc. capacity were sealed onto electrodes Nos. 3 and 4 without disturbing the metal and oxide, making the completed electrodes (Nos. 3a and 4a) appear as shown in the figure. The electrolyte was drawn up into the bulb through the nitrogen inlet tube by applying suction at the outlet tube. After washing the entire electrode thoroughly with the unequilibrated solution, the bulb was filled, a rubber tube, connected to a nitrogen supply,[33] was attached to the inlet tube and nitrogen bubbled through the solution for three or four hours; the solution in the by-pass was displaced by the oxygen-free solution, and the metal was then washed slowly with the deoxygenated solution for ten to twenty minutes. After twelve hours the nitrogen was again started; an hour later a reading was taken and the metal again washed. Twelve

[a] The correction of 3.9 mv. for the liquid junction potential in this case was derived from measurements, to be published soon, on silver-silver chloride electrodes using 0.1 M HCl, 0.1 KCl and 3.5 N KCl solutions.

[b] The *P*H of this sodium hydroxide solution (0.05979 *M*) was calculated from hydrogen electrode measurements on the basis of no liquid junction potential correction.

[c] This value for 0.1330 M sodium hydroxide was derived from the preceding one using activity coefficients for hydroxide ion calculated from activity coefficients of potassium chloride and hydroxide given by Scatchard, THIS JOURNAL, 47, 648 (1925), from the molalities of the two solutions, and on the assumption of equal junction potentials in the two cases: $\Delta P_H = \log (0.1330 \times 0.776)/(0.05979 \times 0.811) = 0.328$.

---

[33] Tank nitrogen was used, purified by passing over hot copper (prepared by reducing the oxide with hydrogen) and washing with strong sodium hydroxide solution, pure water and, finally, a portion of the same solution contained in the electrodes.

hours later the operation was repeated and in most cases the reading was the same as before. If not, this procedure was repeated until two consecutive readings checked within 0.2 mv. The potentials always rose with rinsing and standing. Later on in the work Electrode No. 5 was made up, differing from No. 4a only in that the cubic oxide was prepared from material obtained from the trichloride by water hydrolysis alone and heated in the presence of metallic antimony at 500°. This was to obviate any contamination from sodium salts used in the hydrolysis of the trichloride by the other method, or from pentavalent antimony. The final values in every case are listed in Table IV. After several readings of this series had been taken, it was apparent that, on the basis of the temperature corrections to the buffers which we were able to glean from the literature, the slope would still be slightly less than the theoretical from *P*H 3 to PH 10. The last possibility previously mentioned, that the reported temperature coefficients of the buffers are not correct, seemed the only explanation of this deviation. The simplest solution to this problem was to measure directly the difference in potential between the antimony–antimony trioxide electrode and a hydrogen electrode immersed in solutions of the same acidity.

The Measured Electromotive Force of the Cell Pt, H_2 | Solution Sb_2O_3 | Sb at 25°

In determining E_0 directly, the general procedure was to measure electrode No. 4a or 5 (the preceding solution always having been more alkaline) against the reference electrode for a period of two to three days until the potential had definitely become constant. The hydrogen electrode vessel was then filled with a portion of the same solution which had been used in filling the antimony electrode, and hydrogen was passed through for at least two hours before any measurement was taken. Junction was made in the following manner. The outlet cock on the antimony electrode was closed and a slight excess pressure of nitrogen allowed to develop; the cock on the intake side was closed, the nitrogen supply disconnected and the cock opened slowly, allowing solution to fill the intake tube to the orifice; the volume of solution escaping was sufficient to decrease the pressure inside the bulb enough to balance the hydrostatic pressure of the solution. A short length of carefully cleaned rubber tubing was attached to the hydrogen electrode vessel and filled with solution from the reservoir of this vessel; this was slipped over the intake tube of the antimony electrode making contact; the two cocks on the hydrogen electrode vessel were now opened for the reading, the hydrogen still bubbling. No change in level of the electrolyte on the hydrogen electrode took place, due to the hydrostatic balance previously set up in the antimony electrode.

After the reading had been taken, the electrodes were disconnected and the nitrogen supply reattached to the antimony electrode. From two to four hours later another reading was taken. In two instances the procedure was repeated the following day. Barometric readings were taken coincident with all measurements and the potentials were corrected to 1 standard atmosphere partial pressure of hydrogen at 25°. The maximum deviation from the mean of the two or four corrected readings was 0.16 mv. The measurements are presented in Table V. These results clearly indicate that any previous apparent departure from the theoretical slope was due entirely to errors in the reported temperature coefficients of the buffers; therefore, hydrogen electrode measurements were made on buffers of PH 3, 6 (phthalate), 7, 8 (borate), and 10 of Clark and Lubs, Ringer's buffer of PH 11.29, and 0.05979 M sodium hydroxide solution directly against the reference electrode, using a flowing junction. The correct PH of these buffers at 25° was calculated (Table I, Col. 5) and used in the rest of the tables. In these calculations the Bjerrum extrapolations found by Clark and the value -0.3374_6 v. for the potential of the 0.1 M calomel electrode were used.

TABLE V

THE MEASURED ELECTROMOTIVE FORCE OF THE CELL, PT, H_2 | SOLUTION, SB_2O_3 | SB AT 25°

Solution	E (obs.), v.	Dev. from mean, mv.
0.1000 M HCl	**0.14436**	**– 0.13**
0.0100 M HCl	.14449	.00
C. and L. buffer, PH 7	.14436	– .13
C. and L. buffer, PH 10	.14474	+ .25
Mean	.14449	Mean .13

The results of Table IV may now be considered. The correct value of E_0 was taken as –0.1445 v., the directly determined result. The maximum deviation of the D values of electrodes Nos. 4a and 5, between PH 1 and 10, from this value for E_0, is 1.5 mv. and the mean deviation, 0.5 mv. U values are consistently lower than D by more than 1 mv., except in 0.01 M hydrochloric acid. This bears out the results of Table III with regard to the necessity of approaching equilibrium from the alkaline side for the best results.

Discussion of Results

Our results point definitely to the conclusion that the potential of the antimony–antimony trioxide electrode attains its maximum accuracy only provided that: the presence of any unstable solid phase in the system, notably orthorhombic antimony trioxide, is carefully avoided; dissolved oxygen is eliminated from the solution; and the equilibrium is approached from the alkaline side, a circumstance for which we are unable to offer an adequate explanation. Under these conditions the potential of the electrode is a linear function of the logarithm of the activity of hydrogen ion, with the theoretical slope, from *P*H 1 to 10. It seems conservative to claim a probable accuracy of less than 0.6 mv. or about 0.01 P_H. This compares very favorably with the hydrogen electrode under ordinary conditions. Schuhmann's investigation of the molal electrode potential of antimony provides excellent evidence that our range of applicability may be extended on the acid side to P_H 0 with at least some acids; our own measurements in the two most alkaline solutions indicate that the error at P_H 13 is not more than 2 mv. and with careful pretreatment with a stronger sodium hydroxide solution it may be reduced to 0.5 mv.

Although our results prove that cubic antimony trioxide is the stable solid phase over the range in acidity in which precise activity measurements are ordinarily required, the question may be raised as to the probable extent of its region of stability. Van Bemmelen and other workers[34] have asserted that the stable solid phase in the presence of hydrochloric acid at any dilution contains chloride, but their claims are without adequate support. Lea and Wood[35] found that very finely divided Sb_2O_3 was slowly transformed into $Sb_4O_5Cl_2$ in 0.125 N HCl. However, their material is not comparable with our definitely crystalline oxide; accordingly, to make a direct test of the stability of cubic antimony trioxide, certain acid and alkali solutions were shaken with an excess of the trioxide and the final systems analyzed, with the following results.

Soln.	Concn. of soln. at invariant point at 25°	Soln.	Concn. of soln. at invariant point at 25°
HCl	Approx. 0.10 M	HNO_3	Above 1
H_3PO_4	Approx. 0.06	NaOH	Above 2
H_2SO_4	Approx. 1		

In the last three cases solutions of the concentrations stated produced no new solid phase detectable under the petrographic microscope and underwent no determinable change in concentration after shaking for four days. In the sulfuric acid solution, however, a small amount of a new solid phase was detected after a lapse of one month. The first two invariant points were determined by starting with solutions of different initial strengths, slightly above the concentrations stated, containing a large excess of both solid phases, and analyzing the solutions by titration at one-week intervals for three weeks. The change was very slow after the second week and the results given are very probably within 0.01 M of the true invariant concentration. Above 0.10 *M* HCl and 0.06 *M* H_3PO_4, therefore, antimony trioxide is not the stable solid phase and the

[35] Lea and Wood. *J. Chem. Soc.*, 125, 137 (1924).

antimony–antimony trioxide electrode cannot be subjected to such solutions for long periods of time without injury. However, in solutions as concentrated as 0.16 M HCl or 0.15 M H_3PO_4, initially containing the trioxide only, no new solid phase is formed in a week or more and the solutions undergo no change in concentration; therefore, solutions as strong as these may be safely used in the electrodes for short periods of time (three to four days). This was actually done in the case of hydrochloric acid and the electrode behaved perfectly normally afterward. We are not prepared to state positively that cubic antimony trioxide is stable in all moderately dilute acids; exceptional cases may exist but in any event there need be but little difficulty in their detection.

On comparing the several values for the difference in potential between a hydrogen and an antimony–antimony trioxide electrode in solutions of the same acidity, or E_0, it is interesting to observe that our value obtained with precipitated antimony trioxide checks that found by Schuhmann, who used oxide of the same character, to 1.2 mv., or within the limit of error of both investigations. Our final value, using cubic crystals of the trioxide, is 6.7 mv. more positive than this preliminary result, or —0.1445 v. The work of former authors who used massive metal electrodes is so uncertain and irregular that it provides no reasonable basis for comparison with our own and Schuhmann's.

The use of nitrogen as a gas phase for the antimony electrode has distinct disadvantages for its practical application. However, our results in air so closely approached those in nitrogen as regards the magnitude of the deviations from linearity that the former electrode may be safely recommended for general use, provided that the value of E_0 is fixed by means of two or more buffers in the range desired.

Although the necessity for the very careful preparation of the materials comprising the antimony trioxide electrode has been stressed, emphasis has not been laid on its superior permanency to the hydrogen electrode. With a reasonable amount of care there is no reason why it should not remain in service for an indefinite period, merely displacing one solution with another, with the proper precaution that each is more acid than its immediate predecessor. The electrode is undoubtedly slower than the hydrogen electrode in attaining actual equilibrium but the P_H calculated about thirty minutes after the solution has been introduced is normally within 0.1 P_H of the equilibrium value and, since the error is always on the acid side, the true P_H can probably be estimated to within 0.05 P_H. In order to attain an accuracy of the order of 0.01 P_H or greater, twenty-four hours may be required, as compared with two hours for the hydrogen electrode; however, the relative lack of attention demanded and the inert character of the electrode as regards its effect upon the acidity of the solution itself more than compensate for the required wait.

The Free Energy of Formation of Cubic Antimony **Trioxide** and the Free Energy Change for the Transformation: Sb_2O_3 (orthorhombic) $\longrightarrow$ Sb_2O_3 (cubic) at 25°

If 0.1445 v. is accepted as the best mean value for the electromotive force of the cell Pt, H_2 | Solution, Sb_2O_3 (cubic) | Sb, the free energy change for the cell reaction $3H_2(g) + Sb_2O_3$ (cubic) $\longrightarrow 2Sb + 3H_2O(l)$, ΔF_1, $= -6 \times 0.1445 \times (96{,}500/4.185) = -19{,}992 \pm 20$ cal. If the change in free energy for the reaction $3(H_2(g) + 1^1/_2O_2(g) \longrightarrow 3H_2O(l)$, ΔF_2, $= -169{,}680$ cal. (probable accuracy about 0.1%),[36] the free energy of formation at 25° of cubic antimony trioxide is equal to the difference $\Delta F_2 - \Delta F_1 = -149{,}690 \pm 200$ cal. This value is recommended in place of Schuhmann's $-148{,}600$ cal. because of the indefinite crystalline characteristics of his oxide.

The free energy change for the transformation of orthorhombic to cubic antimony trioxide may be calculated from the electromotive force of the cell Sb | Sb_2O_3 (orthorhombic), Solution, Sb_2O_3 (cubic) | Sb. For this purpose two electrodes similar to Nos. 3a and 4a were made up, using orthorhombic antimony trioxide which had been freshly prepared by fusing precipitated oxide in a platinum boat in an evacuated Pyrex tube and cooling quickly after solidification had taken place. Immediately after setting up, the electrodes were washed, filled with buffer, the nitrogen was turned on and the usual procedure followed. Readings against the same reference electrode as used previously were continued for twenty-four hours; constant potentials were not attained. The final values of the two electrodes containing the two buffers PH 9.905 and PH 3.008 were 0.6350 v. and 0.2255 v., respectively. The best values on these same buffers for cubic oxide were 0.6474 v. and 0.2395 v., giving differences of 12.4 mv. and 14.0 mv., respectively. The average value, 13.2 mv., is judged to be accurate to 10% on the basis of these measurements. The free energy change for the transformation Sb_2O_3 (orthorhombic) $\longrightarrow$ Sb_2O_3 (cubic) at 25° is, therefore, equal to $-6 \times 23{,}059 \times 0.0132 = -1826$ cal., or -1800 ± 200 cal. We can claim this only as a minimum negative value since the work with the precipitated oxide showed that even if the oxide saturating the solutions is mainly orthorhombic, if a certain amount of cubic is present, the electrode tends to assume a potential between that characteristic of the cubic and of the orthorhombic. Thus the difference in E_0 of both Schuhmann's and our precipitated oxide electrodes and of our cubic oxide electrodes is only about half the measured electromotive force of the cell under consideration.

In conclusion, the authors wish to express their gratitude to Dr. John Johnston for the suggestions and help he has given in connection with this work.

[36] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. *485*.

Summary

1. The potential of the electrode Sb | Sb_2O_3, Solution has been shown to depend on three main factors: (a) the crystalline character of oxide used, (b) presence or absence of air in the electrolyte, (c) direction of approach to equilibrium; the best results are obtained with cubic oxide, air-free electrolyte, and by pretreatment with a solution more alkaline than the one being studied. Under these conditions, the potential is a linear function, with theoretical slope, of the PH of the solution; the difference between it and a hydrogen electrode in a solution of the same acidity is 0.1445 v. ± 0.2 mv. at 25°.

2. Equal accuracy may be secured without the necessity of excluding air, provided that the electrode is standardized by the use of two or more solutions of known acidity. Such an electrode is superior to the hydrogen electrode in that once set up it requires little further attention, is permanent and may be readily used for solutions the acidity of which is affected either by hydrogen alone or by hydrogen in combination with platinum black. Hydrochloric acid (and probably hydrobromic and hydriodic acids) may not be used in the electrode in a concentration exceeding 0.16 M, phosphoric acid in a concentration not exceeding 0.15 M and sulfuric acid in a concentration not exceeding 1 M, due to the formation of new solid phases. Nitric acid and sodium hydroxide may be used up to 1 M and 2 M, respectively, and perhaps further.

3. Because the behavior of the antimony–antimony trioxide electrodes indicated that previously determined temperature coefficients applied to the Clark and Lubs buffers were somewhat in error, the *P*H of certain of these solutions (the accepted standards at 20°) were measured at 25° with the hydrogen electrode (Table I, Col. 5).

4. Antimony trioxide formed by the hydrolysis of antimony trichloride has been demonstrated to consist chiefly of orthorhombic crystals; the transition temperature of antimony trioxide has been found to be 570 ± 10°, the cubic form being stable below this temperature.

5. The free energy of formation of cubic antimony trioxide at 25° was found to be −149,690 ± 200 cal. and the free energy of transformation, Sb_2O_3 (orthorhombic) $\longrightarrow$ Sb_2O_3 (cubic), −1800 ± 200 cal.

6. The potential of the decimolal calomel electrode has been derived from two different sources and found to be −0.3341 v.

[CONTRIBUTION FROM THE FERTILIZER AND FIXED NITROGEN LABORATORY OF THE UNITED STATES BUREAU OF CHEMISTRY AND SOILS]

AN APPARATUS FOR CONTINUOUS GAS ANALYSIS

BY ERNEST C. WHITE

RECEIVED MAY 7, 1928 PUBLISHED AUGUST 4, 1928

The apparatus herein described is designed to afford a continuous determination of moderate concentrations of a given constituent in a flowing gas mixture, and to register the concentration automatically by electrical means. The principle is to scrub a definite proportion of the gas with a definite proportion of a suitable absorbent and to determine the titer of the resulting solution by measuring its electrical conductivity.

Apparatus

From a large reservoir R (Fig. 1) the absorbent is fed slowly through a tube terminating in a small bore capillary A[1] of 7 mm. outside diameter, whose flat, fine-edged tip[2] is horizontally disposed. The rate of flow is maintained fairly constant by means of the constant level device S, so that the liquid falls from the tip of the capillary in drops of uniform volume at intervals of about eight seconds.[3] Each drop falls freely through the bulb B upon the aperture C, forming a thick film which traps the gas in the tube CD, of about 4 mm. bore, and forces it along in descending by gravity to the goose-neck at D. The latter is a capillary constriction of about 1.5 mm. bore, suitably bent so as to arrest each droplet until it is displaced by the impact of the succeeding drop.[4] From this it results that the same volume of gas, namely, the volume of the tube between the points G and D, is aspirated by each drop of the liquid.

The temperature is kept constant by immersion in a thermostatic bath contained in the receptacle U, so that the quantity of gas in each sample is assumed to vary only with the barometric pressure. The gas is introduced-at N at a rate slightly in excess of that at which it is being drawn through the coil O by the pump action, the overflow escaping through the side arm P of sufficient length to prevent air from entering the coil. All of these tubes should be of sufficient bore to afford an easy flow of gas.

After having been thus brought into contact in a definite proportion by volume, the liquid and the gas traverse the coiled tube E, which should be long enough to insure practically complete absorption of the desired constituent of the gas. They are separated at the widened lower end F of the coil, where the films are disrupted and the liquid flows into the cell GIJ, the spent gas escaping through the tube Q. The overflow from the cell passes out through the siphon L, the outer arm of which is bent upward at its lower end, the tip M being level with a point just above the electrode H.

---

[1] A bore of about 1 mm. is adequate and the length of the capillary is selected so as to give the desired rate of flow when the liquid is under a pressure head equal to that maintained by the constant level device.

[2] The fine edge may be obtained by grinding the tip in a Wood's metal sleeve, as described by Harkins and Brown, THIS JOURNAL, 41, 499 (1919), and later by Whitman, Young and Wang, Ind. *Eng. Chem.*, **18**, 363 (1926).

[3] At this rate of formation the size of the drop varies by less than 0.3% for a difference of one second in its time of formation; see Whitman and others, ref. 2. A more rapid rate could be used if desired, since the constant level device is capable of maintaining a high degree of uniformity.

[4] No great difficulty is inherent in the correct adjustment of the goose-neck, whose shape can be altered by bending the softened glass until found satisfactory by trial.

In the cell illustrated, the tube I, having an internal diameter of about 2 mm., is bent upward at the ends so as to prevent small gas bubbles from collecting in it. The electrode compartments G and J are similar in shape to an oblique cone, and the electrodes H and K are disks of platinized platinum, each of which is welded to a stout platinum wire about an inch in length. A portion of this wire is imbedded in a glass knob sealed to the wall of the vessel and the upper end is attached to a finer wire leading out of the apparatus. The wire leading through the siphon tube L is of platinum and requires a gas tight seal at V where it emerges. The dimensions and shape of the cell are designed to afford rapid and complete flushing, so as to diminish the time lag attending changes in the composition of the solution.

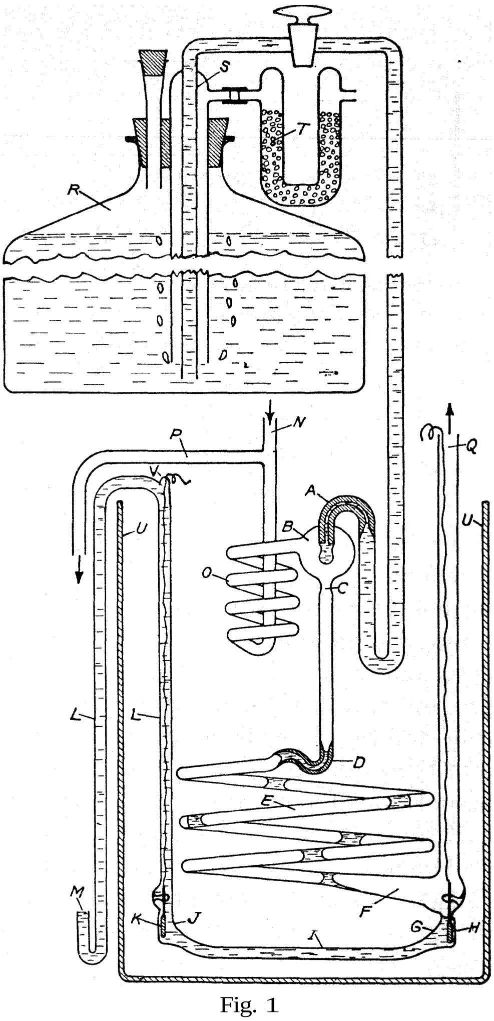

Fig. 1

The long, narrow tube I permits the determination of the conductivity by a method using direct current and possessing the advantages of rapidity and adaptability to recording instruments. This method requires a cell resistance of the order of 10^5 ohms. The cell is connected in series with a low resistance galvanometer in a direct current circuit of about 100 volts, in which the potential is constant or readily adjustable. For this purpose radio "B" batteries have been found very serviceable, if the circuit is closed only for brief intervals. Fig. 2 illustrates an arrangement for detecting and compensating any slight changes in the voltage of the "B" battery. Here the current that flows through a standard fixed resistor, of about the same resistance as that of the cell, is made a measure of the potential and the latter is capable of minor adjustment by means of a variable potential unit, consisting of a 1.5-volt dry cell around which is shunted a rheostat of about 200 ohms. With this arrangement the conductivity of the solution may be assumed to be directly proportional to the current, since variations of the polarization at the electrodes will be only a negligible fraction of the applied voltage, and the total resistance of the circuit will not differ appreciably from that of the cell alone. With a current of about one milliampere the effect of electrolysis is scarcely perceptible.

If a recording instrument is used in place of the simple galvanometer, its timing mechanism should be made to close the circuit a few seconds before registering and open it immediately afterward. An instrument of the self-balancing potentiometer type, such as a Leeds and Northrup recording pyrometer, would have to be shunted with a suitable fixed resistance and might require modification of its range by altering the zero offset.

Calibration

Method I.—An empirical calibration of the apparatus can be obtained by operating with gas mixtures of known composition, and plotting these compositions against the corresponding conductivities observed for the resulting solutions. This method is perhaps preferable for mixtures with a fairly high content, say 5% and above, of the gas sought, or in cases where absorption is incomplete.

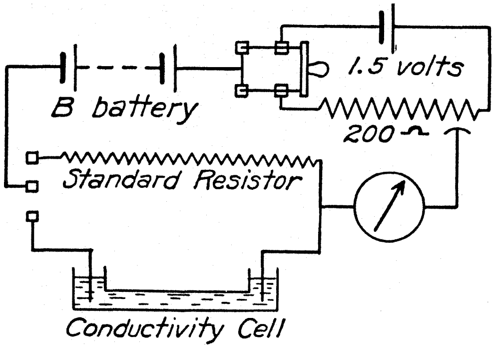

Fig. 2.

Method II.—If the apparatus is to be used for low concentrations of a readily absorbed gas, it is possible to derive a calibration curve where conductance data are available. This second method consists in making careful determinations of the liquid drop size, which will be referred to as a, and of the capacity of the cylinder CD, which will be referred to as b. The former measurement may be obtained by collecting the liquid that overflows at M resulting from the fall of a counted large number of drops during operation at a steady state. The determination of b is best made under similar conditions, using an inert gas and measuring the quantity delivered from the tube Q. If this gas is collected by water displacement, a little care is necessary in order to maintain the pressure at the exit exactly equal to that at the intake, namely, barometric; for otherwise the apparatus will not function properly.

If, during the fall of n drops, an observed volume V cm.^{3} has been collected over water at the room temperature T_r, under barometric pressure P and saturated vapor pressure p_r, while T and p are, respectively, the thermostat temperature and the corresponding aqueous vapor pressure in the tube CD, the capacity b may be calculated as follows:

$$b = \frac{VT(P - p_r)}{nT_r(P - p)} \text{ cm.}^3$$

Although b is a constant for the apparatus, the number of moles m of dry gas aspirated by each drop will vary, of course, with barometric pressure. Assuming perfect gases and expressing pressures in mm. of mercury, the value of m would be

$$m = 273(P - p)b/22{,}420 \times 760\,T = 1.602 \times 10^{-5}(P - p)b/T.$$

From the values thus obtained for a and m it is a simple matter to calculate the relationship of the gas composition to the concentration of the resulting solution, and hence to the conductivity of the latter as computed from conductance data. An example will be given in a later section. In regard to this method of calibration, which is capable of great accuracy for concentrations less than 2%, it must be admitted that it does not take into account the quantity of gas absorbed by a liquid drop before the latter reaches the goose-neck D.[5]

Applications

For gases such as NH_3, HCl or SO_2, the most convenient absorbent would be distilled water, provided the other gases in the mixture are not very soluble. The conductivity of the water, which may be negligible but can be tested from time to time, will then correspond to zero gas concentration. With the aid of conductance data and a single determination of the cell constant, a calibration curve for low concentrations may be obtained by Method II.

Por gases requiring chemical absorption, for example, Cl_2, H_2S or CO_2, a carefully standardized reagent is required and the range of the apparatus is limited by the concentration of the reagent, if the upper limit is to be represented by complete neutralization of the solution. An absorbent should be chosen which does not yield a precipitate. In such cases the zero point corresponds to the conductivity of the unchanged solution; and the maximum gas concentration capable of absorption, as calculated from the known titer of the reagent and the apparatus constants a and b, corresponds to the conductivity of the equivalent salt solution at neutrality. According to the theoretical considerations discussed in a later paragraph, the intermediate concentrations should fall on a straight line when plotted against conductivity.

Adaptation for the Determination of Carbon Monoxide

The apparatus has been used successfully for the determination of small concentrations of carbon monoxide in the presence of hydrogen, methane and other gases.

After the removal of any carbon dioxide that may be present, the gas is passed through a tube containing iodine pentoxide at 140 to 150°, where the carbon monoxide is preferentially oxidized with the liberation of iodine. Vapors of the latter are removed in a tower of moist potassium iodide crystals, and the residual gas is analyzed for carbon dioxide in the apparatus illustrated, using a standard solution of carbonate-free potassium hydroxide as the absorbent.

A stock of 0.5 N potassium hydroxide was prepared in the following manner. To a 4% solution of C. P. caustic potash in which the carbonate content had been determined, the theoretical quantity of barium hydroxide was added to precipitate the

---

[5] It can be shown that, even if absorption were complete in this brief interval of time, the calculated value of the mole fraction would exceed the actual value C only by the quantity $C^2 + C^3 + C^4 + \dots$, which is relatively small when $C < 0.02$.

carbonate. After the latter had settled, the solution was decanted and made up with freshly distilled water to exactly 0.5 N as standardized against benzoic acid, precaution being taken to prevent contact with air containing carbon dioxide. This stock solution was stored in a paraffin lined, tightly stoppered bottle. By means of a large pipet, of about 800 cm.^{3} capacity, a portion of the stock solution was transferred to the reservoir R, and then diluted with freshly distilled water measured from the same pipet. For use in determining carbon dioxide concentrations up to 2%, a supply of about 16 liters of an exactly 0.025 *N* potassium hydroxide solution was thus prepared from time to time without the necessity of repeated purifications and standardizations.

Referring to the diagram, Fig. 1, it will be seen that by connecting the tube P with the tube Q, for example with rubber tubing, the gas in the system will be caused to circulate through the apparatus, so that it will be purged and become inert toward the hydroxide solution. Eventually a pure sample of the latter will fill the cell and a determination of its conductivity can be made at the outset and also whenever desirable later. With the aid of this determination in addition to the measurements of the apparatus constants a and b, as indicated under Method II, the calibration of a particular apparatus was obtained at 25°, and it will be given here as an illustration.

Since the determinations of the conductivities, here indicated by k, were made by measuring the direct current flowing through the cell under a fixed voltage, which in this case was 92.5 volts, the values of k for the sake of simplicity will be given in milliamperes. The observed value of k for 0.025 N potassium hydroxide was $k_o = 1.440$ milliamperes. The equivalent conductances at 25° of potassium hydroxide and $^1/_2$ K_2CO_3 at 0.025 N, as derived from the data of Kohlrausch, were found to be 253 and 126, respectively. Hence the milliampere reading corresponding to 0.025 N K_2CO_3 should be $k_n = 1.440 \times 126/253 = 0.717$ milliamperes.

Readings corresponding to intermediate mixtures of hydroxide and carbonate resulting from partial neutralization, when plotted against the normality of the carbonate present, should fall on a straight line between k_o and k_n, in accordance with the principle introduced by Arrhenius, which may be stated: "In a mixture of two salts with a common ion, each salt has a degree of ionization equal to that which it would have when present alone in a solution in which its ions have a concentration equivalent to that of the common ion in the mixture." In testing this principle Bray and Hunt[6] found in the case of sodium chloride and hydrochloric acid mixtures that the observed values of the specific conductance agreed very closely with the values calculated on the assumption that the degree of ionization, and hence the equivalent conductance, of each substance depended on the total salt concentration. In the present case the total salt concentration, $C_{\text{KOH}} + C_{1/2\text{K}_2\text{CO}_3}$, remains unchanged throughout the series of mixtures, from which it follows that the equivalent conductance

---

[6] Bray and Hunt, THIS JOURNAL, 33,781 (1911).

of each substance does not depart from the value at 0.025 N, and the specific conductance of any mixture in the series should be

$$L = 253\,C_{\mathrm{KOH}} + 126\,C_{1/2\mathrm{K_2CO_3}}$$

or the conductivities in the present calibration units should be

$$k = (1.440\,N_{\mathrm{KOH}} + 0.717 N_{\mathrm{K_2CO_3}})/0.025$$

and since $N_{\mathrm{KOH}} + N_{\mathrm{K_2CO_3}} = 0.025$, this may be simplified to

$$k = 1.440 - 28.92\,N_{\mathrm{K_2CO_3}}.$$

Experimental values for a and b were 0.0941 cm.^{3} and 1.43 cm.^{3}, respectively. For operation under a barometric pressure of 760 mm. of mercury, assuming aqueous vapor saturation, the number of moles m_{760} of dry gas per stroke would be

$$m_{760} = 1.602 \times 10^{-5}\,(760 - 23.5)b/298 = 5.67 \times 10^{-5} \text{ moles}$$

Hence the proportionality between the concentration $[\mathrm{CO_2}]_{760}$ mole fraction of carbon dioxide in the gas and the normality of carbonate in the resulting solution would be

$$[\mathrm{CO_2}]_{760} = aN_{\mathrm{K_2CO_3}} \times 10^{-3}/2m_{760} = 0.830\,N_{\mathrm{K_2CO_3}}.$$

By substituting in the expression for k above, there is obtained

$$[\mathrm{CO_2}]_{760} = 0.0287\,(1.440 - k)$$

an equation by means of which the carbon dioxide concentration can be calculated directly from the milliammeter reading, when the barometric pressure is exactly normal.

The coefficient for the increase of m per mm. increase in barometric pressure is 0.001359, so that the value of $[\mathrm{CO_2}]_P$ when the barometric pressure is P would be

$$[\mathrm{CO_2}]_P = 0.0287(1.440 - k)/[1 + 0.001359(P - 760)]$$

It is obvious that the maximum concentration of carbon dioxide here capable of measurement with 0.025 N alkali is about 2%. The sensitivity depends mainly upon that of the electrical measurements. Thus in the present instance 0.002 milliampere is the equivalent of about 0.006% of carbon dioxide. In a given apparatus the range of concentrations measurable could be varied in direct proportionality to the titer of the alkali employed; the resulting sensitivity, assuming the adoption of a voltage suitable for the same range of currents, would be inversely proportional to the titer. To obtain greater sensitivity without resorting to an extremely weak absorbent, the apparatus itself could be modified by lengthening the tube CD. It may also be worthy of mention that in actual practice the range of an apparatus has been approximately doubled by the very simple expedient of causing each drop of liquid to halt about midway between C and D, continuing its descent only after the fall of the next drop, which results in changing the gas/liquid ratio from b/a to $(b-a)/2a$. This is accomplished by increasing the pressure in the tube Q just enough to balance the increased pressure above the goose-neck, for instance, by making the emergent gas bubble through about 1 cm. depth of oil.

Practical Uses

Two apparatus of this type have been found very advantageous at the Fixed Nitrogen Laboratory in the pursuit of several investigations relating to processes for the removal of carbon monoxide from hydrogen prior to the synthesis of ammonia. The one whose calibration has been described above is used for the estimation of up to 2% of carbon monoxide with a sensitivity of about one volume of carbon monoxide in ten thousand of the mixture; the other, which is connected to a recording instrument is capable of a sensitivity of about one part in thirty thousand in the range up to 0.75% CO. A third apparatus has been used tentatively for the estimation of ammonia in the presence of nitrogen and hydrogen, the absorbent being distilled water. It appears to be satisfactory for experimental work in which the concentration does not change rapidly, and with modification it should be possible to reduce the time lag so as to improve its ability to register fluctuations.

Though somewhat fragile, due to the necessity of glass in its construction, it could be shielded by inclosure in a cabinet; and since it requires no expert attention beyond the occasional renewal of the standard solution and the few other chemicals required for preliminary purification, there are indications that an apparatus of this type could easily be adapted for industrial process control.

Summary

1. An apparatus is described for the continuous automatic analysis of certain gases, utilizing the change in electrical conductivity of a solution that has been exposed to the gas in a device for controlling the volume ratio.
2. Two methods of calibrating the apparatus are given.
3. Among the gases capable of estimation by this means NH_3, HCl, SO_2, Cl_2, H_2S and CO_2 are mentioned.
4. An actual adaptation for the determination of CO in the presence of H_2 and hydrocarbons is described in detail.
5. Possibilities of extended use are indicated.

PHASE EQUILIBRIA IN THE SYSTEM $2CaO\cdot SiO_2$–MgO–$5CaO\cdot 3Al_2O_3$[1]

BY W. C. HANSEN

RECEIVED MAY 10, 1928 PUBLISHED AUGUST 4, 1928

Introduction

This investigation of the system $2CaO\cdot SiO_2$–MgO–$5CaO\cdot 3Al_2O_3$ was undertaken, in connection with researches on the constitution of Portland cement, to determine whether MgO and $2CaO\cdot SiO_2$ existed as individual compounds in this system or reacted to form other crystalline phases.

The system CaO–MgO–SiO_2 was investigated by Ferguson and Merwin[2], but a thorough study was not made of the region below the line $2CaO\cdot SiO_2$–$2MgO\cdot SiO_2$, Fig. 1.[3]

Klein and Phillips[4] studied two series of preparations in an effort to determine the manner in which MgO occurs in Portland cement. Their first series was prepared so as to have molecular replacements of CaO by MgO in the composition $2CaO\cdot SiO_2$. The compositions of the mixtures studied by them fall on the line $2CaO\cdot SiO_2$–$CaO\cdot MgO\cdot SiO_2$, Fig. 1. In the second series of preparations they made percentage replacements of CaO by MgO in the composition $2CaO\cdot SiO_2$. The compositions of this series of mixtures fall in the triangle $2CaO\cdot SiO_2$–$CaO\cdot MgO\cdot SiO_2$–MgO, Fig. 1. From a microscopic study of their preparations, Klein and Phillips concluded that β-$2CaO\cdot SiO_2$ and $CaO\cdot MgO\cdot SiO_2$ formed a limited series of solid solutions, and that a few per cent. of MgO could be combined with $2CaO\cdot SiO_2$ in this way in Portland cement.

The preparations studied by Klein and Phillips contained some SiO_2 in excess of that required to form $2CaO\cdot SiO_2$ with all of the CaO. In Portland cement there is more than sufficient CaO to convert all of the SiO_2 to $2CaO\cdot SiO_2$, and the compositions of Portland cements in terms of CaO, MgO and SiO_2 fall in the triangle $2CaO\cdot SiO_2$–MgO–$3CaO\cdot SiO_2$, Fig. 1. Therefore, if a solid solution of $CaO\cdot MgO\cdot SiO_2$ with $2CaO\cdot SiO_2$ exists in Portland cement, it is necessary that MgO be capable of combining with CaO and SiO_2 to form $CaO\cdot MgO\cdot SiO_2$ in products in which sufficient CaO is present to convert all of the SiO_2 to $2CaO\cdot SiO_2$. Whether MgO

[3] The region below the line $2CaO\cdot SiO_2$–$2MgO\cdot SiO_2$ has been divided arbitrarily into a number of small triangles to simplify the discussion which is to follow.

[4] Klein and Phillips, *8th Int. Cong. Appl. Chem.*, **5**, 73 (1912).

has that ability or not should be shown by the behavior of $2CaO \cdot SiO_2$ and MgO in the system $2CaO \cdot SiO_2$–MgO–$5CaO \cdot 3Al_2O_3$. This system was chosen because the melting temperatures in a part of it are below 1600°, and because the results obtained in the presence of Al_2O_3 should be more nearly applicable to Portland cement than those obtained on mixtures of CaO, MgO and SiO_2 without Al_2O_3.

[5] By H. C. Stecker.

The equipment used in these studies has been described in other papers[6,7] from this Laboratory.

The compositions studied are shown as dots in Fig. 2. Fifteen to twenty gram samples of each of the compositions were made up by melting, in platinum, a carefully prepared mixture of the components. The samples were crushed in a steel mortar and ground to fine powders in an agate mortar for use in the experiments described later.

Small charges of the above samples were wrapped in platinum and held at the temperatures and for the time periods given in Table I, and then quenched by dropping into water. The quenched charges were examined microscopically to determine the temperature and phase relations which are given in Table I and Fig. 2.

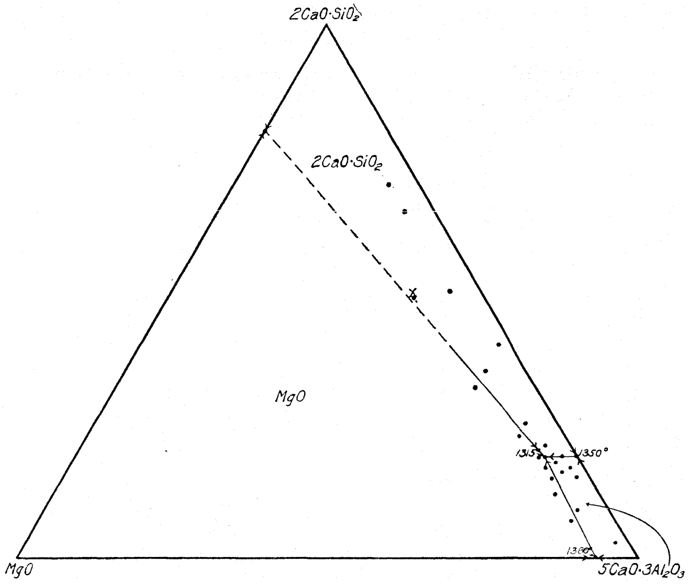

Fig. 2.—Diagram of the system $2CaO.SiO_2$–MgO–$5CaO.3Al_2O_3$, showing fields in which each component separates as a primary phase.

Similar charges were carefully annealed to allow complete crystallization, and these were studied microscopically to determine the optical properties of the crystalline phases. Indices of refraction were determined by the immersion method.

In all of the annealed samples the three compounds γ-$2CaO \cdot SiO_2$, $5CaO \cdot 3Al_2O_3$ and MgO were the only phases present. The indices of refraction of these compounds agreed with those given for them by Wright.[8]

[6] W. C. Hansen and R. H. Bogue, THIS JOURNAL, 48, 1261 (1926).

[7] W. C. Hansen and R. H. Bogue, *Ind. Eng. Chem.*, 19, 1260 (1927).

[8] (a) Wright, *Am. J. Sci.*, 28, 293 (1909); (b) 39, 1 (1915).

No optical evidence was obtained to show the formation of any solid solution of MgO with $5CaO \cdot 3Al_2O_3$ or with γ-$2CaO \cdot SiO_2$.

In all samples annealed below the eutectic temperature, 1315 ± 5°, the $2CaO \cdot SiO_2$ was present as the γ-form. It was necessary, therefore, to quench samples from above this temperature to prevent the inversion of the β-$2CaO \cdot SiO_2$ to the γ-$2CaO \cdot SiO_2$. By doing this, the β-form was obtained embedded in a glass. The microscopic examination of such samples requires that one obtain edges of the grain free from glass for index of refraction determination. The results obtained on such edges are not so reliable as those obtained on crystals entirely free from glass; however, the study of these β-$2CaO \cdot SiO_2$ grains did not give any evidence to indicate any solid solution of MgO with β-$2CaO \cdot SiO_2$.

[a] The formulas for $2CaO \cdot SiO_2$ and $5CaO \cdot 3Al_2O_3$ have been written C_2S and C_5A_3, respectively.

If MgO were capable of replacing a part of the CaO in $2CaO \cdot SiO_2$, the CaO replaced would be expected to react with either $5CaO \cdot 3Al_2O_3$ to form $3CaO \cdot Al_2O_3$ or with $2CaO \cdot SiO_2$ to form $3CaO \cdot SiO_2$. In none of the samples was it possible to identify either $3CaO \cdot Al_2O_3$, $3CaO \cdot SiO_2$ or free CaO.

It is necessary, therefore, to conclude, in the system $2CaO \cdot SiO_2 \cdot MgO$–$5CaO \cdot 3Al_2O_3$, that MgO does not form appreciable solid solutions with γ- or β-$2CaO \cdot SiO_2$, and that MgO is not capable of replacing CaO in $2CaO \cdot SiO_2$.

Discussion

These experiments demonstrate the inability of MgO to form $CaO \cdot MgO \cdot SiO_2$ in certain products in which there is sufficient CaO to convert the SiO_2 to $2CaO \cdot SiO_2$. This is brought out more forcibly if the composition x, Fig. 2, is considered. The composition of x may be expressed as $3(3CaO \cdot Al_2O_3) + 4(CaO \cdot MgO \cdot SiO_2)$ or as $5CaO \cdot 3Al_2O_3 + 4(2CaO \cdot SiO_2) + 4MgO$. A sample of this composition, after being fused, dusted completely, due to the formation of γ-$2CaO \cdot SiO_2$. A charge of it quenched from 1600° consisted of grains of β-$2CaO \cdot SiO_2$ and MgO embedded in a glass. A charge heated to 1600°, cooled slowly during several hours and then annealed for several hours at 1300°, dusted completely and consisted of γ-$2CaO \cdot SiO_2$, $5CaO \cdot 3Al_2O_3$ and MgO.

Further evidence of the inability of $CaO \cdot MgO \cdot SiO_2$ to exist in products where there is sufficient CaO to convert the SiO_2 to $2CaO \cdot SiO_2$ was obtained by fusing a mixture having the composition[10] $4CaO\cdot 2MgO\cdot Al_2O_3\cdot Fe_2O_3 + 2(CaO\cdot MgO\cdot SiO_2)$. This mixture dusted completely owing to the formation of γ-$2CaO\cdot SiO_2$. Also a sample having the composition $4CaO\cdot 2MgO\cdot Al_2O_3\cdot Fe_2O_3 + 2MgO\cdot SiO_2$ dusted completely after being fused.

Summary

1. A study has been made of the system $2CaO\cdot SiO_2$–MgO–$5CaO\cdot 3Al_2O_3$. A diagram is given showing the fields in which each of these compounds separates *as* primary phases.

2. No evidence was obtained to show that MgO formed solid solutions with either $2CaO\cdot SiO_2$ or $5CaO\cdot 3Al_2O_3$ or that MgO was capable of replacing CaO in these compounds.

REACTIONS IN LIQUID HYDROGEN SULFIDE. IV. THIOHYDROLYSIS OF ESTERS

BY A. W. RALSTON[1] AND JOHN A. WILKINSON

RECEIVED MAY 14, 1928 PUBLISHED AUGUST 4, 1928

Esters are well known to hydrolyze in water solutions, forming the free acids and alcohols. In a similar way the esters of the thio-organic acids should thiohydrolyze in liquid hydrogen sulfide to give the free acids and the mercaptans.

Of the several methods that are used to measure the degree of hydrolysis of esters in water solutions the one that is most applicable in the case of the thiohydrolysis in liquid hydrogen sulfide is that based on the determination of the conductance of the solutions.[2] The degree of hydrolysis is determined by measuring the conductance of the hydrogen sulfide solutions of the pure acid, the thiohydrolyzed ester and of the solution of the ester saturated with the base or mercaptan. It has been found that the solution of the mercaptan in liquid hydrogen sulfide does not conduct the current. Therefore, the conductance of the ester solution saturated with the mercaptan will be due to the unhydrolyzed ester alone.

The thiohydrolysis may be calculated from the expression

$$h = \frac{\lambda e - \lambda}{\lambda a - \lambda}$$

where h is the fraction of the ester thiohydrolyzed, λe is the equivalent

conductance of the solution of the ester at that dilution, λa is the equivalent conductance of the pure acid at the same dilution, λ is the conductance of the ester at this same dilution but after the solution has been saturated with the mercaptan.

Experimental

A number of the esters of thioacetic acid were prepared by the method Obermeyer[3] used for the preparation of methyl thioacetate. An alcoholic solution of lead acetate was added to an alcoholic solution of the mercaptan until no further precipitate of the lead mercaptide was formed. The lead mercaptide was filtered, washed with ether and dried in a vacuum desiccator. It was then treated with ice cold acetyl chloride, keeping the reaction flask immersed in an ice–salt mixture. After the reaction had completed itself, the excess of acetyl chloride was destroyed by water, the lead chloride was filtered out and the light oil distilled. The distillate was treated with calcium carbonate to remove any free acetic acid and then further purified by fractional distillation.

With the esters of higher molecular weight such as the *iso*butyl, the reaction took place much more slowly and it was necessary to reflux the mercaptide for several hours with acetyl chloride to obtain the ester.

---

[3] Obermeyer, Ber., 20, 292 (1887).

The esters of thioacetic acid that were made by this method and used had the following boiling points: methyl 95–96°, ethyl 115–116°, propyl 135–137°, *iso*propyl 122–123°, normal butyl 134–135° and phenyl 110–111° at 8 mm.

The conductances were determined in cells similar to those described and used by Quam and Wilkinson.[4] The cell constants were determined with 0.02 N potassium chloride at 25°. No correction was made for the change in the cell constant due to the fact that the cells were then used at −77°. Since the thiohydrolysis is calculated from a ratio this correction will be the same in both the numerator and the denominator and will be eliminated in the calculation.

The concentrations were determined by adding from a weight buret known weights of the ester to definite volumes of liquid hydrogen sulfide. The preceding tables give the data obtained and the percentage of hydrolysis calculated from them. The phenyl thioacetate was found to show no conductance when dissolved in liquid hydrogen sulfide.

Conclusions

1. Esters of thioacetic acid are shown to be thiohydrolyzed in liquid hydrogen sulfide. The degree of thiohydrolysis increases with the molecular weight of the ester.

2. The amount of thiohydrolysis of these esters in liquid hydrogen sulfide even at −77° is several times the value for the hydrolysis of esters of similar oxygen acids in water at room temperature.

THE ATOMIC WEIGHT OF CESIUM

BY THEODORE W. RICHARDS[1] AND MARCEL FRANÇON

RECEIVED MAY 24, 1928 PUBLISHED AUGUST 4, 1928

Introduction

A redetermination of the atomic weight of cesium was undertaken on account of the difference in this value as found by chemical and physical methods. The modern value of 132.81 is based primarily upon the work of Richards and Archibald.[2] Earlier atomic weight determinations are adequately treated by Clarke.[3]

By the mass spectrograph Aston[4] in 1921 found cesium to be a simple element with a mass of **133** ± 0.2. Although the possible error in his early work happens to be as great as the difference, 0.2 unit, there are very few cases of simple elements for which there is such a discrepancy between the atomic weight and the mass number; but, particularly when a negative packing exists, the differences between the true weight of the atoms of an element and an integer are usually smaller than is the case for cesium.[5]

Further interest in a chemical study of the atomic weight of cesium was stimulated by recent efforts to find "element 87,"[6] and also from certain theoretical considerations arising from Aston's discussion of the "packing effect."[7] He has defined the "packing fraction" as the divergence of the mass of an atom from an integral value, divided by its mass number. To this fraction may be related the stability of the atoms and the forces binding the protons and electrons together. A great loss of weight may correspond to a great loss of energy, which is the result of tightly bound electrons, while a small loss of weight might correspond to a loose packing of electrons. Tight packing would then indicate stability and loose packing the reverse. Cesium occurs in the region of tight packing, being only slightly removed from the minimum of Aston's curve. At one end of this curve the light elements may be supposed to build up with a loss of mass corresponding to a loss of energy[8] and at the other end the heavy elements disintegrate into lighter elements.[9] The elements of greatest stability as indicated by their abundance[10] are found to the left of cesium in the curve of packing effect and mass number. An accurate determination of discrepancies from the whole number rule should, according to this interpretation, be of fundamental importance in providing information as to the structure of atoms.

It was with due consideration of these ideas that this determination of the atomic weight of cesium was undertaken.

Procedure

Purification of Materials.—All materials were purified according to the usual methods and the usual standards of purity of reagents were

[5] Examples of cases in which discrepancies have been accounted for recently are boron and strontium. Aston predicted an atomic weight of about 10.85 for boron, and in a redetermination of this value Baxter and Scott, *Proc Am. Acad.*, 59, 21 (1923), found 10.82. On the other hand, strontium, atomic weight 87.63, at first appeared to have only one mass line at 88, but lately Aston, *Phil.* Mag., [6] 49, 1191 (1925), found another faint line at 86.

maintained. The silver used in this work was identical with that used in other researches in this Laboratory.[11]

Cesium chloride was made from pollucite from Maine. After the mineral had been finely ground, it was attacked with hydrochloric acid which had been diluted with an equal volume of water. A small amount of nitric acid was added to oxidize the iron. The solution was filtered, evaporated to dryness, treated with hydrochloric acid and water, and then these steps were repeated twice to separate out silica.

The chlorides were then converted to sulfates by the addition of sulfuric acid and cesium alums were obtained, separated and centrifuged. From this point on quartz dishes were used. The alums were crystallized three more times with centrifuging. It should be noted that to obtain alums it is not necessary to add anything other than sulfuric acid to the material extracted from pollucite, the composition of which as determined by Wells[12] and Kastler[13] indicates enough iron and aluminum for this purpose. The solubility relationships of the alums[14] are very favorable for the separation of other alkali metals. Murman[15] has recommended cesium alums for separation from potassium and rubidium. Godeffroy[16] made use of the alums in preparing pure cesium chloride. Our experience indicates that sodium, which forms stable alums only with the lighter of the tervalent metals, is best removed by crystallization of the alums.

To a hot, dilute solution of the cesium alums was added a hot solution of barium chloride, which had been twice recrystallized from the best obtainable material. After digestion of the precipitated barium sulfate, the solution was filtered through a Gooch-Monroe crucible. This cesium chloride solution was then treated with perchloric acid, carefully purified by Willard.[17] 'The cesium perchlorate crystals thus obtained were centrifuged and recrystallized three times.

The transformation into chloride was accomplished by thermally decomposing the perchlorate in a large platinum boat, placed within a quartz tube, which was heated electrically. It was necessary to carry the temperature to about 800° to decompose the trace of chloroplatinates which resulted on decomposition of the chlorate in platinum. The fused cesium chloride was dissolved in doubly distilled water and filtered through a Gooch-Monroe crucible, to separate a few particles of platinum. This cesium chloride was purified by two crystallizations.

It was then fused in a platinum boat in the well-known bottling apparatus of quartz, described in recent publications.[18] The fusion was made in an atmosphere consisting for the greater part of dry nitrogen with a small amount of hydrogen chloride. The cesium chloride was cooled in a current of dry nitrogen, which was displaced when entirely cold by dry air before transference to a weighing bottle.

Cesium chloride thus prepared reacted neutral to indicators, whereas a solution of cesium chloride which had been fused in an atmosphere of hydrogen chloride alone was acid to methyl red.

The final product was examined in a Féry quartz spectrometer. By comparison with other spectra the cesium chloride did not contain any aluminum, barium, potassium or thallium. The presence of sodium was doubtful, although if it was present, there was only a very faint trace of it. Cesium chloride from the mother liquor seemed almost equally pure spectroscopically and did not react to any chemical tests for impurities.

Weighings were made with the usual care and the cesium chloride was compared nephelometrically with pure silver. The following factors were used in the calculations.

Atomic weights		Vacuum corrections		Densities	
Silver........	107.880	Silver.....	−0.000031	Weights.........	8.3
Chlorine......	35.457	Cesium chloride..	+0.00016	Silver...........	10.49
				Cesium chloride...	3.97

TABLE I

ATOMIC WEIGHT OF CESIUM

Wt. of CsCl in vac., g.	Wt. of Ag in vac., g.	Wt. of Ag added or subtracted	Corrected wt. of Ag, g.	Atomic wt. of cesium
4.42344	2.83611	−0.00001	2.83610	132.802
5.01421	3.21436	− .00020	3.21416	132.832
4.14983	2.66076	+ .00023	2.66099	132.783
4.48842	2.87830	− .00083	2.87747	132.820
			Av.	132.809

The error of the average of these determinations can be evaluated in several ways. The "probable error," calculated from 0.6745 times the mean error, is 0.012. This is within the "experimental error" of 0.015 which is based upon the accuracy of weighing and the accuracy of determining the end-point.

The average of the analyses confirms the present accepted value of 132.81, which Richards and Archibald found by analysis of the chloride, bromide and nitrate. However, since all of these salts were prepared from recrystallized dichloro-iodide, confirmation by analysis of a salt prepared by a different method is of importance.

---

[18] Richards, King and Hall, THIS JOURNAL, 48, 1537 (1926); see also Baxter and Grover, *ibid.*, 37, 1027 (1915).

The deviation from an integral value found corresponds to a packing fraction of -14 ($\times 10^{-4}$), which is much greater than would be indicated by Aston's curve, provided that cesium is a simple element. Another unexpectedly large packing fraction was recently found by Baxter and Butler[19] for titanium, although in this case doubtful indications of another mass line have been reported and the element may not be simple. It may well be that further investigation will prove that cesium is also complex.

Acknowledgment for financial assistance is made to an anonymous benefactor of this Laboratory, and to the Carnegie Institution of Washington.

Summary

An analysis of cesium chloride, prepared by the recrystallization of alums of cesium, by comparison with silver confirmed the atomic weight of cesium to be 132.81.

CAMBRIDGE, MASSACHUSETTS

THE VAPOR DENSITY AND SOME OTHER PROPERTIES OF FORMIC ACID

BY ALBERT SPRAGUE COOLIDGE

RECEIVED MAY 31, 1928 PUBLISHED AUGUST 4, 1928

Introduction

In connection with some work on the adsorption of formic acid vapor, it became necessary to know the density of the vapor at ordinary temperatures and at pressures below the vapor pressure of the liquid. The only measurements seem to be those of Bineau;[1] Peterson and Ekstrand[2] give fragmentary data at higher temperatures and pressures. It seemed necessary to undertake direct determination of the vapor density. The acid prepared for this purpose appeared to be of exceptional purity, and certain other properties were determined for purposes of comparison.

Purification and Preservation of Formic Acid

Even at room temperature, formic acid slowly decomposes into water and carbon monoxide. Bulbs of Kahlbaum's best acid, which had presumably been stored for some time, were found to contain high pressures of the latter, while freshly imported bulbs did not. After fruitless attempts to remove the water by distillation over phosphorus pentoxide, acid sodium sulfate and magnesium perchlorate trihydrate (the first two decomposed the vapor, while the third absorbed it copiously), it was

[19] Baxter and Butler, THIS JOURNAL, 50, **408 (1928)**.

[1] Bineau, *Ann. chim. phys.*, [3] **18, 228 (1846)**.

[2] Peterson and Ekstrand, Ber., **13, 1194 (1880)**.

decided to fall back on vacuum distillation, crystallization and sublimation. (That is, these processes were carried out in a vacuum apparatus, constantly pumped free of all gases other than the vapor of the acid.) As a test of the purity of the acid, the vapor pressure at 0° was observed. This is more than 8 degrees below the freezing point, but no difficulty was encountered in preventing crystallization, provided that the liquid (if formed by recent melting of the solid) was previously heated to about 20° for a minute or two. If this precaution was neglected, the liquid invariably froze upon applying the ice-bath, even though the solid previously present had first been entirely melted.

Distillation was carried out at room temperature, the distillate being condensed in a bulb packed in ice. Heating was avoided, both in order to prevent decomposition, and because the effectiveness of the separation is greater at low temperatures.[3] Five fractional distillations yielded a volatile fraction having a vapor pressure of 11.15 mm. Crystallization was carried out in an apparatus similar to a small ice calorimeter, connected to the source of acid by a mercury trap at the bottom. The inner tube was first filled with solid carbon dioxide, and allowed to collect a sheath of solid formic acid. The mercury trap being closed, the acid was melted and the major portion again frozen out on the inner tube. The mercury was then lowered to allow the mother liquor to be blown out into the evacuated system beyond. The vapor pressure of samples prepared in this way approached the same value, but the method was cumbersome and slow. The most effective procedure was found to be to freeze the whole sample with an ice-bath, and then to pump off about a tenth of it without allowing the rest to melt. The water came off with the volatile fraction, the residue being nearly pure. The vapor pressure of the residue (after fusion, of course) rose rapidly on successive sublimations to the value 11.16 mm., which was repeatedly attained, but never exceeded, in purifying different portions. This may therefore be taken as the value for pure formic acid.

In order to estimate the degree of purity attained, an isolated portion of the acid was successively diluted with known amounts of water, and the vapor pressures observed. The water was weighed into thin glass sealed bulbs, which it nearly filled, and which were placed in fingers depending from the apparatus near the manometer. The bulbs were broken one at a time, by causing their contents to freeze, and the water completely transferred to the sample of acid by immersing the bulb containing the latter in carbon dioxide. At the same time, any air which might have been introduced in sealing the water into the bulbs was pumped off, the volatility of both water and formic acid being negligible at −79°. The acid was then melted, the bulb well shaken to ensure thorough mixing,

---

[3] Jones, *J. Soc. Chem. Ind.*, **38,** 362T (1919).

and the pressure determined. At the conclusion of the series, the diluted acid was sealed off and weighed. No correction was required for the amount of acid existing as vapor in the free space, which was of the same order of magnitude as that occupied by the liquid.

The vapor pressures of the pure acid, as solid and liquid, and of the diluted acids as liquids, are given in Table I. The temperatures other than 0° were read on a tenth-degree thermometer with Bureau of Standards certificate. The values given in International Critical Tables[4] are included for comparison. My values are consistently higher, which is presumably an indication of greater purity. It will be observed that at 0° the vapor pressure is depressed 0.01 mm. by about 0.02% of water. Since the purifying process was repeated twice, even after the vapor pressure had reached a value constant within this limit, it seems probable that the final product was of the order of 99.99% pure.

TABLE I

VAPOR PRESSURES OF PURE AND AQUEOUS FORMIC ACID IN MM. OF HG

Water. %		Pressures			Pressure lowering per 1% of H_2O	
		0°	10°	20°	0°	20°
0.00	(solid)	8.67				
.00	I. C. T.	8.0				
.00	(liquid)	11.16	19.88	33.54		
.00	I. C. T.		18.9	33.1

.59		10.92		32.85	.41	1.17
1.30		10.62		31.99	.42	1.19
4.09		9.47		28.83	.41	1.15
7.96		8.00		25.01	.40	1.09
10.47	I. C. T.		12.4	22.1		1.05

It is of interest to compare the lowering of the vapor pressure produced by water with the theoretical value for an involatile solute of molecular weight 18. Assuming that sufficiently dilute solutions obey van't Hoff's law, the osmotic pressure of such a solute would be $RT\delta m/18$, where 6 is the density of the liquid solvent and m the weight fraction of the solute. The lowering of the vapor pressure bears to the osmotic pressure the ratio which the density of the vapor of the solvent bears to that of the liquid. Now, at 20° and 33 mm. pressure, as will appear later, the density of formic acid vapor can be calculated from the gas law on the basis of an apparent molecular weight of 83. We have, then, for the lowering of the vapor pressure

$$\mathrm{Ap} = \frac{83p}{RT\delta} \times \frac{RT\delta m}{18} = 4.6\,pm = 155\,m$$

The limiting value of the observed ratio is about 120. The discrepancy is doubtless due primarily to the volatility of the dissolved water, 'If

---

[4] Volume III, p. 209 (solid, extrapolated), 215 (liquid), 364 (aqueous).

the water polymerized, an effect in the same direction would be produced; but the degree of polymerization should change with dilution, whereas the observed lowering bears a nearly constant ratio to the concentration over the four lowest values, (The observation on the most dilute solution at 0° is plainly in error.)

It was noticed that the pressure in a bulb half full of pure acid rose at the rate of about a millimeter per day. The actual fraction decomposed. must have been very small, but the carbon monoxide evolved greatly hindered the manipulation of the apparatus. It was found that decomposition could be entirely prevented by keeping the acid frozen. The main supply of purified acid was accordingly kept constantly frozen, the ice-pack never being removed except during the process of drawing off a sample for use, during which the high latent heat of evaporation prevented fusion.

The freezing point of the pure acid was determined in a double-walled tube. The inside tube contained the bulb and stem of the thermometer, while the space between the walls was occupied by partly frozen acid under its own vapor pressure. The whole was surrounded by air at about 8°. The thermometer was constant at 8.26°, even when the proportions of solid and liquid were varied.

The density of the acid was found to be 1.2456 at 0° and 1.2206 at 20°, both at atmospheric pressure.

The Vapor Density Measurements

In order to determine the vapor density, the method adopted was to transfer known quantities of acid (measured volumetrically in the liquid state) to containers of known volume, and observe the pressure developed at a series of temperatures. The apparatus is outlined in Fig. 1. It was necessary to make allowance for possible adsorption on the glass, which would cause the results to be too high. This was accomplished by comparison of the results obtained with two different containers having very different ratios of surface to volume. The first, called the globe (G, Fig. 1), was a 5-liter spherical Pyrex flask, and had, together with its connecting tubing, a volume of 5218 cc. and a wall surface estimated at 1500 cm.^{2}, giving a surface-volume ratio of 0.287 cm.$^{-1}$. The second container took the form of 13 meters of tubing arranged in a coil (C, Fig. 1) containing 324 cc., and having a wall surface of 2284 cm.^{2}, bearing to the volume the ratio 7.05 cm.$^{-1}$. Each container was connected to one arm of its own manometer (M, M, Fig. 1), which was of 2cm. diameter, and could be read to 0.02 mm. by means of a micrometer microscope sliding on parallel ways. The mercury level was adjustable by tube and leveling bulb (not shown in the figure), care being taken always to bring the mercury to the calibration mark for each reading.

By lowering the mercury, the manometers could be made to serve as valves, giving communication to the rest of the apparatus. The containers and manometers were mounted in a large iron tank, fitted with a powerful stirrer, and filled with water (or brine) which could be heated rapidly by running in live steam, or held at any desired temperature during a reading, within 0.05°, by adjustable gas burners. A plate glass window permitted reading of the manometers and also of a tenth-degree thermometer which had been compared with one standardized by the Bureau of Standards.

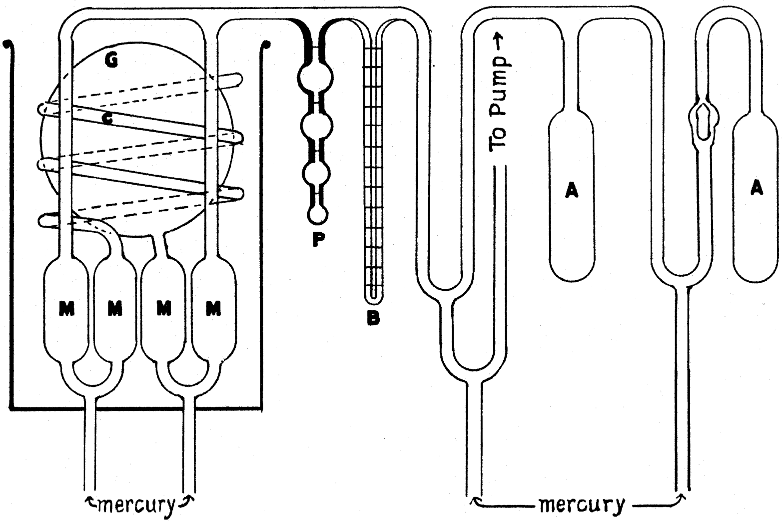

Fig. 1

Outside the tank were located a series of little bulbs (P, Fig. 1), accurately calibrated, and a capillary buret (B) which could be read to 0.1 mg. of liquid. Other mercury valves, operated by leveling bulbs not shown in Fig. 1, gave communication to a mercury diffusion pump, and to several appendixes (two, **A, A,** are shown in Fig. 1) which were useful in subliming the acid during purification, in storing the final product, and in testing the vapor pressure. (For this purpose, the globe was first exhausted and its manometer closed. The sample was then placed in one of the appendixes A, an ice-pack applied, and communication established with the outside arm of the manometer M, upon which the pressure was read. In order to eliminate the possibility of traces of air or carbon monoxide being present, a series of readings was made on each sample, separated by intervals of pumping. When the acid was pure no diminution in pressure could be detected.) The appendix used for storage was fitted with a glass valve, which prevented mercury from being forced over when the pressure in the rest of the apparatus rose, either accidentally or by design.

The diffusion pump was backed by a Hyvac oil pump. In spite of the intermediate presence of a soda-lime tube, a great deal of trouble was caused by corrosion of this pump. It was finally replaced by a 3-stage rotary pump, which was not affected by the acid, even when the protecting tube was removed.

In use, the globe and coil were first evacuated for an hour at about 70° or higher. At the conclusion of the evacuation, the manometers were tested and any required corrections determined. It was anticipated that at temperatures above 70° there might be a correction due to the fact that the inside arms were exposed to the full pressure of saturated mercury vapor, while from the outside arms mercury vapor must have been constantly escaping into the cold connecting tubing. Evidently the rate of escape was small in comparison to the rate of evaporation from the relatively large mercury surface, for no significant difference in levels was observed. The apparatus was then allowed to cool, the manometer valves were closed and a suitable quantity of acid was condensed into one of the measuring devices. The buret was read, or the liquid meniscus adjusted to the mark, keeping the liquid at 0°, and the pressure in the connecting tubing at 11.2 mm. As much as possible of the measured sample was then distilled into the globe or coil, with the aid of a freezing mixture if necessary. The remainder was condensed in the capillary buret and measured, great care being taken that the volume, temperature and pressure of the vapor remaining in the connecting tubing (a small fraction of the whole charge) were exactly as before.

The manometers and connection's were then exhausted, and the pressures in globe or coil determined at 10° intervals. The stirring was momentarily interrupted during the final adjustment of the micrometer. An idea of the reproducibility obtained will be given by comparison of the following figures, obtained entirely independently (except, of course, for the fundamental calibrations).

Volume of liquid used, cc.	0.1962	0.1960
Weight, mg.	0.2432	0.2429
Pressure at 10°, mm.	10.10	10.08
Pressure at 20°, mm.	11.02	11.02
Pressure at 30°, mm.	12.14	12.13
Pressure at 40°, mm.	13.44	13.42
Pressure at 50°, mm.	14.92	14.90
Pressure at 60°, mm.	16.52	16.50
Pressure at 70°, mm.	18.10	18.10

While the data obtained in this manner were sufficient for the original purpose for which the work was undertaken, it seemed worth while to extend the range to somewhat higher temperatures, in order to make possible a comparison with the data of Peterson and Ekstrand. In order to secure a favorable degree of dissociation, it was necessary to work at higher pressures. Therefore, in order to economize material, the apparatus was altered by the substitution of a bulb of 500cc. capacity in place of the 5-liter globe. The work already completed showed that the correction for wall adsorption is negligible above 40°, so that no control with the coil would be required. The bulb contained a pocket in which a standardized Anschutz thermometer was entirely contained. The bulb and manometer valve were heated by a large vapor-jacket, in which was boiled water, toluene, chlorobenzene or bromobenzene. The exact temperature of each determination was noted and the observations corrected to the nearest whole degree (100°, 111°, 132°, 156°) by means of a small correction readily determined from the observed temperature coefficients. In order to reduce the length of the manometer inside the vapor jacket, and to compensate the vapor pressure of mercury, both arms of this manometer were kept at the same pressure by admitting air to the outside arm when the bulb was being heated and the inside pressure was increasing, until a steady state was reached. The pressures were adjusted to equality within 0.1 mm. by small variations in the volume of the system outside the vapor jacket, accomplished by slightly changing the position of the mercury in one of the valves. The reading was finally taken on an outside manometer by the aid of a cathetometer.

In order to determine whether significant decomposition occurred, during the determination at the highest temperature (156°), in one experiment the acid was cooled to 100° at the completion of the series and its pressure compared with that initially determined at the same temperature. No significant difference was detected..

Reduction of Experimental Data

It is convenient to express gas densities in terms of apparent molecular weight; that is, the weight which 22.41 liters of the gas would possess if, in passing from the observed conditions of temperature and pressure to standard conditions, it expanded and contracted as a perfect gas. Changes in M, the apparent molecular weight, are a measure of the departure from the gas laws.

The results are set forth in Table II. The first column gives the pressures at which determinations were made with the globe or bulb and the second gives the calculated values of M. These data are represented by circles on Fig 2, in which the logarithm of the pressure serves as abscissa. The data obtained with the coil are not tabulated, but are entered as crosses on Fig. 2. As was anticipated, they are somewhat higher than those yielded by the globe at the same temperatures and pressures; the difference, however, is negligible except below 50°. Since the pressures in the two series were not identical, it was necessary to interpolate the coil values to the same pressures as the globe values. This was done with the aid of smooth curves, drawn dashed in Fig. 2. The results so obtained are entered in the third column for the five lowest temperatures in Table II. Now, the differences between corresponding globe and coil values are due to surface condensation, the error in each value due to this cause being proportional to the surface-volume ratio of the container in question. The error in the coil values must therefore be about 25 times that in the globe values. The values in the fourth column, marked "corrected," were computed by subtracting from each globe value one-twenty-fourth of the difference between it and the corresponding coil value. It will be seen that in order to determine this correction with an absolute accuracy equal to that of the globe values, comparatively rough coil values will suffice.

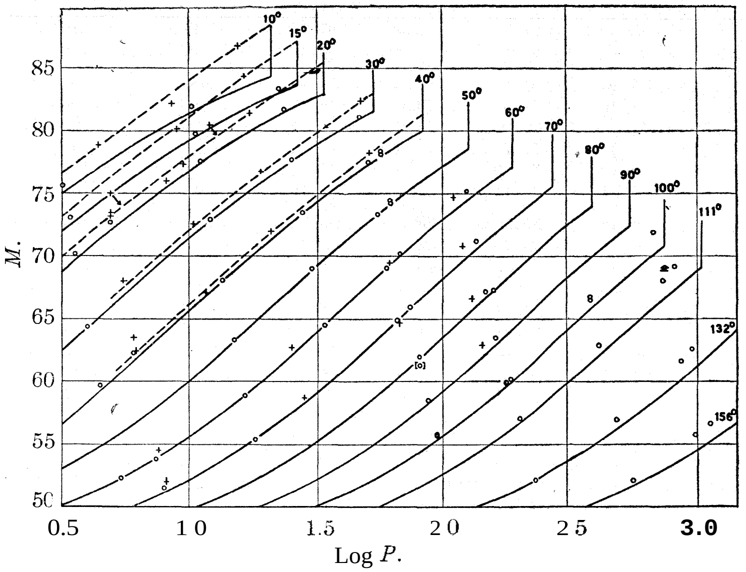

Fig. 2.—Circles represent experiments with globe or bulb. Crosses represent experiments with coil. Triangles represent experiments of Peterson and Ekstrand. Solid lines are solutions of Equations (2) and (3). The vertical portions at the upper ends show the pressures at which condensation occurs. Dashed lines are smooth curves drawn through the crosses.

Adsorption

The amount of adsorption on the glass walls, in mg. per square meter, was calculated by interpolation from the curves in Fig. 2 and is shown in Table III. Being obtained as the differences between much larger numbers, these values have no claim to accuracy, but indicate the order of magnitude of the effect.

Theory of the Vapor Density

The simplest assumption concerning the density of the vapor of formic acid is that it is the weighted mean of the densities of two perfect gases having molecular weights 46.02 and 92.03, and present in proportions given by the mass law, the equilibrium constant being an exponential function of the temperature. Thus, if δ be the density of the vapor in grams per liter, we have for the apparent molecular weight

$$M = \frac{\delta \times 22.41 \times 760 \times T}{273 \times P} \qquad (1)$$

and for the dissociation constant (in terms of partial pressures, and having the physical dimensions of pressure, in millimeters of mercury)

$$K = \frac{P \times (92.03 - M)^2}{46.02(M - 46.02)} \qquad (2)$$

In Fig. 2 the curves represent the values of M which satisfy this equation, when K is calculated from the equation

$$\text{Log } K = 10.755 - 3090/T \qquad (3)$$

Inspection shows that this formula satisfactorily reproduces the observed densities at low temperatures and pressures, but that at higher temperatures and pressures the observed densities are systematically greater. There appear to be three directions in which the explanation of this discrepancy may be sought. In the first place, the individual gases supposed to constitute the mixture may not be perfect gases, but may have densities greater than that calculated from their molecular weights. In the second place, the mixture of the two gases may not obey the laws of ideal solutions. Finally, it is possible that the dissociation constant does not increase with rising temperature strictly according to Equation (3), but that at higher temperatures its temperature coefficient is somewhat smaller. Since the whole discrepancy is small, it will obviously be impossible to determine with certainty the degree in which the three factors contribute; the best that can be done is to show that reasonable assumptions can be made, by the aid of which the observed densities can be reproduced.

It is certain that some allowance must be made for the departure of the individual gases from the gas law. We can advantageously follow the treatment of Lewis and Randall.[5] We suppose that, for each single gas, were it capable of independent existence, the equation of state would be reducible, within the range of temperature and pressure here considered, to the form

$$PV = RT(1 - \alpha P) \tag{4}$$

where a is a function of temperature only, and is small, so that $1 - \alpha P$ may be considered equal to $1/(1 + \alpha P)$. We shall assume provisionally that the mixture of gases is an ideal solution. This means that the single molecules behave, not as if the double molecules were absent, but as if their places were taken by equal numbers of single molecules, and ***vice versa,*** since only in this way can the necessary condition he fulfilled that when the two pure gases at the same pressure are allowed to interdiffuse, there will be no expansion or cooling. Now, the apparent molecular weights of the pure gases would be $M_1 = 46.02(1 + \alpha_1 P)$ and $M_2 = 02.03$ $(1 + \alpha_2 P)$, respectively, and that of the mixture $M = n_1M_1 + n_2M_2 = 46.02\,[n_1(1 + \alpha_1 P) + 2n_2(1 + \alpha_2 P)]$, where n_1 and n_2 are the mole fractions of single and double molecules, respectively. Solving for n_1 and n_2, we obtain

$$n_1 = \frac{92.03(1 + \alpha_2 P) - M}{46.02[1 + (2\alpha_2 - \alpha_1)P]} \text{ and } n_2 = \frac{M - 46.02(1 + \alpha_1 P)}{46.02[1 + (2\alpha_2 - \alpha_1)P]} \tag{5}$$

The degree of dissociation is

$$x = \frac{92.03(1 + \alpha_2 P) - M}{M + 92.03(\alpha_2 - \alpha_1)P} \tag{6}$$

To calculate the equilibrium, we use the relations advocated by Lewis and Randall, namely, that the fugacity of a pure gas whose pressure is only slightly less than the ideal pressure is itself less than the actual pressure by the same ratio, and that in a mixture of gases the fugacity of each component is to be found by multiplying its fugacity in the pure state at the same total pressure by its mole fraction. We therefore write, for the fugacities in the mixture, $f_1 = n_1P(1 - \alpha_1 P)$ and $f_2 = n_2P(1 - \alpha_2 P)$.

The condition for equilibrium is

$$K = \frac{f_1^2}{f_2} = \frac{n_1^2}{n_2}P[1 + (\alpha_2 - 2\alpha_1)P] = \frac{P[92.03(1 + \alpha_2 P) - M]^2}{46.02[M - 46.02(1 + \alpha_1 P)]}[1 - (\alpha_1 + \alpha_2)P] \tag{7}$$

It will be seen that the departure from the gas law affects the observed apparent molecular weight not only directly, by increasing the densities

---

[5] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, pp. 198,226.

of the components, but indirectly, by displacing the equilibrium; the latter effect is represented by the factor $1 + (\alpha_2 - 2\alpha_1)P$. As would be expected, this vanishes in case the mutual attractive energy of two single molecules is equal to that of one double molecule.

In order to see how far the observations can be accounted for by thus modifying the original simple Equation (2), it is necessary to assume values for α_1 and α_2, reasoning by analogy from observations on vapors of molecular weight of the same order of magnitude, which are known to be monomolecular. Such observations seem to be lacking, except in the cases of saturated vapors .or superheated vapors under several atmospheres' pressure. Inspection of the orthobaric densities of several organic vapors, as given in Volume **3** of International Critical Tables, indicates that at 100° these densities exceed those calculated from the gas law by 2 or 3% per atmosphere, as a rule. The deviation is greater than that calculated by van der Waals' equation with the usual values of the constants computed from critical data. It should decrease with rising temperature, and, in general, would be expected to be greater for heavy than for light molecules. For a first trial, the following values for α_1 and α_2 in % per **atm.** were arbitrarily assumed:

T	10°	15°	20°	30°	40°	50°	60°	70°	80°	90°	100°	111°	132°	156°
α_1	4.5	4.2	4.0	3.6	3.3	3.0	2.8	2.6	2.4	2.2	2.0	1.8	1.5	1.3
α_2	6.7	6.3	6.0	5.5	5.0	4.5	4.2	3.9	3.6	3.3	3.0	2.7	2.3	2.0
K	0.684	1.060	1.618	3.605	7.64	15.41	29.90	56.60	100.2	175.0	296.0	511.0	1336	3573

The values of K, given by Equation (3), are also included.

The apparent molecular weights which satisfy Equation (7) for the experimental temperatures and pressures, and with the numerical constants just given, are tabulated in Table II under the heading "Calcd." It will be seen that the discrepancies remaining are very small, except in the case of experiments at pressures below 10 mm., where an error of 0.01 mm. would suffice to cause a discrepancy of 0.2 unit in M. The agreement is so satisfactory that it seems needless to seek to improve upon the original, supposedly preliminary, assumptions.

Equation **(3)** indicates that the heat of dissociation at constant pressure is 14,125 calories per mole, and does not vary within the temperature range covered by the experiments. This range, however, is too small to permit drawing reliable conclusions about the temperature coefficient of the dissociation heat, which depends on the difference in the specific heats of the two forms. The customary assumption[6] is that a reaction which produces one new gas molecule involves an increase of 3.5 in the molecular heat. The equation

$$\text{Log } K = 5.542 + 1.75 \log T - 2827/T \qquad (8)$$

---

[6] See A. Eucken, "Fundamentals of Physical Chemistry," First English Edition, McGraw-Hill Book Co., New York, 1925, p. *417.*

has been adjusted to take this increase into account, and to reproduce as well as possible the results of experiment. It leads to values for M which exceed those calculated from Equation (3) by about 0.1 unit at 10° and 156°, fall below them by the same amount at 70°, and are indistinguishable at 40° and 111°.

It seems to be by no means certain that an increase in specific heat is theoretically necessary. True, it is always found to accompany the dissociation of gas molecules which are held together by primary valence, presumably because in such molecules certain possible modes of vibration are not developed at the temperatures in question, But when liquids evaporate without breaking primary valence bonds, a decrease of specific heat ensues, in spite of the increase in the number of gas molecules. It is conceivable that the dissociation of a double molecule of formic acid is a process of intermediate character and really involves very little change in specific heat. Unfortunately, the chemical instability of the single molecules prevents the extension of the temperature range which would be necessary to decide the question.

Summary

Formic acid probably 99.99% pure has been prepared by vacuum sublimation and some of its physical properties have been determined.

The density of the vapor has been determined at temperatures between 10 and 156°, and at pressures favorable to partial dissociation. A correction for wall adsorption has been determined and applied.

The results can be satisfactorily interpreted by assuming that the vapor is an ideal mixture of two gases, having single and double molecules, respectively, each of which deviates from the perfect gas laws in the same way as would a monomolecular vapor of similar molecular weight.

A FURTHER STUDY OF THE REACTION BETWEEN NITROGEN DIOXIDE AND LIQUID MERCURY

BY WILLIS CONWAY PIERCE AND W. ALBERT NOYES, JR.

RECEIVED JUNE 6, 1928 PUBLISHED AUGUST 4, 1928

In an earlier article[1] a report was made of some experiments on the reaction, both thermal and photochemical, between nitrogen dioxide and liquid mercury. In that article it was reported that radiation of frequency greater than the threshold frequency of mercury caused the reaction to proceed more rapidly than in the dark. This effect was ascribed, at that time, to an activation of the mercury surface which was in some way associated with the photoelectric emission. In a somewhat later article[2] a revised explanation of the phenomenon was given in which the formation of negative ions due to the electron affinity of the nitrogen dioxide was suggested as the crucial factor in the acceleration of the reaction by short wave length radiation. Moore[3] has attempted to activate a mercury surface by electron bombardment. He offered a tentative explanation based on the formation of a monomolecular layer of mercuric oxide by the action of the filaments used. This film might hold mechanically any electrons emitted from the filament.

The experiments to be reported in this article were undertaken with the object of elucidating some of the factors involved in the reaction between mercury and nitrogen dioxide. The phenomena to be reported agree, in so far as they overlap, with results previously reported. It is, however, demonstrated that there are many variable factors, some of which are difficult, if not impossible, to control. A heterogeneous reaction of the type under consideration may be affected by many things such as the state of the surface, impurities in the gas and the possibility of the development of surface charges which lead to spurious effects. The present results may be deemed to be somewhat inconclusive, but they are reported at this time as it seems doubtful whether further experimentation along the lines indicated will lead to important results.

I. Preliminary Discussion

The reaction between liquid mercury and nitrogen dioxide presumably leads to the formation of mercuric oxide and nitrogen.[4] These final products are doubtless not formed quantitatively. The initial step in the process would seem to be, logically, the formation of a salt of the type of a

nitrite. Nitrogen dioxide has many of the characteristics of a free radical and possesses, as far as can be ascertained, an appreciable electron affinity.[5] One might expect the formation of a polar compound of the type of a mercurous (or mercuric) nitrite to be brought about by the transfer of an electron from the mercury to the nitrogen dioxide molecule. The reaction might be initiated, or accelerated, by the presence of negative ions in the nitrogen dioxide or by a positive charge on the mercury surface. In the experiments previously reported a large number (at least 10^8) molecules reacted per electron, assuming that the reaction with light is the sum of the normal dark plus the photochemical reaction. It is necessary, therefore, to postulate a chain mechanism to account for the results or to ascribe the action to the formation of nuclei on the surface.

The reaction between mercury and nitrogen dioxide is exothermic. If the activated state consists in the removal of the electron from the mercury, one should expect a relatively high energy of activation and consequently a high temperature coefficient for the reaction rate. The results to be reported indicate a low temperature coefficient. Since the reaction does not seem to be termolecular (or of higher order with respect to the pressure of nitrogen dioxide), the activated state for the dark reaction does not seem to be greatly different from the normal state. This means that the same proportion of the collisions between nitrogen dioxide molecules and the mercury surface will be effective regardless of temperature. The manner of the growth of the film indicates that nuclei on the surface act as centers of film formation. Since the number of molecules of gas hitting the surface will vary as the square root of the absolute temperature, the temperature coefficient of the reaction rate might be low if the reaction took place only around nuclei already present. However, the dependence of reaction rate on pressure of nitrogen dioxide does not indicate that the reaction is first order with respect to nitrogen dioxide. In fact under certain conditions lowering the pressure of nitrogen dioxide will cause an increase in reaction rate. This, upon consideration, would seem to indicate that the process of diffusion of some molecules through the gas phase plays an important part. The nuclei on the surface may well be, therefore, minute amounts of oxide formed by the reaction of mercury vapor with nitrogen dioxide or removed from the walls by the rush of incoming gas. That the latter effect is important is indicated by the gradual acceleration of the reaction with use of the reaction vessel.

II. Experimental

A. A Study of the Thermal Reaction

1. Effect of Length of Use of the Reaction Vessel on the Rate of Reaction.—After a lengthy consideration of the possible ways of measur-

---

[5] Gibson and Noyes, THIS JOURNAL, 43, **1255** (1921).

ing the rate of reaction between mercury and nitrogen dioxide, it was decided to adopt the technique used in the previous investigation.[1] This consists in admitting the nitrogen dioxide and in observing the time of formation of a solid film on the surface. This method leaves something to he desired in a quantitative sense, but the rate of reaction may be considered to vary inversely with the time of formation of the film.

In the earlier experiments* only one reaction vessel was used. The times of formation of the film were found to be very reproducible over short intervals of time, providing the nitrogen dioxide was carefully dried. A reduction in the pressure of the nitrogen dioxide caused a slight increase in the time of formation of the film.

In the present experiments, certain reaction vessels gave values of the time of formation of the film (t_0) which were in good agreement with previous values. However, many reaction vessels gave times of formation which differed by more than the experimental error from the values previously reported. In general, the values of t_0 decreased with use of a given reaction vessel. Table I shows values of t_0 for a certain reaction vessel.

TABLE I

EFFECT OF LENGTH OF USE ON THE TIME OF FORMATION OF A SOLID FILM

Run numbers	1–18	19 36	3746	47–53"
t_0 (av.) secs.	48	38	24	37

[a] Cell cleaned before making these runs.

2. Effect of the Shape of the Reaction Vessel on the Rate of Reaction.—It became clear early in this work that some factors were present and caused variation in the values of t_0 and which were not of obvious importance. Factors which, at first glance, would seem to be of importance are: radiation, temperature, purity of the mercury and purity of the nitrogen dioxide. There seemed, however, to be a great variation between various reaction vessels. Table II illustrates the point in question. The two reaction vessels were sealed together so that the same pressure of nitrogen dioxide was introduced into the two vessels at the same time. The mercury used was from the same source.

TABLE II

VARIATION OF t_0 WITH REACTION VESSEL

Run numbers	3–8	1418
t_0 (av.) secs. I	34	23
t_0 (av.) secs. II	55	33

Many different reaction vessels were used in these experiments and many changes in design were made. As a result of all of the observations made, the following statements seem justified: the values of t_0 do not depend in any obvious manner on the ratio of surface to volume in the reaction vessel. While less accuracy was possible with small surfaces of mercury than with large, the value of t_0 does not depend primarily on the surface. The only factor of importance in this connection we were able to discover was in the relation of the entrance of the gas to the mercury surface. If the inlet was so placed that any dust particles or impurities from the wall would be carried to the surface of the mercury, the rate of reaction seemed to be rapid. Reaction vessels with the well containing the mercury large compared to the diameter of the vessel seemed to exhibit abnormally fast reactions. In cells of this type any impurity removed from the walls by the rush of incoming gas would be sure to impinge upon the surface.

3. Effect of Moisture on the Values of t_0.—A vessel which had shown an average value of t_0 with dry nitrogen dioxide of forty-three seconds, was filled with water vapor at a pressure of 5 mm. prior to admitting the nitrogen dioxide. The value of t_0 then became twenty seconds and remained short for several runs.

4. Effect of Temperature on the Values of t_0.—Most of the experiments reported in this article were carried out at room temperature. Minor variations in temperature did not seem to produce a marked change in the values of t_0. One vessel which showed an average value of t_0 of forty-five seconds at a temperature of 23° showed a value of sixty seconds at a temperature of 2°.

5. Effect of Pressure on the Values of 20.—In the previous work[1] it was found that the time of formation of the film increased with reduction in pressure of the nitrogen dioxide. The change was not very great, an increase in time from seventy to one hundred seconds being noted as the pressure fell from 400 mm. to 40 mm. Phenomena similar to those previously reported could be obtained when the reaction vessel had been freshly cleaned and the values of t_0 were of the same order as those previously reported. However, after the reaction vessel had been used for some time and the time had become appreciably shorter than those previously reported, a reduction in pressure led to a reduction in time of formation of the film until very low pressures had been reached. Very low pressures invariably led to an increase in the values of t_0. However, it was observed that the thickness of the film was considerably greater for high pressures than for low pressures. Table III shows data illustrating this point.

TABLE III

EFFECT OF PRESSURE ON THE VALUES OF t_0

(T = 25°)

Run no.	1	2	3	4	5	6	7
Press. of NO_2, cm.	46	30	26	17	10	5	2
t_0, seconds	43	47	48	42	46	28	34

At lower pressures t_0 became as long as three minutes or more. Runs 1 to 5 agree within experimental error.

6. Effect of Foreign Gases on the Values of t_0.—After each run the reaction vessel was flushed out with either nitrogen or hydrogen which had been dried by passage through phosphorus pentoxide. The system was then evacuated to a pressure below a tenth of a millimeter before admitting the nitrogen dioxide. No difference in behavior was noticed between cells flushed with hydrogen and those flushed with nitrogen. In order to determine the effect of foreign gases, nitrogen and oxygen were mixed at different times with the nitrogen dioxide before admitting it to the reaction vessel. The time of formation of the film seemed to be independent of the pressure of foreign gas at constant pressure of nitrogen dioxide. This point is shown in Table IV.

TABLE IV

EFFECT OF FOREIGN GASES ON THE VALUE OF t_0 ($T = 25°$)

Number of runs	Press. of NO_2, cm.	Foreign gas	Press. of foreign gas, cm.	t_0 secs.

4	24	O_2	24	42
4	24	N_2	24	44

B. Attempts to Accelerate the Reaction by Various Means.

1. The Effect of Radiation.—An attempt was not made to repeat all of the previous work on the acceleration of the reaction by radiation. The effect of radiation shown in the previous work[1] could be duplicated if the reaction vessel was clean, that is, before the value of t_0 had become very short. Accelerating and retarding potentials produced about the same effect as those found previously. For example, a vessel which showed a value of t_0 of eighty-eight seconds (average of twelve determinations) showed a time of formation of the film under the influence of radiation from a quartz mercury arc lamp of sixty-five seconds (average of sixteen determinations) when small accelerating potentials were used. However, the behavior of the reaction was much more erratic than was found previously. Great care in drying the nitrogen dioxide, changing the type of stopcock grease and even rebuilding the entire apparatus to eliminate possible impurities did not produce any distinct improvement in the reproducibility of the results. Some factor which we were unable to discover caused variations in the results. However, there is no reason to doubt the previous work and the effect of radiation can be duplicated under proper conditions.

As shown in the preliminary discussion, the effect of radiation may be open to a variety of interpretations, so that it was thought desirable to carry out a series of experiments which would permit a decision as to the relative merits of the various hypotheses.

2. Effect of a High Potential Discharge.—The reaction vessel was thoroughly swept out with either dry nitrogen or dry hydrogen and then pumped out to a pressure of about a tenth of a millimeter. A discharge was started, either with a spark coil or with a 1/4 kw. transformer. Small amounts of residual gas would frequently cause a film of oxide to form on the surface. The surface was always renewed before admission of the nitrogen dioxide. The admission of the nitrogen dioxide stopped the discharge due to its relatively high pressure. However, the gas is admitted into a space plentifully supplied with ions (and radiation), certainly a far higher concentration than was ever obtained by the photoelectric effect. Several possibilities may now be discussed. 1. In some experiments the discharge was passed between the mercury and an electrode placed above the surface. 2. In other experiments the discharge was passed between two electrodes placed in the tube through which the nitrogen dioxide passed in entering the reaction vessel. Varying low potentials were imposed between the mercury and an electrode placed above the surface of the mercury at a distance of about one and a half centimeters. Table V presents a summary of data obtained with one reaction vessel.

TABLE V

EFFECT OF DISCHARGE ON THE VALUES OF t_0

Number of runs	Pressure of NO_2, cm.	t_0, secs., av.	Remarks
..	17–20	180–300	Hg one electrode. Light, uniform film formed instantly. Heavy film very slow in forming
10	17–20	54	No discharge
6	17–20	43	Discharge in entrance tube. Potentials on Hg with ref. to electrode above surface of –35 to +35 volts produced no regular effect
8	17–20	61	No discharge
27	17–20	39	Discharge in entrance tube

3. Effect of Electrons Emitted by Radiation from a Platinum Electrode Placed Above the Mercury Surface.—A few experiments were tried in which the nitrogen dioxide entered the reaction vessel in such a manner that it passed in front of a platinum plate on which radiation from a quartz mercury arc lamp was incident. No acceleration of the reaction was observed although the photoelectric current was so small that no decided effect would have been expected.

4. Effect of a Beam of Cathode Rays.—One reaction vessel was arranged in such a way that an electron beam formed in a low pressure discharge in hydrogen (with heated cathode) was directed into the space directly above the mercury surface. The beam could be deflected toward or away from the mercury surface by varying the potential between the mercury surface and an electrode placed above the surface. No definite acceleration was noted.

5. Effect of Strong Radiation (not Incident on the Mercury Surface).—

It has been shown by Norrish[6] that nitrogen dioxide decomposes under the influence of radiation. It is possible that the nitrogen dioxide might be activated by the radiation which it absorbs and react more rapidly than normally with mercury. However, radiation in the visible and near ultraviolet regions was found to be without effect. This agrees with previous observations.[1]

An attempt was also made to accelerate the reaction between nitrogen dioxide and hydrogen by radiation. Norrish[6] had found that hydrogen produced little effect on the pressure increase when nitrogen dioxide was illuminated by radiation from a quartz mercury arc lamp. This observation has been confirmed for the three regions of the spectrum, *(a)* visible, (b) to the limit of transmission of quartz and (c) through fluorite, using a condensed discharge through hydrogen.? A discharge through the hydrogen–nitrogen dioxide mixture caused an explosion. This indicates, presumably, that activation of nitrogen dioxide is in itself not sufficient to cause reaction with hydrogen. This evidence, coupled with the lack of effect of visible radiation on the rate of reaction of nitrogen dioxide with mercury, indicates that activated nitrogen dioxide molecules are not appreciably more reactive chemically than normal molecules toward mercury and hydrogen.

6. Effect of Electrons Emitted by Thermal Means from a **Filament** Placed Above the **Surface.**—A few experiments were made in which a heated filament was placed in the reaction vessel above the mercury surface. A high vacuum was attained before the admission of the nitrogen dioxide. Table VI shows results obtained in this manner with one reaction vessel.

TABLE VI

EFFECT OF ELECTRON EMISSION FROM FILAMENT

Pressure of nitrogen dioxide, 7–10 cm.; $T = 25°$

Number of runs	to, av.	Remarks
12	45	No filament
30	46	Filament on. Potential between filament and Hg surface varied from +6 to −6 volts

The thermoelectric currents observed in these experiments were far greater than the photoelectric currents observed in paragraph 1.

III. Discussion of Results and Conclusions

From the results on the thermal reaction, it is obvious that the time of formation of the film is not solely a function of the pressure of the nitrogen dioxide, the temperature and the purity of the mercury. Indeed, it

[6] Norrish, J. *Chem. Soc.,* 1927,761. See also Dickinson and Baxter, THIS JOURNAL, 50, 774 (1928).

[7] Kassel and Noyes, THIS JOURNAL, 49,2495 (1927).

seems that some factor which depends on the geometry of the reaction vessel must be taken into account. The authors are inclined to the conclusion that impurities may be removed from the walls by the incoming gas and that these impurities, if carried to the mercury surface, may catalyze the reaction. The impurities would seem to be mainly mercuric oxide. This hypothesis satisfactorily explains the decrease in the values of t_0 with increased use of the cell. Also, we may have here an explanation of the peculiar effect of pressure. Indeed one may derive an equation which fits the data reasonably well by assuming that two effects are to be considered, one dependent on the pressure of the nitrogen dioxide directly and the other a diffusion process involving some impurity which must diffuse through the gas. The diffusion would be more rapid at low pressures and only at exceedingly low pressures would the values of t_0 increase markedly. The phenomena are doubtless very complex and it is entirely possible that other effects due to stopcock grease and to spurious charges induced by the rush of gas must be considered. However, the authors are inclined to the belief that the above explanation will account for many of the facts observed.

When attention is turned to an explanation of the various attempts to accelerate the reaction, the following facts seem to be proved. The presence of ions in the gas (nitrogen or hydrogen) in the reaction vessel at the time the nitrogen dioxide is admitted will cause an increase in the rate of reaction between nitrogen dioxide and mercury. In the case of some of the extremely long times observed when the discharge method was used, it is obvious that there is a very rapid reaction which caused a uniform film, exceedingly thin, to be formed on the surface and that this film acts as a protective coating. With the discharge in the entrance tube so that the mercury did not serve as one electrode, the film seemed to be normal in character but formed more rapidly than in the absence of discharge. These facts indicate that the presence of ions will cause an increase in the rate of reaction between mercury and nitrogen dioxide. However, the presence of small numbers of ions (comparable to the number given off due to the photoelectric effect or somewhat larger) is without effect that can be detected. Activation of the nitrogen dioxide by radiation is also without effect. There is no evidence to indicate that negative ions produce more effect than positive ions.

The effect of the light announced in the previous article[1] and confirmed in the present investigation must, therefore, be associated with the activation of a surface layer of gas (or perhaps of mercury). This activation seems to be associated in some way with the photoelectric effect.

As a general conclusion we may state that the thermal reaction between mercury and nitrogen dioxide depends on conditions which vary with the geometry and cleanliness of the reaction vessel. The rate (as determined by the formation of a surface film) is accelerated by the presence of relatively large numbers of ions in the gas at the time it is admitted. There may, however, be a rapid reaction uniform over the surface which will hinder the formation of a heavy film. Evidence indicates that positive and negative ions are equally effective in producing acceleration of the reaction. The action of light is best ascribed to the activation of a surface film on the mercury, perhaps adsorbed gas or a small amount of oxide, which is associated with the photoelectric emission. Numbers of ions in the gas comparable to the number produced by the photoelectric effect do not produce noticeable changes in the time of formation of heavy films. This view is more in accord with the views first expressed,[1] but the phenomena are shown to be more complicated than had been supposed. Acceleration due to radiation is not observed when the reaction vessel has become dirty and the dark reaction has become very fast.

Summary

1. The rate of reaction between mercury and nitrogen dioxide as measured by the time of formation of a uniform visible film is dependent, among other things, on the shape of the reaction vessel. The times tend to become short as the reaction vessel is used. There are variable factors which have not been entirely determined.

2. The reaction is accelerated by the presence of large numbers of ions. Positive and negative ions, as far as can be determined, have equal effects.

3. The action of light in accelerating the reaction is most probably to be ascribed to the activation of a surface film. This seems in some way to be associated with the photoelectric effect.

4. Acceleration of the dark reaction with continued use of the vessel may be due to the contamination of the surface by minute crystals swept in by the nitrogen dioxide. This acceleration may obscure the action of the light.

WATER CONCENTRATION AND THE RATE OF HYDROLYSIS OF SUCROSE BY INVERTASE

By J. M. Nelson and Maxwell P. Schubert

Received June 7, 1928 Published August 4, 1928

Many investigators[1] have studied the relation between the rate of hydrolysis of sucrose by invertase from yeast and the concentration of the sugar. This relationship, as observed by Ingersoll, is shown graphically by the heavy lined Curve 1, in Fig. 1. It will be seen that the velocity rises gradually as the sucrose concentration is increased until the latter reaches about 5%, after which there is a dropping off, and at 70% of sucrose the velocity is only about one-fourth of the maximum value reached at 5%. So far no very satisfactory explanation has been found

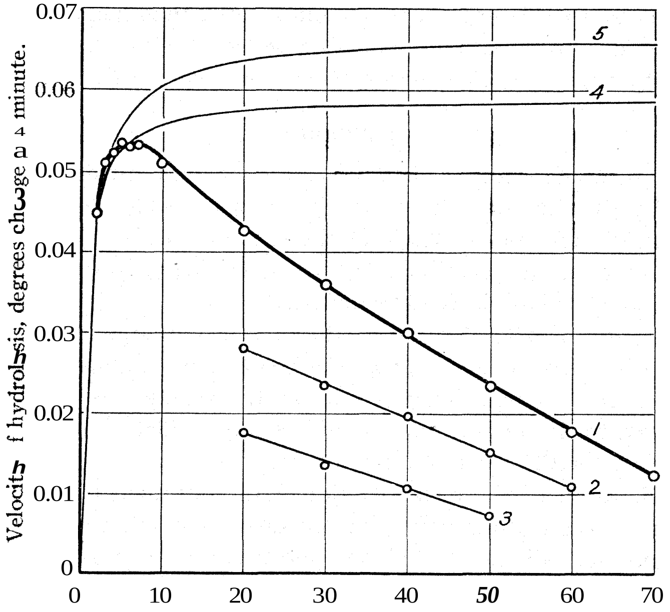

Fig. 1.—Curve 1, sucrose and no alcohol; 2, sucrose and 10% alcohol; 3, sucrose and 20% alcohol; 4, theoretical curve, K = 0.017; 5, theoretical curve, K = 0.030.

for this peculiar relationship. It is apparent from the shape of Curve 1 in Fig. 1 that in the more concentrated region, 10 to 70% sucrose, it approaches very closely to a straight line and at a first glance it might seem that the velocity is some simple function of the sucrose concentration. But, as Ingersoll has pointed out, the water concentration also drops off linearly with the increase in sucrose concentration and if the velocity is plotted against the concentration of water instead of the concentration of sucrose, then a curve, heavy lined in Fig. 2, is obtained which it will be noticed is very similar in shape to the velocity–sucrose concentration

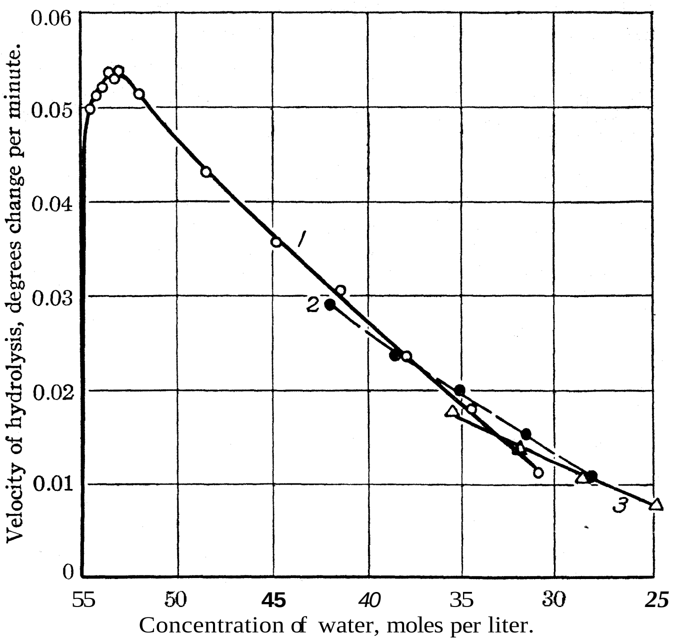

Fig. 2.—Curve 1, sucrose and no alcohol; 2, sucrose and 10% alcohol; 3, sucrose and 20% alcohol.

Curve 1, in Fig. 1. In other words, the velocity in the case of sucrose solutions ranging in concentration from 10 to 70%, drops off as the sucrose concentration increases and as the water concentration decreases, and for this reason Ingersoll was unable to decide whether it is the concentration of sucrose or the concentration of water or both together which determines the magnitude of the velocity of hydrolysis when the concentration of sucrose is greater than 5%.

In the present study, the authors have tried to avoid the difficulty encountered by Ingersoll, that is, not being able to vary the sucrose concentration without simultaneously varying that of the water, by adding to the sucrose solutions alcohol, which has only a small retarding effect, thereby making it possible to vary the sucrose and water concentrations independently of each other. For this purpose several series of solutions, varying in sucrose content from 20 to 70%, were made up. Each solution of these series contained a constant quantity of alcohol, and the composition of the solutions and their respective rates of hydrolysis are given in Table I. These values have been plotted in two different ways; that is, in Fig. 1 the velocities have been plotted against the corresponding sucrose concentrations, while in Fig. 2 the velocities are plotted against the corresponding concentrations of water. Upon comparing the curves in the two figures, it will be seen that when the velocities are plotted against water concentration, then Curves 2 and 3, Fig. 2, lie very close to the curve (1) for sucrose alone. On the other hand, when the velocities are plotted against sucrose concentration, Curves 2 and 3, Fig. 1, then they are spread much farther apart.

TABLE I

HYDROLYSES AT VARIOUS CONCENTRATIONS OF SUCROSE AND ALCOHOL

Constant amount of a yeast invertase preparation, "Convertit," diluted 200 times used in all hydrolyses. Buffer, 0.01 molar sodium citrate, $P_H = 4.5 \pm 0.1$. Velocity given in degrees change in rotation per minute. Hydrolyses run at 25.00'. All rotations determined at 25.0°; light source, 5461 Å. Water concentrations given in moles per liter of solution

Sucrose, g /100 cc. of soln.	No alcohol		10% alcohol		20% alcohol	
	Vel.	Water concn.	Vel.	Water concn.	Vel.	Water concn.
2	0.0448	54.6	...	..	...	..
3	.0511	54.2	...	..	...	
4	.0522	53.9	...	..	. .	..
5	.0534	53.5	...		...	..
6	.0530	53.2	...	..	...	
7	.0532	52.8	...		...	
10	.0512	51.8	...		. .	..
20	.0428	483	0.0280	41.9	0.0177	36.5
30	.0360	44.9	.0236	38.4	.0137	32.0
40	.0301	41.4	.0197	35.0	.0106	28.5
50	.0235	38.0	.0153	31.5	.00716	24.9
60	.0178	34.4	.0109	28.0	...	..
70	.0124	30.9	...	..	...	..

The fact that the alcohol curves in Fig. 2 fall so close to the sucrose only curve indicates that the velocities of hydrolysis are nearly the same, irrespective of the amounts of alcohol and sucrose which the solutions contain (provided the water concentration is the same). Thus it does not make so very much difference in the magnitude of the velocity whether, for example, the following three solutions contain: 20% of alcohol and 20% of sucrose; 10% of alcohol and 45% of sucrose; or no alcohol and 60% of sucrose, the velocities for these three solutions being 0.0177, 0.0175 and 0.0178, respectively. In other words, the above results indicate that the concentration of water is the primary factor, while the concentrations of alcohol and sucrose and possibly some other influences are of minor significance in determining the magnitude of the velocity of hydrolysis when the concentration of sucrose is beyond 20%.

Significance of Results for Current Theories.—The theory of the mechanism of the invertase inversion of sucrose most widely accepted is that of Michaelis. The two fundamental assumptions of this theory are (1) that sucrose combines with invertase according to the mass law and (2) that the velocity of inversion is proportional to the amount of invertase combined with sucrose. With these assumptions, the mass law is used to calculate from measurements of velocities of hydrolysis the affinity constants of various invertases for sucrose. The relation between velocity of inversion and sucrose concentration derived on these assumptions is represented in Curve 4, Fig. 1. According to this theory, as the sucrose concentration is increased, more and more of the invertase combines with sucrose to form a complex and the velocity of hydrolysis increases until a sufficiently high sucrose concentration is reached so that practically all of the invertase exists in the combined form. Then the velocity has reached a maximum value and further increase of sucrose should have no effect on the velocity.

One of the methods for determining the affinity constant of invertase for sucrose requires the determination of the maximum velocity of hydrolysis with a given amount of invertase, the assumption being that then all the invertase is in combination with sucrose. But the experimentally determined relation (Curve 1, Fig. 1) shows that the velocity maximum is attained at 5% or 0.176 M sucrose. Since the velocity drops off beyond this sucrose concentration, it has been customary with workers determining affinity constants to neglect the portion of the curve corresponding to sucrose concentrations above 5 to 6% and to assume that, at the experimental maximum, all of the enzyme is combined with sucrose. Yet examination of the curves in Fig. 1 shows that at 5% of sucrose the theoretically derived curve (4) is still 10% short of the true maximum velocity attainable. Curve 4 is plotted,[2] using Michaelis and Menten's original value of 0.017 as the dissociation constant of the sucrose–invertase complex. More recent work, like that of Kuhn and Münch[3] and also the results obtained by Nelson and Larson, give an average value for the above dissociation constant of about 0.030. Using this value in the Michaelis and Menten equation, Curve 5, in Fig. 1 is obtained, where at 5% of sucrose the velocity is still 17% short of its maximum. This means that the affinity constant

---

[2] The data for Curves 4 and 5 in Fig. 1 were obtained by substituting for S, in the equation $V = S/(S + K)$, the sucrose concentrations above, and multiplying the values obtained by the factors 0.590 and 0.6688, respectively, to make the curves coincide roughly with the first portion of Curve 1.

[3] Kuhn and Münch, *Z. physiol. Chem.*, **163**, 1 (1927); Nelson and Larson, *J. Biol. Chem.*, **73**, 223 (1927).

of invertase for sucrose determined by the method of Michaelis and Menten, if it exists at all, is probably wide of its true value.

The results obtained in the present work with alcohol and more concentrated sucrose solutions make it look as if the decrease in water concentration might be the disturbing factor. As the sucrose concentration increases, the influence of the decreasing water concentration becomes relatively more significant and therefore will tend to mask the increase in velocity brought about by the increasing sucrose concentration forming a higher concentration of the enzyme–sucrose complex. From this point of view, the peculiar shape of the curve relating velocity of hydrolysis to sucrose concentration (Fig. 1, Curve 1) must be considered to be the resultant of at least two effects, both due to the increase in sucrose: (1) the increasing formation of sucrose–invertase complex and (2) the decrease in water concentration. Furthermore, the influence of the decreasing water concentration, which predominates at sucrose concentrations above 7% has very probably begun to operate at lower sucrose concentrations. Thus it seems that even in the first segment of the velocity–sucrose concentration curve (Curve 1, Fig. 1) up to 6% of sucrose, the water concentration factor of which the Michaelis theory takes no account will have to be considered. In view of the extensive application of the affinity constant of an enzyme as an essential characteristic in its description, and also in accounting for its specificity,[4] this influence of the water concentration becomes a matter of considerable importance.

Experimental Procedure.—The hydrolyses were run by making up 250 cc. of solution containing sucrose, alcohol for some and buffer of such concentrations that when 200 cc. was placed in a bottle and 25 cc. of invertase solution added, the resulting solution was of a certain desired sucrose and alcohol concentration as well as 0.01 M with respect to buffer (sodium citrate was used) and at a PH of 4.5 ± 0.1. Solutions of 30%, that is, 30 g. per 100 cc. of solution, total (sucrose and alcohol) concentration or less were measured out by pipetting, using calibrated pipets; those of higher total concentration were weighed, using the specific gravities to calculate the weight of 200 cc. Hydrolyses were started by allowing the 200 cc. of sucrose and alcohol solution at least forty minutes to come to the bath temperature (25.00 ± 0.02°), then delivering into it 25 cc. of invertase solution, which had also come to that temperature, and shaking vigorously. The invertase delivery was made by a pipet calibrated to deliver 25.00 ± 0.02 cc. of invertase solution in seven seconds. For solutions below 30% total concentration, 25cc. samples were withdrawn at various intervals of time after the start and added to 5 cc. of 0.2 *M* sodium carbonate solution to stop the reaction and complete mutarotation. In the case of solutions of total concentration above 30%, sample were withdrawn and 25 cc. weighed out as recommended by Ingersoll[1h,i] and then 5 cc. of the carbonate solution added. Hydrolyses were run at 30% total concentration, using both methods to make sure they checked. Individual hydrolyses were run as

---

[4] Kuhn, *Z. physiol. Chem.*, **125**, **1** (1923); Euler, "Chemie der Enzyme," Bergmann, Munich, **1925**, p. 350; Waldschmidt-Leitz, "Die Enzyme," Vieweg and Son, Braunschweig, **1926**, p. 67; Oppenheimer, "Die Fermente," Georg Thieme, Leipzig, **1925**, p. 193.

far as they could be without showing deviations of more than the experimental error from a linear course.

The method of calculating the initial velocity of hydrolysis consists in dividing the change in rotation for each sample of the hydrolyzing sucrose solution taken by the time in minutes after the start at which that sample was taken. The change in rotation for a given sample is the difference between the initial rotation of the hydrolyzing solution and the rotation of that sample after the addition of 5 cc. of sodium carbonate solution. This ratio was calculated for each sample and the mean taken as the velocity for that particular sucrose solution. This procedure made it quite essential to determine the initial rotation very accurately and this was found to be rather difficult in the more concentrated solutions where slight errors in weighing out samples (weighed to the nearest drop) were liable to make a considerable error in the observed rotation. So in addition to synthetic initials, made by mixing 3.125 cc. of invertase solution with 5.625 cc. of the carbonate solution and then adding 25.00 cc. of the original 250 cc. of sucrose solution made up for the hydrolysis, a sample was taken within three to six minutes after the start of the reaction and its rotation used as a basis for extrapolating back to find the rotation at zero time. The mean of these two, the synthetic and the extrapolated initials, was used as the true initial rotation.

Summary

The above study shows that the concentration of water is a factor in determining the magnitude of the velocity of hydrolysis of sucrose by invertase.

THE HEAT CAPACITY OF HYDROGEN BROMIDE FROM 15°K. TO ITS BOILING POINT AND ITS HEAT OF VAPORIZATION. THE ENTROPY FROM SPECTROSCOPIC DATA

BY W. F. GIAUQUE AND R. WIEBE

RECEIVED JUNE 18, 1928 PUBLISHED AUGUST 4, 1928

In a recent paper[1] we have shown that the entropy of hydrogen chloride as calculated with the assistance of spectroscopic data is in agreement with the value as obtained from measurements of heat capacity and the third law of thermodynamics. Here we shall present similar calorimetric data on hydrogen bromide and show, in this case, also, agreement between the two methods of obtaining the entropy.

Preparation of Hydrogen Bromide.—Hydrogen bromide was prepared directly from the elements. The hydrogen was prepared by electrolysis and the oxygen present

---

[1] Giauque and Wiebe, THIS JOURNAL, 50, 101 (1928).

by diffusion was reduced to 0.01% by means of a nickel catalyst. Analysis of the bromine used showed no trace of chlorine or of iodine.

Dry hydrogen was bubbled through liquid bromine and the resulting mixture passed over a platinum spiral supported on a quartz rod and electrically heated to about 600–700°. The reaction tube was immersed in water which boiled during the procedure. To prevent excessive lowering of the vapor pressure of the liquid bromine due to cooling by evaporation, it was found desirable to immerse the mixing flask in warm water. The hydrogen bromide and unreacted bromine were condensed in a trap by means of liquid air. When enough material, approximately ten moles, had been prepared, the collection line was evacuated and most of the bromine separated by a rough distillation. The remaining bromine was easily removed by means of mercury, which had previously been condensed on the walls of a bulb. A small amount of mercury in the bottom of a bulb had previously proved to be rather slow in its action. The hydrogen bromide was then distilled into a bulb containing an amount of phosphorus pentoxide sufficiently large to bring it into intimate contact with all of the liquid. The material was dried for about one week, the liquid state being retained by means of a bath made from solid carbon dioxide and ether. Following this the material was distilled several times, the middle fractious being retained.

Heat Capacity Measurements and the Data.—The heat capacity determinations were made in gold calorimeter II. This calorimeter has been described in our previous paper[1] which also includes a description of the experimental method; 3.05 moles of hydrogen bromide were used for the measurements. The data are given in Table I. The first column gives the run number, which is included because the chronological order of the measurements is of interest in connection with the transition phenomena.

The data are also shown graphically in Fig. 1. The heat capacity of hydrogen bromide has previously been measured by Eucken and Karwat[2] and their data have been included in Fig. 1 for comparison. The disagreement between the two pieces of work is large and is very similar to the disagreement previously observed in the case of hydrogen chloride.[1]

Excepting certain measurements in the transition ranges which will be referred to later, most of our data are accurate to two or three tenths of one per cent. Runs 70, 71 and 72 may be somewhat in error due to heat effects associated with accidental distillation effects in the connecting tube of the calorimeter. Runs 66, 67, 68 and 69 on the liquid were made under poor conditions of vacuum around the calorimeter. This resulted from the presence of a small variable pressure of water vapor which reduced the accuracy of the heat interchange corrections. Below 20°K. the measurements may be in error by one per cent. This is largely due to the rapid decrease of the dR/dT of the gold thermometer in this region.

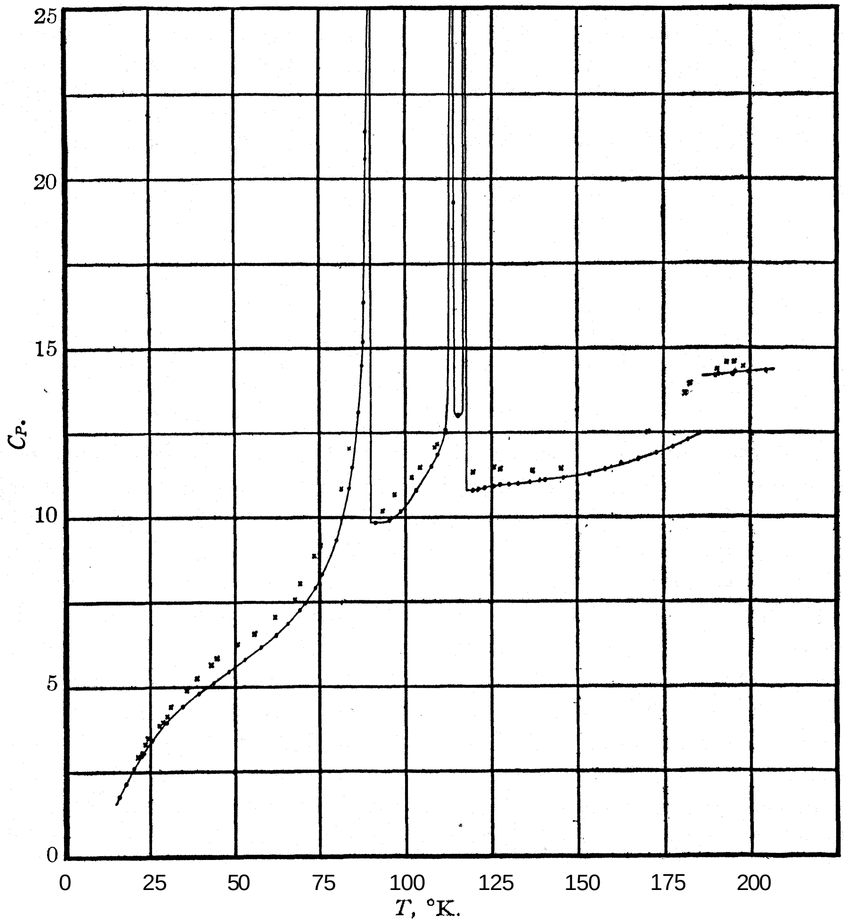
The Transitions of Hydrogen Bromide.—The three high maxima indicate gradual transitions of the type observed by Simon[3] in the case of ammonium chloride. The measurements of heat capacity within the transition range were of two types. Some were designed to have as high an accuracy as possible for use in obtaining the entropy of the substance. Others, made in order to obtain information about the character of the transitions, had a small temperature rise and were thus necessarily less

---

[2] Eucken and Karwat, *Z. physik. Chem.*, 112,467 (1924).

[3] Simon, *Ann. Physik.*, 68, 241 (1922).

accurate. The question of thermal equilibrium during measurement of such a transition naturally arises and we may say that while the process is one in which the measurements indicate that equilibrium is attained with difficulty, the evidence is against lack of equilibrium as a primary factor in preventing sharpness. For example, suppose that the transition is one that would occur sharply only if sufficient time were allowed. On cooling, a portion of the form stable at the higher temperature might fail to undergo the transition. When a sufficiently low temperature had been reached, the rate of approach to true equilibrium might easily become negligible. However, on heating to temperatures near to but below that of the true transition, it would be expected that a change



× Eucken and Karwat. ● **Giauque** and Wiebe.

Fig. 1.—Heat capacity in calories per mole of hydrogen bromide.

toward equilibrium would proceed with the evolution of heat, but this was not observed. It would be rather surprising if equilibrium could not be attained with sufficient rapidity to show a heat effect at temperatures within a degree or two of what might be called the transition temperature.

The two maxima near 115°K. were first noted by observing the rate of change of current with time while energy was being introduced. This was possible since the gold thermometer-heater used for introducing the energy increased in resistance as the temperature rose. The rate of change dropped to a small value at the first maximum, then increased and having maintained the increased rate for some time, it again decreased at the second maximum. These effects might result from unusual changes in thermal conductivity but the heat capacity measurements in this region eliminate that possibility. Measurements 55 and 56 between the two maxima cover a range of over three degrees of low heat capacity. It is probable that the molal heat capacity is lower than 13 cal. per degree, since the temperature rise in these two measurements was too large to give true differential values in this region.

It is difficult to decide whether the curve should be discontinuous on the high temperature side of the transitions. Measurements 55 and 59 supply little evidence on this question in the case of the two close maxima. However, measurements 41, 42 and 14 indicate a continuous drop in the case of the lower transition.

It may be noted from the run order during the transitions, particularly the lower transition, that the values fall on a smooth curve even when the measurements are taken in somewhat erratic order.

It seems plausible that such transitions may be due to internal changes in the molecular structure, as has been suggested by Simon and Simson,[4] who found, by x-ray analysis, that the similar behavior of ammonium chloride was not accompanied by a change in crystal form. Simon, Simson and Ruhemann[5] have found similar maxima in the heat capacities of the other ammonium halides.

Heats of Fusion and Transition.—The heat of fusion was found to be 575.1 cal. per mole. Eucken and Karwat[2] obtained 616 and 623. The discrepancy is about the same as was found in the case of hydrogen chloride.

It is not possible to obtain heats of transition in the ordinary sense. The amounts of energy added over the various regions of principal heat absorption are tabulated in Table II.

Purity **of** the Hydrogen Bromide.—The previously described method of preparation of the hydrogen bromide left very little possibility of appreciable impurity. It is, however, worth noting that the absence of pre-melting effect in the heat capacity measurements below the melting

TABLE II

HEAT ABSORBED IN TRANSITION REGIONS OF HYDROGEN BROMIDE

Temp. intervals, °A.	**Heat** absorbed, cal /mole
87.37–92.19	124.7
87.39–93.21	133.5
110.97-120.38	256.3
112.35–117.25	204.3
112.39–114.86	93.3
115.04–118.31	122.1

point is the best evidence for the absence of an impurity which could affect the various measurements. This observation is especially important in that it eliminates the effect of impurity as an appreciable factor in the gradual transitions.

Melting and Boiling Point Temperatures.—The melting point was determined by introducing energy at intervals and waiting for equilibrium. Sufficient energy to melt about one-fourth of the substance at a time was added until fusion was complete. The material was then resolidified and the procedure repeated a week later. The first series covered a period of thirty hours, the second series twenty-four hours. The deviation between extremes was 0.06° on both the thermocouple and on the resistance thermometer. The average deviation from the mean was 0.02° on each. The melting point temperature was found to be 186.24 ± 0.05°K.

The measurements of pressure made in connection with the determination of the heat of vaporization gave the temperature of the boiling point as 206.38 ± 0.05°K.

A summary of the melting and boiling point temperatures obtained by various observers has been collected in Table III.

TABLE III

ments.[1] In Method I, the evolution of hydrogen bromide from the calorimeter and energy input were measured simultaneously. In Method II, the total amount of material evaporated by the introduction of a definite amount of energy was measured. Most of the measurements were made in gold calorimeter I, which has not previously been described. It was practically identical with gold calorimeter II, except for a 0.5 mm. wall thickness. It was equipped with two thermocouples, one on the bottom and one in the middle of the side. A constantan heater wound on the lower half was used instead of the gold thermometer-heater later placed on gold calorimeter II. The data are given in Table IV.

TABLE IV

HEAT OF VAPORIZATION OF HYDROGEN BROMIDE

Boiling point, 206.38°K. Molecular weight, 80.924

.2980	I	75	4205				

The values of the heat of vaporization obtained by various observers are given in Table V.

TABLE V

HEAT OF VAPORIZATION OF HYDROGEN BROMIDE

Heat of vaporization, cal./mole	Method	Observer
4160	Vapor pressure	(1906) McIntosh and Steele)[9]
4130	Direct	(1908) Elliott and McIntosh[12]
3939	Direct	(1910) Estreicher and Schnerr[10]
3953	Vapor pressure	Estreichcr and Schnerr
4405	Vapor pressure	(1923) Henglein and Roth[11]
4210 ± 4	Direct	Giauque and Wiebe

The value given by McIntosh and Steele is not corrected for gas imperfection. The vapor pressure value given by Estreicher and Schnerr is calculated from the data of McIntosh and Steele and includes a correction for gas imperfection. The value given by Henglein and Roth is uncorrected and would fall near our value if a reasonable correction were applied. The corresponding difference was 180 calories in the case of hydrogen chloride.

---

[12] Elliott and McIntosh, J. Phys. Chem., 12, 163 (1908).

The Entropy of Hydrogen Bromide from the Third Law.—The entropy was calculated graphically by plotting heat capacity against the logarithm of temperature. The graphical method presented some difficulty in the transition ranges so the following procedure was used. The graph included all heat capacity up to sixteen calories per degree per mole. From the total heat input over the transition range and a plot of heat capacity against temperature, the energy represented by the area under each maximum and above 16 cal. per degree was calculated. The value of 16 cal. per degree was selected only for convenience. Since this energy was added over a narrow temperature range in each case, single temperatures could be chosen as divisors in order to obtain the respective entropy changes. The temperatures were chosen as a center of gravity on a $(C_p - 16)$ against T plot.

The temperatures and heats obtained are given in Table V. They are, of course, not to be taken as temperatures or heats of transition.

The extrapolation below 14.5°K. was carried out by means of the Debye function with an $h\gamma/k = 92$. The consideration of Einstein functions in addition seemed to offer little further advantage. The low temperature heat capacity measurements show a definite tendency to approach six calories per degree per mole as was the case with hydrogen chloride. This indicates that the molecules, having lost some of their degrees of freedom, are acting with sufficient approximation in the manner of a monatomic solid. Thus no great error would be expected in the extrapolated amount of one half entropy unit per mole.

The detail of the entropy calculation is given in Table VI.

TABLE VI

CALCULATION OF MOLAL ENTROPY OF HYDROGEN BROMIDE GAS

0–14.5°K., extrapolation	0.546	14.5–186.24°K., graphical	17.27

Transition 78.8/113.4	.695	Liquid	....
Transition 85.7/116.8	.734	186.24–206.38°K., graphical	1.464
"Transitions" are $\int(C_p-16)dT$	...	Vaporization 4210/206.38	20.40
		Entropy at the boiling point	44.9±0.1 E.U.

The critical pressure of hydrogen bromide has not been measured, which makes it difficult to determine the decrease in entropy due to the imperfection of the actual gas at its boiling point. However, the amount must be nearly the same as that for hydrogen chloride, which was estimated as 0.1 cal./deg. per mole. This value is very uncertain.

The Entropy of Hydrogen Bromide from Spectroscopic Data.—The entropy of hydrogen bromide may be calculated by combining the Sackur equation with the equation.

$$S_{R+V} = R\left[\ln \Sigma_m\Sigma_n p_{m,n}\, e^{-\frac{E_{m,n}}{kT}} + \frac{1}{kT}\,\frac{\Sigma_m\Sigma_n p_{m,n}\, E_{m,n}\, e^{-\frac{E_{m,n}}{kT}}}{\Sigma_m\Sigma_n p_{m,n}\, e^{-\frac{E_{m,n}}{kT}}}\right]_0^T$$

where S_{R+V} is the contribution made to the entropy by the rotation and vibration of the molecules. $E_{m,n}$ is the energy of the state having m and n as its rotation and vibration quantum numbers, respectively. While $p_{m,n}$ is the corresponding *a priori* probability of the state, $p_{m,n}$ was taken equal to $2m$. A full discussion of the above calculation may be found in connection with the similar calculation for hydrogen chloride.[1]

The values for the various energy levels of the hydrogen bromide molecule were obtained from the work of Czerny[13] on the pure rotation band of this substance and from the earlier work of Kratzer[14] on the first rotation-vibration band.

The value obtained for the entropy of the ideal gas at the temperature of the boiling point is 44.92 or 44.60 cal./deg. per mole, corresponding, respectively, to the use of the Tetrode or Lewis constant for the Sackur equation. The entropy has also been calculated for a temperature of 298.1°K. (25°C.). The results of the above calculations are compared with the third law values in Table VII.

TABLE VII

COMPARISON OF SPECTROSCOPIC AND THIRD LAW VALUES OF THE ENTROPY OF HYDROGEN BROMIDE

	Spectroscopic		Third law	
T, °K.	Tetrode constant	Lewis constant	Actual gas	Corrected to ideal state
206.38	44.92	44.60	44.9 ± 0.1	45.0
298.1	47.53	47.21	......	47.6

The third law value given at 298.1°K. was obtained by adding the spectroscopic difference between 206.38 and 298.1°K. to the 45.0 cal./deg. per mole obtained at 206.38°K.

The value for the chemical constant obtained in the paper of Eucken, Karwat and Fried[15] is given in terms of entropy in the German edition of Lewis and Randall[16] as $S_{\mathrm{HBr}} = 48.99 \pm 0.3$ E. U. at 298°K., which is 1.5 E. U. higher than the value obtained with the assistance of spectroscopic data.

Our measurements support the Tetrode rather than the Lewis constant for the Sackur equation. The close agreement supports the third law of thermodynamics.

Summary

The heat capacity of solid and liquid hydrogen bromide has been measured from 14.7 °K. to its boiling point.

Three regions of very high heat capacity were found in the solid state. These appear to be transitions of an internal molecular nature which do not occur at a definite temperature. The melting point is **186.24 ± 0.05° K.** The boiling point is **206.38** ± 0.05°K.

Calorimetric determinations of the heat of fusion and of the heat of vaporization have been made.

The entropy of hydrogen bromide has been calculated from the experimental data and the third law of thermodynamics.

The entropy due to the rotational-vibrational energy has been calculated from the energy levels of the molecule as obtained from band spectra. This amount added to the entropy as given by the Sackur equation with the Tetrode constant agrees with the value obtained from the third law thus supporting this law.

THE HEAT CAPACITY AND ENTROPY OF CESIUM ALUM FROM 18 TO 300° ABSOLUTE. THE ENTROPY OF ALUMINUM ION. THE POTENTIAL OF THE ALUMINUM ELECTRODE FROM THERMAL DATA

BY WENDELL M. LATIMER AND BERNARD S. GREENSPELDER

RECEIVED JUNE 19, 1928 PUBLISHED AUGUST 4, 1928

The direct measurement of the potential of the aluminum electrode is a task of singular difficulty. The literature[1] abounds in discordant results and contradictory explanations of their disparity. It has therefore seemed desirable to make an independent evaluation from thermal data with respect to the reaction

$$Al + 3H^+ = Al^{+++} + 3/2H_2$$

employing values for the entropies of aqueous ions in the manner developed by Latimer and Buffington.[2]

The heat of this reaction, AH, is known from the precise work of Richards

and Burgess[3] on the heat of solution of aluminum in acid. Then in order to get the free energy, ΔF, and the electromotive force from the relation $\Delta F = -nEF = \Delta H - T\Delta S$, it is necessary to determine the entropy change, ΔS, for the reaction. The entropies of metallic aluminum and hydrogen gas are known and the experimental portion of this article consists in the determination of the entropy of Al^{+++} with respect to that of H^+. In order to accomplish this, the entropy, at 25°, of some aluminum salt and its entropy of solution must be measured. To permit an accurate evaluation of the free energy of solution, the salt must have a low solubility, must be capable of existing in stable equilibrium with its ions and should be definitely crystalline in character. An extended investigation indicated that no simple aluminum salt possessed such qualifications; amorphous modifications in metastable equilibrium with basic hydrates were predominant. However, the alkali metal alums, which have been thoroughly described in the literature, offered promise. Of these, the cesium alum, $CsAl(SO_4)_2 \cdot 12H_2O$, has the lowest solubility ($M/70$ at 25°). It is easily obtained in a high degree of purity, is stable at room temperature with respect to its full quota of water,[4] and has been the subject of several solubility determinations over a wide temperature range.

The following measurements were made: (1) the heat capacity of cesium alum from 18 to 300° K.; (2) the freezing points of solutions of cesium and rubidium alums; and **(3)** the heat of solution of cesium alum.

The values in (1) were employed to calculate the entropy by the relation $S_{298} = \int_0^{298} C_p d \ln T$. The freezing point data were necessary in order to calculate the free energy of solution from the solubility. This free energy combined with the experimental heat of solution (3) sufficed to give the entropy of the aqueous solution of the salt.

Heat Capacity and Entropy of Cesium Alum

Material.—C. P. cesium alum was obtained from Eimer and Amend, containing 37.98% of H_2O; theoretical, 38.05%. Pycnometer determinations gave $d_4^{20} = 1.978$. The reported values are 1.984,[5a] 1.911[5b] and 1.93–1.96.[5c]

Apparatus.—Considerable attention was given to the design of a vacuum calorimeter suitable for measuring the heat capacity of solids from the triple point of hydrogen to room temperature. The present apparatus is expected to be so employed in this Laboratory over a period of years and it was eminently desirable to unite mechanical durability with ease of manipulation and delicacy of control. The general disposition of the apparatus is similar to that of Latimer and Hoenshel,[6] but the dimensions have been approximately doubled. This change decreases the possibility of electrical or

mechanical breakdown, increases the constancy of temperature control, accelerates evacuation by reason of the larger lead-in tubing, and facilitates assembly and take-down.

The more important newer characteristics are as follows (see Fig. 1). The calorimeter A of 115cc. capacity was wound with 300 turns of No. 40 D. S. C. gold wire (215 ohms at 25°). This wire was made by the Shreve Gold Products Company of San Francisco, from proof gold alloyed with 0.1% silver and drawn to No. 30 B. and S. gage through steel dies, washing with hot concentrated sulfuric acid after each draw. Diamond dies effected reduction to No. 40, and thorough annealing at 375° followed. This process is similar to that described by Giauque and Wiebe.[7] The entire winding gave a dR/dT of approximately 0.6 ohm/deg. from room temperature to 40°K. At 25° K. it fell to 0.4 and then rapidly diminished to 0.14 at 14°K.

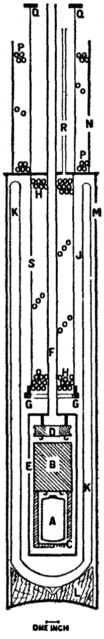

Fig. 1.

Manganin exhibits a nearly constant dR/dT at these lower temperatures, offering a means of eliminating the error introduced in estimating the mean dR/dT of the gold winding for a given ΔT in this region. The gold winding was therefore spaced at the center and $16^1/_2$ turns of No. 40 D. S. C. manganin (192 ohms at 25°) wound in the gap. The wire was further insulated from the calorimeter shell by a single layer of porous tissue paper saturated with bakelite lacquer and slowly baked to dryness, overheating being carefully avoided to prevent crackling. Exchange of thermal radiation was reduced by sheathing the calorimeter with 0.0005-inch gold foil.

For temperature calibration a copper–constantan thermocouple was located on the bottom of the calorimeter, the body of the junction entering a $^1/_{16}$-inch copper tube filled with Rose metal. For temperature control both the 4.6-kg. lead block B and the 1.4-kg. copper radiation shield C were equipped with resistance heaters proportioned to give an equal temperature rise at 80°K. The auxiliary lead block D was secured to the outer brass container E by three No. 10 brass machine screws. The evacuating tube F was of 0.75-inch Monel tubing 3.5 ft. long and carried the electrical leads. A vacuum of 10^{-6} mm. of mercury was maintained during the runs.

The built-in hydrogen liquefier consisted of a double-wound regenerative liquefying coil H, by-passed at the middle thirds, using 300 ft. of copper tubing (0.070 in. I. D., 0.125 in. O. D.). The superposed liquid air immersion pre-cooling coil P consisted of 40 ft. of copper tubing (0.125 in. I. D., 0.188 in. O. D.). Two special blow-out tubes were affixed thereto to clean out obstructions. Duplicate expansion valves G were provided, the valve stems extending to the hand wheels Q. The valves were connected by a circular 0.25-inch copper tube, designed to act as a trap for solid oxygen particles, thereby preventing plugging of the valve bore. The accumulated oxygen presents the hazard of electrostatic discharge due to crystal cleavage, igniting the hydrogen gas and solid oxygen. A recent explosion in one of the older liquefiers in this Laboratory might be so explained, although it is possible that the ignition was due to the sudden fracture of a circular steel tube leading to the valve. Copper is superior to steel under these conditions of repeated stress; its use offers a possible safeguard. Duplicate valves are advantageous; in case of "plugging" by solid oxygen or "freezing" by thermal contraction of the valve seat, the spare valve will as a rule be found free. Whether the accumulation of solid oxygen in the tube joining the valves is more likely to ignite than the constant stream of solid oxygen particles ejected through the valve at the beginning of liquefaction is most

---

[7] Giuque and Wiebe, This Journal, 50,101 (1928).

uncertain, and indeed the amount, location and physical state of this troublesome impurity varies capriciously during each run. The hydrogen analyzed **0.03** ±0.01% of O_2 on leaving the compressor.

In operation, 3 or 4 liters of liquid hydrogen could be produced in two hours from a total circulation of 1270 cu. ft. of hydrogen gas at 1200 lb. pressure, sufficient to maintain a temperature below 18°K. for fourteen hours. The coil *H* was wrapped in a sheet S of Monel metal, this in turn being surrounded by a wool blanket in the space J. Thermal insulation was provided by the 36-inch Pyrex Dewar K, seated in a felt-lined wood block L. A vacuum-tight Monel can M served as container; when assembled the entire apparatus was lowered into a silk floss insulating case 4.5 ft. deep, 7 in. I. D., 14 in. O. D. Inlet and outlet tubes similar to the hydrogen return line R were provided for liquid air intake and blow-out, evacuation and outside control thermocouples. These are not shown for the sake of clarity.

All of the electrical measurements were made with the set-up described by Gibson and Giauque.[8]

Thermocouples.—Nine thermocouples measuring **305** cm. from ice to cold junction were made up of three parallel No. 30 D. S. C. constantan wires and one No. 36 D. S. C. copper. They were then calibrated against the laboratory standard couple No. 179 with Mr. R. T. Milner. All nine couples showed similar characteristics, the average deviation from the standard being +2.5 microvolts at 16° K., rapidly falling to +0.5 microvolt at 100° K. and maintaining such a value to room temperature. **A** couple designated as No. 109 was selected for its particularly uniform behavior and used as standard throughout the measurements. All temperatures are expressed in terms of the hydrogen thermometer.[9,10]

Operation of Calorimeter.—The specific heat measurements were made as follows. The block and radiation shield were adjusted to the mean temperature of the run; sufficient energy was then supplied over a period of several minutes (usually ten) to heat the calorimeter five or six degrees. The method of measurement and calculation was similar to that of Gibson and Giauque,[8] and included the smaller correction terms for apparent heat effect in the resistance thermometer winding described by Giauque and Wiebe.[11] Over half of the runs were timed with the automatic device described by Johnston[12] with an accuracy of 0.003 sec. The remainder were timed with a stop watch, the observer's error averaging ±0.2 sec.

Results.—The data are summarized in Table I.

The points fall on a smooth curve (Fig. 2) with an average deviation of less than 0.25%, excepting (1) those in the range 210–230° K., where water vapor adsorbed on the metallic surfaces of the apparatus always causes a temporary disturbance while being pumped off; and (2) the two measurements at the ice point, where the presence of 0.05 g. of uncombined water would completely account for the observed deviation from the smooth curve. The effect of this amount of water on the observed heat capacity at any other point is less than one-tenth the estimated experimental error. It is important to be aware of this phenomenon when investigating hydrated salts.

The entropy of cesium alum at 298° K. was found by plotting C_p against log T, multiplying the area under the curve by 2.3026 (Fig. 3).

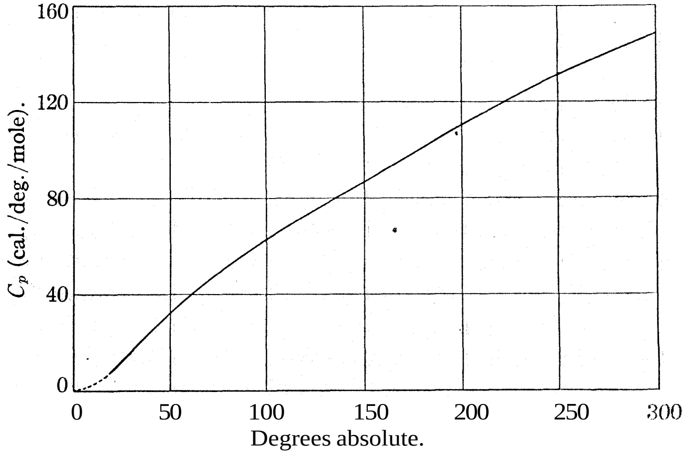

Fig. 2.—Molal heat capacity of cesium alum.

The curve was graphically extrapolated from the lowest measurement at 18.71 down to 10° K. A large scale plot was then drawn for this region and composite "Debye curves" were computed for the entropy due to Cs^+, Al^{+++}, $SO_4^=$ and $12H_2O$. The cesium alum curve was then extended parallel to the sum of the latter, giving the heat capacity to 3°. Below this point the Debye T^3 rule was assumed to be valid. These figures are summarized in Table II. The estimated accuracy is to within 0.5%.

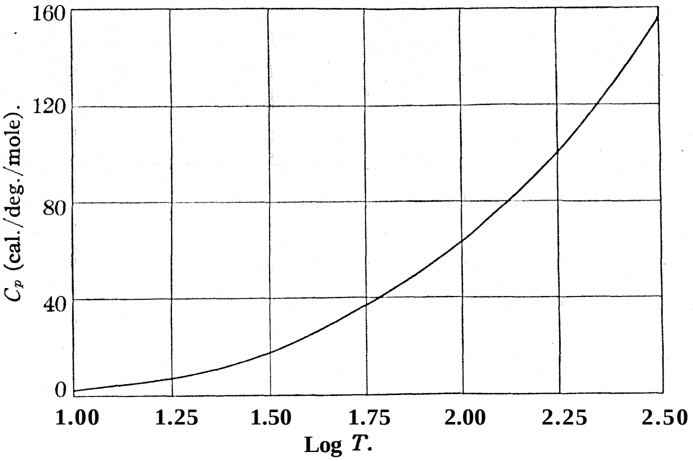

Fig. 3.—Molal entropy of cesium alum.

Entropy of cesium alum at 298.1° K. = 163.85 E. U.

Activity and Free Energy of Solution of Cesium Alum

The freezing point lowering of dilute solutions of cesium and rubidium alum was measured in the apparatus of Randall and Vanselow,[13] using the fifty junction thermo-element. In this way a temperature difference of 0.00005° could easily be observed. The measurements were carried out on a nearly saturated solution, gradually diluted over the desired range. The concentrations were determined by gravimetric analysis.

To evaluate the free energy of solution at 298.1°K., the activity of the aqueous salt must be determined for the corresponding concentration. The freezing points of dilute solutions of cesium alum were first measured, the results being shown in Fig. 4 and Table III. As a check both upon

---

[13] Randall and Vanselow, THIS JOURNAL, 46, 2418 (1924).

the method and the behavior of cesium alum, a similar series of determinations was made on rubidium alum. The points fall smoothly on the same straight line within the limits of experimental error. The activity coefficient at the 25° saturation concentration is then obtained without extrapolation, since saturated rubidium alum at 0° has about the same molality as cesium alum at 25°.

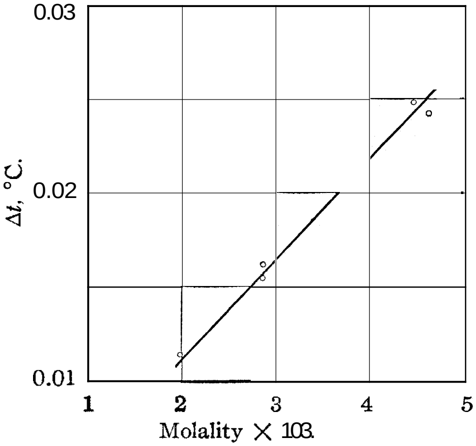

Fig. 4.—Freezing point lowering of cesium alum.

The activity coefficient was graphically calculated from the expression $\ln \gamma = -j - 2\int_0^m (j/m^{1/2})d(m^{1/2})$, which may be simply derived from the Duhem equation.[14] The limit, $j/m^{1/2} = 5.05$ when $m^{1/2} = 0$, was deduced from the Debye-Hückel theory; the segment of the curve between this point and that corresponding to the mast dilute solution capable of measurement was drawn in agreement with the best data available for comparable valence types, as shown in Fig. 5. The sharp maximum in

---

[14] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 286.

this curve should, of course, be rounded off, but as the area difference is not large we have left it in this limiting form.

The activity coefficients so established are valid at 25° if the heat of dilution is negligible. Experimental verification was made by diluting 200 cc. of saturated solution at 25° to one-tenth its concentration. A Beckmann thermometer sensitive to 0.001° indicated no measurable temperature difference.

The results are shown in Table III. It may be noted that the freezing points are somewhat lower than those obtained for potassium alum and sodium alum by Jones and Mackay.[15] No definite interpretation can be made in view of the uncertainty of the values of these investigators. The values of γ for rubidium alum and cesium alum fall about 25% below the curve calculated from the table of individual ionic activities given by Lewis and Randall,[16] using their figures for Cs^+, Al^{+++} and SO_4^{--}. The two curves are nearly identical in shape; the numerical agreement is adequate, taking cognizance of the specific differences entering into any given combination of ions.

TABLE III

FREEZING POINT LOWERING

Cesium Alum Molality	Cesium Alum F. p. lowering, °C.	Rubidium Alum Molality	Rubidium Alum F. p. lowering, °C.
0.00456	0.0243	0.01236	0.0598

.00197	.0108	.00527	.0286
		,00343	.0198
		.00242	.0139
		.00170	.0099

Activity Coefficients for Rubidium and Cesium Alum

Molality	0.001	0.002	0.004	0.006	0.008	0.010	0.01167	0.01403	0.01690
γ	.462	.406	.353	.310	.276	.251	.233	.217	.200

The last three values of γ correspond to the saturated cesium alum at 20, 25 and 30°, respectively. An additional check was obtained from the experimental heat of solution (see below). Assuming a constant second derivative of the curve ln γm against $1/T$ between 20 and 30°, it is found that $\gamma\ 0.01690/\gamma\ 0.01167 = 0.84$; from Table III, $\gamma\ 0.01690/\text{-}\gamma\ 0.01167 = 0.86$.

The effect of the solute on the activity of the water, a twelfth-power factor, was calculated to be less than 25 cal./mole in terms of ΔF.

Heat of Solution of Cesium Alum.—Since it is a difficult matter to evaluate accurately ΔH of solution from the temperature solubility curve, even where activity corrections are applied, the direct experimental determination was carried out with Dr. F. D. Rossini in the accurately

---

[15] Jones and **Mackay,** *Am. Chem.* J., **19,** 83 (1897).

[16] Ref. 14, p. 382.

calibrated apparatus described by Randall and Rossini.[17] It was found that $\Delta H_{298.1} = +13{,}560$ cal./mole, the estimated accuracy being ±25 cal./mole.

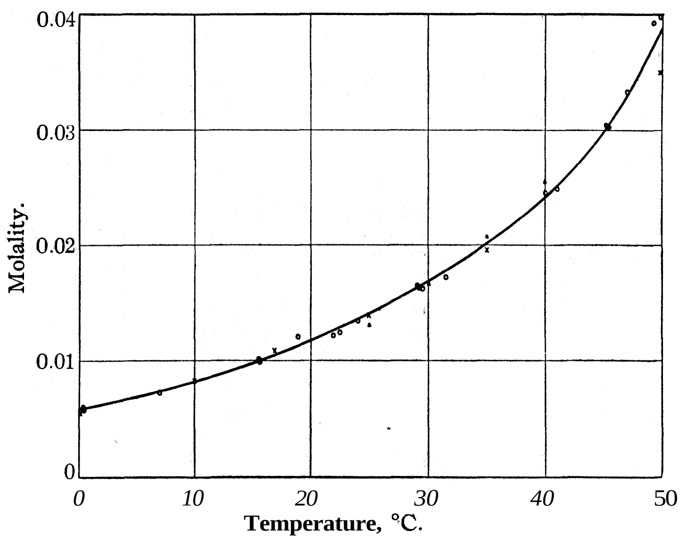
Entropy of Aluminum Ion

The entropy of aluminum ion may now be calculated. Writing the solubility reaction as

$$\mathrm{CsAl(SO_4)_2{\cdot}12H_2O = Cs^+ + Al^{+++} + 2SO_4^{--} + 12H_2O}$$

$\Delta F^\circ_{298.1} = -\mathrm{RT\ ln\ K} = -1363.7 \log 4(\gamma m)^4 = -5454.8 \log (1.4142)(0.217)(0.01403) = +12{,}910$ cal./mole.

The solubility, m, of cesium alum[18] has been accurately determined by Berkeley and confirmed by others, as illustrated by Fig. 6.



Berkeley; ○ Hart and Huselton; △ Locke; × Setterberg.

Fig. 6.—Solubility of cesium alum.

Then employing our experimental value for the heat of solution, $\Delta H_{298.1} = +13{,}560$ cal./mole, we obtain for the entropy of solution

$$\Delta S^\circ_{298.1} = \frac{\Delta H - \Delta F}{T} = +2.18 \text{ E. U.}$$

We may now write for the entropy of $\mathrm{Al^{+++}}$

$$S_{\mathrm{Al^{+++}}} = \Delta S_{(\mathrm{sol})} + S_{\mathrm{Cs\ alum\ (solid)}} - 12S_{\mathrm{H_2O\ (liq)}} - 2S_{\mathrm{SO_4^{--}}} - S_{\mathrm{Cs^+}}$$

The first two terms on the right have been obtained above. The entropy of H_2O has been computed from the specific heat of ice given from 9 to

273.1°K. by Simon[19] in a tabulation in advance of formal publication. His measurements at the ice point show the influence of pre-melting. The extraordinarily precise data of Dickinson and Osborne[20] is used in this range. At lower temperatures the two series coincide exactly. Callendar's work[21] on the specific heat of water has been used for the range 0–25°.

The Simon curve compares favorably up to 210°K. with that derived from the earlier work of Nernst and of Pollitzer.[22] The value of Dickinson and Osborne is used for the heat of fusion, $\Delta H = 1436.6$ cal./mole. The calculation of the entropy of water at 298.1°K. follows in Table IV.

TABLE IV

ENTROPY OF WATER

	E. U.
0–10°K. Debye T^3 Rule	0.02
10–273.1 Graphical	9.06
Entropy of fusion, 1436.6/273.1	5.26
273.1–298.1 Graphical	1.58
$S°_{298.1}$ =	15.92 ±0.02 E. U.

For the entropy of sulfate and cesium ions we have 9 and 27.9, respectively. The sulfate value is from the paper by Latimer and Buffington[2"] and that for cesium is calculated from the expression deduced by these authors relating the entropy of solution of gas ions and the ionic radius. Although this expression is empirical, the excellent agreement shown by the other alkali metal ions warrants confidence in its accuracy.

Substituting these values in the equation given above, we find for the entropy of Al^{+++} at 298.1°K. in a hypothetical one-molal solution, $S_{Al^{+++}298.1} = -70.9$ cal./deg./mole.

Potential of the Aluminum Electrode

The entropies of $^1/_2H_2$ and Al, as calculated by Lewis, Gibson and Latimer,[23] are 14.7 and 6.82, respectively. The recent work of Cornish and Eastman[24] changes the hydrogen value to 14.6. Using our value for the entropy of aluminum ion, we find for the reaction,

$$Al + 3H^+ = Al^{+++} + 3/2H_2;\quad AS = -70.9 + 43.8 - 6.8 = -33.9 \text{cal./deg.}$$

AN° from the work of Richards and Burgess[3] is −127.0 k. cal., whence $\Delta F°_{298} = \Delta H°_{298} - T\Delta S°_{298} = -116{,}900$ cal./mole and $E° = -\Delta F/NF = 116{,}900/(3 \times 23{,}074) = +1.69$ v.

Discussion of Results

The probable error is rather difficult to estimate. The electrode potential changes about 0.01 volt per 700 cal. change in ΔF, and we believe the free energy is known with this accuracy. The largest uncertainty appears to exist in the extrapolation of the freezing point data to obtain the activity coefficient. The largest numerical quantity is evidently the heat of solution of aluminum metal in acid. For Richards' determination, —127.0 k. cal., with hydrochloric acid in 200 moles of water a correction might be made for the heat of dilution, but this is certainly much less than other errors involved in the determination. Richards' value, -126.0 k. cal., for a more concentrated solution, that is, for $HCl \cdot 20H_2O$ is substantiated by the work of Biltz and Hohorst,[25] who give 125.1 k. cal. for $HCl \cdot 8.8H_2O$.

Among the direct determinations of the aluminum electrode, that of Heyrovsky[26] appears to be the most reliable. He employed the electrode sat. Al amalg. || X *m* $AlCl_3$, and obtained the value $+1.337$ volts, which he believed corresponded to the reaction, $Al + 3H_2O = Al(OH)_3 + 3/2H_2$. This could be checked against our value if the solubility product of aluminum hydroxide were accurately known. For this quantity we find 4×10^{-18} by Remy and Kuhlmann[27] and 10^{-33} by Heyrovsky.[28] Whence we may write

		Volts
$Al + 3H_2O$	$= Al(OH)_3 + 3/2H_2$	1.337
$Al(OH)_3$	$= Al^{+++} + 3OH^-$	-0.344 or -0.650
$3H^+ + 3OH^-$	$= 3H_2O$	0.828
$Al + 3H^+$	$= Al^{+++} + 3/2H_2$	$+1.821$ or $+1.515$

Our value, $+1.69$ volts, falls as a close mean.

The free energy of the reaction $Al + 3H_2O = Al(OH)_3 + 3/2H_2$, has been calculated by Drossbach[29] from the reaction heats and entropies, and agrees with the potential found by Heyrovsky.

A correction, estimated from the data of Denham[30] as \$0.004 volt, might be applied on the assumption of hydrolysis to $Al(OH)^{++}$. However, the stoichiometrical hydrolysis may be considered as due to the distributed polarization of the water molecules, and it then would be as unsuitable to attempt to specify an appropriate equilibrium constant as it is to define a dissociation constant for a strong electrolyte. For this reason no correction has been made and the hydrolysis effect is thus included in the standard state of hypothetical unit molal aluminum ion which corresponds to the experimental activities.

The authors wish to express their appreciation of the helpful suggestions of Professor W. F. Giauque pertaining to the specific heat measurements, the skilful execution of the mechanical design by Mr. G. F. Nelson, the work on the heat of solution of cesium alum by Dr. F. D. Rossini, and the laboratory assistance of Mr. J. E. Ahlberg.

Summary

The heat capacity of cesium alum, $CsAl(SO_4)_2 \cdot 12H_2O$, has been measured from 18 to 300°K.; the molal entropy at 298.1°K. is computed to be 163.8 cal./deg.

The activity of dilute solutions of rubidium and cesium alums has been determined from freezing point measurements.

The entropy ($H^+ = 0$) of Al^{+++} in hypothetical 1 M solution at 298.1°K. has been determined as −70.9 cal./deg./mole.

The electrode potential at 298.1°K. of aluminum, $Al = Al^{+++} + 3E^-$, has been calculated from thermal data to be +1.69 ± 0.01 volts.

THE TRANSITION TEMPERATURE OF CARBON TETRACHLORIDE AS A FIXED POINT IN THERMOMETRY

BY JAMES C. MCCULLOUGH AND HARRIS E. PHIPPS[1]

RECEIVED JUNE 22, 1928 PUBLISHED AUGUST 4, 1928

An enantiotropic or reversible transition has been discovered when carbon tetrachloride is cooled below its freezing point. This solid–solid transition is a change from the cubic to the monoclinic system and takes place at −48.54 ± 0.02°. The hold in the time–temperature curve (Fig. 1) is of approximately the same duration as that at the freezing point. With proper precautions the transition temperature is as constant as the freezing temperature. Since the freezing point of carbon tetrachloride is given as a fixed point in thermometry,[2] the transition point should be equally valuable. The purification of one substance would thus serve to fix two points on the thermometer scale, saving the purification of *a* second material, such as chlorobenzene.

No reference has been found in the literature indicating that more than one solid form of carbon tetrachloride has been known at atmospheric pressure. Tammann,[3] working with high pressures, at one time believed that he had found three solid forms. Later, in "Kristallisieren und Schmel-

---

[1] This paper represents part of the work done by Mr. Phipps in meeting the requirements for the degree of Master of Arts.

[2] (a) "International Critical Tables," Vol. I, p. 54; (b) Timmermans and Martin, *J. chim. phys.*, **23**, 747–787 (1926).

[3] Tammann, "Kristallisieren und Schmelzen," E. Barth, Leipzig, 1903, p. 222.

zen," he retracted his former statements, and explained the irregularities which he had observed when carbon tetrachloride solidified at various temperatures and pressures by assuming the existence of two polymorphic forms. Bridgman,[4] using very high pressures, found three solid forms of carbon tetrachloride. Extension of his curves indicates that the second form should exist below − 48° with one atmosphere pressure. In this connection Bridgman says: "It should be possible to realize the phase II at atmospheric pressure at low enough temperatures. Such an attempt was made by cooling CCl_4 in carbon dioxide snow to − 80°, but the depression of temperature was not sufficient to overcome the viscous resistance to the reaction." There are two possible explanations as to why Bridgman did not observe the solid–solid transition: (1) he may have failed to identify it and (2) the solid may have supercooled. If the third phase recorded by Bridgman exists at atmospheric pressure, the transition temperature would probably be close to absolute zero.

The transition was first observed by us with a polarizing microscope equipped with a cold stage. Samples of carbon tetrachloride from three different sources were examined. Each exhibited the same behavior. The first crystal form is cubic, as is well known. The form existing below —48.54' appears to be monoclinic, for it exhibited a biaxial interference figure and both parallel and oblique extinction with polarized light.

Apparatus

The apparatus used in measuring the transition temperature consisted of two large test-tubes, made from heavy walled Pyrex tubing, one of which slipped inside the other. These were then placed in a one-quart thermos bottle of the wide-mouthed type which was filled with solid carbon dioxide and ether. A four-terminal, compensated lead, platinum resistance thermometer and Mueller type bridge, made by the Leeds and Northrup Company were used for the major portion of the work. This pyrometer was calibrated at the sulfur boiling point by the method of Mueller and Burgess,[5] at the steam and ice points, and at the sublimation point of solid carbon dioxide.[6] Since no information could be found regarding the calibration at the sublimation point of solid carbon dioxide, the technique is here given in detail.

The solid carbon dioxide was purchased from the Dry-Ice Corporation in the usual form of a dense cube about ten inches on an edge. The resistance thermometer was placed in a one-quart thermos bottle of the wide-mouthed type which was filled with small pieces of solid carbon dioxide. The bottle was closed with a cork which fitted the thermometer loosely. The cork had a second hole about 4 mm. in diameter so as to ensure atmospheric pressure without undue circulation of air. Equilibrium was reached in about two hours. The readings could be checked by this method. The temperature of the solid carbon dioxide in the thermos bottle was also measured by a pentane thermometer which had been calibrated at −40° and other temperatures by the U. S. Bureau of Standards. The value obtained with this thermometer agreed with the published value for carbon dioxide in the solid state, as given in the "International

Critical Tables."[6] It was first thought that the sublimation temperature of the solid carbon dioxide could best be obtained by placing the thermometer in a deep hole drilled in the cake of Dry-Ice. This was done and after equilibrium was established, which took about seventeen hours, a temperature of −97° was obtained. It appears that this must be due to the escape of carbon dioxide gas and the rapid sublimation of the solid. If the solid carbon dioxide were not in equilibrium with its vapor, the temperature at the surface of the block would naturally fall. This point was tested by placing some pieces of solid carbon dioxide in a thermos bottle and rapidly drawing off the carbon dioxide gas by means of a suction tube extending nearly to the bottom of the bottle. A temperature of −102° has been obtained by this method and further study of it is under way.

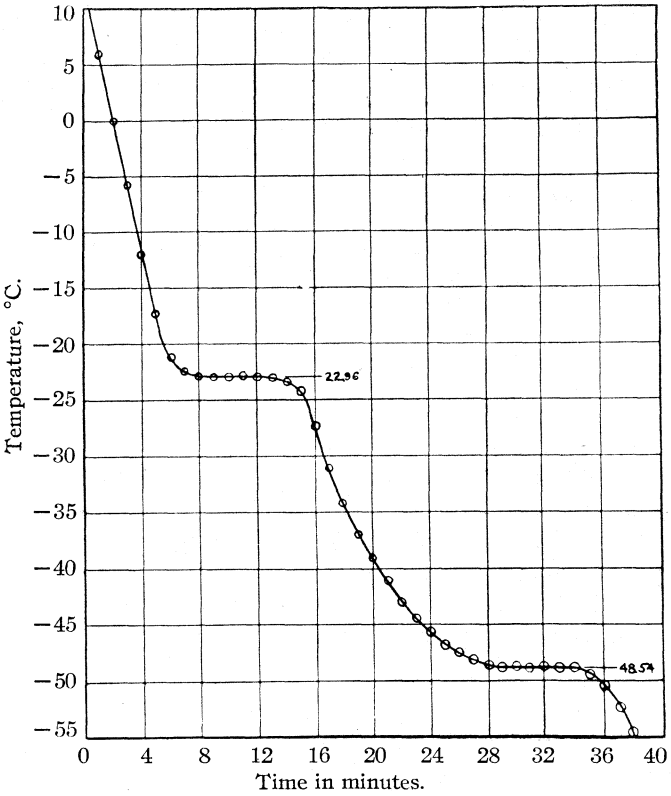

Fig. 1.—Enantiotropic transition of carbon tetrachloride. E. K Co., 444-A.

Procedure and Results

Time–temperature curves were made by cooling various samples of carbon tetrachloride, some of which were purified by fractional distillation. A Young pear-head fractionating column was used and the temperature of the condensing vapor was taken with a mercury thermometer calibrated by the U. S. Bureau of Standards. The boiling point was calculated to atmospheric pressure (760 mm.) by the method of Smith and Menzies.[7] When freezing, the liquid carbon tetrachloride was vigorously stirred until it was nearly all in the solid state. After it had all solidified and the temperature was again falling, the tube containing the solid carbon tetrachloride was occasionally removed from the freezing bath and gently tapped. When this was done the temperature was fairly constant even with an impure sample. The temperatures recorded in the table below are the average temperatures obtained, plus or minus the fluctuations observed during the hold. The platinum resistance thermometer was accurate to 0.006'.

TABLE I

BOILING, FREEZING AND TRANSITION POINTS OF CARBON TETRACHLORIDE

Thermometer	Sample of CCl_4	B. p., °C.	F. p., °C.	Transition point, °C.
Resistance	444	....	−22.946±0.008	−48.563±0.006
	444	....	−22.967±0.01	−48.551±0.007
Pentane	444	....	−22.97	−48.5
Resistance	444-A	76.8	−22.968±0.005	−48.541±0.005
	444-B	76.8	−22.973±0.006	−48.531±0.008
	444-C	76.8–77.3	−22.889±0.02	−48.395±0.02
	P.W.R.	....	−23.225±0.3	−48.925±0.3
	P.W.R.-A.	76.6–76.8	−23.14±0.2	−48.71±0.3
Pentane	P.W.R.-A.	76.6–76.8	−23.0 to −23.2	−48.7 to −48.9
	Stock		−22.9 to −23.5	−48.6 to −49.2

Sample 444 was obtained from the Eastman Kodak Company and is listed as E. K. Co. 444 carbon tetrachloride; 444-B was a sample obtained by fractional distillation; 444-C was a small amount of the higher boiling fraction; 444-A was obtained in the same way as 444-B but a more efficient pear-head fractionating column was used. The P.W.R. was a sample of the Powers-Weightman-Rosengarten Company product marked purified. The sample marked stock was a cheap commercial grade.

Summary

The results obtained show quite definitely that carbon tetrachloride has a solid–solid transition. The change from the cubic to the monoclinic system takes place at −48.54 * 0.02 when pure material is used. It is suggested as a fixed point in thermometry, since the hold is as constant and as fixed as the freezing point which is given as a fixed point in "International Critical Tables" and elsewhere.

NOTE

A Simplified Method of Differential Potentiometric Titration.—The excellent differential method of MacInnes and Jones[1] requires the use of a glass device of a certain complexity for temporarily withholding from reaction a small portion of the titrated solution while at the same time electrolytic contact is maintained between this portion and the remainder. The construction of this apparatus becomes unnecessary if the following modification is used. The electrodes may be two identical wires, one (A) enclosed in a dropper or syringe of the form shown in the figure, the other (B) wound around the stem of the dropper. B may be thrust through the rim of the bulb to hold it in place.

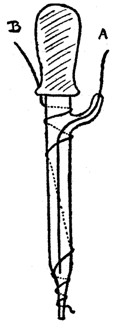

Fig. 1.—Double electrode for differential potentiometric titration.

Simply by squeezing the bulb a small part of the liquid is withdrawn and caused to surround the inner electrode, while electrolytic contact is maintained through the capillary tip. After the measurement, repeated squeezing of the bulb causes rapid mixing of the entire liquid. The method has been tested by students both in neutralization and oxidation reactions with entirely satisfactory results, the curves of $\Delta E/\Delta V$ against the percentage titration showing extremely sharp maxima when the reaction was of suitable type. The double maxima reported by MacInnes and Jones have also been observed. The apparatus may, of course, be used with a galvanometer and high resistance instead of a potentiometer and is extremely cheap and easy to prepare. Even an ordinary medicine dropper, with the inner electrode wire thrust directly through the rubber bulb, is quite satisfactory for temporary use.

BENZYLIDENE ANILINE AND BENZYLIDENE PARA-TOLUIDINE AS AMMONO ALDEHYDE-ACETALS

BY HAROLD H. STRAIN

RECEIVED MARCH 7, 1928 PUBLISHED AUGUST 4, 1928

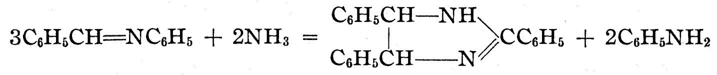
Introduction

According to the views of Franklin and his co-workers, the Schiff's bases are aldehyde-acetals of an ammonia system of compounds.[1] Moreover benzylidene aniline and benzylidene *p*-toluidine, typical aromatic Schiff's bases, are known to form addition compounds with hydrocyanic acid[2] and with Grignard reagents[3] which are analogous to the familiar addition products formed from aquo aldehydes and these same reagents. Benzylidene aniline is also reduced by nascent hydrogen to a secondary amine[4] which is a primary ammono alcohol.

As ammono aldehyde-acetals the aromatic Schiff's bases should be expected to undergo the Cannizzaro reaction and the benzoin condensation. These ammono compounds should also be nitridized to ammono acids and ammonolyzed to ammono aldehydes and ammono alcohols.

The reactions outlined in the previous paragraph have all been found to take place. In addition, a reaction resulting in the formation of a possible polymerized ammono aldehyde-acetal has been observed.

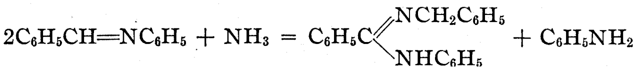
Ammonolysis.—When benzylidene aniline is ammonolyzed, amarine and aniline are the reaction products.



$$3C_6H_5CH{=}NC_6H_5 + 2NH_3 = \begin{array}{l} C_6H_5CH{-}NH \\ \quad | \\ C_6H_5CH{-}N \end{array}\!\!\!>\!CC_6H_5 + 2C_6H_5NH_2$$

The benzylidene imine which one should expect to find as a product of the reaction must condense to form amarine, a reaction known to take place.[5] Benzylidene *p*-toluidine is ammonolyzed to amarine and *p*-toluidine.

Cannizzaro Reaction.—The Cannizzaro reaction of the ammono aldehyde-acetals takes place readily when these compounds are treated with an excess of an ammono base. In this reaction, however, the ammono acids and the ammono alcohols which are formed are found in the form of ammono esters; namely, benzylphenylbenzamidine and benzyl-*p*-tolylbenzamidine.[6]



$$2C_6H_5CH{=}NC_6H_5 + NH_3 = C_6H_5C\begin{array}{l} {\nearrow}NCH_2C_6H_5 \\ {\searrow}NHC_6H_5 \end{array} + C_6H_5NH_2$$

[6] The formation of benzylyhenylbenzamidinc can perhaps be best explained by

Benzoin Condensation.—When treated with an alkaline cyanide in liquid ammonia the ammono aldehyde-acetals undergo the benzoin condensation forming ammono benzoin-acetals; namely, benzoin-anil-anilide and benzoin-*p*-tolyl-*p*-toluide.[7] This reaction, which is analogous to the benzoin condensation of aquo aldehydes, is illustrated by the following parallel equations

$$2C_6H_5CH{=}O \quad = \quad \begin{array}{l} C_6H_5CH{-}OH \\ \quad | \\ C_6H_5C{=}O \end{array}$$

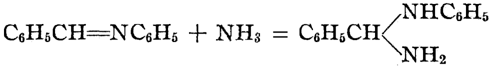
(aquo aldehyde) (aquo benzoin)

$$2C_6H_5CH{=}NC_6H_5 \quad = \quad \begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ \quad | \\ C_6H_5C{=}NC_6H_5 \end{array}$$

(ammono aldehyde-acetal) (ammono benzoin-acetal)

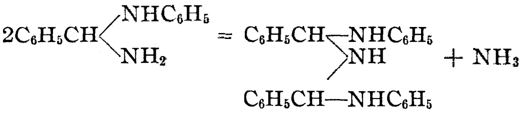
---

the following series of equations



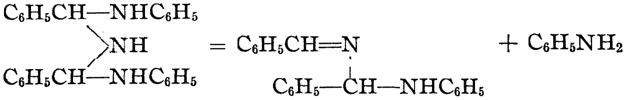
$$C_6H_5CH{=}NC_6H_5 + NH_3 = C_6H_5CH\begin{cases} NHC_6H_5 \\ NH_2 \end{cases}$$

(ammono aldehyde-acetal) (ammono acetal)



$$2C_6H_5CH\begin{cases} NHC_6H_5 \\ NH_2 \end{cases} = \begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ \qquad \rangle NH \\ C_6H_5CH{-}NHC_6H_5 \end{array} + NH_3$$

(ammono acetal) (ammono acetal)



$$\begin{array}{l} C_6H_5CH{-}NHC_6H_5 \\ \qquad \rangle NH \\ C_6H_5CH{-}NHC_6H_5 \end{array} = \begin{array}{l} C_6H_5CH{=}N \\ \qquad\quad | \\ C_6H_5{-}CH{-}NHC_6H_5 \end{array} + C_6H_5NH_2$$

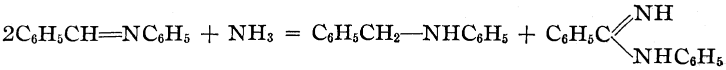
(ammono acetal) (ammono aldehyde-acetal)

The ammono aldehyde-acetal last written may undergo intramolecular oxidation and reduction, the aldehyde group being reduced to an ammono alcohol, the acetal group being nitridized (oxidized) to an ammono acid. This reaction, obviously an example of the Cannizzaro reaction, is shown herewith.

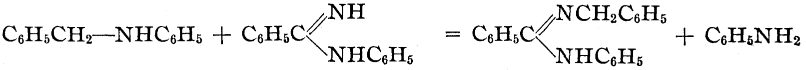
$$C_6H_5CH\begin{cases} N{=}CHC_6H_5 \\ NHC_6H_5 \end{cases} = C_6H_5C\begin{cases} {=}NCH_2C_6H_5 \\ NHC_6H_5 \end{cases}$$

(ammono aldehyde-acetal) (ammono acid-ester)

The formation of benzylphenylbenzamidine from benzylidene aniline can also be explained by assuming the Cannizzaro reaction to take place before the ester formation, as follows



$$2C_6H_5CH{=}NC_6H_5 + NH_3 = C_6H_5CH_2{-}NHC_6H_5 + C_6H_5C\begin{cases} {=}NH \\ NHC_6H_5 \end{cases}$$



$$C_6H_5CH_2{-}NHC_6H_5 + C_6H_5C\begin{cases} {=}NH \\ NHC_6H_5 \end{cases} = C_6H_5C\begin{cases} {=}NCH_2C_6H_5 \\ NHC_6H_5 \end{cases} + C_6H_5NH_2$$

It is interesting to note that these reactions take place in accordance with the theories proposed by Lachman [THIS JOURNAL, 45, 2356 (1923)] who observed the aquo ester benzylbenzoate as an intermediate product when benzaldehyde undergoes intermolecular oxidation and reduction.

[7] Evidence will be presented in a following paper to show that these compounds undergo a number of reactions which substantiate the view that they are related to ammonia as the familiar benzoin and acetals are related to water.

Nitridation.—Benzylidene aniline is nitridized with difficulty with the result that tar-like decomposition products are formed along with small quantities of benzonitrile (benzoic anammonide).

Polymerization.—When treated with small quantities of alkali in liquid ammonia the ammono aldehyde-acetals form polymerized compounds whose structure has not been definitely established. The proposed formulas will therefore be described in the experimental part.

Experimental

Ammonolysis.—The ammonolysis reaction was carried out by allowing the ammono aldehyde-acetals to stand in liquid ammonia solution for thirty to thirty-five days. The ammonia was then evaporated and the residue extracted with alcohol which was then diluted with water, whereupon an oil separated. The clear liquid was then decanted from the oily layer, the latter was dissolved in a little concentrated hydrochloric acid, the solution diluted with an equal volume of water and cooled. When crystals ceased to form, the mixture was filtered and the crystals removed to a flask, where they were boiled with alcoholic ammonium hydroxide until a clear solution was obtained. Upon cooling and diluting this solution with water, large crystals of amarine were obtained. The identity of the crystals was established by a mixed melting point. The yields varied from 60 to 91% of the theoretical. The aniline and p-toluidine were identified in the respective filtrates.

It was also found that the ammonolysis reaction could be completed in ten to fourteen hours by heating the ammono aldehyde-acetals with liquid ammonia in the presence of ammonium chloride to a temperature of 120–150°.[8]

Cannizzaro Reaction.—Benzylidene aniline, or benzylidene p-toluidine, was treated with two or more molecular equivalents of potassium amide in liquid ammonia solution at room temperature. A considerable quantity of heat was evolved, indicated by the vigorous boiling of the solution, and a deep blue color was produced. This color disappeared upon the addition of more of the respective ammono aldehyde-acetal and reappeared upon the further addition of potassium amide. The reaction products could not be induced to crystallize from this dark blue solution even when the latter was concentrated and cooled to −35°. The ammonia was, therefore, allowed to escape, when a flaky blue residue was obtained. This material was dissolved in hot 95% alcohol (the blue color immediately disappeared) and the alcoholic solution then diluted with water until a slight turbidity appeared. Upon cooling, the solution was found to deposit beautiful, colorless, needle-shaped crystals of benzylphenylbenzamidine, or benzyl-p-tolylbenzamidine. A considerable quantity of aniline or *p*-toluidine was always found in the mother liquor. The yield of the ammono acid esters usually amounted to 60% of the weight of the ammono aldehyde-acetals used in the reaction.

The benzylphenylbenzamidine melted at 99–100° and when mixed with benzylphenylbenzamidine prepared by the action of phosphorus pentachloride and aniline on benzanilide[9] the mixture melted at 99–100°.

The crystals were analyzed and their molecular weight was determined in benzene solution by the cryoscopic method.

[8] For method of heating, see Blair, THIS JOURNAL, **48,** 87 (1926).

[9] (a) Beckmann and Fellrath, *Ann.,* 273, 9 (1893); (b) Pechmann and Heinze, *Ber..* 30, 1787 (1897).

In order to make more certain of the structure of the benzylphenylbenzamidine, the benzenesulfonyl derivative was prepared by treating some finely pulverized crystals with benzenesulfonylchloride and alkali. The white, crystalline derivative thus obtained was insoluble in alkalies and melted at 148°. It was analyzed by the method of Carius.

And. Calcd. for $C_{26}H_{22}O_2N_2S$: S, 7.5. Found: S, 7.1.

The benzyl-*p*-tolylbenzamidine prepared from benzylidene p-toluidine melted at 127–127.5°. The molecular weight in benzene solution was determined by the cryoscopic method.

Mol. wt. Calcd. for $C_{21}H_{20}N_2$: 300. Found: 294,259. *Anal.* Calcd. for $C_{21}H_{20}N_2$: C, 84.0; H, 6.7; N, 9.3. Found: C, 83.9, 84.1; H, 7.0, 6.9; N, 9.1, 8.9.

Since benzyl-p-tolylbenzamidine was not known it seemed advisable to prepare this compound in order to compare it with the material obtained by the Cannizzaro reaction. The synthesis was accomplished by heating benz-p-toluide with phosphorus pentachloride and benzylamine. The crystals thus obtained melted at 127° and when mixed with those obtained from benzylidene *p*-toluidine, the mixture melted at 127°. The two preparations appeared to be identical in crystalline form and solubility, being insoluble in water, moderately soluble in alcohol and acetone, and readily soluble in ether and benzene.

Benzoin Condensation.—From 3 to *5* g. of ammono aldehyde-acetal and ***0.5*** to 1.0 g. of freshly pulverized potassium cyanide were dissolved in about ***20*** cc. of liquid ammonia and the clear solution was allowed to stand at room temperature. After several hours a heavy, viscous liquid separated from the solution. Twenty-four hours later a few crystals had formed in this liquid, but due to its high viscosity the growth of the crystals was retarded to such an extent that it seemed best to repeat the experiment, using the crystals first formed to seed the reaction product before any large quantity of the viscous material could be formed. Accordingly, the crystals were drained of the mother liquor and uncrystallized oil, dried and transferred to a freshly prepared solution of the aldehyde-acetal and potassium cyanide in liquid ammonia. After standing for several hours the solution was found to be filled with crystals.

The crystals formed from benzylidene aniline were hexagonal yellow prisms having a greenish fluorescence. These crystals were washed, dried and analyzed.[10]

Anal. Calcd. for $C_{26}H_{22}N_2$: C, 86.2; H, 6.1; N, 7.7. Found: C, 85.9, 85.9; H, 6.2, 6.2; N, 7.5. *Mol. wt.* (Benzene). Calcd. for $C_{26}H_{22}N_2$: 362. Found: 321, 331.

The yellow crystals of benzoin-anil-anilide are insoluble in water, moderately soluble in boiling alcohol and very soluble in hot benzene and toluene, from which they may be recrystallized. When heated these crystals begin to soften at 185° but do not melt completely until a temperature of 200° is reached. At a higher temperature the benzoin-anil-anilide distils with only slight decomposition.

The ammono benzoin obtained from benzylidene p-toluidine is slightly soluble in liquid ammonia, separating as a clear, colorless, viscous liquid or as colorless crystals. It is moderately soluble in hot alcohol and crystallizes from a concentrated solution in

---

[10] It is interesting to note at this time that Schiff reported a compound having the empirical formula $C_{26}H_{22}N_2$ which he obtained by heating benzylidene aniline in a sealed tube [*Ann.* Suppl., **3**, 354 (1864); *Ann.*, **148**, 336 (1868)]. However, Voigt, [*J. prakt.* Chem., ***[2]*** **31**, 544 (1885); [2] 34, *2* (1886)] and v. Miller and Plöchl ***[Ber.,*** 25, ***2020*** (1892)], and the writer were unable to duplicate Schiff's results. In attempting to prepare benzoin-anil-anilide by the action of aniline on benzoin, Lachowicz [*Monatsh.*, 15, 402 (1894)], found that benzoin-anil was the sole product of the reaction, the ammonolysis failing to go to completion.

beautiful colorless prisms. After recrystallization this compound was found to melt at 122°.[11]

Anal. Calcd. for $C_{28}H_{26}N_2$: C, 86.2; H, 6.7. Found: C, 86.2, 86.3; H, 6.8, 6.8.

Nitridation.—Benzylidene aniline (1 g.) in solution in liquid ammonia was treated with an excess of iodine and the temperature of the solution maintained at 0° until the iodine color had completely disappeared (eight hours). During this time a considerable quantity of nitrogen was evolved while the solution became quite dark in color. Upon evaporation of the ammonia, a dark, tarry mass was obtained which smelled strongly of phenylisocyanide. Neither benzamidine or phenylbenzamidine could be detected in the aqueous and dilute acid extracts of the residue. From the ether extract a few drops of an oily liquid which smelled strongly of benzonitrile were obtained; boiling point of benzonitrile, 191°; found, 180°.

Polymer from Benzylidene Aniline.—After standing in a solution of potassium amide in liquid ammonia containing less than one molecular equivalent of potassium amide, benzylidene aniline is converted into a very soluble material which is best obtained by evaporating the ammonia and recrystallizing the residue from alcohol. The time necessary for this reaction varies from five to fifteen days. The yields vary between 10 and 60% of the weight of benzylidene aniline used.

The crystals obtained from alcohol grow very slowly and take the form of prisms. They melt at 132–134°. After digestion with dilute alcoholic potassium hydroxide, the crystals melt at 136°, but upon recrystallization from alcohol they melt again at 132–134°.

This new substance is insoluble in acids, alkalies and water, but is moderately soluble in benzene and toluene. It is only slowly attacked by aqueous hydrochloric acid at the boiling temperature, a blue-green coloring matter being produced. Ammono hypoiodous acid failed to nitridize the material in liquid ammonia solution.

When treated with an excess of potassium amide, 0.4 g. of the unknown crystals produced 0.3 g. of phenylbenzylbenzamidine and when heated with a solution of ammonium chloride in liquid ammonia the crystals gave rise to another compound which melted at 168° and which has not as yet been identified.

The composition and the molecular weight of the crystals melting at 132–134° were determined, the latter in benzene solution by the cryoscopic method.

Anal. Calcd. for $C_{33}H_{29}N_3$: C, 84.8; H, 6.2; N, 9.0. Found: C, 85.1, 85.0, 85.1; H, 6.5, 6.2, 6.5; N, 8.6, 8.6. *Mol.* wt. Calcd. for $C_{33}H_{29}N_3$: 467. Found: 418, 438.

When this compound obtained by the action of potassium amide on benzylidene aniline is treated with alcoholic hydrochloric acid, it forms a soluble hydrochloride which separates as a white, finely crystalline mass when the solution is diluted with water. Upon heating this hydrochloride with ammonium hydroxide, the original base is regenerated. Two preparations of the hydrochloride were made.

Anal. Calcd for $C_{33}H_{29}N_3 \cdot HCl$: Cl, 7.1. Found: Cl, 6.9, 7.4.

Polymerization of three molecules of benzylidene aniline to a six membered heterocyclic ring with the subsequent elimination of one molecule of aniline by ammonolysis would yield a compound whose hydrochloride would have the formula $C_{33}H_{29}N_3 \cdot HCl$.

Polymer from Benzylidene *p*-Toluidine.—When treated with potassium amide,

---

[11] Schiff [*Ann.*, 140, 96 (1866)] reported a compound having the formula $C_{28}H_{26}N_2$ and melting at 120–125°, which he obtained by heating benzylidene p-toluidine in a sealed tube at 180° for twenty-four hours. However, v. Miller and Plochl [*Ber.*, 25, 2020 (1892)] and, more recently, the writer were unable to duplicate Schiff's results. Nevertheless, the melting point of Schiff's compound agrees fairly well with that of the ammono benzoin obtained as a result of the benzoin condensation in liquid ammonia.

as just described above for benzylidene aniline, benzylidene *p*-toluidine forms a compound which melts at 136–137° when recrystallized from alcohol. The crystals thus obtained are much more difficult to purify than those obtained from benzylidene aniline. Furthermore, they are very easily converted into benzyl *p*-tolylbenzamidine, this reaction taking place when less than one molecular equivalent of potassium amide is present in the ammonia solution.

Anal. Calcd. for $C_{35}H_{33}N_3$: **C,** 84.8; **H, 6.7.** Found: C, 84.6, 84.3; H, 6.7, 6.3. *Mol. wt.* Calcd. for $C_{35}H_{33}N_3$: **495.** Found: **399,401.**

It is with the greatest pleasure that the writer takes this opportunity to express his thanks to Dr. E. C. Franklin for the care which he exercised in directing the experimental work and in reading this manuscript.

Summary

Experimental evidence has been presented to show that the aromatic Schiff's bases, benzylidene aniline and benzylidene *p*-toluidine, are aldehyde-acetals of the ammonia system of compounds.

The ammonolysis of ammono aldehyde-acetals has been accomplished.

Benzylphenylbenzamidine and benzyl-p-tolylbenzamidine have been prepared by the Cannizzaro reaction.

Benzoin-anil-anilide and benzoin-*p*-tolyl-*p*-toluide have been prepared by the benzoin condensation.

THE REACTION BETWEEN ORGANOMAGNESIUM HALIDES AND ALKYL SULFONATES

BY HENRY GILMAN AND LLOYD L. HECK

RECEIVED MARCH 7, 1928 PUBLISHED AUGUST 4, 1928

Introduction

Alkyl esters of sulfonic acids differ from aryl esters of sulfonic acids in their reaction with organomagnesium halides. With alkyl esters, alkylation takes place, and this reaction has generally been formulated as follows[1]

$$2RSO_2O\text{–Alkyl} + 2R'MgX \longrightarrow 2R'\text{–Alkyl} + (RSO_2O)_2Mg + MgX_2 \qquad (1)$$

With aryl esters, sulfones and phenols are formed, as follows

$$RSO_2\text{–OAryl} + R'MgX \longrightarrow RSO_2R' + \text{ArylOMgX} \qquad (2)$$

When molecular equivalents of alkyl sulfonate and Grignard reagent are used, according to Reaction 1, the yield of alkylation product does not generally exceed 50%.[2] This prompted a further investigation of the

---

[1] Gilman, Robinson and Beaber, THIS JOURNAL, 48, **2715 (1926).** References to earlier studies are contained in this paper.

[2] Gilman and Beaber, *ibid.*, **47,518 (1925).** The only exception to the **18** alkylation reactions reported by them was in the reaction between benzyl *p*-toluenesulfonate and benzylmagnesium chloride. In this case a 55% yield of dibenzyl was obtained, but it is quite probable that part of this high yield is due to some dibenzyl that is generally

reaction. The results described here show that Reaction 1 is only partly correct. In addition to the alkylation product an alkyl halide is formed, the alkyl group coming from the ester and the halogen from the Grignard reagent.

The following reactions are proposed to account for the formation of these compounds.

$$\mathrm{RSO_2O\text{-}Alkyl + R'MgX \longrightarrow R'\text{-}Alkyl + RSO_2OMgX} \qquad (3)$$

$$\mathrm{RSO_2OMgX + RSO_2O\text{-}Alkyl \longrightarrow Alkyl\,X + (RSO_2O)_2Mg} \qquad (4)$$

In strict accordance with these reactions the yield of alkylation product should be increased when two moles of alkyl sulfonate are used with one mole of Grignard reagent. This is supported by experiment. Also it has been shown that when two moles of ester are used for one of RMgX compound, the R-Alkyl and RX compounds are formed in essentially equivalent quantities. It is obvious that after some RSO_2OMgX has been formed according to Reaction **3,** this salt would react with ester to give the RX compound according to Reaction 4 even when equivalent molecular quantities of ester and Grignard reagent are used. This, too, has been found to be the case.

The correctness of Reaction 4 has been established by treating anhydrous @-naphthalenesulfonic acid with methylmagnesium iodide to form β-$C_{10}H_7SO_2OMgI$, and then treating this salt with n-butyl *p*-toluenesulfonate to form n-butyl iodide and magnesium β-naphthalenesulfonate, as follows

$$\beta\text{-}\mathrm{C_{10}H_7SO_2OH + CH_3MgI \longrightarrow} \beta\text{-}\mathrm{C_{10}H_7SO_2OMgI + CH4} \qquad (5)$$

$$\beta\text{-}\mathrm{C_{10}H_7SO_2OMgI} + p\text{-}\mathrm{CH_3C_6H_4SO_2OC_4H_9}\,(n) \longrightarrow n\text{-}\mathrm{C_4H_9I} + (\beta\text{-}\mathrm{C_{10}H_7SO_2O})_2\mathrm{Mg} \qquad (6)$$

Kenyon, Phillips and Turley[3] obtained ethyl a-bromopropionate and not ethyl a-phenylpropionate (as might have been expected in accordance with Reaction 1) when the *p*-toluenesulfonic ester of optically active ethyl lactate was treated with phenylmagnesium bromide. Also, Rossander and Marvel,[4] in a study of the lengthening of carbon chains by three carbon atoms wherein y-chloropropyl *p*-toluenesulfonate was treated with various RMgX compounds, obtained not only the normal reaction[5] leading to the introduction of the chloropropyl group but also the dihalide formed from the γ-chloropropyl group and the halogen of the Grignard reagent.

---

formed in significant quantities in the preparation of benzylmagnesium chloride. Two other yields in excess of 50% have been reported by Gilman and Beaber with halogen alkyl sulfonates, ibid., **45,** 839 (1923). The high yields obtained with dialkyl sulfates may be due to the presence of two alkyl groups in these esters in contrast with the one alkyl group in alkyl p-toluenesulfonates.

[3] Kenyon, Phillips and Turley, J. *Chem. Soc.,* 127, 399 (1925). They also obtained ethyl a-bromopropionate from the lactyl ester and ethylmagnesium bromide. With ethoxymagnesium iodide (C_2H_5OMgI) and the lactyl ester they got ethyl a-iodopropionate. No other products from these three reactions were reported by them.

[4] Rossander and Marvel, THIS JOURNAL, **50,** 1491 (1928).

[5] Gilman and Beaber, *ibid.,* **45,** 839 (1923).

In some of their reactions where one mole of ester was used with one mole of Grignard reagent, they obtained significant quantities of the hydrocarbon that would be expected from the hydrolysis of the RMgX compound. An explanation for the formation of these hydrocarbons is to be found in Reactions 3 and 4. From these reactions it will be noted that the ester is competing for the RMgX and the RSO_2OMgX compounds, and inasmuch as these reactions probably take place concurrently (R-alkyl and RX are both formed from one mole of ester and one mole of RMgX) some of the RMgX compound will remain unused. This unused Grignard reagent would then give the corresponding hydrocarbon when the reaction mixture is subsequently hydrolyzed in the course of working up the reaction products.

In connection with the formation of hydrocarbon when equimolecular proportions of ester and Grignard reagents are used,[6] it is possible to formulate other reactions to account for the alkylation product and the alkyl halide. Kenyon, Phillips and Turley, and Holmberg[7] have proposed the following reaction to account for the formation of the ethyl a-bromopropionate

$$RSO_2O\text{–Alkyl} + R'MgX \longrightarrow \text{Alkyl X} + RSO_2OMgR'. \qquad (7)$$

Unless this reaction is peculiar to the lactyl ester of *p*-toluenesulfonic acid, and there is no reason at present to believe so in view of the several diverse alkylations that have been reported,[2] it should account for general alkylations involving the Grignard reagent. Their scheme of Reaction (7) accounts for the formation of alkyl halide; it can also explain the formation of hydrocarbon observed in some cases by Rossander and Marvel[4,6]; but it offers no satisfactory explanation for the alkylation action that is so common with alkyl sulfonates. It can account for the formation of hydrocarbon, because the RSO_2OMgR' compound postulated there has the highly reactive $-MgR'$ group that should show many, if not all, of the reactions of RMgX compounds. Hydrolysis of it, for example, should yield the hydrocarbon R'H.

A series of reactions has been proposed,[4] independently of the formulation just considered, to account for all of the products so far obtained in the reaction between alkyl sulfonates and RMgX compounds. This scheme admits Reaction 3 to account for a part of the alkylation; it admits Reaction 7 to account for the alkyl halide, and then with Reaction 7 as a basis it accounts for the formation of the remainder of the alkylation product and the hydrocarbon by the following reactions that assume the intermediate formation of RSO_2OMgR'

$$RSO_2O\text{–Alkyl} + RSO_2OMgR' \longrightarrow R'\text{–Alkyl} + (RSO_2O)_2Mg \qquad (8)$$

$$RSO_2OMgR' + HOH \longrightarrow R'H + RSO_2OMgOH \qquad (9)$$

---

[6] When Marvel and Rossander (ref. 4) used two moles of ester with one of Grignard reagent they isolated a hydrocarbon in only one experiment.

[7] Holmberg, ***Ber.***, 59, 1560 (1926).

Admittedly this series of Reactions (3, 7, 8 and 9) offers not only an explanation for all of the products so far observed, but also accounts for the improvement of yield in the alkylation reaction when two moles of ester are used for one mole of Grignard reagent. There are, however, some objections to such a scheme of reactions. First, it calls for a manner of scission of the RMgX molecule that is unusual. Grignard reactions generally have been explained as involving, at some stage, a scission or dissociation of the molecule to give R– and –MgX and not RMg– and –X. Second, Reactions 7, 8 and 9 postulate a compound (RSO_2OMgR') which is unknown, so that it is impossible at present to verify these three reactions by the use of the RSO_2OMgR' compound about which all three reactions turn. Over and against such a proposal that has no confirmation in experiment is Reaction 4, which has found support in experiment. Reactions 3 and 4 account for (1) alkylation, (2) alkyl halide, (3) magnesium sulfonate, (4) hydrocarbon corresponding to the RMgX when insufficient ester is used and (5) the improvement in alkylation yield noted when an excess of ester is used.

The alkyl halides formed in accordance with Reaction 4 may also be prepared from the alkyl sulfonate when the –MgX group is attached to practically all elements, and not only to carbon as in the Grignard reagent. This was shown when n-butyl halides were obtained from n-butyl *p*-toluenesulfonate and ethoxymagnesium iodide (C_2H_5OMgI), phenoxymagnesium iodide (C_6H_5OMgI), *p*-tolylsulfinylmagnesium bromide (*p*-$CH_3C_6H_4S(=O)OMgBr$), methylanilinomagnesiumbromide (C_6H_5N-(CH_3)-$MgBr$), thiophenylmagnesium iodide (C_6H_5SMgI), magnesium iodide and magnesium bromide.

The formation of RX from the alkyl sulfonate and the magnesium halides is of more than passing interest. Some magnesium halide is formed in the ordinary preparation of all Grignard reagents, but the extent of this side reaction is altogether too slight to account for the high yield of RX compound obtained in the several experiments with alkyl sulfonates. Of much greater significance is its bearing on the constitution of the Grignard reagents. Very recently a renewed interest has been shown in Jolibois'[8a] formula for oganomagnesium halides. He suggested that RMgX compounds are really magnesium dialkyls or diaryls with magnesium halide, and that the correct formulation is $R_2Mg + MgX_2$ instead of RMgX. For our present purposes it is of no great significance whether we ascribe

---

[8] (a) Jolibois, *Compt. rend.*, 155, 353 (1912); 183, 971 (1926); (b) Kierzek, *Bull. soc. chim.*, *41*, 1299 (1927); (c) Grignard, *Compt. vend.*, 185, 507 (1927); Terentiev, *Z. anorg. allgem. Chem.*, 156, 73 (1926); Job, *Bull. soc. chim.*, *39*, 583 (1926); Ivanoff, *Compt. rend.*, 185, 505 (1927). Meisenheimer and Schlichenmaier, *Ber.*, 61, 720 (1928), have just reported on the molecular weight and the constitution of the Grignard reagent. In dilute solutions the organomagnesium halides are apparently monomolecular and therefore best represented as RMgX and not as $R_2Mg + MgX_2$.

to the Grignard reagents the "mixed molecule" formula or whether we designate this complex as being in equilibrium with the RMgX form.

$$2RMgX \rightleftharpoons R_2Mg + MgX_2 \qquad (10)$$

Gilman and Schulze[9] have shown that the following equilibrium under certain conditions exists between beryllium dialkyls and alkylberyllium halides.

$$2RBe \rightleftharpoons R_2Be + BeX_2 \qquad (11)$$

In this connection it is interesting to note that other inorganic halides have split alkyl sulfonates to give alkyl halides. Kenyon, Phillips and Turley,[3] for example, used lithium chloride, sodium bromide and potassium iodide with their lactyl sulfonate to get the corresponding ethyl α-halogenopropionates. Further studies[10] of the chemistry of R_2Mg compounds should throw more light on this problem.

The formation of sulfones (Reaction 2) is not restricted to aryl esters of sulfonic acids. n-Butyl *p*-toluenesulfonate and phenylmagnesium bromide gave, in addition to large amounts of normal products that would be expected from Reactions 1, **3** and 4, a small quantity of phenyl *p*-tolyl sulfone. A corresponding reaction was reported some years before by Ferns and Lapworth,[1] and Strecker,[1] who showed that ethyl ethanesulfonate and phenylmagnesium bromide underwent reactions in accordance with 1 and 2.

Experimental

In general, stock solutions of the appropriate Grignard reagent in ether were used. These solutions were filtered free of any unused magnesium and aliquots[11] and were slowly added to the ester until a positive color test[12] was obtained. In a few cases the ester was added to the Grignard reagent, but no essential differences were noted. After refluxing for one to two hours, the mixture was hydrolyzed by iced acid. The ether layer, after washing with water, was steam distilled in order to effect a more ready separation of alkyl halide and hydrocarbon from any unused ester. All of the alkyl halides were identified by conversion to the alkylmercuric halides,[13] and these in turn were identified by a mixed melting point determination made with authentic specimens.

The magnesium sulfonates were obtained from the water layer by crystallization after concentration. They are much less soluble in water than the magnesium halides. Some of the magnesium sulfonates were analyzed for water of crystallization as well as for magnesium in the anhydrous salt.

[a] In studies where esters other than those of the halogen acids (or RX compounds) were treated in ether with magnesium, diethyl sulfate gave a positive color test when a trace of iodine was added. Unquestionably this was due to the formation of some magnesium iodide, which split the diethyl sulfate to form ethyl iodide and this then reacted with the magnesium present to give ethylmagnesium iodide.

[b] An 85–87% yield of magnesium p-toluenesulfonate was obtained.

[c] The quantity of n-propylmagnesium bromide required for a positive test was 0.2 mole. No attempt was made to separate the low boiling n-heptane. The yield of magnesium p-toluenesulfonate was 65 g. or 70%.

[d] n-Butyl chloride was not isolated here; however, qualitative tests showed it to be present. The large quantity of ether used in this experiment was undoubtedly responsible for the difficulty in separating the butyl chloride. This was shown in a blank experiment where 18 g. of butyl chloride was added to the same volume (550 cc.) of ether and fractional distillation with the same column gave no separation. From a corresponding reaction, using one mole of ester and one mole of benzylmagnesium cloride, Marvel[4] succeeded in separating butyl chloride. The yield of magnesium p-toluenesulfonate from this experiment was 70%.

[e] In this experiment 0.22 mole of phenylmagnesium bromide was required to give a positive color test that persisted after two hours of refluxing. The yield of magnesium *p*-toluenesulfonate was 86 g. or 86.5%. The anhydrous salt was analyzed for magnesium after drying to constant weight at 110°. Anal. Calcd. for $(C_7H_7SO_3)_2Mg$: Mg, 6.64. Found: 6 65, 6.64. A sodium hydroxide extraction of the ether layer gave some phenol. The residue from steam distillation gave 2.0 g. of phenyl-*p*-tolyl sulfone. This was identified by a mixed melting point determination with an authentic specimen.

[f] The yield of magnesium p-toluenesulfonate was 67%. In another run a special search failed to reveal any n-butylphenyl ether. The phenol was almost quantitatively recovered as 2,4,6-tribromophenol.

[g] The *p*-thiophenylmagnesium iodide was prepared from 44 g. or 0.4 mole of *p*-thiophenol and an equivalent quantity of n-propylmagnesium iodide. Subsequent to hydrolysis the ether layer when extracted with sodium hydroxide yielded no thiophenol. The yield of n-butylphenyl sulfide was 39 g. or 52%.

[h] The methylanilinomagnesium bromide was prepared from 55 g. or 0.5 mole of methylaniline and ethylmagnesium bromide. Twenty *g.* of an amine boiling at 225–230" was obtained. This was very probably the expected methyl-n-butylaniline, $C_6H_5N(CH_3)(n\text{-}C_4H_9)$. The boiling point agrees with that reported by Komatsu, J.

Coll. *Sci.* Imperial University *of* Tokio, **3,** 371 (1912), *C. A.*, 7, 1021 (1913), but not with that reported by Frohlich and Wedekind, Ber., 40, 1648 (1907). Accordingly, the picrate was prepared and found to melt at 93° and not at 141–142°, as reported by Komatsu. There is a possibility of a typographical error in Komatsu's work, because among the large number of picrates reported by him is a related one melting at 93–94°, namely, methyl-iso-amylaniline.

p-Toluenesulfonic Ester of Ethyl Lactate and Phenylmagnesium Bromide.—From 12 g. or 0.04 mole of the ester and 0.05 mole of phenylmagnesium bromide, there was obtained 4 g. or a 55% yield of ethyl a-bromopropionate. Its identity was confirmed by the preparation of the ammonium salt prepared from m-nitraniline according to the method of Bischoff.[14] A mixed melting point determination was then made with an authentic specimen and the observed melting point was 247–248°.

Because of the small size of the experiment none of the expected ethyl α-phenylpropionate was isolated. Probably some of the phenyl ester, if formed, reacted with the excess of Grignard reagent to give some of the corresponding ketone or ester. These products are to be sought in a larger run, for they should be present if Reactions 3 and 4 are correct and if the lactyl ester is not an exceptional compound.

Ethyl Cyclohexylsulfonate and Phenylmagnesium Bromide.—From 35 g. or 0.18 mole of ester and a slight excess (color reaction) of phenylmagnesium bromide, there were obtained 3.5 *g.* of ethylbenzene, some ethyl bromide (characterized as ethylmercuribromide) and 1 g. of a compound melting at 107°. It was thought that this solid was cyclohexylphenyl sulfone. However, this could not be confirmed because when experiments were carried out to synthesize such a sulfone by standard procedures, the melting point of the synthetic compound was 73°. This latter compound was prepared by the oxidation of the sulfide obtained from sodium thiophenate and bromocyclohexane. The properties of the cyclohexylphenyl sulfide are: b. p. 145° (11 mm.); $d^{20}_{20} = 1.0031$; $n_{25} = 1.5663$. The magnesium cyclohexylsulfonate was analyzed.

Anal. Calcd. for $(C_6H_{11}SO_3)_2Mg\cdot6H_2O$: H_2O, 24.88. Found: 24.28, 24.25. Calcd. for $(C_6H_{11}SO_3)_2Mg$: Mg, 7.45. Found: 7.34, 7.45.

This experiment with ethyl cyclohexylsulfouate shows that alkyl alicyclic sulfonates alkylate after the manner of alkyl arylsulfonates according to Reaction 1.

n-Butyl *p*-Toluenesulfonate and Ethylmagnesium Bromide with Water.—By means of the color test[11] it was shown that 0.1–0.12 mole of water in ether was required to destroy 0.1 mole of ethylmagnesium bromide. To this mixture, which may be magnesium bromide and magnesium hydroxide and not basic magnesium bromide,[8b] there was added 23 g. or 0.1 mole of n-butyl p-toluenesulfonate. After refluxing for two hours and then working up in the customary manner, there were obtained 2 g. or 14% of n-butyl bromide and 18 g. or 40% of magnesium p-toluenesulfonate.

n-Butyl p-Toluenesulfonate and Bromomagnesium *p*-Tolylsulfinate (p-$CH_3C_6H_4S(=O)OMgBr$).—The bromomagnesium sulfinate was prepared by the addition of sulfur dioxide to a 0.4 mole solution of p-tolylmagnesium bromide until there was no color reaction.[11] After reaction with 92.4 g. or 0.4 mole of n-butyl *p*-toluenesulfonate, there were obtained 32 g. or 58% of n-butyl bromide and 80 g. of a mixture of the magnesium salts of *p*-toluenesulfinic and *p*-toluenesulfonic acids. From another run, 7 g. of *p*-toluenesulfinic acid was obtained.

n-Butyl p-Toluenesulfonate and Iodomagnesium β-Naphthalenesulfonate, β-$C_{10}H_7SO_2OMgI$.—The anhydrous β-naphthalenesulfonic acid was prepared according to the directions of Kraft and Roos[15] and was chesked by a melting point determination

---

[14] Bischoff, Ber., 30, 2766 (1897).

[15] Kraft and Roos, Ber., 26, 2823 (1893).

in vacuo[16] and a neutralization equivalent. Sufficient anhydrous acid was used to react with 0.2 mole of methylmagnesium iodide until no color test was obtained. From the iodomagnesium sulfonate obtained in this manner and 46 g. or 0.2 mole of n-butyl *p*-toluenesulfonate, there was obtained 12 g. or 33% of *n*-butyl iodide.

A part of the magnesium β-naphthalenesulfonate, which incidentally is less soluble in water than magnesium p-toluenesulfonate, was analyzed after drying to constant weight at 110°.

Anal. Calcd. for $(\beta\text{-}C_{10}H_7SO_3)_2Mg$: Mg, 5.99. Found: 6.09.

Phenyl *p*-**Toluenesulfonate** and Magnesium Bromide.—An ether–toluene solution containing 50 g. or 0.2 mole of phenyl p-toluenesulfonate and 0.25 mole of magnesium bromide etherate was refluxed for two hours at 100°. After hydrolysis, an ether extract of the steam distillate gave no test for halogen and there was no indication of the formation of magnesium p-toluenesulfonate. This experiment illustrates a difference between aryl and alkyl sulfonates (see Reactions 1 and 2).

Summary

Alkylation is not the only reaction that takes place when alkyl sulfonates are treated with organomagnesium halides. Alkyl halides are also formed. The reactions proposed to account for these products have a direct bearing on the formula for the Grignard reagent proposed some time ago by Jolibois.

NEW CONDENSATIONS OF KETONES WITH PHENOLS. THE PHORONE DI-META-CRESYL ETHER

BY JOSEPH B. NIEDERL

RECEIVED MARCH 28, 1928 PUBLISHED AUGUST 4, 1928

Introduction

The importance of the condensations occurring between aldehydes and phenols gave the impulse to a number of investigations of the behavior of ketones toward phenols under the influence of dehydrating agents.

Previously the following four types of condensations of ketones with phenols had been established: (1) the formation of diphenylmethane derivatives,[1,2] (2) the formation of ketals,[2,3,4] (3) the formation of molecular addition compounds and (4) the formation of oxygen heterocyclics.[5]

It has now been found that diaryl derivatives of di-iso-butyl ketone

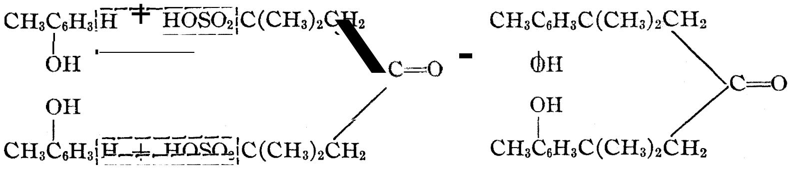
result on treatment of phenols with acteone in the presence of concentrated sulfuric acid.

The discussion of this condensation is the purpose of the present communication.

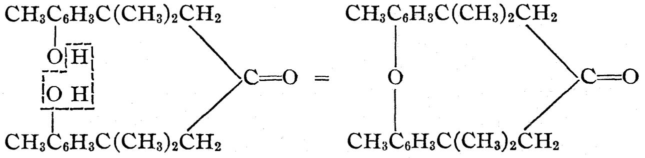
Discussion

The first condensation product of this type, phorone di *m*-cresyl ether, was obtained by the author[6] by treating a mixture of m-cresol and acetone with concentrated sulfuric acid.

It apparently formed in four steps: (1) the formation of phorone from 3 molecules of acetone, with mesityl oxide as intermediate;[7,8] (2) the addition of 2 molecules of sulfuric acid, forming phorone di-sulfuric acid, analogous to the addition of halogen acids, which has already been observed;[9] (3) the re-elimination of 2 molecules of sulfuric acid and subsequent addition of 2 molecules of *m*-cresol.



(4) ether formation, yielding the final reaction product, the phorone di-m-cresyl ether.



$C_{23}H_{28}O_2$: Mol. wt., 336

The assigned structure is in harmony with the fact that the same product was also obtained when phorone was treated with 2 moles of m-cresol in the presence of concentrated sulfuric acid under the same reaction conditions.

Derivative.—The phorone di-m-cresyl ether very readily forms a bromine derivative, the phorone di-bromo-m-cresyl ether; it is also easily nitrated, whereby the phorone di-(di-nitro)-m-cresyl ether results.

Oxidation Products.—In order to substantiate more fully the assigned structure of the compound, its oxidation products were studied. On oxidation with chromic acid two simpler products were isolated. One of them was shown to be dimethyl malonic acid; the other appears to

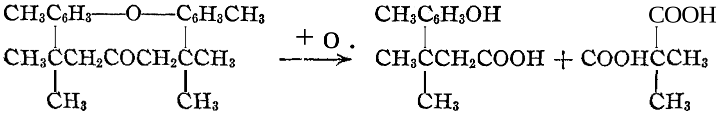
[6] Niederl, *Inaugural Dissertation*, University of Graz, Austria, April, 1925.

[7] Claisen, *Ann.*, **180,** 22 (1875).

[8] Orndorff and Young, THIS JOURNAL, 15,255 (1893).

[9] Vorlander and Hayakawa, *Ber.*, 36, 3536 (1903).

be m-cresyl isovaleric acid. Their formation may be represented as follows.



$$\begin{array}{c} \mathrm{CH_3C_6H_3{-}O{-}C_6H_3CH_3} \\ |\qquad\qquad | \\ \mathrm{CH_3CCH_2COCH_2CCH_3} \\ |\qquad\qquad | \\ \mathrm{CH_3}\qquad\quad \mathrm{CH_3} \end{array} \xrightarrow{+\,\mathrm{O}} \begin{array}{c} \mathrm{CH_3C_6H_3OH} \\ | \\ \mathrm{CH_3CCH_2COOH} \\ | \\ \mathrm{CH_3} \end{array} + \begin{array}{c} \mathrm{COOH} \\ | \\ \mathrm{COOHCCH_3} \\ | \\ \mathrm{CH_3} \end{array}$$

Dimethyl malonic acid is one of the oxidation products of phoronic acid;[10] its formation in the present case indicates that the compound under discussion is also a derivative of phorone.

Of the m-cresyl isovaleric acid, its di-bromo and mono-nitro derivative and di-sodium salt could be isolated and identified.

Experimental Part

Phorone Di-m-cresyl Ether, **2,6-Dimethyl-2,6-di-(4-oxy-2-methyl)-phenyl heptanone-(4) Ether, Di-(*m*-tolyl)-*iso*-butyl** Ketone Ether, $C_{23}H_{28}O_2$.—For the preparation of this compound use was made at first of Baeyer's[11] aldehyde condensation process. Later the following procedure was adopted as being most effective.

Three moles of concentrated sulfuric acid was added to an ice-cold mixture of three moles of acetone and two moles of m-cresol, keeping the temperature at 0°.

This reaction mixture was allowed to stand at room temperature for forty-eight hours, precautions being taken to exclude all moisture, and was then heated on a water-bath for one hour.

On cooling a solid red mass was obtained. This was washed successively with cold and hot water, to remove the sulfuric acid, the m-cresol sulfonic acid-(4) and the m-cresol di-sulfonic acid, which formed in the reaction as by-products.

The remaining tar was then treated with hot potassium or sodium hydroxide in order to extract any unchanged m-cresol and again with water until free of alkali.

The tar was then dissolved in hot ethyl alcohol and on cooling the phorone di-*m*-cresyl ether crystallized out.

The tar, as obtained after purification with water and alkali, yielded on distillation a fraction boiling between 270 and 300°, from which the ether could be obtained on dilution with ethyl alcohol.

The treatment of either acetone or m-cresol separately with concentrated sulfuric acid under identical conditions yielded no new products.

However, when 1 mole of phorone was mixed with two moles of m-cresol and then subjected to the action of concentrated sulfuric acid, as before, the phorone di-m-cresyl ether also formed. The yields obtained by this method were as high as 80% of the theoretical, while in the previous experiment only about 15% could be isolated.

Phorone di-m-cresyl ether crystallizes in various forms, depending on the conditions and the solvents. Usually it is obtained in cubes, 2 to 3 mm. in diameter; on slow crystallization it forms prismatic aggregates or large hexagonal crystals; m. p. 127° (uncorr.); b. p. 270° (uncorr.) with partial decomposition.

It is insoluble in hot and cold water, dilute and concentrated alkalies and dilute acids. It is sparingly soluble in cold ethyl alcohol but dissolves easily on warming;

---

[10] Pinner, Ber., 14, 1072, 1077 (1881); *Ber.*, 15,585 (1882).

[11] Baeyer, Ber., 5,280, 1095 (1872).

it dissolves in hot concentrated sulfuric and nitric acids and is very soluble in ether, chloroform, carbon tetrachloride and glacial acetic acid.

Anal. Calcd. for $C_{23}H_{28}O_2$: C, **82.14**; H, 8.33. Found: **C, 81.92, 82.04;** H, **8.26,** 8.29.

Mol. **wt.** Calcd.: **336.** Found (cryoscopic method): **325, 329;** found (ebullioscopic method): 318, 322.

Qualitative tests show that the compound is saturated and that the two oxygen atoms in this compound are neither hydroxylic nor carboxylic in nature.

Dibromo Derivative, $C_{23}H_{26}O_2Br_2$.—Phorone di-m-cresyl ether was dissolved in carbon tetrachloride, an excess of bromine in carbon tetrachloride added and the mixture left standing in the dark at room temperature for twenty-four hours.

After this time the evolution of hydrogen bromide had completely ceased. The carbon tetrachloride was then distilled off, the residue dissolved in boiling glacial acetic acid and allowed to crystaliize.

It crystallizes in large, colorless, prismatic rosets. It melts at 215° (uncorr.). It is insoluble in cold and hot water, cold and hot mineral acids and alkalies. It dissolves slightly in boiling alcohol and is freely soluble in ether, chloroform and carbon tetrachloride. It dissolves also in boiling glacial acetic acid and concentrated sulfuric acid.

Anal. Calcd. for $C_{23}H_{26}O_2Br_2$: C, **55.86;** H, **5.26;** Br, **32.39.** Found: C, **55.61;** H, **5.59;** Br, **32.51.**

Tetranitro Derivative, $C_{23}H_{24}O_{10}N_4$.—By treating the phorone di-m-cresyl ether with boiling concentrated nitric acid and diluting the resulting solution with cold water, a yellow, crystalline solid separated out. This substance was freed from adhering oxidation products formed simultaneously by repeated washings with alkalies and recrystallization from ethyl alcohol. Yellow crystals were obtained which melt at **243"** (uncorr.).

The product is insoluble in cold and hot water and alkalies, but dissolves in ethyl alcohol, ether, chloroform, carbon tetrachloride and glacial acetic acid.

Anal. Calcd. for $C_{23}H_{24}O_{10}N_4$: C, **53.49;** H, **4.65;** N, **10.85.** Found: C, **53.48;** H, **4.44;** N, **10.87.**

Oxidation Products

m-Cresyl Isovaleric Acid, $HO(CH_3)C_6H_3C(CH_3)_2CH_2COOH$.—The phorone di-m-cresyl ether was dissolved in hot glacial acetic acid and to this mixture an equal amount of chromic acid anhydride, dissolved in the same solvent, was added in small portions.

The mixture was refluxed for six hours and the solution then poured into cold water. A white precipitate consisting chiefly of the m-cresyl isovaleric acid separated. It was repeatedly dissolved in alkalies and reprecipitated with mineral acids. Finally it was crystallized from acetone.

It melts at 107° (uncorr.). It is soluble in alkalies, forming dark red solutions, and in organic solvents such as acetone, ethyl alcohol, ether, chloroform, carbon tetrachloride, etc.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, **69.23;** H, 7.69. Found: **C, 68.94, 69.70;** H, **7.24, 7.73.**

Dibromo-*m*-cresyl Isovaleric Acid, $C_{12}H_{14}O_3Br_2$.—This substance was prepared by treating the solution of the m-cresyl isovaleric acid in glacial acetic acid with bromine water. The di-bromo-m-cresylisovaleric acid precipitated out immediately.

It was purified by repeated precipitation from its solution in aqueous alkali (potassium or sodium hydroxide) and finally crystallized from ethyl alcohol; m. p. 140° (uncorr.).

Anal. Calcd. for $C_{12}H_{14}O_3Br_2$: C, 39.30; H, 3.82. Found: C, 39.67; H, 3.65.

Nitro-m-cresyl **Isovaleric** Acid, $HO(CH_3)C_6H_2(NO_2)C(CH_3)_2CH_2COOH$.—This acid was obtained as the oxidation by-product in the nitration of the phorone di-m-cresyl ether.

When the solution of the nitration and oxidation products in concentrated nitric acid was diluted with water, both the phorone di-(dinitro) m-cresyl ether and the nitro-m-cresyl isovaleric acid separated out. Subsequent treatment with aqueous alkalies dissolved the acid, which could be precipitated again easily from the colored alkaline solutions by mineral acids. It was finally crystallized from benzene; m. p. 108° (uncorr.). It is insoluble in water and dilute mineral acids but dissolves readily in alkalies and organic solvents.

Anal. Calcd. for $C_{12}H_{15}NO_5$: C, 56.92; H, 5.93; N, 5.53. Found: C, 57.13; H, 6.10; N, 5.44.

Its disodium salt could be obtained by neutralizing an alcoholic solution of the acid with sodium alcoholate. On standing a finely divided precipitate formed. It was isolated and finally crystallized from dilute methyl alcohol.

Anal. Calcd. for $C_{12}H_{13}O_5NNa_2$: Na, 15.48. Found: Na, 15.50, 15.35.

Dimethyl Malonic Acid.—This acid was obtained together with the m-cresyl isovaleric acid.

When the aqueous filtrate obtained after the removal of the m-cresyl isovaleric acid was treated with lead acetate, a heavy, white precipitate formed, which proved to be the insoluble lead salt of dimethyl malonic acid. It was purified by repeated precipitations and washings with water, alcohol and ether.

Anal. Calcd. for $C_5H_6O_4Pb$: C, 17.77; H, 1.78; Pb, 61.42. Found: C, 17.57; H, 1.51; Pb, 61.26, 61.32.

This lead salt was decomposed with hydrogen sulfide and the lead-free filtrate on evaporation left a residue which, when purified, corresponded for the tests (m. p., solubility) of dimethyl malonic acid as recorded in the literature.

All the quantitative determinations were carried out micro-analytically according to Pregl[12] and the author desires here to thank Miss Edith P. Silbert for her assistance in carrying out these analyses.

The author wishes to acknowledge here his appreciation for laboratory facilities placed at his disposal and repeated courtesies extended by Professors John A. Mandel of the University and Bellevue Hospital Medical College and William C. MacTavish of the Washington Square College, New York University.

Summary

(1) New condensations of ketones with phenols were investigated, resulting in the formation of aryl substituted ketones, the phorone di-*m*-cresyl ether being the first one isolated; (2) the mechanism of their formation is explained, and *(3)* the proof for their structure is given.

Further investigations of the condensation possibilities of phorone and

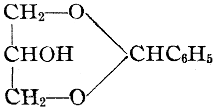
STUDIES ON THE REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES.

XV. THE ISOMERIC BENZYLIDENE GLYCEROLS

BY HAROLD S. HILL,[1] MYRON S. WHELEN[2] AND HAROLD HIBBERT[2a]

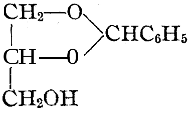
RECEIVED APRIL 14, 1928 PUBLISHED AUGUST 4, 1928

Fischer[3] was the first to describe a definite condensation product from the interaction of glycerol with benzaldehyde and the molecular structure of the cyclic acetal formed was represented as being



I

or



II

The same reaction product was more thoroughly investigated by Irvine, Macdonald and Soutar[4] with a view to determining its structure, and by methods of direct synthesis the material in hand was shown to possess the five membered cyclic configuration (II). While these authors pointed out the possibility of the existence of the isomeric form (I), they were unable to detect its presence in their product. It is because of this fact, together with the generally accepted finished character of their research, that their results have been interpreted as indicating the absence of the six membered benzylidene derivative, and the conclusion that the condensation of benzaldehyde with a poly-alcohol takes place only through *adjacent* hydroxyl groups.

This is especially true since the formula for monobenzylidene a-methyl glucoside was given earlier as containing a five membered acetal ring[5] (A),

B

a conclusion based partly on the assumption of α-methyl glucoside containing the five membered butylene oxide structure. More recent investigations,[6] however, have brought forth considerable evidence that the transformations of α-methyl glucoside are best explained on the basis of the six membered oxidic form. If the latter view be correct, then formula (A) for the benzylidene derivative becomes less probable than that of a six membered acetal ring (B). The question of the possibility of the formation of the latter grouping is, therefore, of interest.

In view of the great ease of formation of both five and six membered cyclic acetals in general, as shown by various partition experiments carried out by Hibbert and co-workers,[7] it was concluded by these authors that benzylidene glycerol should exist not only in both isomeric forms, but also that in the condensation of benzaldehyde with glycerol a "partition" should take place to give a reaction product consisting of a mixture of a five and six membered cyclic benzylidene glycerol, (I) and (II). The present investigation shows this to be the case and deals with the actual separation and identification of the isomers. The assumption that benzaldehyde condensations involve only adjacent hydroxyl groups is, therefore, unjustified.

Separation of the Isomeric Benzylidene Glycerols.—Glycerol was condensed with benzaldehyde essentially as described by Gerhardt[8] and a product obtained, b. p. 142–147° (2.5 mm.), which proved to be a mixture of the two benzylidene glycerols. A fortunate difference in solubility of the isomers in a mixture of cold ligroin and benzene permitted a fairly quantitative separation, the 1,3-benzylidene glycerol crystallizing out and leaving the 1,2-derivative in solution. The former product melts sharply at 83.5°.

Distillation and fractionation of the mother liquor yields 1,2-benzylidene glycerol as an oil, b. p. 143–144° (2 mm.) which presumably still holds a small amount of the 1,3-isomer in solution.

The benzoate of the crystalline isomer, prepared by means of benzoyl chloride in dry pyridine solution, is a well crystallized product, m. p. 103°, whereas that from the liquid 1,2-benzylidene glycerol is an oil.

It is of interest to compare the above results with those obtained by Irvine and co-workers, who also followed Gerhardt's patent in their prepa-

---

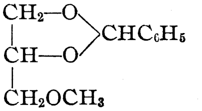
[6] A review of the subject by W. N. Haworth is to be found in Chem. *Soc.* Annual Reports, 1926, pp. 74–92.

[7] Hill and Hibbert, THIS JOURNAL, 45, 3117 (1923).

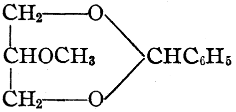
[8] Gerhardt, German patent 255,083 (1913).

ration of benzylidene glycerol. They obtained only one product, a benzylidene glycerol whose melting point was originally 65°, but which rose on standing to 76° and which was proved beyond question to be the 1,2-derivative. In the present investigation it is shown that the crystalline benzylidene glycerol, m. p. 83.5°, is a pure 1,3-isomer and that the liquid product is a mixture of a small amount of this with the 1,2-derivative as the main product. The liquid isomer would not crystallize even on long cooling either alone or from solvents. This difference from Irvine's 1,2-benzylidene glycerol may be due to the fact that although it has the same ring system, it represents the alternate *cis* or *trans* geometric isomer. On the other hand, the small amount of the 1,3-derivative present may prevent crystallization.

Determination of Structure.—For the identification of the isomeric benzylidene glycerols the methylation–hydrolysis method of Irvine and co-workers was followed. The use of dimethyl sulfate and sodium hydroxide as a methylating agent[9] proved to be unsuitable, owing to extensive hydrolysis of the acetal group. Methylating with silver oxide and methyl iodide, however, gave satisfactory yields of the corresponding benzylidene glycerol methyl ethers



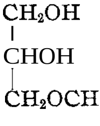
III



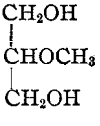
IV

the crystalline benzylidene glycerol, m. p. 83.5°, giving exclusively the new six membered acetal ether (IV) as a crystalline product, whereas the liquid isomer yielded an oil identical with Irvine's benzylidene glycerol methyl ether which was shown by him to have the five membered cyclic structure (III).

Hydrolysis of the latter product gave glycerol a-methyl ether (V), identical with that described by Irvine. Hydrolysis of the isomeric benzylidene glycerol ether (IV) yielded a new glycerol monomethyl ether, VI, quite different from the a-derivative and which must, therefore, be glycerol β-methyl ether,



$$\begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OCH_3 \end{array} \quad V$$



$$\begin{array}{l} CH_2OH \\ | \\ CHOCH_3 \\ | \\ CH_2OH \end{array} \quad VI$$

It is now possible to assign definitely to the crystalline benzylidene glycerol, m. p. 83.5°, the six membered cyclic acetal structure (I) and to the liquid isomer the alternate formula (II). It should be noted that while the liquid benzylidene glycerol, by the above methylation–hydrolysis method,

---

[9] Haworth, *J. Chem. Soc.*, **107**, 8 **(1915)**.

yielded for the most part glycerol a-methyl ether, it also gave a small amount of the β-ether, showing that the liquid acetal still holds some of its isomer in solution.

Glycerol β-methyl ether, as isolated above, marks the first definite β-derivative of glycerol to be recorded in the literature, and for this reason it should prove to be a reference compound of some importance. Its physical constants in comparison with glycerol a-methyl ether are given in the following table.

TABLE I

PHYSICAL PROPERTIES OF ETHERS

Glycerol a-methyl ether (Irvine)	Glycerol a-methyl ether (The authors)	Glycerol β-methyl ether (The authors)
B. p., 110–111° (13 mm.)	**B. p., 110–111° (13 mm.)**	**B. p., 123° (13 mm.)**
$d_{4°}^{17°}$ = **1.1197**	$d_{4}^{17°}$ = **1.1202**	$d_{4}^{17°}$ **1.1306**
$n_{D}^{17°}$ = **1.4460**	$n_{D}^{17°}$ = **1.4449**	$n_{D}^{17°}$ **1.4505**

Partition and Interconversion of the Isomeric Benzylidene Glycerols.—Taking advantage of the fact that the crystalline 1,3-benzylidene glycerol is practically insoluble in a strongly cooled mixture of ligroin and benzene, while the other isomer remains in solution, it is possible by carefully controlled conditions to determine the relative amounts of the isomers present in the primary reaction product. In the material isolated by the use of Gerhardt's method, it was found that the five membered cyclic form (II) exceeds that of the six membered (I) in the ratio of 7.5 to 1. On the other hand, if the preparation of benzylidene glycerol was carried out by a different method, namely, by heating glycerol and benzaldehyde with a small amount of 40% sulfuric acid, a mixture was obtained in which the same isomers were present in a ratio of 3 to 1.

Obviously the "partition" varies somewhat with the conditions used in the preparation, and it is even possible that in some cases the above ratio might be reversed. The fact remains, however, that both isomers are always formed and that in all cases investigated the smaller ring structure predominates.

In this connection it seemed desirable to ascertain whether the "partition" was the result of chance formation of varying amounts of the isomers, or whether it represented a state of equilibrium between the two forms. If the latter interpretation be correct, then, as shown previously in other cases, either isomer, when treated with a trace of acid, should be transformed into the other until an equilibrium mixture results, and for a given set of conditions the same ratio of products should be obtained, regardless of which isomer is used, and this is found to be the case. When 1,3-benzylidene glycerol is treated with a trace of dry hydrogen chloride and heated at 100° for one hour, a mixture is obtained in which the ratio of the five membered cyclic acetal to the six is 5:1. Starting with 1,2-benzylidene glycerol, the ratio of these isomers found in the equilibrium product is 5.5:1.

This transformation is rapid and takes place even under very mild conditions. Thus crystalline 1,3-benzylidene glycerol treated with a trace of dry hydrogen chloride and warmed to 30° liquefies immediately as a result of its partial conversion into the 1,2-isomer.

On the other hand, 1,2-benzylidene glycerol, when allowed to stand for one month at room temperature with a trace of dry hydrogen chloride, reaches approximately the same equilibrium with its 1,3-isomer as when heated to 100°, the ratio being 5.7 to 1.

These interconversion experiments are to be considered as being more of a qualitative than an exact quantitative nature, since it is admittedly impossible to separate all of the crystalline isomer from the liquid. The possibility of cis-trans interconversions in the same ring system must also be considered as a complicating factor.

These results are significant, however, since they bring out the labile character of these carbon-oxygen cyclic structures, many closely related examples of which exist in various sugar and polysaccharide derivatives. The marked ease of transformation of one form into the other emphasizes the need for great caution in assigning a definite structure to an original compound on the basis of the structure of one of its derivatives, especially if the latter has been prepared under conditions involving an acid medium as, for example, in the case of the two different cellobiosans obtained by Bergmann and Knehe, *Ann.*, 448, 76 (1926), and Hess and Friese, Ann., **450,** 40 (1926); **456,** 38 (1927), respectively.

It is believed that the formation of isomeric glycerol methyl ethers by the methylation–hydrolysis method, as applied to the corresponding ethylidene glycerols, lends considerable support to the claims of Irvine and coworkers regarding their method of methylation technique based on Purdie's original observations.

Their procedure of complete methylation, subsequent hydrolysis and identification of the resulting methylated sugars is taken as indicating the positions of the free hydroxyls and of the point of union in the original polysaccharide. In such reasoning there is always the possibility that a rearrangement in the oxide ring of the sugar residues may take place under the conditions of methylation. The present investigation with the simpler glycerol derivatives shows that under these same conditions the relatively sensitive five and six membered acetal rings involved undergo no change, one into the other, and that the methylated products obtained are an authentic proof of the constitution of the parent substances.

Experimental Part

Preparation and Separation of Isomeric Benzylidene Glycerols.—One hundred fifty g. of pure benzaldehyde and 120 g. of glycerol were heated in an atmosphere of carbon dioxide with stirring for one hour at 145–155°, and then for thirty minutes at 165°. The product upon fractionation under reduced pressure yielded 170 g. of a crude mixture,

b. p. 140–149° (3 mm.). This was taken up in ether, washed several times with water to remove traces of glycerol, dried over solid potassium carbonate and refractionated; yield, 120 g. of mixed benzylidene glycerols, b. p. 142–147° (2.5 mm.); $d^{17°}_{4°}$, 1.19838; n_D, 1.5400.

Anal. Subs., 0.2244: CO_2, 0.5464; H_2O, 0.1340. Calcd. for $C_{10}H_{12}O_3$: C, 66.67; H, 6.67. Found: C, 66.41; H, 6.66.

Sixty g. of mixed benzylidene glycerols from the above preparation was dissolved in a mixture of 150 cc. of ligroin (b. p. 60–70°) and 90 cc. of benzene and cooled to −15° until crystallization had taken place. Enough benzene was slowly added, with shaking, until there was no longer undissolved oil present with the precipitated crystals. After standing at −15° for one hour, the crystals were filtered from the cold solution and washed with 40 cc. of a cold mixture of equal parts of ligroin and benzene; yield, 7 g. Recrystallization from ligroin-benzene mixture with practically no loss gave pure 1,3-benzylidene glycerol, m. p. 83.5°.

Anal. Subs., 0.2020: CO_2, 0.4947; H_2O, 0.1182. Calcd. for $C_{10}H_{12}O_3$: C, 66.67; H, 6.67. Found: C, 66.79; H, 6.50.

Benzylidene glycerol was also prepared using sulfuric acid as a catalyst.

Method.—One hundred fifty-nine g. of benzaldehyde, 150 g. of glycerol and 2 cc. of 40% sulfuric acid were heated on a steam-bath for eight hours in an atmosphere of carbon dioxide. The product was taken up in ether, neutralized with potassium carbonate and dried over this reagent. Fractionation yielded 105 g. of mixed benzylidene glycerols, b. p. 163–168° (11 mm.).

Fifty g. of this mixture, separated as described above, gave 13 g. of crystalline 1,3-benzylidene glycerol, m. p. 83°. In another experiment 28 g. of the mixture yielded 7 g. of 1,3-benzylidene glycerol.

1,2-Benzylidene Glycerol.—The ligroin–benzene mother liquor from the above separation of 1,3-benzylidene glycerol was evaporated under reduced pressure, taken up in ether, washed with concentrated potassium carbonate solution to remove traces of acid and dried over the solid carbonate. Fractionation gave pure 1,2-benzylidene glycerol, b. p., 143–144° (2 mm.); $d^{17°}_{4°}$, 1.1916; n_D, 1.5389. This product showed no tendency to crystallize.

Anal. Subs., 0.2170: CO_2, 0.5295; H_2O, 0.1301. Calcd. for $C_{10}H_{12}O_3$: C, 66.67; H, 6.67. Found: C, 66.55; H, 6.66.

Benzoates of Benzylidene Glycerol.—The respective benzylidene glycerols were benzoylated by dissolving each of them at room temperature in four times the weight of dry pyridine containing the theoretical amount of benzoyl chloride and allowing the reaction, with development of heat, to proceed spontaneously for about twenty minutes. On pouring into water, the product from 1,3-benzylidene glycerol crystallized at once, while that from 1,2-benzylidene glycerol remained as an oil. The benzoate of 1,3-benzylidene glycerol was recrystallized from ligroin, m. p. 103°.

Analysis of the Benzoate from **1:2-Benzylidene** Glycerol.—Subs. 0.2153: CO_2, 0.5674; H_2O, 0.1103. Calcd. for $C_{17}H_{16}O_4$: C, 71.83; H, 5.63. Found: C, 71.87; H, 5.69.

Methylation of **1,3-Benzylidene** Glycerol.—Fifty-four g. of crystalline 1,3-benzylidene glycerol was recrystallized from ligroin–benzene solution (1:1), pressed as dry as possible on a suction filter and methylated immediately in the usual manner, using 115 g. of silver oxide and 230 g. of methyl iodide. The reaction mixture was thoroughly extracted with ether from which, on partial evaporation and cooling, benzylidene glycerol methyl ether separated. Recrystallization from mixture of ligroin–benzene (1:1) yielded 31 g. of long, coarse, transparent needles, m. p. 52°. No other substance could be isolated from the reaction product.

Anal. Subs., 0,1446: CO_2, 0.3570; H_2O, 0.0878. Calcd. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.22. Found: C, 67.38; H, 6.79.

Hydrolysis of Benzylidene Glycerol &Methyl Ether.—Twenty-seven g. of benzylidene glycerol β-methyl ether (m. p. 52°) was hydrolyzed by boiling under reflux for seventy minutes with 220 cc. of 75% aqueous ethyl alcohol containing 3 cc. of concd. hydrochloric acid; 65 cc. of water was added and the alcohol removed under reduced pressure. Three or four extractions with ether removed benzaldehyde. The aqueous solution was neutralized by shaking with lead carbonate, filtered, concentrated and fractionated under diminished pressure. Redistillation yielded 9 8 g. (64%) of pure @-methyl glycerol ether, b. p. 123° (13 mm.); $d^{17°}_{4°} = 1.1300$; $n^{17°}_{D} = 1.4505$.

Anal. Subs., 0.1419: CO_2, 0.2350; H_2O, 0.1176. Calcd. for $C_4H_{10}O_3$: C, 45.28; H, 9.27. Found: C, 45.17; H, 927.

Methylation of **1,2-Benzylidene Glycerol.**—Seventy-five g. of the liquid 1,2-benzylidene glycerol was methylated in the usual manner with 145 g. of freshly prepared silver oxide and 290 g. of methyl iodide. Extraction of the reaction mixture with ether and fractionating gave 50 g. of a mixture, b. p. 139–145° (10 mm.).

Fraction I	28 g.	b. p. 138–139° (10 mm.)	$n^{17°}_{D} = 1.5128$
Fraction II	12 g.	b. p. 139–141° (10 mm.)	$n^{17°}_{D} = 1.5135$
Fraction III	8 g.	b. p. 141–145° (10 mm.)	$n^{17°}_{D} = 1.5159$

Analysis of the lower and higher fractions showed both to be benzylidene glycerol methyl ether.

Anal. Fraction *I*. Subs., 0.2281: CO_2, 0.5678; H_2O, 0.1472. Calcd. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.22. Found: C, 67.89; H, 7.17.

Anal. Fraction III. Subs., 0.2180: CO_2, 0.5127; H_2O, 0.1408. Calcd. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.22. Found: 67.92; 7.19.

Hydrolysis of Benzylidene Glycerol a-Methyl Ether.--Twenty-eight g. of benzylidene glycerol a-methyl ether (fraction (I) above), hydrolyzed in the same manner as the @-derivative yielded 13.4 g. (87%) of glycerol a-methyl ether, b. p. 110° (13 mm.), $d^{17°}_{4°} = 1.1202$; $n^{17}_{D} = 1.4449$.

Anal. Subs., 0.2073: CO_2, 0.3424; H_2O, 0.1747. Calcd. for $C_4H_{10}O_3$: C, 45.28; H, 9.43. Found: C, 45.05; H, 9.36.

Hydrolysis of the higher boiling fractions from the preparation of 1,2-benzylidene glycerol or-methyl ether gave for the most part glycerol a-methyl ether, b. p. 112° (13 mm.), $n^{17°}_{D} = 1.4446$, but also a smaller fraction, b. p. 112–118°, indicating the presence of a small amount of the higher boiling β-methyl glycerol ether.

Interconversion of the Benzylidene **Glycerols.**—Several bubbles of dry hydrogen chloride were passed into 3 g. of 1,2-benzylidene glycerol contained in a tube so small that there was very little free air space when stoppered. This was heated for one hour at 100°, allowed to stand at room temperature for twelve hours and taken up with 10 cc. of ether. The solution was shaken with 0.5 g. of solid potassium carbonate to neutralize the acid, filtered and evaporated under reduced pressure. The residue was taken up with 15 cc. of a 50% mixture of ligroin (b. p. 60–70") and benzene and cooled to −15° for one hour. The crystals of 1,3-benzylidene glycerol which separated were filtered from the cold solution, washed with 10 cc. of the cold ligroin-benzene mixture and dried in a vacuum; yield, 0.5 g. (m. p. 81°). It was recrystallized with practically no loss and then melted at 83.5°.

Three g. of 1,3-benzylidene glycerol, when subjected to an as nearly as possible parallel treatment, as above, yielded 0.46 g. of unchanged 1,3-benzylidene glycerol, m. p. 80–82°.

An experiment carried out with 3 g. of 1,2-benzylidene glycerol, similarly treated with dry hydrogen chloride but without any preliminary heating and allowed to stand for one month at room temperature, yielded 0.45 g. of 1,3-benzylidene glycerol.

Summary

1. The preparation, isolation, quantitative separation and interconversion of the isomeric 1,2- and 1,3-benzylidene glycerols are described.

2. The corresponding methyl ethers have been prepared and their physical constants determined.

3. The remarkably labile character of the oxygen ring is shown by the ease of partial transformation of either of the acetals into the corresponding isomer at a low temperature under the influence of traces of gaseous hydrochloric acid. The bearing of this on polysaccharide investigations is pointed out.

4. Glycerol 8-methyl ether has been isolated for the first time in a pure state. It is apparently the first pure 8-derivative of glycerol to be reported in the literature.

XVI. SEPARATION AND IDENTIFICATION OF THE ISOMERIC ETHYLIDENE GLYCEROLS[1]

BY HAROLD S. HILL,[2] ALLAN C. HILL[3] AND HAROLD HIBBERT[4]

RBCEIVED APRIL 14, 1928 PUBLISHED AUGUST 4, 1928

The importance of the cyclic acetal and ketal glycerols has long attracted the interest of investigators in the field of carbohydrate chemistry. Such workers as Tollens,[5] Fischer,[6] Karrer,[7] Irvine,[8] and more recently

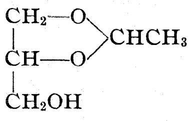
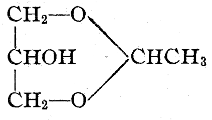
Hibbert and his pupils[8] have studied or used this class of compounds in their efforts to explain, by analogy, certain features of the chemical behavior of the more complex polysaccharides. It is remarkable, therefore, that up to the present time the molecular structure of one of the simplest glycerol acetals, namely, ethylidene glycerol, has remained undetermined, its formula being given as either, or both, of the two possible isomeric forms



(A)

or



(B)

Schulz and Tollens,[5] working with the lower homolog, methylidene glycerol, indicated the existence of both of the corresponding isomeric forms since, under different experimental conditions, they were able to obtain products which, in one case, yielded a benzoate as *a* crystalline product, in the other as an oil. The isomers were not identified, however, and the method used in their preparation left some doubt as to their existence as different chemical individuals.[9a]

With respect to the structure of ethylidene glycerol, however, there has been no evidence brought forward as to which of the two forms, A or B, should be assigned as its molecular constitution. This is due in large part to the extreme ease of hydrolysis of this product and the consequent difficulty of obtaining any derivative not involving rupture of the acetal ring.

Ethylidene glycerol was first prepared by Harnitzky and Menschutkine[10] and later, in much purer form, by Nef,[11] the formula being given as either A or B.

Recent work[12] has shown that in benzaldehyde condensations with glycerol a "partition" occurs, both the five and the six membered cyclic acetals being formed simultaneously. In view of these results, as well as those from earlier experiments in this field,[9] it was concluded that ethylidene glycerol would also prove to be a mixture of the two ring systems (A) and (B). The present investigation deals with the separation and identification of these isomers, and of several of their derivatives.

The isomeric ethylidene glycerols are obtained as a mixture in either of the two recognized methods of preparation.[9] The crude product in both

cases boils at 176–187° (760 mm.), the rise in temperature during distillation, even with a fractionating column, being very gradual. Operating under reduced pressure, however, it is possible, by several fractionations, to obtain two distinct products, Fraction I, b. p. 86–88° (21 mm.), and Fraction II, b. p. 101–103.5° (20 mm.), neither of which, however, can be considered as a pure material.

The acetylene method of preparation yielded the sharpest boiling low fraction, while that from the paraldehyde method gave the most definite high boiling product. From this observation it would appear that the partition between the two isomeric forms of ethylidene glycerol may vary considerably, according to the method and conditions of preparation.

The fractions from either method have the same percentage composition and each, upon hydrolysis with dilute phosphoric acid, yields the same theoretical amount of acetaldehyde. Differences in the densities and refractive indices, however, further indicate the presence of isomers.

Many unsuccessful attempts were then made, using the low boiling fraction from the acetylene method and the high boiling from the paraldehyde process (as representing the purest samples), to isolate an acylated product, and this was finally achieved by the use of benzoyl chloride in dry pyridine solution. This reagent causes no hydrolysis of the acetal ring and readily yields two well defined glycerol-acetal-benzoates, that from the low boiling fraction being crystalline (m. p. 86°) and that from the high boiling product an oil, b. p. 163 (11 mm.).

The isolation of these benzoates in a pure state proved to be the key to this research, especially since a fortunate difference in solubility in ligroin permitted of an almost quantitative separation.

Employing the mixture of isomers obtained by the acetylene method, benzoylating the product and separating the mixed benzoates by the use of cold ligroin, it was possible to isolate the isomeric benzoates, the ratio of the amounts of the crystalline to the liquid form being 1:1.8. This ratio may be regarded as an approximately accurate value of the extent of the partition between the low and high boiling ethylidene glycerols, respectively, as prepared by this method.

Applying the same procedure to the mixture of ethylidene glycerols obtained from the reaction of paraldehyde with glycerol, the relative amounts of the low and high boiling isomers were found to be 1:4.

Two conclusions may be drawn from these partitions. 1. The formation of the high boiling isomer—later shown to have the five membered cyclic configuration (A)—is definitely favored over that of the six membered derivative (B). *2.* The partition ratio is a variable one, the relative amounts of each isomer formed depending on experimental conditions such as temperature, concentration of acid, etc. There is no reason to suppose that the actual mechanism of ring closure is any different in the preparation from acetylene than from paraldehyde. Furthermore, it is to be expected, as found in the preceding paper[12] (Part XV) on the isomeric benzylidene glycerols that under standard conditions, there will always exist a final equilibrium mixture which should be the same irrespective of whether this is approached from the side of the five or from that of the six membered acetal.

Structural Identification of the Isomers.—Since the isomeric ethylidene glycerol benzoates may thus be separated and isolated in a pure condition, these derivatives were used as the starting point to determine the structure of the original acetals. It was found possible to hydrolyze off the benzoyl group, leaving the acetal ring intact.

In this way, starting with the pure benzoates, two isomeric ethylidene glycerols were obtained for the first time, as pure individual compounds.

The structures of these acetals were determined essentially as in the case of the benzylidene glycerols, namely, by the methylation–hydrolysis method developed by Irvine and co-workers. Silver oxide and methyl iodide was used as the methylating agent, since Haworth's methyl sulfate method proved unsatisfactory.

Each of the two ethylidene glycerols yielded an isomeric ethylidene glycerol methyl ether which, in turn, on hydrolysis, gave an isomeric glycerol monomethyl ether.

The low boiling ethylidene glycerol (purified through its crystalline benzoate) gave only glycerol β-methyl ether, identical with that isolated for the first time from 1,3-benzylidene glycerol, while the higher boiling ethylidene glycerol (from its liquid benzoate) yielded only the glycerol α-methyl ether.

In the latter case, while the α-ether was the main product, there was also a small amount of the β-derivative present. This was due to its imperfect removal in the purification of the benzoate, since it is admittedly impossible to separate completely all of the solid from the liquid benzoate, but this fact does not affect the conclusions drawn as to the structure of the products.

It is considered proved, therefore, that in the preparation of ethylidene glycerol, a partition occurs between the five and six membered rings, and also that the low boiling acetal has definitely the 1,3-configuration (B) while the higher boiling isomer has the alternate 1,2-structure (A).

Comparative Properties of the Isomers.—Four pairs of isomeric glycerol derivatives, namely, 1,2- and 1,3-ethylidene glycerols, their corresponding benzoates, their methyl ethers and α- and β-glycerol methyl ethers, have now been synthesized and it is believed that their properties offer an interesting physico-chemical study. For purposes of comparison some properties and physical constants are collected in the following table.

Certain generalizations may be drawn from the results in Table I. In all

TABLE I

PHYSICAL CONSTANTS OF COMPOUNDS

Compound	B. p., °C.	$d^{17°}_{4°}$	$n^{17°}_{D°}$
1,3-Ethylidene glycerol	52 (1 mm.)	1.1477	1.4532

[a] Melting point, crystalline compound.

cases the more symmetrical 1,3-derivatives have higher densities, higher refractive indices and show greater tendency to crystallize (also noted in the benzylidene series) than their isomeric 1,2-forms.

There is one anomaly, however, for which no explanation can be offered. It is seen that the boiling point of the 1,3-ethylidene glycerol is considerably lower than that of the 1,2-derivative, but that when these products are methylated the relative boiling points are reversed, the six membered cyclic form having the higher boiling point. In this connection it should be noted that ethylidene 1,3-propylene glycol, b. p. 108°, and ethylidene 1,2-propylene glycol, b. p. 92°, agree with the relationship of the methylated ethylidene glycerols rather than with the acetals themselves. The various isomers exhibit almost identical properties.

An attempt was made to prepare glycerol a- and β-monobenzoates starting from the purified isomeric benzoates of ethylidene glycerol and hydrolyzing off the acetal groups with dilute acid but only negative results were obtained.

Experimental Part

Preparation of Ethylidene Glycerol from Acetylene.—The directions given by Hill and Hibbert[8] for the preparation of cyclic acetals from acetylene were followed. Eight g. of mercuric sulfate was triturated in a mortar with 8 cc. of concentrated sulfuric acid, and the resulting paste added, with stirring, to 184 g. (2 moles) of pure glycerol in the reaction flask. After sweeping out the air with acetylene, 45 liters (2 moles) of the latter gas was led in under slight hydrostatic pressure from a gasometer. The reaction flask was surrounded by a water-bath maintained at 70°. After the required amount of acetylene had been absorbed (during about two hours) the reaction product was taken up in ether, filtered and neutralized with solid potassium carbonate. The ether was removed and the product fractionated under reduced pressure. Two hundred and thirty-four g. of mixed ethylidene glycerols was obtained, b. p. 86–101" (20 mm.).

Preparation of Ethylidene Glycerol from Paraldehyde.—Two hundred and seventy-six g. of glycerol was mixed with 5 cc. of 50% sulfuric acid in a three-necked flask fitted with a reflux condenser and a stirrer with a mercury seal. While heating to 100° in a water-bath, 144 g. of paraldehyde was gradually added during the course of one-half hour and the mixture heated for three hours. After cooling, ether was added, the small glycerol layer separated and the ether solution dried over potassium carbonate. Fractionation under reduced pressure yielded 233 g. of mixed ethylidene glycerols, b. p. 79–89 (13 mm.).

Fractional Distillation of Ethylidene Glycerol.—Using a long bead fractionating column and diminished pressure, it was possible, by repeated fractionations, to effect a partial separation of the isomeric acetals. From the mixture obtained by the paraldehyde method the sharpest high boiling fraction was obtained, b. p. 80–81° (8 mm.); 187–188 (760 mm.). The mixture from the acetylene method, on the other hand, gave the sharpest low boiling fraction, b. p. 86–88 (20 mm.); 176–177 (760 mm.).

Although these fractions still do not represent completely separated isomers, it was from them that the first definite indication of isomerism was obtained. From them also the benzoates of the isomers were first obtained (using benzoyl chloride with dry pyridine), the low boiling ethylidene glycerol yielding a crystalline product, m. p. 86°, and the high boiling acetal an oil, b. p. 163° (11 mm.). After the properties of these benzoates had been studied the separation of the isomers became a relatively simple matter.

Determination of Relative Amounts of 1,2- and 1,3-Ethylidene Glycerol Formed by Paraldehyde and Acetylene Methods

The method of isolating and determining the relative amounts of the 1,2- and 1,3-ethylidene glycerols formed depends on the difference in physical character of their benzoates, particularly the difference in solubility in cold ligroin.

Forty-five g. of benzoyl chloride was mixed with 90 cc. of pure, anhydrous pyridine (which had been carefully dried by boiling over barium oxide for 24 hours) and 39 g. of mixed ethylidene glycerols (prepared by the acetylene method, b. p. 94–100" (24 mm.)) added. The reaction was accompanied by the evolution of a large amount of heat. The mixture was allowed to stand for 20 minutes and then added slowly, with constant stirring, to a liter of cold water. The precipitated oil was dissolved in ether, the ether solution washed with 5% sodium hydroxide, then with 3% sulfuric acid, finally with water and dried with potassium carbonate. The ether was removed and the remaining oil heated for two hours at 100° under vacuum to remove traces of pyridine. To this mixture of benzoates was added 100 cc. of ligroin, b. p. 60–70°, and the solution cooled to 0°. Crystals separated out which were washed with cold ligroin and weighed. The remaining oil was fractionated under reduced pressure, yielding the α-benzoyl derivative. In this way 17 g. of crystalline benzoate (from 1,3-ethylidene glycerol) and 30 g. of liquid benzoate (from 1,2-ethylidene glycerol) were obtained, representing a combined yield of 47 g. or 70%.

The crystalline benzoate melted at 86°. The liquid product boiled at 163° (11 mm.); n_D, 1.5146; $d_{4°}^{20°}$, 1.1618. The relative amounts of the low boiling isomer (1,3-ethylidene glycerol) and the high boiling isomer (1,2-ethylidene glycerol) are thus in the ratio of 1 to 1.8.

In the same manner 39 g. of the mixed ethylidene glycerols, prepared by the paraldehyde method, gave a yield of 49 g. (71%) of the mixed benzoates, of which 10 g. was ethylidene glycerol β-benzoate (m. p. 86°) and 39 g. ethylidene glycerol a-benzoate (b. p. 164° (12.5 mm.); n_D, 1.5145). The amounts of 1,3-ethylidene glycerol and 1,2-ethylidene glycerol in this case are in the ratio of 1 to 4.

A carefully refractionated sample of ethylidene glycerol, obtained from the low boiling fraction of the acetylene method, and a similarly purified fraction from the high boiling fraction of the paraldehyde method were benzoylated in a similar manner. In the first case the product was almost exclusively the crystalline benzoate, m. p. 86°.

Anal. Subs., 0.2200: CO_2, 0.5230; H_2O, 0.1245. Calcd. for $C_{12}H_{14}O_4$: C, 64.86; H, 6.31. Found: 64.83; 6.33.

In the second case the product obtained was an oil, b. p., 164° (12.5 mm.); n_D, 1.5146; $d_{4°}^{20°}$, 1.1618.

Anal. Subs., 0.1936: CO_2, 0.4603; H_2O, 0.1090. Calcd. for $C_{12}H_{14}O_4$: C, 64.86; H, 6.31. Found: 64.84; 6.30.

Preparation of Pure 1,3-Ethylidene Glycerol by Hydrolysis of 1,3-Ethylidene Benzoate.—Fifty-four g. of 1,3-ethylidene benzoate, m. p. 86°, was treated with 15 g. of sodium hydroxide in 150 cc. of water by shaking vigorously and warming until it had melted and completely dissolved. The clear solution was cooled at once and, after adding 100 g. of potassium carbonate, extracted with ether during four hours by means of a continuous extraction apparatus. The ether solution, dried over potassium carbonate and fractionated yielded, besides the solvent, only one product, namely, 17 g. of 1,3-ethylidene glycerol, b. p. 52° (2 mm.); $n_D^{17°} = 1.4532$; $d_{4°}^{17°} = 1.1477$; yield, 59% of the theoretical. The product was a colorless, nearly odorless oil completely miscible in water.

Anal. Subs., 0.1859, 0.1837: CO_2, 0.3482, 0.3283; H_2O, 0.1431, 0.1441. Calcd. for $C_5H_{10}O_3$: C, 50.84; H, 8.47. Found: C, 50.35, 50.23; H, 8.62, 8.79.

Preparation of 1,2-Ethylidene Glycerol.—The liquid 1,2-ethylidene glycerol benzoate used for this preparation was freed as far as possible from the crystalline isomer, as described above, and further by standing at −10° for several days after seeding with the crystalline benzoate. Filtration at −10°, followed by fractionation, gave a nearly pure 1,2-derivative, b. p. 144–145° (2 mm.); $n_D^{17°} = 1.5145$; $d_{4°}^{17°} = 1.1618$.

The product was hydrolyzed exactly as in the case of the 1,3-isomer, 140 g. of the benzoate yielding 50 g. of 1,2-ethylidene glycerol, b. p. 68–70' (1 mm.); $n_D^{17°} = 1.4415$; $d_{4°}^{17°} = 1.1243$.

Anal. Subs., 0.2144, 0.1927: CO_2, 0.3965, 0.3555; H_2O, 0.1621, 0.1464. Calcd. for $C_5H_{10}O_3$: C, 50.88; H, 8.47. Found: C, 50.39, 50.32; H, 8.47, 8.51.

Methylation of the Ethylidene Glycerols.—After using methyl sulfate with poor results, this reaction was carried out successfully with methyl iodide and silver oxide. It was found that efficient agitation greatly increased the yield. Fifteen g. of 1,3-ethylidene glycerol, methylated with 105 g. of methyl iodide and 52 g. of silver oxide gave 15 g. (89% of theoretical) of the corresponding ethylidene glycerol methyl ether, b. p. 80" (23 mm.); $n_D^{17°} = 1.4375$; $d_{4°}^{17°} = 1.0705$. The product was a colorless oil completely miscible with water.

In the same way 17 g. of 1,2-ethylidene glycerol treated with 110 g. of methyl iodide and 54 g. of silver oxide yielded 16 g. (85% of theory) of a methylated product, b. p. 53–58° (22 mm.). Refractionation gave 14 g., b. p. 56–58° (23 mm.), and a small higher fraction, b. p. 58-61" (23 mm.), which presumably contains some of the 1,3-derivative. The product was a colorless oil, not completely miscible with water, in contrast with its isomer; $n_D^{17°} = 1.4177$; $d_{4°}^{17°} = 1.0224$.

Hydrolysis of Ethylidene Glycerol Methyl Ethers.—The method used by Irvine and co-workers for the hydrolysis of isopropylidene glycerol methyl ethers was followed except that a smaller volume of aqueous alcohol was used. Fifteen grams of 1,3-ethylidene glycerol methyl ether was refluxed for ninety minutes with 50 cc. of 75% aqueous alcohol containing 0.3 cc. of concd. hydrochloric acid. (The theoretical amount of acetaldehyde was collected in a strongly cooled trap, keeping the reflux condenser at 40–50°.) After neutralizing with lead carbonate, filtering, washing the precipitate with absolute alcohol (adding in all 50 cc. of the latter) and fractionating, 9 g. (72% of theoretical) of pure glycerol β-methyl ether, b. p. 125 (14 mm.), was obtained; $d^{17°}_{4°}$ = 1.1300; $n^{17°}_{D}$ = 1.4500.

In like manner, 17 g. of 1,2-ethylidene glycerol methyl ether yielded 10 g. of glycerol a-methyl ether, b. p. 111–112° (13 mm.), and a small higher fraction containing some β-isomer. That the main fraction was a practically pure a-ether was shown by its refractive index and density, $n^{17°}_{D}$ = 1.4462 and d = 1.1191, compared with $n^{17°}_{D}$ = 1.4460 and $d^{17°}_{4°}$ = 1.1197 reported by Trvine for pure glycerol methyl ether.

Hydrolysis of the Isomeric Ethylidene Glycerols.—Twenty g. of each of the acetals was heated at 130° for one hour with 10 cc. of 5% phosphoric acid, using a reflux condenser maintained at 40°. The latter in turn was connected to a well cooled spiral condenser to collect the acetaldehyde. 20.26 g. of 1,2-ethylidene glycerol (A) gave 7.53 g. of acetaldehyde; yield, 99%. 18.81 g. of 1,3-ethylidene glycerol (B), treated in like manner, gave 6.93 g. of acetaldehyde; yield, 98%.

Summary

1. The preparation, isolation and quantitative separation of the two isomeric ethylidene glycerols are described.
2. The corresponding methyl ethers and benzoates have been prepared and their physical constants determined.

THE SYNTHESIS OF CERTAIN IODO-ALKOXY ACIDS AND THE MECHANISM OF THE REACTIONS BY WHICH THEY ARE FORMED

BY ERNEST L. JACKSON AND L. PASIUT

RECEIVED APRIL 16, 1928 PUBLISHED AUGUST 4, 1928

The ready substitution of the chlorine atom in α-iodo-β-chlorophenylpropionic acid by the hydroxyl, methoxyl and ethoxyl groups was demonstrated by Erlenmeyer[1] in 1896. The reaction of α-iodo-β-chlorophenylpropionic acid with water was shown to produce α-iodo-β-hydroxyphenylpropionic acid, while its reaction with solutions of potassium hydroxide in absolute methyl and ethyl alcohols gave, respectively, α-iodo-β-methoxyphenylpropionic acid and α-iodo-β-ethoxyphenylpropionic acid.

In applying the procedure of Erlenmeyer to the synthesis of a variety of α-iodo-β-alkoxyphenylpropionic acids, the fact soon came to our attention that the use of potassium hydroxide is unnecessary. When solutions of α-iodo-β-chlorophenylpropionic acid in a number of different alcohols were allowed to stand for several hours, the α-iodo-β-alkoxyphenylpropionic acids resulted. The yields of the iodo-alkoxy acids depend upon the alcohol, being lowest in the case of *iso*propyl and *tert.*-butyl alcohols. The reaction is not precluded by the substitution of the

---

[1] Erlenmeyer, *Ann.*, 289, 259 (1896).

a-hydrogen atom in α-iodo-β-chlorophenylpropionic acid by the methyl group, since a-iodo-a-methyl-p-chlorophenylpropionic acid was shown to react with absolute methyl alcohol to yield a-iodo-a-methyl-/3-methoxyphenylpropionic acid. Although the methyl ester of α-iodo-β-chlorophenylpropionic acid does not react with water,[1] it reacts readily with absolute methyl alcohol to give methyl α-iodo-β-methoxyphenylpropionate.

A more suitable method for the preparation of the α-iodo-β-alkoxyphenylpropionic acids was found to be the reaction of iodine monochloride with cinnamic acid and the appropriate alcohol. In order to avoid esterification of the acids, the reaction was carried out in the presence of calcium carbonate. The methoxy and ethoxy acids were also prepared by the introduction of chlorine into solutions of cinnamic acid and iodine, or an alkali iodide, in the appropriate alcohol. The reaction of iodine monochloride and absolute methyl alcohol with crotonic acid yields iodomethoxybutyric acid.

In addition to the synthesis of α-iodo-β-hydroxyphenylpropionic acid by the reaction of water with a-iodo-p-chlorophenylpropionic acid, Erlenmeyer showed that the compound may be prepared by the reaction of the hydrochloride of iodine monochloride with sodium cinnamate in aqueous solution. We have found the introduction of chlorine into a suspension of iodine and cinnamic acid in water to be a convenient procedure for the preparation of the iodohydroxy acid.

For the synthesis of the iodo-alkoxy acids by the reaction of α-iodo-β-chlorophenylpropionic acid with the various alcohols, it was necessary to prepare the iodochloro acid in large quantities. The addition of iodine monochloride to cinnamic acid in carbon tetrachloride[2] solution proved to be more convenient and to produce higher yields than the procedure of Erlenmeyer,[1] who treated cinnamic acid in ether solution with the hydrochloride of iodine monochloride. Also, the reaction of iodine monochloride with a-methylcinnamic acid in carbon tetrachloride solution is a satisfactory method for the preparation of a-iodo-a-methyl-P-chlorophenylpropionic acid.

The yields of the iodo-alkoxy acids by the different methods of preparation are given in Table I.

Erlenmeyer assumed the methoxyl group in the iodomethoxyphenylpropionic acid to be in the β-position by analogy with the corresponding iodohydroxy acid. We confirmed this structure by the reaction of the iodomethoxy acid with zinc and absolute methyl alcohol to give β-methoxyphenylpropionic acid. One would expect the alkoxyl groups in the other acids, which were prepared from a-iodo-p-chlorophenylpropionic acid, to be in the β-position from the method by which the compounds were prepared. It will be shown below, in the discussion of the mechanism

[a] Methods.—(1) The reaction of the appropriate alcohol with the α-iodo-β-chloro acid, or ester; (2) the reaction of iodine monochloride with the unsaturated acid and the appropriate alcohol in the presence of calcium carbonate; (3) the reaction of chlorine with a solution of the unsaturated acid and iodine, or alkali iodide, in the appropriate alcohol.

[b] Erlenmeyer gives 164–165°.

[c] Obtained by rapid heating (melting point varies with rate of heating).

of the reactions, that the compounds result either from the direct replacement of the chlorine atom by the alkoxyl groups, or from the addition of the alkyl hypoiodites to cinnamic acid. In the first case, there could be no question of the structure of the iodo-alkoxy acids. In the latter case, the alkoxyl groups would be in the β-position, if the mode of addition of the alkyl hypoiodites to cinnamic acid is the same as that of the alkyl hypobromites and hypochlorites.[3] As a check we have proved the compound, prepared with isopropyl alcohol, to be α-iodo-β-*iso*propoxyphenylpropionic acid by the preparation of acetophenone[3c] through its reaction with alcoholic potassium hydroxide, followed by hydrolysis of the product with dilute sulfuric acid solution. By similar reactions, the iodomethoxy acid, obtained from α-iodo-α-methyl-β-chlorophenylpropionic acid, was shown to yield propiophenone. The formation of propiophenone from a-iodo-a-methyl-P-methoxyphenylpropionic acid is shown by the following reactions.

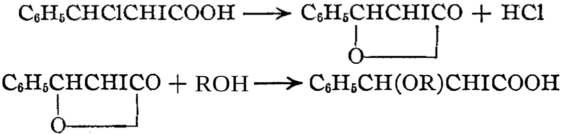
$$C_6H_5CH(OCH_3)CI(CH_3)COOH \xrightarrow{KOH} C_6H_5C(OCH_3)=C(CH_3)COOH \xrightarrow{\text{dil. } H_2SO_4} C_6H_5COCH(CH_3)COOH \longrightarrow CO_2 + C_6H_5COCH_2CH_3$$

The structure of the iodomethoxybutyric acid, which was prepared from crotonic acid, has not yet been established.

The Mechanism of the Reactions

The formation of the α-iodo-β-alkoxy acids from α-iodo-β-chlorophenylpropionic acid could result from any of the following mechanisms

$$C_6H_5CHClCHICOOH + ROH \longrightarrow C_6H_5CH(OR)CHICOOH + HCl \qquad (1)$$



$$C_6H_5CHClCHICOOH \longrightarrow C_6H_5\underbrace{CHCHICO}_{O} + HCl \qquad (a)\ (2)$$

$$C_6H_5\underbrace{CHCHICO}_{O} + ROH \longrightarrow C_6H_5CH(OR)CHICOOH \qquad (b)$$

$$C_6H_5CHClCHICOOH \longrightarrow C_6H_5CH{=}CICOOH + HCl \qquad (a)\ (3)$$

$$C_6H_5CH{=}CICOOH + ROH \longrightarrow C_6H_5CH(OR)CHICOOH \qquad (b)$$

$$C_6H_5CHClCHICOOH \longrightarrow C_6H_5CH{=}CHCOOH + ICl \qquad (a)\ (4)$$

$$ROH + ICl \longrightarrow ROI + HCl \qquad (b)$$

$$C_6H_5CH{=}CHCOOH + ROI \longrightarrow C_6H_5CH(OR)CHICOOH \qquad (c)$$

Erlenmeyer[1] considered the formation of α-iodo-β-hydroxyphenylpropionic acid, as well as the corresponding methoxy and ethoxy acids, to proceed through the β-lactone as shown in mechanism (2). In the case of the hydroxy acid, he regarded the direct replacement of the chlorine atom by the hydroxyl group improbable, since the methyl ester of α-iodo-β-chlorophenylpropionic acid failed to react with water. Mechanism (3), as well as the direct substitution of the chlorine atom by the alkoxyl groups as shown in mechanism (1), was considered unlikely for the lack of analogous examples. Erlenmeyer did not take mechanism (4) into consideration.

By the preparation of methyl α-iodo-β-methoxyphenylpropionate through the reaction of absolute methyl alcohol with the methyl ester of α-iodo-β-chlorophenylpropionic acid, we have shown that a β-lactone need not be an intermediate compound in the formation of the iodo-alkoxy acids. We have also eliminated mechanism (3) by the synthesis of α-iodo-α-methyl-β-methoxyphenylpropionic acid through the reaction of absolute methyl alcohol with α-iodo-α-methyl-β-chlorophenylpropionic acid, which has not the necessary hydrogen atom on the α-carbon atom. The iodo-alkoxy acids are formed, therefore, either according to mechanism (1) or mechanism (4).

Although we have no decisive experiments to distinguish between mechanisms (1) and (4), we nevertheless have obtained certain facts which favor mechanism (4). In the reaction of α-iodo-β-chlorophenylpropionic acid with the various alcohols, there was formed in each instance a certain amount of cinnamic acid, the quantity varying with the alcohol used. In the case of methyl alcohol the amount of cinnamic acid was small, while with *iso*propyl alcohol 75% of the iodochloro acid was converted into cinnamic acid. The data given in Table I show that the yields of the iodo-alkoxy acids, obtained by this method, vary from 75% with methyl alcohol to 8% with *tert.*-butyl alcohol. Erlenmeyer has shown that α-iodo-β-hydroxyphenylpropionic acid is almost completely changed into cinnamic acid by means of 25% hydrochloric acid solution, a reaction which he interprets as proceeding through α-iodo-β-chlorophenylpropionic acid. The production of cinnamic acid in the reaction of the alcohols with a-iodo-p-chlorophenylpropionic acid might, therefore, be attributed to the accumulation of hydrochloric or hydriodic acid in the solution. This, however, seems unlikely in view of the fact that the reactions were carried out in the presence of calcium carbonate. The simplest explanation of the formation of cinnamic acid is the elimination of a molecule of iodine monochloride from α-iodo-β-chlorophenylpropionic acid, as shown in Equation (a) of mechanism (4). This hypothesis is in accord with the usual practice of employing a considerable excess of the reagent in the determination of iodine values by the methods which involve the addition of iodine monochloride. In the presence of methyl alcohol the cinnamic acid, which was formed by the dissociation of iodine monochloride, is almost completely converted into α-iodo-β-methoxyphenylpropionic acid, as shown by Equations (b) and (c) of mechanism (4). When, however, the solvent is isopropyl or *tert.*-butyl alcohol, most of the iodine monochloride, formed in the initial reaction, is used up in side reactions with the alcohols, while a small amount simultaneously reacts to produce the alkyl hypoiodite, which by addition to the double linkage of the unsaturated acid gives a low yield of the α-iodo-β-alkoxy acid. This view is consistent with the results of experiments in which the iodo-alkoxy acids were synthesized by the reaction of iodine monochloride with cinnamic acid and the alcohols. Thus, when cinnamic acid reacts with methyl alcohol and iodine monochloride (1.25 moles), α-iodo-β-methoxyphenylpropionic acid results in 88% yield, while under similar conditions the reactions with isopropyl and *tert.*-butyl alcohols give the iodo-alkoxy acids in only 22 and 15% yields, respectively. In this connection it should be mentioned that the yields obtained in the reaction of an excess of iodine monochloride with cinnamic acid and the various alcohols were in each case higher than resulted in the reaction of a-iodo-p-chlorophenylpropionic acid with the corresponding alcohol. In the latter case a low concentration of iodine monochloride would be maintained throughout the reaction by the gradual elimination of iodine monochloride from the molecule of the iodochloro acid. In order to approximate these conditions, the calculated amount of iodine monochloride was added, a few drops at a time, to a dilute solution of cinnamic acid in isopropyl alcohol over approximately the same period that was used for the reaction of α-iodo-β-chlorophenylpropionic acid with *iso*propyl alcohol. The yield of α-iodo-β-*iso*propoxyphenylpropionic acid thus obtained was comparable to that produced in the reaction with a-iodo-β-chlorophenylpropionic acid.

The formation of the iodo-alkoxy acids according to mechanism (4) involves the assumption that iodine monochloride reacts with the various alcohols to give the alkyl hypoiodites. That iodine monochloride reacts with the alcohols in this manner seems practically certain from our experiments with *tert.*-butyl alcohol. *Tert.*-butyl alcohol was found to be almost without action on α-iodo-β-chlorophenylpropionic acid in the time which was used for the preparation of α-iodo-β-*tert.*-butoxyphenylpropionic acid by the reaction of cinnamic acid with iodine monochloride and *tert.*-butyl alcohol. Also, in the latter reaction no α-iodo-β-chlorophenylpropionic acid was recovered. This indicates that α-iodo-β-chlorophenylpropionic acid is not formed as an intermediate compound in the production of α-iodo-β-*tert.*-butoxyphenylpropionic acid by the reaction of cinnamic acid with iodine monochloride and *tert.*-butyl alcohol. The iodo-*tert.*-butoxy acid is probably formed by the addition of *tert.*-butyl hypoiodite to cinnamic acid, the *tert.*-butyl hypoiodite being a product of the reaction of iodine monochloride with *tert.*-butyl alcohol. The production of the other iodo-alkoxy acids, by the reaction of iodine monochloride with the unsaturated acids and the different alcohols, probably involves a similar mechanism.

Although the facts outlined are in accord with mechanism (4), we do not consider the direct replacement of the chlorine atom excluded. If the iodo-alkoxy acids are formed according to mechanism (1), the slow rate of reaction of *tert.*-butyl alcohol, as well as isopropyl alcohol, with α-iodo-β-chlorophenylpropionic acid would be expected as a consequence of the small reactivity of the hydroxyl hydrogen atoms[4] in these alcohols. However, this slow rate of reaction could equally well be interpreted as a solvent effect on the reactions of mechanism (4).

In previous papers[3a,b,c] it has been shown that bromine and chlorine react with ethylene derivatives and certain alcohols to give bromo and chloro-alkoxyl compounds. This reaction was interpreted as involving the addition of the alkyl hypobromites and hypochlorites to the double linkage of the unsaturated compounds. In connection with the reaction of the different alcohols with α-iodo-β-chlorophenylpropionic acid to give the iodo-alkoxy acids, the question arises whether the bromo and chloro-

alkoxyl compounds are formed in a similar manner by the reaction of the alcohols with the appropriate dibromides or dichlorides. The latter possibility is eliminated by the fact that cinnamic acid dibromide was shown by Werner[5] to be unchanged on heating with methyl alcohol, while we have found the dichloride of cinnamic acid in absolute methyl alcohol solution, containing hydrogen chloride, to undergo only the esterification reaction after standing for sixty-five hours. Under similar conditions the high-melting isomer of α,β-dichloro-β-phenylpropiophenone was shown to be unchanged.

Experimental Part

Preparation of the Iodochloro Acids

Ten g. of the unsaturated compound, cinnamic acid, methyl cinnamate or a-methyl cinnamic acid, was dissolved in carbon tetrachloride. To this was added **1.25** moles of iodine monochloride, which was prepared by the method of Hannay.[6] After standing for about fifteen hours, the solid material was filtered off and washed with carbon tetrachloride. The α-iodo-β-chlorophenylpropionic acid, obtained from cinnamic acid, melted with decomposition at 124–126°; yield, 92%. It was further purified by recrystallization from chloroform containing a small amount of petroleum ether. The methyl α-iodo-β-chlorophenylpropionate resulting from methyl cinnarnate was recrystallized from carbon tetrachloride; yield, 77%. It melted at 97–98°, which is the melting point given by Erlenmeyer.' The yield of α-iodo-α-methyl-β-chlorophenylpropionic acid prepared from a-methyl cinnamic acid was 74%. After recrystallization from carbon tetrachloride, the compound melted at 104–105° with decomposition.

Anal. Calcd. for $C_{10}H_{10}ClIO_2$: Cl and I, 50.04. Found: 49.99.

Synthesis of Iodo-alkoxy Acids by the Reaction of Alcohols **with the Iodochloro** Acids.—Two and one-half to 10 g. of the **α-iodo-β-chloro** acid or ester was dissolved in the appropriate alcohol. In order to avoid esterification of the acids, there was added precipitated calcium carbonate **(3** to 12 **g.)**. After standing at room temperature for thirty-five to ninety-eight hours, the calcium carbonate was filtered off and washed with the proper alcohol. The filtrate was poured into a large volume of water. This in some cases precipitated solid material and in others an oil, which crystallized alter standing for several hours. Saturation of the filtrate from this material with sodium chloride gave a small amount of crystals. By dissolving the calcium carbonate in hydrochloric acid, an additional quantity of solid was obtained. For purification the substance was dissolved in sodium carbonate solution and treated with potassium permanganate solution in small excess. By filtering off the manganese dioxide, extracting the filtrate with ether and acidifying, the somewhat impure compound was obtained. Recrystallization from the solvent given in Table I yielded the pure substance.

In the preparation of methyl α-iodo-β-methoxyphenylpropionate and a-iodo-α-methyl-β-methoxyphenylpropionic acid, the general procedure was varied in that the solvent was distilled under diminished pressure at 25–35' instead of pouring into water. The resulting products were purified by recrystallization from the solvents specified.

The principal product in the reaction of isopropyl alcohol with **α-iodo-β-chlorophenylpropionic** acid was cinnamic acid. Thus, from 2.5 g. of **α-iodo-β-chlorophenylpropionic** acid there was obtained 0.9 g. of cinnamic acid melting at 130–131° (75%

---

[5] Werner, *Ber.*, 39, 27 (1906).

[6] Hannay, **J.** *Chem. Soc.*, **26, 815** (1873).

of the calculated amount). The substance was shown to be cinnamic acid by a mixed melting point determination and by its complete oxidation by potassium permanganate solution.

The rate of the reaction of *tert.*-butyl alcohol with α-iodo-β-chlorophenylpropionic acid was found to be very slow. After a solution of 10 g. of the iodochloro acid in 75 cc. of *tert.*-butyl alcohol had stood for twenty-two hours, it was poured into water. The solid thus precipitated weighed 7 g. and melted with decomposition at 126–127°. It was shown to be principally unchanged a-iodo-j3-chlorophenylpropionicacid by a mixed melting point determination and by its reaction with methyl alcohol to produce a-iodo-@-methoxyphenylpropionicacid; m. p. 167–168°. However, when a solution of the iodochloro acid in *tert.*-butyl alcohol, containing calcium carbonate in suspension, was allowed to stand for ninety-eight hours, the products were cinnamic acid and α-iodo-β-*tert.*-butoxyphenylpropionic acid (8% yield).

The compounds prepared by this method together with the yields, melting points and analyses are given in Table I.

Structure of the Iodomethylmethoxyphenylpropionic Acid.—To a solution of 4.3 g. of potassium hydroxide in 25 cc. of absolute alcohol there was added 3.6 g. of the iodomethylinethoxyphenylpropionic acid melting at 169–170°. After boiling under a reflux condenser for eight hours, the alcohol was distilled off, the residue dissolved in water and acidified. The oil thus precipitated was extracted with ether. The ether was distilled and to the residue was added 100 cc. of 10% sulfuric acid solution. It was then steam distilled until oil ceased to pass over. By extracting the distillate with ether, drying over sodium sulfate and distillation of the solvent, an oil was obtained which partially crystallized on cooling to about 18°. It was shown to be propiophenone by the preparation of its semicarbazone. To a solution of the substance in alcohol was added a concd. aqueous solution of 0.5 g. of seinicarbazide hydrochloride and 0.8 g. of sodium acetate. After boiling under a reflux condenser for about ten minutes, the solution was set aside overnight. Needle-shaped crystals resembling propiophenone semicarbazone as described by Stobbe[7] had then separated. It is insoluble in water. The crude product melted at 168–171". After recrystallization from alcohol, it melted at 173–174°, which agrees with the melting point of propiophenone semicarbazone given in the literature. The formation of propiophenone by these reactions shows that the methoxyl group is in the @-position to the carboxyl group and the substance is α-iodo-α-methyl-β-methoxyphenylpropionic acid.

Structure of the Iodo-*iso*propoxy Acid.—One g. of the iodo-isopropoxy acid melting at 113–114" was treated with alcoholic potassium hydroxide and sulfuric acid according to the procedure described for the iodomethylmethoxyphenylpropionic acid. The product was an oil (0.3 g.) resembling acetophenone in appearance and odor. It reacted with semicarbazide hydrochloride and sodium acetate to give acetophenone semicarbazone; m. p. 195–196". The melting point was unchanged when mixed with known acetophenone semicarbazone. The formation of acetophenone by these reactions shows that the isopropoxyl group is in the @-position to the carboxyl group.

Synthesis of Iodo-alkoxy Acids by the Reaction of Unsaturated Acids with Iodine Monochloride and Alcohols.—To a solution of 5 to 10 g. of cinnamic acid or crotonic acid in the appropriate alcohol, containing in suspension 7 to 15 g. of calcium carbonate, there was added 1.25 moles of iodine monochloride. After standing for sixteen to forty-two hours, the calcium carbonate was filtered off and washed with the appropriate alcohol. However, in the case of crotonic acid the reaction mixture was stirred for ten hours. The filtrate from the calcium carbonate was poured into a large volume of water and decolorized with sodium sulfite. The products from cinnamic acid were

---

[7] Stobbe, *Ann.*, 321, 103 (1902).

precipitated as solids, except those resulting from the reactions with *n*-butyl and *iso*-butyl alcohols. Crotonic acid and methyl alcohol gave material soluble in water. The solids thus precipitated were filtered off and the filtrate saturated with sodium chloride, which yielded a small amount of crystals. Additional substance was obtained by dissolving the calcium carbonate in hydrochloric acid. The compounds were purified by dissolving in sodium carbonate solution and treating with potassium permanganate as previously described. Recrystallization from the solvents given in Table I yielded the pure substances. After recrystallization of α-iodo-β-*tert.*-butoxyphenylpropionic acid from chloroform, it was found to retain the solvent and its correct melting point was obtained only after standing in a vacuum desiccator for about twenty-four hours. The compound also combines with benzene.

The product obtained by pouring into water the solution resulting from the reaction of cinnamic acid, iodine monochloride and *n*-butyl alcohol was an oil which did not crystallize after standing for fifteen hours. The oil was separated from the aqueous solution and dissolved in ether. After drying the ethereal solution over calcium chloride and distillation of the solvent, an oil was recovered which crystallized, in part, on cooling in ice. The substance was partially dissolved in benzene and allowed to stand in an open beaker for several days. The crystals were then separated from the oil by suction filtration and recrystallized from benzene.

Likewise, the product of the reaction of cinnamic acid, iodine monochloride and isobutyl alcohol was an oil which did not crystallize on standing in water for two days. Most of the aqueous layer was decanted from the oil, which was then combined with a small amount of oil obtained by dissolving the calcium carbonate in hydrochloric acid. By extracting the oil with ether, drying over sodium sulfate and distillation of the ether, a solution of the substance in isobutyl alcohol was obtained. The isobutyl alcohol was distilled off under diminished pressure, the bath temperature being 85–95°. The resulting product was dissolved in sodium carbonate solution and treated with potassium permanganate in the usual manner. Acidification of the sodium carbonate solution precipitated colorless crystals which were then recrystallized from chloroform.

The iodine precipitated by pouring the solution obtained in the reaction of crotonic acid, iodine monochloride and absolute methyl alcohol into water was filtered off. The excess of iodine monochloride was removed by precipitation with quinoline.[8] The solution was made distinctly acid with hydrochloric acid and quinoline added until precipitation ceased. The solid material was then filtered off and discarded. The filtrate was strongly acidified with hydrochloric acid and thoroughly extracted with ether. The calcium carbonate was dissolved in hydrochloric acid and the solution extracted with ether, which was then combined with the main portion. After drying over sodium sulfate and distillation of the ether, an oil was obtained which partially crystallized on standing overnight. The crystals were separated from the oil by filtration and recrystallized from benzene.

The reaction of 10 g. of cinnamic acid and 1.25 moles of iodine monochloride in 90 cc. of isopropyl alcohol during forty-two hours produced a 22% yield of α-iodo-β-*iso*-propoxyphenylpropionic acid, as given in Table I. In order to test the effect of the concentration of the reacting substances on the yield of the iodo-isopropoxy acid, one mole of iodine monochloride was added in small portions at intervals of several hours to a more dilute solution of cinnamic acid in isopropyl alcohol. To a solution of 5 g. of cinnamic acid in 105 cc. of isopropyl alcohol, containing in suspension 12 g. of calcium carbonate, there was added two or three drops of iodine monochloride; it was then allowed to stand for several hours. This process was repeated until one mole of iodine monochloride had been added during ninety-seven hours. The product was separated

---

[8] German patent, 30,358.

as described under the general procedure and purified by treatment with potassium permanganate solution. The yield of α-iodo-β-*iso*propoxyphenylpropionic acid melting at 108–112° was 0.6 g. or 5.3%.

The reaction of unsaturated acids with iodine monochloride and alcohols in the absence of calcium carbonate produces the esters of the iodo-alkoxy acids. Thus, a solution of 10 g. of cinnamic acid and 11 g. of iodine monochloride in 82 cc. of absolute methyl alcohol, after about forty-eight hours, gave 12 g. of solid melting at 65–74° and a small amount of higher melting material. By recrystallization from carbon tetrachloride, or petroleum ether, the pure methyl ester of a-iodo-@-methoxyphenylpropionic acid melting at 68–69° was obtained.

The compounds prepared by this method and the yields are summarized in Table I.

Synthesis of Certain Iodo-alkoxy Acids by the Reaction of Chlorine with Unsaturated Acids, Iodine and Alcohols.—On chlorinating a solution of cinnamic acid and iodine, or an alkali iodide, in absolute methyl alcohol, a-iodo-@-methoxyphenylpropionic acid results. The introduction of chlorine (about 2 liters) into a vigorously stirred solution of 10 g. of cinnamic acid in 50 cc. of absolute methyl alcohol, to which 9 g. of iodine was added in small portions during ten hours, gave a 34% yield of α-iodo-β-methoxyphenylpropionic acid. In a similar manner, a 48% yield of the iodomethoxy acid was obtained by the reaction of about 2 liters of chlorine with a solution of 10 g. of cinnamic acid and 2.4 g. of potassium iodate in 75 cc. of absolute methyl alcohol, to which 8.2 g. of sodium iodide was added over a period of ten hours. Continuation of the reaction over a relatively long period of time yields the ester of the iodomethoxy acid. Thus, the introduction of about 12 liters of chlorine, during two days, into a solution of 20 g. of cinnamic acid in 190 cc. of absolute methyl alcohol, to which 46 g. of potassium iodide was gradually added, produced methyl α-iodo-β-methoxyphenylpropionate (37% yield).

α-Iodo-β-ethoxyphenylpropionic acid was prepared by the reaction of chlorine with cinnamic acid and sodium iodide in absolute ethyl alcohol solution. To a thoroughly stirred solution of 20 g. of cinnamic acid in 200 cc. of absolute ethyl alcohol was added 20 g. of sodium iodide in small portions, chlorine being simultaneously introduced until the iodine had completely reacted, about 4.5 liters being required. After recrystallization of the product from alcohol, there was obtained 6.5 g. of substance melting at 75–125" and 2.5 g. melting at 70–105°. Another crystallization of the material melting at 75–125° from benzene gave 2 g. of crystals melting at 128–138° and some lower melting substance. By dissolving the material melting at 128–138° in sodium carbonate solution and treating with potassium permanganate in the usual manner, crystals melting at 137–138° resulted. No depression of the melting point was produced on mixing with known a-iodo-j3-ethoxyphenylpropionicacid, which was prepared by the procedure of Erlenmeyer.'

The reaction of chlorine with crotonic acid and iodine in absolute methyl alcohol solution, containing calcium carbonate in suspension, gave iodomethoxybutyric acid. However, the yield by this method was less than that obtained with the use of iodine monochloride and the product was more difficult to purify. When the reaction was carried out in the absence of calcium carbonate, the product was a liquid consisting of esters which could not be obtained in the solid state. To a thoroughly stirred solution of 5 g. of crotonic acid in 50 cc. of absolute methyl alcohol, in which was suspended 7 g. of calcium carbonate, there was added 8 g. of iodine in portions of about 1 g. each. The solution was treated with about 2 liters of chlorine during six hours, the iodine color having then disappeared. The resulting oil was distilled at 5 mm. pressure until the boiling point reached 125°. The residue in the distilling flask partially crystallized on standing overnight. The yield of substance melting at 50–60° was 3 g. After several recrystallizations from benzene, pure iodomethoxybutyric acid was obtained.

α-Iodo-β-hydroxyphenylpropionic acid was prepared by treating a suspension of iodine and cinnamic acid in water with chlorine. To a vigorously stirred suspension of 10 g. of cinnamic acid in 1.3 liters of water, there was added 11 g. of finely powdered iodine in small portions, chlorine being simultaneously introduced until the iodine had completely reacted. About 3.5 liters of chlorine were required. The solid was filtered off and the filtrate extracted with ether. After recrystallization of the product from chloroform, 9 g. of slightly impure α-iodo-β-hydroxyphenylpropionic acid melting at 136–142° resulted. Further recrystallization gave the pure compound; m. p. 141–142°.

Summary

α-Iodo-β-chlorophenylpropionic acid has been shown to react with methyl, n-propyl, isopropyl, n-butyl and *tert.*-butyl alcohols to yield the corresponding α-iodo-β-alkoxyphenylpropionic acids.

A more suitable method for the preparation of the iodo-alkoxy acids was found to be the reaction of iodine monochloride with cinnamic acid and the appropriate alcohol. This reaction has been applied to methyl, n-propyl, isopropyl, n-butyl, isobutyl and *tert.*-butyl alcohols. By the reaction of crotonic acid, iodine monochloride and absolute methyl alcohol, iodomethoxybutyric acid was formed. The iodomethoxy and iodoethoxyphenylpropionic acids were also prepared by reaction of chlorine with solutions of cinnamic acid and iodine, or an alkali iodide, in the appropriate alcohol.

That a β-lactone is not an intermediate compound in the formation of the iodo-alkoxy acids from α-iodo-β-chlorophenylpropionic acid was shown by the preparation of methyl α-iodo-β-methoxyphenylpropionate through the reaction of methyl alcohol with the methyl ester of α-iodo-β-chlorophenylpropionic acid. Also, the iodo-alkoxy acids are not formed by the elimination of hydrogen chloride from α-iodo-β-chlorophenylpropionic acid followed by the addition of the alcohols to the double linkage thus produced, since methyl alcohol reacts with α-iodo-α-methyl-β-chlorophenylpropionic acid to give α-iodo-α-methyl-β-methoxyphenylpropionic acid. The iodo-alkoxy acids are produced either by the direct replacement of the chlorine atom by the alkoxyl groups, or by the dissociation of iodine monochloride from the molecule of the iodochloro acid, followed by its reaction with the alcohols to produce the alkyl hypoiodites, which then add to the double linkage of the unsaturated acid. Facts supporting the latter mechanism have been submitted.

Evidence has been given which indicates that in the reaction of iodine monochloride with the alcohols and unsaturated acids, the iodo-alkoxy acids are probably formed by the addition of the alkyl hypoiodites to the unsaturated acids.

The preparation of α-iodo-β-chlorophenylpropionic acid and α-iodo-α-methyl-β-chlorophenylpropionic acid, by the addition of iodine monochloride to the unsaturated acids in carbon tetrachloride solution, has been found to be more convenient than the procedure of Erlenmeyer,

who used an ether solution of the hydrochloride of iodine monochloride. The introduction of chlorine into a suspension of iodine and cinnamic acid in water proved to be a convenient method for the preparation of α-iodo-β-hydroxyphenylpropionic acid.

REDUCTION OF PYRIDINE HYDROCHLORIDE AND PYRIDONIUM SALTS BY MEANS OF HYDROGEN AND PLATINUM-OXIDE PLATINUM BLACK. XVIII[1]

BY T. S. HAMILTON[2] AND ROGER ADAMS

RECEIVED APRIL 17, 1928 PUBLISHED AUGUST 4, 1928

Although the catalytic reduction of pyridine and pyridine derivatives has been described in the literature,[3] no systematic work has been done which makes possible a prediction of satisfactory conditions for reducing compounds which contain the pyridine nucleus. A study has therefore been made of the reduction with hydrogen and platinum-oxide platinum black, of pyridine hydrochloride and pyridonium salts, quinoline and benzyl quinolonium chloride.

It has been found that pyridine alone in most solvents poisons platinum-oxide platinum black and no reduction takes place. On the other hand pyridine hydrochloride can be reduced readily. The selection of the proper solvent, however, is important. Absolute alcohol proved to be the best of those used, with glacial acetic acid second. Peculiarly enough, water in the alcohol inhibits the reduction very markedly and no satisfactory results were obtained using 95% ethyl alcohol or commercial methyl alcohol as a solvent. Absolute methyl alcohol could be used but it did not give such consistent results as absolute ethyl alcohol. Acetone and ethyl acetate do not dissolve the pyridine hydrochloride readily and, therefore, are not suitable.

As a standard run, 0.1 mole of pyridine hydrochloride in 150 cc. of solvent with 0.15 g. of platinum-oxide platinum black from C. P. chloroplatinic acid was used. The time required for the complete reduction was six to seven hours. In fact 0.15 g. of catalyst was the minimum which would allow complete reduction. Increase of the amount of catalyst to 0.3 g. lowered the reduction time to one hour and using 0.5 g. of catalyst lowered

[3] Skita and Brunner, *Ber.*, 49, 1597 (1916); Darzens, *Compt. rend.*, 149, 1001 (1909); Ipatiew, *Ber.*, 41,992 (1908).

the reduction time to thirty minutes. The yields were essentially quantitative in all instances.

Increasing the temperature increased the rate of reduction. With the standard run the reduction was carried out at room temperature. If the temperature was increased to 50°, the time for reduction dropped from six or seven hours to less than two hours.

Small amounts of ferrous salts and other mineral salts, which acted as promoters in the reduction of aldehydes, did not affect the reduction of pyridine hydrochloride. Oxygen and air, however, revivified a catalyst which had begun to be sluggish, and were employed in reductions which required a good many hours for completion.

Although all of these various conditions were not studied in the reduction of the pyridonium salts, a sufficient number of experiments was completed to show that, qualitatively, the pyridine hydrochloride and pyridonium salts were affected in the same way by changes in conditions. Using 0.1 mole of salt in 150 cc. of absolute alcohol and 0.15 g. of platinum-oxide platinum black, the following substances were reduced quantitatively to the corresponding hexahydro compounds in the following times: pyridine hydrochloride, six to seven hours; phenyl pyridonium chloride, two and one-quarter to two and one-half hours; n-butyl pyridonium chloride, one and one-half to two hours; ethyl pyridonium chloride, one to one and one-quarter hours; benzyl pyridonium chloride, one-half to three-quarters hour; carbo-ethoxymethyl pyridonium chloride, one-half to three-quarters hour; β-hydroxyethyl pyridonium chloride, three to three and one-quarter hours; γ-hydroxypropyl pyridonium chloride, one and three-quarters to two and one-half hours.

It is interesting that the pyridonium salts are in every instance more readily reduced than pyridine hydrochloride.

The quinoline and quinoline derivatives can be reduced to the tetrahydro compounds in exactly a similar manner. The reaction was carried out with quinoline hydrochloride and benzyl quinolonium chloride.

The general method should be of value in the reduction of alkaloids containing pyridine or quinoline nuclei.

Experimental

Catalyst.—The platinum-oxide platinum black was made by the method of Adams and Shriner[4] from C. P. chloroplatinic acid. Platinum oxide prepared by dissolving spent catalyst and reprecipitating without purification was not satisfactory for these reductions. The apparatus was that usually used and the procedure was exactly that which has been described before. Platinum oxide was reduced to platinum black in every instance in the presence of *a* solution of pyridine hydrochloride or pyridonium salt. The lag was approximately three minutes in most cases.

Preparations of Compounds to Be Reduced.—The pyridine used in the preparation of all compounds boiled between 116 and 118°.

---

[4] Adams and Shriner, THIS JOURNAL, 45, 2171 (1923).

Pyridine hydrochloride was prepared by passing dry hydrogen chloride into dry pyridine dissolved in dry ether. It was necessary that the mixture be kept cold and that it be stirred constantly. The pyridine hydrochloride precipitated from the ethereal solution in a white, flocculent mass and settled quickly to the bottom of the flask. After the flask had increased to a weight indicating that approximately 85% of the pyridine had been changed to the hydrochloride, the salt was rapidly filtered into a Büchner funnel, taken up twice with absolute ether and the last traces of ether were removed by placing in a desiccator over calcium chloride and repeatedly evacuating. Because of the very deliquescent nature of the pyridine hydrochloride, it was stored in tightly stoppered bottles in a desiccator.

The ethyl and butyl chloride addition compounds of pyridine were made by mixing pyridine and the alkyl chloride in molecular proportions (usually the alkyl chloride in slight excess) and heating the mixture in a sealed tube on a steam-bath for several days or until the entire mixture had solidified. After opening the tube, the contents were washed out with as small as possible a quantity of warm absolute alcohol, the solution was cooled and the addition compound thrown out of the alcoholic solution by the addition of cold absolute ether. The ethyl and butyl chloride addition compounds were amber colored oils.

The phenyl pyridonium chloride was prepared by the method of Weitz, Konig and v. Wistinghausen.[5]

The benzyl chloride, chloroacetic acid, chloroacetic ester, ethylene and trimethylene chlorohydrin addition compounds were all prepared by the interaction of equimolecular quantities of pyridine and the compound to be added. The benzyl chloride, ethylene and trimethylene chlorohydrin derivatives were made by warming the mixture to start the reaction. It was sometimes necessary to cool the flask to prevent too vigorous boiling (especially true of the benzyl chloride compound). The chloroacetic acid and ethyl chloroacetate compounds were made merely by adding these compounds to pyridine and allowing the mixtures to stand in casseroles in a desiccator for a few days. The contents solidified after that time.

The addition compounds were isolated by crystallization from an ether–alcohol solution. Usually the compound was dissolved in a small amount of warm absolute alcohol, the solution cooled and the compound precipitated by the addition of cold ether, and by allowing to stand in a cold place. All compounds are very hygroscopic and the utmost care must be taken in order to obtain the salts in crystalline form, and to eliminate small quantities of water which inhibit the reductions.

Isolation of Products.—For the isolation of the reduced compounds the hydrogen was removed from the reduction bottle by suction and the bottle then shaken with air for ten to fifteen minutes in order to coagulate the platinum black, which was then filtered off. All reduced compounds were less hygroscopic and also less soluble in absolute alcohol than the unreduced. Piperidine hydrochloride may be quantitatively recovered from the alcoholic solution by concentration and crystallization. In all other cases, however, it was better to precipitate the reduced compound by adding ether until a precipitate just failed to appear and allowing to cool.

In the identification of all compounds, both those to be reduced and those reduced, the melting point of the hydrochloride was taken if possible (this was possible in but few cases), or a double salt, usually with platinum chloride, was made, or the free base was obtained by saturating with 40% sodium hydroxide and extracting with ether. In the latter case, after distillation of the ether, the boiling point of the free base was determined.

[5] Weitz, König and v. Wistinghausen, Ber., **57**, 166 (1924).

The compounds prepared in this investigation are listed in Table I.

Summary

It has been shown that pyridine hydrochloride, quinoline hydrochloride or the corresponding pyridonium and quinolonium salts are readily reduced by means of hydrogen and platinum-oxide platinum black to the hexahydro compounds in the case of pyridine and tetrahydro compounds in the case of quinoline. The reductions under various conditions are described.

A SECOND NEW METHOD FOR THE COMPLETE RESOLUTION OF EXTERNALLY COMPENSATED ACIDS AND BASES

BY. A. W. INGERSOLL

RECEIVED MAY 17, 1928 PUBLISHED AUGUST 4, 1928

In a previous paper[1] the author has described a new method for the resolution of externally compensated acids and bases by which both active forms are obtained completely pure.[2] In its simplest form the method requires two main steps. First, for example, an inactive base (dl-B) is combined with an active acid, for example, d-A, and the resulting salts d-B-d-A and *l*-B-*d*-A are fractionally crystallized until the less soluble one, for example, 2-B-d-A, is pure. From this salt pure *l*-B is obtained by hydrolysis. From the mother liquors there will be obtained on hydrolysis a mixture of the two active bases with d-B in excess. For convenience this mixture may be regarded as dl-B + d-B.

In the second step this mixture is dissolved with an equivalent amount of the inactive form of the acid originally used (dl-A), or with any suitable externally compensated acid. Upon crystallization the ions now in solution may combine in one of two ways, depending on whether the inactive acid is resolved by the active base present in excess (Equation 1) or forms a half racemic salt with it (Equation 2).

$$(\text{dl-B} + \text{d-B}) + \text{dl-A} \longrightarrow \text{dl-B-dl-A} + \text{d-B-d-A} + \text{d-B-I-A} \qquad (1)$$

$$(\text{dl-B} + \text{d-B}) + \text{dl-A} \longrightarrow \text{dl-B-dl-A} + \text{d-B-dl-A} \qquad (2)$$

When the situation is represented by Equation 1 and when the d-B-I-A salt is the least soluble, the latter can be obtained pure by fractional crystallization. From the pure 2-B-d-A and d-B-I-A salts thus obtained in the two steps, both active forms of the base, and of the acid as well, may be obtained by hydrolysis. Two cases in which a complete resolution was effected in this way were described in the previous paper.

It is apparent, furthermore, that a complete resolution of the base (though not of the acid) is also possible when Equation 2 represents the second step of the process. Thus whenever the half racemic salt d-B-dl-A is less soluble than the inactive salt, the former, and its component base, can be obtained pure. The present paper contains a description of a complete resolution based upon this behavior. Thus inactive *iso*-diphenylhydroxy-ethylamine was partially resolved in the usual way with d-camphor-10-sulfonic acid,[3] the less soluble d-B-d-A salt being obtained

---

[1] Ingersoll, THIS JOURNAL, 47, 1168 (1925).

[2] Some interesting modifications of the older methods have recently been described by Read and Reid, J. *Soc.* Chem. *Ind.*, 47, 8T (1928).

[3] The resolution of *iso*-diphenylhydroxy-ethylamine was first carried out by Erlenmeyer, Ber., 32, 2377 (1899); 36, 978 (1903); *Ann.*, 337, 307 (1904), using helicin or tartaric acid. The resolution with tartaric acid has recently been improved by Read

pure in the first step. The base recovered from the mother liquors (dl-B + *l*-B) was combined with inactive camphorsulfonic acid and the salts fractionally crystallized. The half racemic salt 2-B-dl-A was the first to separate and was readily purified. Alkaline hydrolysis of the pure d-B-d-A and *l*-B-*dl*-A salts thus obtained gave the pure isomeric bases in excellent yields. The pure *l*-B-*d*-A and dl-B-dl-A salts were also synthesized for comparison. All the salts of this series have one molecule of water of crystallization. The solubilities in water at 25° were in the order d-B-d-A < *l*-B-*dl*-A < l-B-d-A < dl-B-dl-A.

Generality of the Combined Methods

So far as the second step is concerned, both of the methods (depending on Equation 1 and Equation 2, respectively) appear to be new in principle and of rather general utility. Since the same reagents and procedure are used in both methods, these are mutually complementary and afford a double chance for successfully completing a resolution. They may be applied equally well to the resolution of an acid or a base. They should hold also for ester, amide, hydrazone, imine and similar combinations as well as for salts.

It is clear, however, that each method depends for its success on a favorable order of solubility of the isomeric compounds involved. This point has been discussed in the previous paper, for resolutions depending on Equation 1. While there seems to be no rule known at present from which it can be predicted that the order of solubility will always be favorable, it is remarkable that of the three cases thus far studied all have resulted in complete resolutions. A fourth case now being studied, that of the acid tartrates of iso-diphenylhydroxy-ethylamine, has also given preliminary results indicating a similar behavior. The uniformity of these results points to the probable existence of an underlying rule and the study is being continued in the hope of disclosing such a rule.

Experimental Part

Partial Resolution of the Base.—In one experiment a solution containing 42.6 g. of inactive iso-diphenylhydroxy-ethylamine, m. p. 130°, and 48.0 g. of d-camphor-10-sulfonic acid in 1 liter of water was decolorized and the solute fractionally crystallized. While the first crop of crystals showed a strongly positive rotation the following crops showed an alternation of low and high rotations. The further separation of these was therefore best carried out by combining similar fractions in fresh solvent and seeding with samples of the extreme fractions. Working in this way there was obtained 35.2 g. of the pure d-B-d-A salt in the less soluble

---

and Steele, *J. Chem. Soc.*, 131, 910 (1927), who mentioned also the use of camphorsulfonic acid but gave no details.

fraction. In later experiments it was found that the separation could also be effected readily by using moist ethyl acetate (3% water) as solvent.

d-iso-**Diphenylhydroxy-ethylamine** d-Camphorsulfonate forms masses of small prisms from water or distinct crystals from moist ethyl acetate, both being hydrated. It is soluble in about 59 parts of water at 25°. The anhydrous salt melts indistinctly at 207–208' (corr.) but the melting points of this series of salts are not good indications of purity.

Anal. Subs., 1.8429: lost 0.0704 g. at 105°. Calcd. for $C_{24}H_{31}O_5NS \cdot H_2O$: H_2O, 3.88. Found: H_2O, 3.82.

Rotation (Hydrated salt). Subs., 0.8005: made up to 50 cc. in water gave $\alpha^{22}_{D} = +1.88°$ in a 2-dm. tube. Hence $[\alpha]^{22}_{D} = +58.7°$. (Anhydrous salt). Subs., 0.9442: made up to 50 cc. in water gave $\alpha^{22}_{D} = +2.31°$ in a 2-dm. tube. Hence $[\alpha]^{22}_{D} = +61.2°$; $[M]_D = +272°$. Assuming $+52°$ as the molecular rotation of the d-camphorsulfonate ion, $[M]_D$ for the base ion is $+220°$.

d-iso-**Diphenylhydroxy-ethylamine.**—A warm solution of the d-B-d-A salt was treated with excess ammonium hydroxide. The precipitated base after one crystallization from alcohol melted at 115.2" (corr.) and had $[\alpha]^{22}_{D} = +125.1°$ in absolute alcohol, values that confirm those of Read and Steele.[3]

l-iso-**Diphenylhydroxy-ethylamine *d*-Camphorsulfonate.**—The more soluble fractions obtained in the resolution were combined and recrystallized several times from water. The extreme specific rotation observed was –33.5'. In a later experiment the pure I-B-d-A salt was obtained by combining the pure 2-base (obtained as described in the next section) with *d*-**camphorsulfonic** acid. As its specific rotation was –36.1° the salt obtained in the resolution was still somewhat impure. The pure salt crystallizes from water in long, tetragonal prisms. It is soluble in about 32 parts of water at 25° and is hydrated. It is much more soluble in ethyl acetate than the d-B-d-A salt. The anhydrous salt melts at 205–206° (corr.).

Anal. Subs., 1.1226: lost 0.0434 g. at 105°. Calcd. for $C_{24}H_{31}O_5NS \cdot H_2O$: H_2O, 3.88. Found: H_2O, 3.87.

Rotation. (Hydrated salt). Subs., 0.8113: made up to 50 cc. in water gave $\alpha^{22}_{D} = -1.17'$ in a 2-dm. tube. Hence $[\alpha]^{22}_{D} = -36.1°$. (Anhydrous salt). Subs., 1.0792: made up to 50 cc. in water gave $\alpha^{22}_{D} = -1.62°$ in a 2-dm. tube. Hence $[\alpha]^{22}_{D} = -37.5°$: $[M]_D = -167°$; $[M]_D$ for the base ion –219".

Completion of the Resolution

A sample of the base (16.0 g.) recovered from the intermediate fractions of the original resolution ([a], = –58°; 46% excess I-base) was combined with inactive camphorsulfonic acid (18.0 g.) in sufficient water (450 cc.) so that about half of the total salt separated on cooling. The first crop (15.3 g.) had $[\alpha]_D = -43°$. By systematic crystallization there was finally obtained 12.7 g. of pure, hydrated *l*-B-*dl*-A salt in the less soluble fraction. In a further experiment 12.3 g. of base having [a], = –108° (87% excess I-base) was combined with 14.0 g. of inactive camphorsulfonic acid. There was easily obtained 20.3 g. of pure I-B-dl-A salt.

l-iso-**Diphenylhydroxy-ethylamine *dl*-Camphorsulfonate** crystallizes from water in small prisms or feathery clusters. It is soluble in about 42 parts of water at 25° and is hydrated. The anhydrous salt melts at 206–207° (corr.).

Anal. Subs., 3.3332: lost 0.1306 g. at 105". Calcd. for $C_{24}H_{31}O_5NS \cdot H_2O$: H_2O, 3.88. Found: H_2O, 3.92.

Rotation (Hydrated salt). Subs., 0.8397: made up to 50 cc. in water gave $\alpha^{22}_{D} = -1.62'$ in a 2-dm. tube. Hence $[\alpha]^{22}_{D} = -48.4'$. (Anhydrous salt). Subs., 0.8443:

made up to **50** cc. in water gave $\alpha_D^{22} = -1.72°$ in a 2-dm. tube. Hence $[\alpha]_D^{22} = -50.3°$; $[M]_D = -223°$.

l-iso-Diphenylhydroxy-ethylamine was obtained from the pure **I-B-dl-A** salt and purified as described for the d-base. It melted at 115.2° (corr.) and had $[\alpha]_D^{22} = -125.6'$ in absolute alcohol; values in agreement with those of the d-base.

d-iso-Diphenylhydroxy-ethylamine *dl*-Camphorsulfonate.—For comparison this salt was made from the pure components. It is similar in all respects to the enantiomorphous *l*-B-*dl*-A salt.

Rotation (Hydrated salt). Subs., **1.0242:** made up to 50 cc. in water gave $\alpha_D^{22} = +1.98°$ in a 2-dm. tube. Hence $[\alpha]_D^{22} = +48.2°$.

dl-iso-Diphenylhydroxy-ethylamine *dl*-Camphorsulfonate.—From the mother liquors from the separation of the *l*-B-*dl*-A salt there was obtained a much more soluble salt in masses of poorly formed prisms. It still showed **a** faint negative rotation. For comparison the pure salt was made from the pure components. It is soluble in about **26** parts of water at 25° and is hydrated. The anhydrous salt melts at 198–199° (corr.).

Anal. Subs., **3.6527:** lost **0.1392 g.** at 105°. Calcd. for $C_{24}H_{31}O_5NS{\cdot}H_2O$: H_2O, **3.88.** Found: H_2O, **3.81.**

The author is indebted to the University of Illinois for part of the chemicals used and for laboratory facilities during part of the work.

Summary

A second new method for the complete resolution of externally compensated compounds has been described in connection with a related method previously described. The method was applied to the resolution of inactive iso-diphenylhydroxy-ethylamine with d- and dl-camphorsulfonic acids.

THE MECHANISM OF CARBOHYDRATE OXIDATION. IX. THE ACTION OF COPPER ACETATE SOLUTIONS ON GLUCOSE, FRUCTOSE AND GALACTOSE[1]

BY W. L. EVANS, W. D. NICOLL, G. C. STROUSE AND C. E. WARING[2]

RECEIVED MAY 19, 1928 PUBLISHED AUGUST 4, 1928

The mechanisms proposed in some of the more recent literature dealing with the oxidation of carbohydrates in alkaline solutions rest on one or more of the following ideas: *(a)* that carbohydrates in alkaline solutions are converted into equilibrated systems consisting of a number of isomeric carbohydrates;[3] (b) that these carbohydrates give rise to a series of three

---

enediols which form a restricted equilibrium;[4] (*c*) that the general equilibrium consisting of the components in (*a*) and (b) may be influenced by certain experimental factors, such as a change in both the temperature of the reaction and also the concentration of the alkali used.[5] Nef[6] states that these enediols do not exist in solutions of an alkalinity less than $N/30$, and that they begin to decompose in systems above an alkalinity of $N/20$. In view of the data obtained in this Laboratory with reference to the behavior of glucose, mannose and fructose toward aqueous solutions of potassium hydroxide, the question arises whether one or more of these enediols may not exist in alkaline solutions of even lower normality than $N/30$ and possibly in solutions of less PH value than 7; that is, would the molecular mechanism involved in the oxidation of these sugars in an acid solution be in harmony with the concept which postulates the presence of enediols as intermediate substances in reactions of this character?

Experimental Part

The following is an account of the experimental methods used by us in this investigation.

Oxidizing Agent.—Copper acetate was chosen as our oxidizing agent by reason of the following distinct advantages. (*a*) A saturated solution of this salt is acid. (*b*) Since the cupric ion is reduced to the cuprous condition during the progress of the reaction, the cuprous oxide thus formed becomes an accurate measure of the oxygen consumed in the oxidation. (c) Although preliminary experiments showed that the rate of oxidation of fructose with copper acetate is greater than that of either glucose or galactose under the same conditions, yet the reaction proceeds slowly enough for the purposes of measurement and it may be stopped at any desired time. (*d*) Certain compounds formed in the oxidation of carbohydrates in acid solutions may escape detection when the same sugars are oxidized in alkaline solutions by reason either of their very rapid rearrangement to other compounds or a further oxidation of the intermediates. (e) The unused copper ion is easily removed from solution with hydrogen sulfide.

Oxidation Procedure.—Nine-tenths g. of either glucose, fructose or galactose was placed in a 250-cc. Florence flask containing 25 cc. of **a** copper acetate solution pre-

---

[6] Nef, *Ann.*, 403, 224 (1915).

viously saturated at 50°. To this mixture an excess of copper acetate was added, the amount of it depending on the duration of the experiment. For all experiments of less than one hundred hours 10 g. was added, while 15 g. was sufficient for the longer periods. The flask was closed with a tightly fitting rubber stopper and was then shaken by means of a mechanical agitator in a thermostat kept at 50".

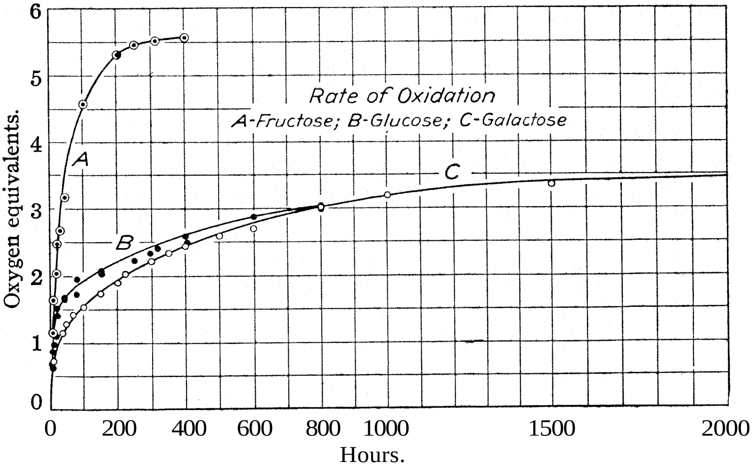

Fig. 1.—Rate of oxidation.

Determination of Consumed Oxygen.—When the sugar had been oxidized for the desired length of time, the flask was removed and cooled with tap water before taking out the stopper in order to avoid the loss of volatile products, for instance, formic acid. The cuprous oxide and unchanged copper acetate were collected in a weighed Gooch crucible, the excess of the acetate being removed by washing the residue with about 50 cc. of cold water. The crucible contents were dried in a vacuum oven at 70–80° without any appreciable oxidation of the cuprous oxide. The rate at which oxygen is used up by these carbohydrates in solutions of copper acetate at 50° is shown in Fig. 1. In Fig. 2, it is seen that the relation between the logarithm of the oxygen equivalents and that of the experimental period is a linear one.

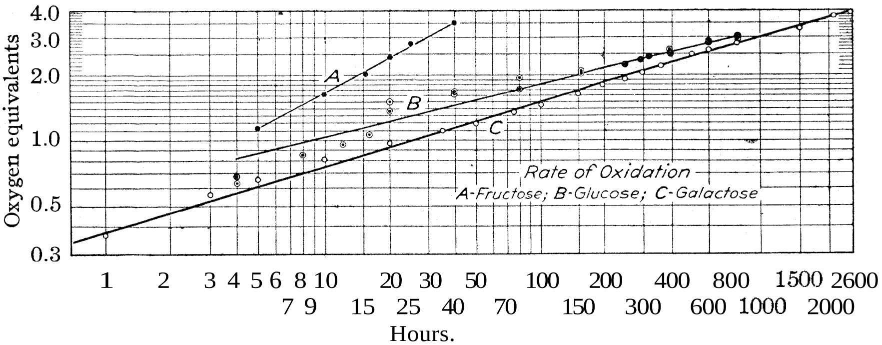

Fig. 2.—Rate of oxidation.

Reaction Products.—Our reaction mixtures were examined for oxalic, formic, glyoxylic and carbonic acids, and glucosone. The percentages of the hexose carbon converted into each of these compounds is expressed as a function of the time in Figs. **3,** 4 and **5.** The number of oxygen equivalents used per gram molecular weight of the hexose was calculated by dividing the weight of the cuprous oxide by the factor 0.716.

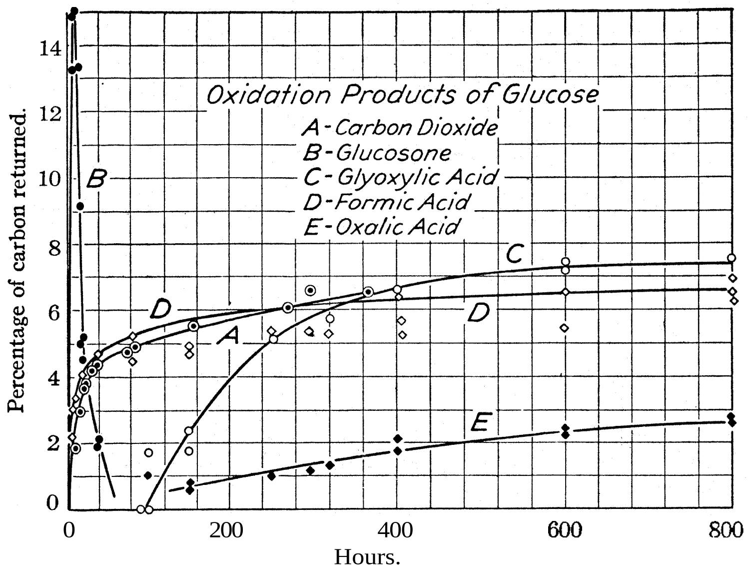

Fig. 3.—Oxidation products from glucose.

The percentages of the hexose carbon converted to the reaction products for which our mixtures were examined is expressed as a function of the oxygen equivalents in each case in Figs. 6, 7 and 8.

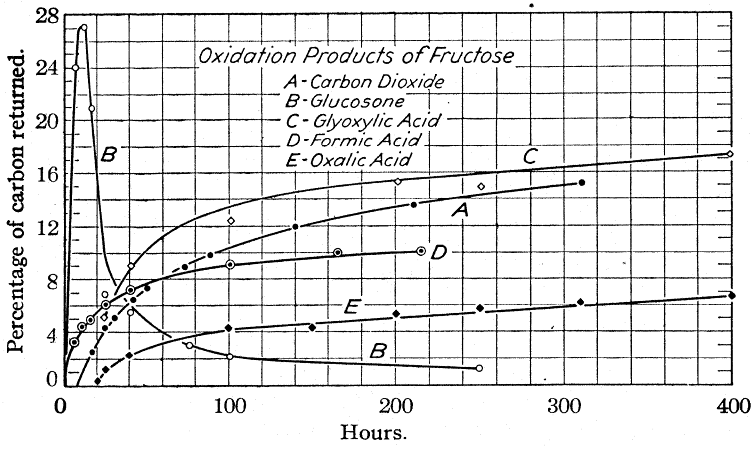

Fig. 4.—Oxidation products from fructose.

Oxalic Acid. (a) Qualitative Identification.—When the cuprous oxide and the unused solid copper acetate from the oxidations of longer duration had been filtered and washed with water, a greenish-white, scaly material was found associated with the residual cuprous oxide. From the work of McLeod[7] it was thought that this substance might be copper oxalate, although this investigator states that the cuprous oxide obtained by him contained no copper oxalate. Our suspected oxalate was soluble in dilute ammonium hydroxide solution. Its identity was established by its conversion to the calcium salt, the composition of which was determined by titrating with potassium permanganate in the presence of sulfuric acid, and also by converting a weighed portion dried in *vacuo* at 120° into the sulfate. This specimen of calcium oxalate contained 27.3% of calcium, while the monohydrate contains 27.43%. Furthermore, the oxalic acid present in the above ammoniacal solution was also converted into the highly insoluble phenylhydrazine oxalate.[8]

(b) Quantitative betermination.--The oxalic acid in these oxidations was determined quantitatively essentially as just described. The cuprous oxide residue was

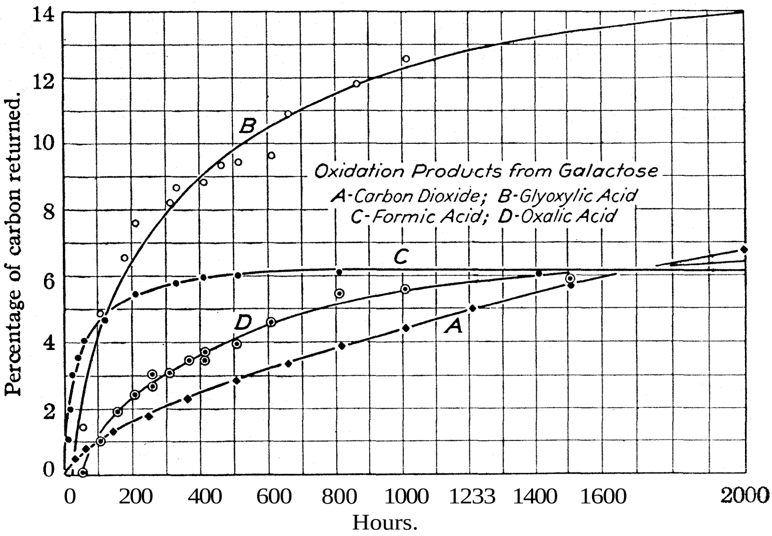

Fig. 5.—Oxidation products from galactose.

treated with 25 to 30 cc. of dilute ammonium hydroxide (1:19). By this procedure small amounts of the cuprous oxide as well as the cupric oxalate were dissolved. In all of the quantitative data throughout this report, the necessary corrections for the solubility of cuprous oxide have been made at the appropriate places. After acidifying the ammoniacal filtrate with acetic acid, the oxalic acid was precipitated as calcium oxalate, which was measured in the way described above.

The formula given by Schaefer[9] for cupric oxalate is $CuC_2O_4\cdot{}^1/_2H_2O$. This formula was used in determining the correction to be applied to the weight of the cuprous oxide obtained in our oxidation curves. The solubility of the oxalate, as determined by Schaefer by conductivity methods at 25°, is 0.02364 g. per liter. It was conclusively proved that all of the oxalic acid obtained in these oxidations was present as the in-

soluble oxalate, since the original filtrates showed no evidence of the presence of this acid.

Formic Acid.—The original filtrate obtained in the procedure described above under "Determination of Consumed Oxygen" was made copper ion-free in the cold by means of hydrogen sulfide. The addition of 1 g. of sodium chloride to this filtrate was found to be fairly effective in preventing the formation of colloidal cupric sulfide. After removing the copper sulfide by suction and washing with water, the filtrate usually had a volume of approximately 150 cc. The presence of formic acid was established by distilling a portion of this copper ion-free filtrate in a vacuum apparatus through which a small amount of natural gas instead of air was allowed to pass. This distillate was examined for formic acid by Fincke's method.[10] It was also found to decolorize dilute alkaline potassium permanganate solutions in the cold. Formic acid was determined quantitatively by using a modification of Jones' well-known method.[11]

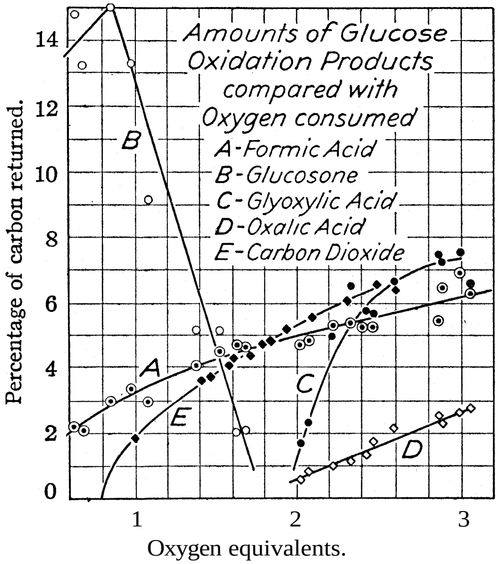

Fig. **6.**

Glyoxylic Acid. Qualitative Identification.—(a) The solution obtained by the removal of the copper ions from the filtrate from the cuprous oxide, unused solid copper acetate and the copper **oxalate** resulting from the oxidation of 0.90 g. of fructose for 165 hours was evaporated to dryness, thus removing formic and acetic acids. On theoretical grounds, we had reason to think that glyoxylic acid should be one of the reaction products in these oxidations. The solution obtained by dissolving the residue resulting from this evaporation in 100 cc. of water was treated with a calcium acetate solution in the hope that calcium glyoxalate would precipitate. By reason of the known insolubility of copper oxalate, we were much surprised to learn that our fine, white precipitate was calcium oxalate. In the filtrate from this precipitate, there began a deposition of comparatively large crystals which were shown by microscopic examination to be different from calcium oxalate. A solution obtained by the same procedure from an experiment with 0.90 g. of fructose for 215 hours yielded almost 0.30 g. of these same crystals. When 0.2806 g. of the crystals, previously dried in a desiccator, was fumed with sulfuric acid, 0.1775 g. of calcium sulfate was obtained. This corresponds to 18.62% of calcium, while calcium glyoxalate dihydrate ($Ca(C_2HO_3)_2 \cdot 2H_2O$) contains 18.02% of calcium. In a similar procedure, 0.90 g. of these crystals was obtained from the 200, 300 and 400 hour experiments with galactose. On analysis these were found to contain 18.35% of calcium. When the solution from a 200-hour experiment with galactose was treated with barium acetate instead of calcium acetate, a white and fairly crystalline compound

was obtained after twenty-four hours' standing. When filtered immediately after precipitation and dried at 100°, this substance had a barium content of 49.9% when fumed with sulfuric acid. An air-dried specimen obtained by slow precipitation was found to contain 47.06% of barium. Anhydrous barium glyoxalate contains 48.48% of barium, the monohydrate 45.59%, and the oxalate monohydrate 56.54%. (b) Positive identification of glyoxylic acid was made as follows. After the original filtrates from a 200-hour experiment with fructose and a 300-hour experiment with galactose had been made copper ion-free, they were treated without previous distillation with 3 cc. of phenylhydrazine. If the slow-forming precipitate contained glyoxylic acid phenylhydrazone, then according to Fischer's[12] observations, the latter should be soluble in alkali and be reprecipitated on treatment with hydrochloric acid. When so treated the lemon-yellow colored precipitate was found to melt at 143° (uncorr.). Fischer gave 138°, Pechmann[13] found 143–145°.

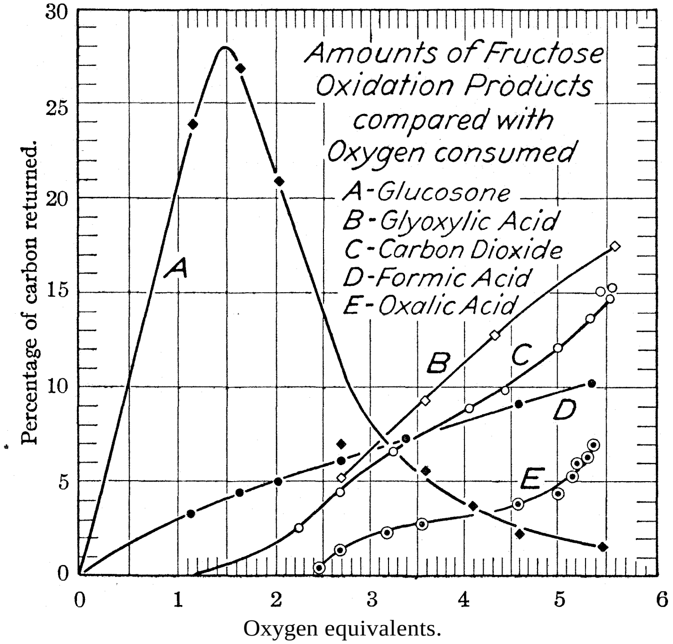

Fig. 7.

Qualitative Identification of **Glucosone.**—When the original filtrates from the glucose and fructose oxidations of five to ten hours' duration were made copper ion-free and were then treated with phenylhydrazine in the cold, glucosazone was immediately precipitated. This behavior corresponds with that of glucosone, which is known to form the osazone in the cold immediately. A control test on glucose and fructose under similar conditions showed that it took several hours for the osazone to precipitate. No galactosone was found in our experiments.

Presence of Unchanged Glucose and Fructose.—If the glucosazone formed on standing at room temperature for about an hour is filtered, and the resulting filtrate is

---

[12] Fischer, *Ber.*, 17, 577 (1884).

[13] Pechmann, *Ber.*, 29, 2163 (1896).

heated at 100° for an hour, the amount of precipitated glucosazone is so large that it can hardly be accounted for on the ground that it resulted only from the osone still remaining in the solution.

Determination of **Glyoxylic** Acid, Glucosone and Unchanged Carbohydrate.—The following method was adopted for the estimation of glyoxylic acid, glucosone and unchanged carbohydrate. The solution which had been made copper ion-free was made up to 100 cc. and then treated with 3 cc. of phenylhydrazine. The mixture was allowed to stand at room temperature for three hours. Parallel experiments with fructose and glucose showed no reaction during this time.[14] At the end of this period, the osazone was filtered, allowed to remain in contact with 25 cc. of a saturated sodium carbonate solution for two or three hours, again filtered, washed with water, dried *in vacuo* at 60° and weighed About 25 cc. of cold benzene was allowed to percolate through the glucosazone in the crucible, which was again dried and weighed. This weight was considered as that of the osazone of glucosone. The sodium carbonate extract was now acidified with hydrochloric acid, which caused a precipitation of any glyoxylic acid phenylhydrazone which might have been present. This yellow-colored precipitate was transferred to a Gooch crucible, dried in a vacuum oven and weighed. From this weight the amount of glyoxylic acid formed in these oxidations was calculated. Fischer[15] states that phenylhydrazine will detect one part of glyoxylic acid in 300 parts of water.

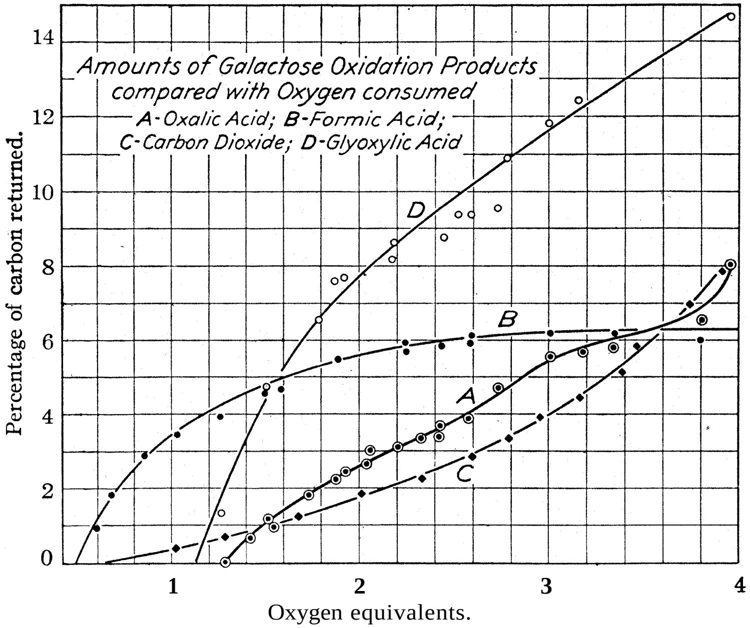

Fig. 8.

The filtrate from the above osazone was now heated on a boiling water-bath for an hour, after which it was cooled in an ice-bath and filtered. After treatment with sodium carbonate, the residue was washed, dried and weighed as described above, in order to determine the osazone of the unchanged sugar. In all but one case it was found that all

---

[14] See Morrell and Crofts, *J. Chem. Soc.*, 75, 787 (1899).

[15] Fischer, *Ber.*, 17,577 (1884).

of the glyoxylic acid phenylhydrazone was completely removed in the first precipitation with phenylhydrazine. The osazone thus obtained was regarded as that of the unoxidized carbohydrate. The first melting points of the osazones prepared in this way were usually low, 185–190°, but percolation of the crucible contents with two crucible volumes of cold benzene to remove traces of tar resulted in obtaining a pure product, m. p. 206–208°. Previous tests on pure glucosazone had shown that the loss in weight on treatment with cold benzene was well within the limits of error of our method.

With reference to the accuracy of the separation of glucosone and unchanged sugar, our method leaves much to be desired, but every attempt was made to make it relatively accurate. Morrell and Crofts[14,16] found that both glucose and glucosone were precipitated only very incompletely by phenylhydrazine. From this it is to be concluded that our glucosone was not completely precipitated in the cold and that the remainder would be found with the osazone of the unchanged sugar. However, the formation and the partial estimation of the glucosone present as a reaction product, together with the very accurate measure of the oxygen consumed, have aided us very greatly in the interpretation of the mechanism involved in the oxidation of these carbohydrates with copper acetate solutions. Mr. E. F. Schroeder, of this Laboratory, is at present studying the properties of glucosone.

Carbon Dioxide.—During these oxidations gas pressure developed within the reaction flasks. The gas was found to be carbon dioxide. In some cases, especially that of fructose, the pressure became so great that the stoppers were blown from the flasks with considerable force. The apparatus used for the quantitative determination of carbon dioxide consisted of a sufficiently large flask (500–1000 cc.), closed with a stopper fitted with an inlet tube for the admission of carbon dioxide-free natural gas, an outlet tube attached to a small Liebig condenser inclined at an angle of 45° and a mercury seal through which a mechanical stirrer passed. The condenser was connected to two ordinary gas washing bottles arranged in series. These contained barium hydroxide solution. To the outlet of the last wash bottle a soda lime tube was attached. The natural gas used to sweep the carbon dioxide to the absorption train was passed very slowly through a large soda lime tower attached to the inlet tube of the reaction flask. All stoppers were coated with shellac. The reaction flask was immersed in the thermostat. The following oxidation charges were used lor the carbon dioxide determinations in these experiments. (a) Eighteen grams of glucose was dissolved in 500 cc. of copper acetate solution saturated at 50°. To this solution, 300 g. of solid copper acetate was added, the total reaction mixture being contained in a 1000-cc. Pyrex flask. *(b)* Nine grams of fructose and 27 g. of galactose were used, the other agents and size of reaction flask being in the same ratio as that given for glucose. The barium carbonate formed in the absorption train was removed by filtration through a porous Alundum crucible, then thoroughly washed with recently boiled water, dried in a vacuum oven and weighed. The crucible was freed from the barium carbonate with dilute acetic acid, carefully washed with water, dried and weighed. The difference between the two weights was regarded as that of barium carbonate.

Hydrogen Ion Concentration.—Preliminary work had shown that the hydrogen electrode could not be used for this work because the platinized platinum electrode soon became coated with copper. However, the quinhydrone electrode gave satisfactory results if the temperature was not too high.[17] We used two general methods in actual practice. *(a)* In one, **3.6** g. of glucose was dissolved in saturated copper acetate

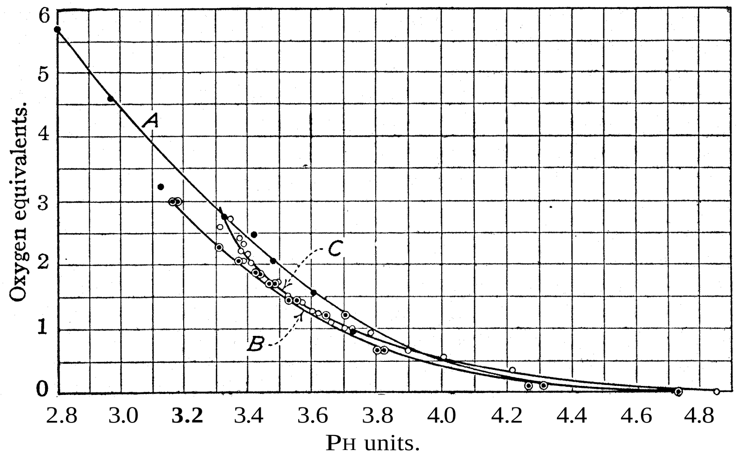
[17] (a) Mathews, Trans. Faraday *Soc.*, July 6 (1925); (b) Eucken, Jette and LaMer, "Fundamentals of Physical Chemistry," McGraw-Hill Book Company, New York, 1925, p. **396.**

solution. The reaction mixture was kept under exactly the same conditions as described for the oxidation procedure. At suitable intervals 5cc. samples were withdrawn and the voltages measured with the saturated calomel electrode and the quinhydrone electrode, using the standard potentiometric method. *(b)* Our second method, employed with fructose and galactose, consisted in using individual reaction mixtures for each reading. In both cases the PH values were calculated from the equation PH = $7.68-(E/0.059)$, in which E is the observed voltage.[18] The change in the hydrogen ion concentration throughout these oxidations is shown in Fig. 9.



A, fructose; B, glucose; C, galactose.

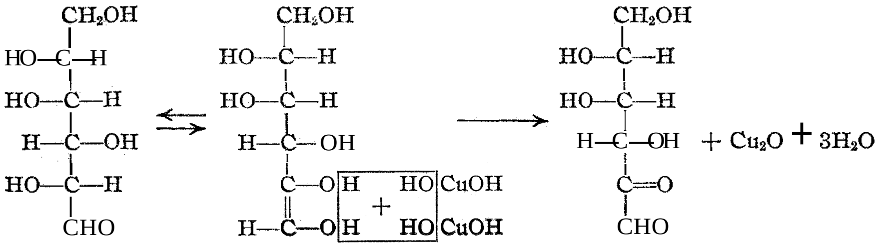
Theoretical Part

Glucosone.—It has been pointed out above that one of the main objectives in these experiments was to determine whether the general principles underlying the mechanism of carbohydrate oxidation in alkaline solutions were sufficient to explain the course of such oxidations in acid solutions. Our experimental data show that 13.25% of the glucose carbon and 23.83% of that of fructose were recovered from the reaction mixture of each carbohydrate as glucosone at the end of the first five-hour period. These facts and the relative rate of formation of the hexosone from these two sources are shown in Fig. 10. Galactosone was not detected in the reaction mixtures of galactose. Its absence may have been due to its being oxidized at a greater velocity than that at which it was formed.[19] The presence of glucosone in these reactions is easily understood on the assumption that the common 1–2 hexose enediol of glucose and fructose is present in these acidic solutions, and that this enediol is oxidized in accordance with the following reactions.

[18] LaMer and Rideal, THIS JOURNAL, 46, 224 (1924).

[19] See Morrell and Crofts, J. Chem. *Soc.*, 77, 1220 (1900).



Glucose Glucose 1–2 enediol Glucosone

Such an explanation would regard the enediol as being an acid. In addition to the well-known behavior of these hexoses in alkaline solutions of varying concentrations, the following evidence seems to support this point of view. (*a*) Michael and Rona[20] determined the dissociation constants of some very weak acids, particularly the carbohydrates, and found that the value for fructose was 8.8 X 10^{-13}, for glucose 6.6 X 10^{-13} and for galactose **5.3** X 10^{-13}. (*b*) Powell[21] has shown both by conductivity methods and also by the change of rate in the hydrolysis of ethyl acetate in the presence of fructose and glucose that these carbohydrates form definite compounds with the base, and in the case of sodium hydroxide the reaction takes place in the ratio of one molecule of each. (*c*) Kling[22] found that

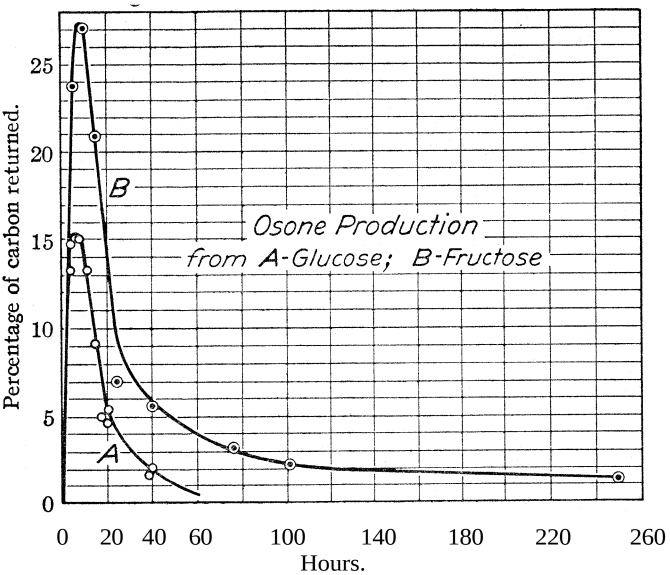


Fig. 10.—Osone production.

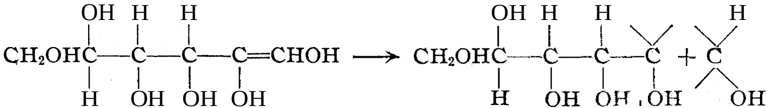
acetol gives an acid reaction when dissolved in water and that the acidity returns even after neutralization. Acetol may undergo the following reaction

$$CH_3COCH_2OH \rightleftarrows CH_3C(OH){=}CHOH$$

This observation of Kling with reference to the behavior of acetol toward aqueous solutions of alkalies suggests an analogous behavior in the carbohydrates, especially fructose. (d) Wolfrom and Lewis[23] have shown recently that the P_H value of one liter of lime water to which had been added one mole of d-glucose is changed from 12.6 to 10.6. In a separate experiment it was established that gluconic acid is not oxidized with copper acetate under the same experimental conditions as those employed with fructose, glucose and galactose. The same observation was made with galactonic acid lactone. Therefore, it is clear that these oxidations proceed by some mechanism other than through the formation of these acids.

Existence of Hydroxymethylene. Formic Acid.—If the hexose-1,2-enediol of these carbohydrates exists in these solutions, the presence of formic acid as an oxidation product shows that the common 1,2-enediol of fructose and glucose and that of galactose are suffering decomposition according to the following equation.



$$CH_2OH\overset{OH}{\underset{H}{C}}-\overset{H}{\underset{OH}{C}}-\overset{H}{\underset{OH}{C}}-\underset{OH}{C}{=}CHOH \longrightarrow CH_2OH\overset{OH}{\underset{H}{C}}-\overset{H}{\underset{OH}{C}}-\overset{H}{\underset{OH}{C}}-\underset{OH}{C} + \overset{H}{\underset{OH}{C}}$$

(Galactose-1,2-enediol) (Lyxose—active form) + (Hydroxymethylene)

The active form of the pentose and that of formaldehyde may be oxidized to the pentonic and formic acids, respectively. This interpretation is

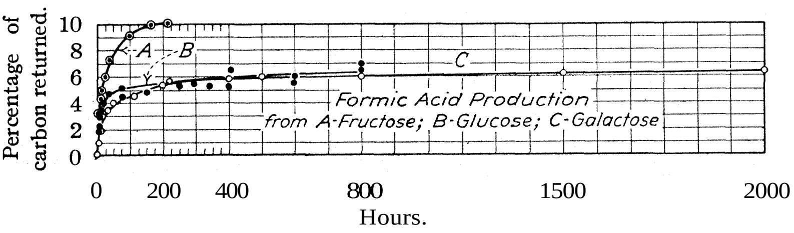


Fig. 11.—Formic acid production.

strongly supported by the recent convincing experiments of Gustus and Lewis on the oxidation of 2,3,4,6-tetramethyl glucose.[4h] The percentages of the hexose carbon converted to formic acid through oxidation with copper acetate is expressed as a function of the time in Fig. 11.

The postulated existence of hydroxymethylene as an intermediate product in these carbohydrate oxidations made it necessary to ascertain

[23] Wolfrom with Lewis, THIS JOURNAL, 50, 842 (1928).

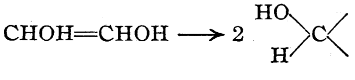
whether, if formed, it could be oxidized with copper acetate directly to formic acid. In order to obtain information on this very important point, we carried out the following experiments.

(a) **Hydroxypyruvic** Acid and Copper Acetate.—The action of hydroxypyruvic acid toward copper acetate was first studied. It was prepared by the following modification of Wills'[24] method. A solution of 40 g. of collodion in 160 g. of ether added to 500 cc. of 10% sodium hydroxide solution was allowed to stand for thirty-six hours. The solution obtained by acidifying the final lower layer of this mixture was evaporated to 200 cc., boiled with animal charcoal, made just alkaline with ammonium hydroxide and then treated with lead acetate. After filtration, the thick, white precipitate was suspended for an hour in water through which a current of air was passing to remove any free ammonia. A portion of the light yellow filtrate obtained after decomposing the suspended white precipitate with hydrogen sulfide gave an osazone which melted at 200–201° without purification. Wills found 205° for the pure substance. Aliquot portions (25 cc.) of a 200cc. solution containing 0.1544 g. of hydroxypyruvic acid were treated with 2 g. of solid copper acetate in the thermostat at 50° for 360 hours. The mixtures gave positive reactions when examined qualitatively for formic acid by the methods of Fincke and Bender. Another reaction mixture containing 0.193 g. of hydroxypyruvic acid was found to contain 0.0482 g. of cuprous oxide (1.81 oxygen equivalents per one g.m.w. of hydroxypyruvic acid), and 0.0162 g. of formic acid (6.66 cc. of 0.1 N $KMnO_4$). The carbon dioxide evolved in one sample gave 0.0365 g. of barium carbonate (0.008 g. of CO_2). If hydroxypyruvic acid should undergo the following reaction in the presence of copper acetate

$$CH_2OHCOCOOH \longrightarrow CH_2OHCHO + CO_2$$

the glycol aldehyde thus formed should in turn undergo an enolization to ethenediol and this tautomer then subsequently decompose according to the following equations

$$CH_2OHCHO \rightleftarrows CHOH{=}CHOH$$



$$CHOH{=}CHOH \longrightarrow 2\ \begin{matrix}HO\\H\end{matrix}\!\!>C<$$

two molecules of formic acid and one molecule of carbon dioxide should be found in the reaction products. Our experimental data are compared with the demands of these assumptions in the following table.

	$CH_2OHCOCOOH$ used, g.	Oxygen equivalents	CO_2	HCOOH
Found	0.193	1.81(90.5%)	0.008	0.0162(95%)
Theoretical	.193	2.00	.008	.0171

---

[24] Wills, Ber., 24, 401 (1891).

(b) Glycol Aldehyde and Copper Acetate.—Dihydroxymaleic acid (3.4 g.) was converted into glycol aldehyde according to the directions of Nef,[25] a procedure which should yield 1.2 g. of the desired compound. In this experiment we removed the carbon dioxide with carbon dioxide-free natural gas instead of air. On treating 25 cc. of a 200cc. aqueous solution of this product with *p*-nitrophenylhydrazine hydrochloride and sodium acetate, 0.5058 g. of the hydrazone was obtained,[26] thus showing that our solution contained 0.736 g. of the aldehyde instead of 1.2 g. Since the hydrazone is somewhat soluble, this figure may be a little too low. Six 25cc. portions of our standard solution were treated with 2 g. of solid copper acetate and agitated on the thermostat at 50°. Their distillates, prepared as described above, were examined for formic acid. Cold alkaline potassium permanganate and Fincke's test gave positive reactions. Denigès' test for hydroxy acids gave only a faint response. A quantitative determination showed that 25% of the aldehyde had been converted into formic acid. Neither of the final reaction mixtures in (a) and (b) reduced Fehling's solution nor did they affect Schiff's reagent. (c) In this connection we confirmed the observations of McLeod with reference to the fact that aqueous solutions of formaldehyde do not reduce copper acetate.[27] This investigator used a temperature of 100°, while ours was 50°.

From these experimental results it is clear that the active form of formaldehyde must be hydroxymethylene. Baly[28] in his lecture on "Photosynthesis" said, "In view of the remarkable reactivity of activated formaldehyde it seems to me that it is necessary to picture a different formula from that given to ordinary formaldehyde. This abnormal activity is well expressed by the Nef formula,  $\mathrm{C}\begin{smallmatrix}\diagup\mathrm{H}\\ \diagdown\mathrm{OH}\end{smallmatrix}$, with the carbon atom bivalent." Nef himself had given expression previously to a similar opinion in the statement,[29] "Die physiologischen Wirkungen des Formaldehyds beruhen zweifellos auf einer Dissociation desselben in Oxymethylen." ("The physiological activities of formaldehyde doubtless depend upon a dissociation of it into oxymethylene.")

We feel that our experimental results given above in (a), (b) and (c) are convincing evidence for this general point of view, and that the hydroxymethylene obtained from these sugars must be oxidized to formic acid under the conditions of our experiments.

Carbon Dioxide.—Carbon dioxide was being evolved from galactose in decreasingly smaller amounts at the end of 2000 hours and in similar amounts from glucose and fructose at the end of 366 hours and 315 hours, respectively. Our quantitative data show that this gas begins to appear as one of the reaction products of fructose and glucose at about the same time that the glucosone production has reached a maximum. In view of this fact, we concluded that a-ketogluconic acid was being formed by the direct oxidation of the osone, and that this compound was undergoing decomposition into carbon dioxide and arabinose. Since α-ketogluconic acid is unknown as a stable substance,[30] hydroxypyruvic acid was chosen for our study as being representative of hydroxy-α-keto acids. This acid under the same experimental conditions decomposes with an evolution of carbon dioxide, as pointed out above. As the time of oxidation of these carbohydrates is increased, it is seen from Figs. **3,** 4 and 5 that the glucosone gradually is being used up. The percentage of the hexose carbon being converted to carbon dioxide is expressed as a function of the time in Fig. 12. It is seen that fructose is the most sensitive of the three sugars to copper acetate. Ruff found that gluconic acid on being oxidized with bromine was converted into a-ketogluconic acid. In our experiments with fructose and glucose we found no derivative of a-ketogluconic acid. By the following special experiments it was conclusively proven that carbon dioxide was not a decomposition product of the following compounds.

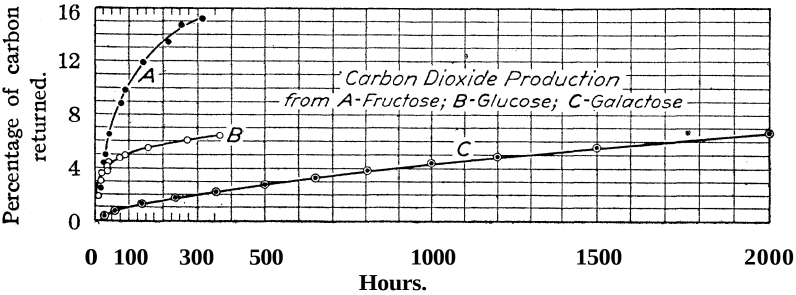

Fig. 12.—Carbon dioxide production.

(a) Galactonic and Gluconic Acids.—One gram of gluconic acid and of galactonic acid lactone were each treated for one week at 50° with copper acetate. Only a trace of cuprous oxide was formed. This was probably due to some slight impurity. The solid copper acetate disappeared and the solution took on the well-known dark blue color.

(b) **Glyoxal.**—No trace of cuprous oxide was found when glyoxal was treated with copper acetate.

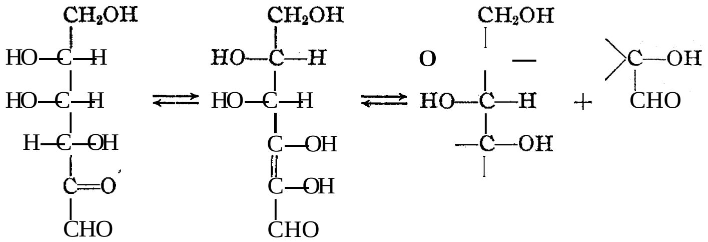
---

[30] Ruff, *Ber.*, **32**,2269 (1899).

(c) Glycolic Acid.—This acid gave the merest trace of reduction.

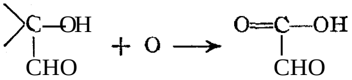
(d) McLeod made the same kind of observations with formic acid, formaldehyde, glycolic acid and oxalic acid,

Hexosone-2,3-enediol. Glyoxylic, Oxalic and Glycolic Acids.—(a) The hexosones formed in these oxidations may also undergo an enolization. The hexosone-2,3-enediol thus formed may then split at the double bond, thus giving rise to a tetrose and glyoxal. These changes may be represented by the following reactions.



Glucosone Glucosone-2,3-enediol Active form of erythrose Half active form of glyoxal

Although Fischer[31] does not record the nature of the insoluble lead compound of glucosone which he prepared by the interaction of lead hydroxide and the hexosone, it is quite probable that it is a lead salt of the hexosone-2,3-enediol. No compounds were formed in our reaction products which indicated that the hexosone-2,3-enediol itself had undergone oxidation with copper acetate. *(b)* In quite the same manner as hydroxymethylene is oxidized to formic acid, so also is the half active form of glyoxal converted to glyoxylic acid according to the following reaction.



In connection with this point of view concerning the half active form of glyoxal, it is of importance to emphasize that glyoxal itself is unacted upon by copper acetate under the experimental conditions of this work. The oxalic and glycolic acids obtained in these experiments are undoubtedly derived from the glyoxylic acid, a compound which Debus[32] observed would rearrange into these two acids. He also noticed that its calcium salt was converted into calcium oxalate and glycolate in the presence of lime water. Debus furthermore observed that glyoxylic acid does not reduce copper acetate. In solutions of copper acetate containing this acid, we found that copper oxalate was being formed without the formation of any cuprous oxide. With reference to the decomposition of the hexosone-2,3-enediol, it is of much interest to note that Morrell and Crofts[33]

---

[31] Fischer, *Ber.*, 21,2631 (1888); **22,** 87 (1889).

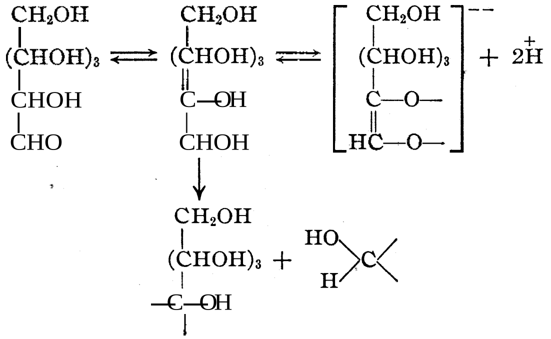
[32] Debus, Ann., 338,336 (1905).

[33] Morrell and Crofts, J. Chem. *Soc.*, 81, 67 (1902).

oxidized glucosone with bromine and isolated the erythronic acid so formed as the calcium salt.

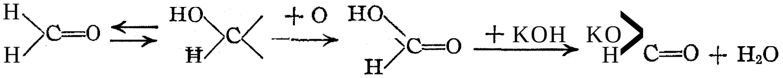
Hydrogen Ion Concentration.—It has been pointed out previously that an increase in the alkali normality of aqueous solutions of the hexoses and potassium hydroxide causes a shifting in the equilibrium existing between the three isomeric enediols in the direction of the 3,4-form. The relation existing between the amounts of lactic acid formed from these sugars and the alkali normality favors this point of view, as do also the character and amounts of oxidation products obtained when these aldohexoses are oxidized with alkaline potassium permanganate. The observations of Amick concerning the influence of alkalinity on the copper number of glucose is especially significant in this connection. Therefore, it is clear that an increase in the hydrogen ion concentration of the oxidizing mixtures containing copper acetate should have the opposite tendency and that the degree of ionization of these enediols should be diminished through the mass action effect of the common ion. The recent work of Wolfrom with Lewis on the de-enolization of an equilibrated mixture obtained from 2,3,4,6-tetramethyl glucose supports this point of view.

The equilibrium represented by the following equation would be shifted to the left by an increase in the hydrogen ion concentration.



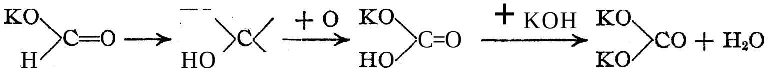
Since this would tend to diminish the concentration of the hexose-1,2-enediol, it follows that the amount of hydroxymethylene would diminish accordingly. This would result in the yield of formic acid being a decreasing function of the time. That this is so is seen in Fig. 11. That the oxidation of the hexose to a hexosone still continues after the cessation of formic acid is evidenced by the fact that glyoxylic and carbonic acids are still forming. In this connection it is of interest to point out that the oxidation of these hexoses with aqueous solutions of copper sulfate proceeds very much more slowly than with copper acetate. Furthermore, when copper acetate solutions are treated with highly ionized acids, the oxidation of the sugars practically stops. We found no evidence for the oxidation of the hexosone-2,3-enediol, since phenylhydrazine did not yield a trihydrazone.

Applying this point of view to the following equation it is seen that alkaline oxidizing agents should yield alkali metal formates.



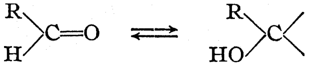
$$\begin{matrix}\text{H}\\\text{H}\end{matrix}\!>\!\text{C{=}O} \rightleftarrows \begin{matrix}\text{HO}\\\text{H}\end{matrix}\!>\!\text{C}\!< \xrightarrow{+\text{O}} \begin{matrix}\text{HO}\\\text{H}\end{matrix}\!>\!\text{C{=}O} \xrightarrow{+\text{KOH}} \begin{matrix}\text{KO}\\\text{H}\end{matrix}\!>\!\text{C{=}O} + \text{H}_2\text{O}$$

The conversion of formates into carbonates in alkaline potassium permanganate oxidations must be preceded by a further enolization before oxidation takes place. These changes may be represented by the following equation.



$$\begin{matrix}\text{KO}\\\text{H}\end{matrix}\!>\!\text{C{=}O} \longrightarrow \begin{matrix}\text{--}\\\text{HO}\end{matrix}\!>\!\text{C}\!< \xrightarrow{+\text{O}} \begin{matrix}\text{KO}\\\text{HO}\end{matrix}\!>\!\text{C{=}O} \xrightarrow{+\text{KOH}} \begin{matrix}\text{KO}\\\text{KO}\end{matrix}\!>\!\text{CO} + \text{H}_2\text{O}$$

In this general interpretation it is obvious that the ionization of hydroxymethylene after the same manner as the sugar enols might be considered, but we have assumed that the monose is probably oxidized instantly to formic acid. From this discussion one must conclude that the direct oxidation of aldehydes in general seems to involve an equilibrium condition in which a certain portion of the aldehyde molecules is in the activated condition. This may be expressed by the following equation



$$\begin{matrix}\text{R}\\\text{H}\end{matrix}\!>\!\text{C{=}O} \rightleftarrows \begin{matrix}\text{R}\\\text{HO}\end{matrix}\!>\!\text{C}\!<$$

Inactive to oxidation Active to oxidation

In harmony with this point of view with reference to the experiment of Upson and Jensen in which these investigators obtained only 0.5 g. of gluconic acid from 200 g. of glucose is the observation of Amick to the effect that "enolization must occur before oxidation."

Summary

1. Aqueous solutions of fructose, glucose and galactose have been oxidized with copper acetate at 50° for the purpose of ascertaining whether the general principles underlying the mechanism of carbohydrate oxidation in alkaline solutions are sufficient to explain the course of such oxidations in acid solutions. The advantages in the use of copper acetate are outlined.

2. The reaction mixtures were examined for glucosone, formic, carbonic, glyoxylic and oxalic acids. The presence of glycolic acid was proved qualitatively but it was not measured quantitatively. The quantities of these are expressed both as functions of the time and the oxygen consumed. The oxygen consumed by each sugar is expressed as a function of the time. The hydrogen ion concentration is expressed as a function of the oxygen consumed.

3. The hexose-1,2-enediols are regarded as being oxidized to the

hexosones. The glucosone is obtained as the osazone. The galactosone was not obtained as a reaction product. It is probably used up as rapidly as it forms.

4. The formic acid arises from the oxidation of the hydroxymethylene obtained by the decomposition of the hexose-1,2-enediols. That hydroxymethylene will undergo this change was shown by a study of the behavior of copper acetate toward glycol aldehyde and hydroxypyruvic acid.

5. It is thought that carbon dioxide arises from the decomposition of the unstable α-ketohexonic acids. Hydroxypyruvic acid loses a molecule of carbon dioxide when oxidized with copper acetate.

6. The hexosones may form hexosone-2,3-enediols, which are thought to decompose into the active form of the tetrose (tetrose methylenol) and glyoxal (half active form). The latter is oxidized to glyoxylic acid, which in part is converted into oxalic and glycolic acids. Glyoxal does not reduce copper acetate solutions, hence it is thought that the glyoxylic acid comes from an activated form (glyoxal-half-methylenol).

7. The increase in the hydrogen ion concentration tends to reverse the equilibrium between the enediols in the direction of suppressing enediol formation. This would lead to a reduction in the formic acid yields with increasing time. The increase in the hydrogen ion concentration would tend to suppress the enolization of the hexosone-2,3-enediol. This harmonizes with the fact that no derivatives were found of 2,3-diketohexoses when the reaction mixtures were treated with phenylhydrazine.

8. The view is expressed that aldehydes exist in two forms, those active toward oxidizing agents and those not. The former are derivatives of methylenols; that is, the hydrogen is bound to oxygen and the carbon is bivalent. In the inactive molecules the carbon is tetravalent. An equilibrium exists between these two forms which may be shifted by a change in the hydrogen ion concentration. The conversion of aldehydes to carbonates in alkaline solutions is explained on this basis.

4-AMINO-5-BROMO-1,3-DIMETHYLBENZENE

BY ALVIN S. WHEELER AND R. E. THOMAS[1]

RECEIVED MAY 28, 1928 PUBLISHED AUGUST 4, 1928

5-Bromo-m-xylidine (old nomenclature) has been prepared by bromination of m-4-xylidine in hydrochloric acid solution[2] and also in glacial acetic acid,[3] the latter method being adopted in this investigation. Bromination of the free base produces the 5-bromo isomer, while the acetate gives the 6-bromo with a small amount of the 2-bromo form. The hydrochloride, benzoate, xylenol,[4] methyl and ethyl ethers and two dyes were also prepared.

Experimental Part

4-Amino-5-bromo-1,3-dimethylbenzene.—The method of preparation given by Noelting, Braun and Thesmar[3] was followed. However, in order to avoid the formation of an oil, the bromination product, instead of being poured into water, was filtered off, washed with glacial acetic acid and dried. The base was set free with sodium carbonate solution and recrystallized from dilute methyl alcohol; m. p. 46°.

Hydrochloride.—The hydrochloride consists of white crystals which are quite stable, not changing in a year. It readily sublimes without decomposition.

Anal. Calcd. for $C_8H_{10}NBr\cdot HCl$: HCl, 15.25. Found: 15.28.

Benzoate.—The benzoate was prepared by the Schotten-Baumann reaction. The product, obtained in nearly quantitative yield, was recrystallized from dilute alcohol. It forms prismatic needles melting at 186°.

Anal. Calcd. for $C_{15}H_{14}ONBr$: Br, 26.29. Found: 26.20.

Methyl Ether of 4-Hydroxy-5-bromo-1,3-dimethylbenzene, $C_6H_2(CH_3)_2BrOCH_3$.—The bromoxylidine was diazotized in the presence of sulfuric acid and converted into the xylenol (b. p. 228–230°) by boiling the solution; 3.1 g. of the xylenol was mixed with 1.2 cc. of methyl iodide and 0.36 g. of sodium in 10 cc. of methanol. After heating for two hours over steam, the volatile portion was boiled off, water added to the residue and the mixture extracted with ether. The oil obtained boiled chiefly at 232°; sp. gr. 1.362 (25°/25°); yield, high.

Anal. Calcd. for $C_9H_{11}OBr$: Br, 37.1. Found: 37.7.

Ethyl Ether.—Yield, high; boils chiefly at 246°; sp. gr. 1.290 (25°/25°).

Anal. Calcd. for $C_{10}H_{13}OBr$: Br, 34.9. Found: 34.9.

4-Chloro-5-bromo-1,3-dimethylbenzene, $C_6H_2(CH_3)_2ClBr$.—The bromoxylidine was diazotized in the presence of hydrochloric acid and copper paste was added. The product from the distillation with steam was extracted with ether. The oil recovered from the ether boiled over a wide range. The portion boiling a little below to a little above 250° was analyzed.

---

Anal. Calcd. for C_8H_8ClBr: Cl, 16.16. Found: 16.00.

1,3-Xylyl-5-bromo-4-nitrile, $C_6H_2(CH_3)_2BrCN$.—The bromoxylidine was converted into the nitrile by the Gattermann-Sandmeyer reaction. In the distillation with steam the nitrile crystallized in the condenser, from which it was removed with hot alcohol. It crystallized in needles which melted at 86–87°. A by-product appeared in the receiver. It boiled at 205° and was therefore regarded as 5-bromo-13-dimethylbenzene.

Anal. Calcd. for C_9H_8BrN: Br, 38.05. Found: 38.00.

1-(5-Bromo-1,3-xylyl-4-azo)-2-naphthol, $C_6H_2(CH_3)_2BrN_2C_{12}H_6OH$.—The bromoxylidine was diazotized and coupled with 2-naphthol in the presence of sodium hydroxide. The crude red precipitate melted at 132°. Recrystallization from a mixture of alcohol and petroleum ether gave rich red needles melting at 136°.

Anal. Calcd. for $C_{18}H_{15}ON_2Br$: Br, 23.50. Found: 23.15.

1-(5-Bromo-1,3-xylyl-4-azo)-4-phenol, $C_6H_2(CH_3)_2BrN_2C_6H_4OH$.—On coupling phenol with diazotized bromoxylidine a dark yellow precipitate formed, weight 3 g. from 2 g. of the xylidine. It was recrystallized from 90% acetic acid, or from a mixture of 3 parts of benzene and 7 parts of alcohol, to give small orange-colored crystals which melt at 166°.

Anal. Calcd. for $C_{14}H_{13}ON_2Br$: Br, 26.20. Found: 26.14.

Summary

1. The preparation of 4-amino-5-bromo-1,3-dimethylbenzene was improved upon.
2. Its hydrochloride and benzoate are described.
3. The methyl and ethyl ethers of the bromoxylenol were prepared.
4. The amino group was replaced by Cl and by CN.
5. Two azo dyes were made by coupling the diazotized bromoxylidine with phenol and with 2-naphthol.

SYNTHETIC HOMOLOGS OF *d,l*-EPHEDRINE

BY J. F. HYDE,[1] E. BROWNING[1] AND ROGER ADAMS

RECEIVED MAY 31, 1928 PUBLISHED AUGUST 4, 1928

The interesting and important drug, ephedrine (I) has in recent years been brought to the attention of the medical profession and has become widely used chiefly through the brilliant investigations of Dr. K. K. Chen.[2] Although a careful comparison of the pharmacological action of *l*-ephedrine with *d,l*-ephedrine and pseudo-ephedrine has been completed, no study has as yet been made of the comparative values of 1-ephedrine or *d,l*-ephedrine with a series of homologs, particularly those in which an

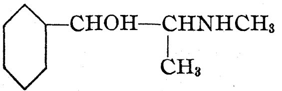
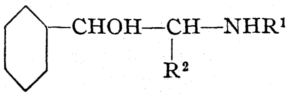
[2] Chen and Kao, *J. Am. Pharm. Assocn.*, **15**, 625 (1926). At the end of this article is given a bibliography of chemical, pharmacological and medical articles on ephedrine.

alkyl group other than methyl is found on the nitrogen or on the β-carbon atom from the benzene ring.

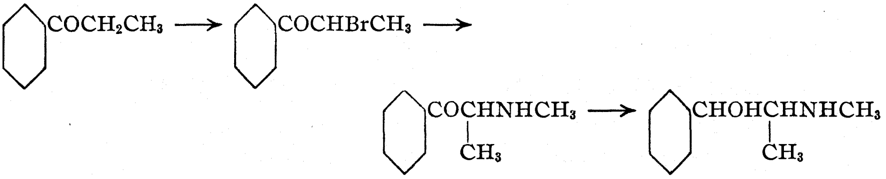


I



II

In this investigation a series of racemic compounds of the general formula (II) has been prepared where R^1 is methyl, ethyl, n-propyl, *iso*-propyl, n-butyl or n-amyl, and where R^2 is hydrogen, methyl, ethyl or n-propyl. In addition, one or two compounds were made in which both hydrogens of the nitrogen were replaced by alkyl groups. The methods of synthesis of *d,l*-ephedrine have been reviewed in the article of Chen previously referred to and so need not be repeated here. It is sufficient to say that for this work no attempt was made to find the process which might prove the most advantageous from a commercial standpoint, but merely the one which could be used most conveniently in the laboratory for obtaining small quantities of material. The one selected for the preparation of *d,l*-ephedrine and then applied to the preparation of its homologs was first described by Eberhard[3] and later repeated by Fourneau and Kanao[4] and Fourneau and Torres.[5] This consists in the bromination of propiophenone to a bromopropiophenone, condensation with methylamine to form the a-methylaminopropihphenone, and finally reduction to the corresponding amino alcohol. It is reported that if sodium amalgam was used as a reducing agent in the last step, a mixture of *d,l*-ephedrine and pseudo-ephedrine was usually formed. With palladium and hydrogen, however, Eberhard obtained *d,l*-ephedrine.



In this investigation *d,l*-ephedrine was first synthesized and the work carried out by H. A. Graffis. No particular comments are necesssary on the bromination. In the second step, however, the method of purification of the α-methylaminopropiophenone is worthy of mention, since the purity is important for the success of the subsequent reduction. The reaction mixture containing α-methylaminopropiophenone hydrochloride and excess methylamine hydrochloride was evaporated to dryness in a vacuum. The crude mixture obtained was extracted several times with chloroform, which left methylamine hydrochloride insoluble and dissolved

the amino ketone hydrochloride. The latter was recrystallized and reduced by means of hydrogen and platinum-oxide platinum black to the amino alcohol.

This method of catalytic reduction proved to be an excellent procedure, not only on account of its convenience for the production of amino alcohol but also because apparently just one of the two possible isomeric amino alcohols resulted. The product isolated proved to be exclusively *d,l*-ephedrine, which was essentially pure after one crystallization.

The various homologs in which the alkyl group attached to the β-carbon atom was varied in size were made in the same general manner as that used for ephedrine, except that acetophenone, butyrophenone, valerophenone, etc., were halogenated in place of propiophenone and the subsequent steps carried out with these halogenated products.

In the series in which merely the alkyl group on the nitrogen was varied, the method of isolation of the amino ketones had to be modified because the excess alkylamine hydrochloride was soluble in chloroform. In this case the mixture of the amino ketone and excess of alkyl amine was isolated and the excess of the amine removed by distillation in *vacuo* at room temperature.

Dr. E. C. Kendall of the Mayo Clinic has kindly made tests on the amino ketones and amino alcohols to determine the effect of the compounds on blood sugar. His detailed results will be published elsewhere but it is sufficient to remark here that in the series where the methylamino group remains constant' and the alkyl group on the β-carbon atom is varied in size (in formula II, R^1 is methyl and R^2 varies from hydrogen to n-propyl) the molecule where the $R^2 = H$ is the most effective, and the increase in blood sugar becomes less as the group is varied from methyl to propyl. On the other hand, if the alkyl group on the β-carbon atom remains a methyl and the alkyl group on the nitrogen is varied in size (in formula II, R^2 is methyl and R^1 varies from methyl to n-amyl) the blood sugar steps up with the increase in the number of carbon atoms in the alkyl group. The butyl and amyl derivative cause convulsions and respiratory paralysis following the injection. Those substances in which two hydrogens of the nitrogen were replaced by alkyl groups showed no physiological effect.

The ketones corresponding to the effective alcohols gave essentially the same results as the alcohols in the effect on blood sugar.

The amount of blood sugar increase was dependent to a certain extent on the size of the dose.

The effect of these products on blood pressure was ascertained by Mr. C. Nielsen and assistants of the Abbott Laboratories, North Chicago, Illinois. They report that of the various homologs only one caused any marked rise in blood pressure. It was the homolog of ephedrine in which the methyl group of the β-carbon atom was replaced by hydrogen. Practically all of the others either caused merely a very slight rise in blood pressure preceded usually by a fall, or else caused a direct fall in blood pressure. The results were not of sufficient regularity to warrant drawing quantitative conclusions concerning this physiological effect.

These compounds are now being studied by Dr. K. K. Chen in order to determine their possible medical value as compared with 1-ephedrine.

Experimental

Brominated Ketones.—The procedure for the preparation was that of Schmidt,[6] according to which the ketone is brominated in glacial acetic acid.

α-Bromo-*n*-valerophenone.—As this substance has not previously been described in the literature, it may be mentioned that it is a straw-colored liquid boiling at 150° at 2.5 mm.; n_D^{20}, 1.5600; d_4^{20}, 1.3993.

Reaction of the Bromo Ketones with Methylamine.—One-tenth of a mole of the bromo ketone was added drop-wise with vigorous stirring to 0.25 mole of methylamine (in the form of a 30% solution in absolute alcohol) over the required period of time (one hour for bromopropiophenone, seventeen to eighteen hours for a-bromobutyrophenone, twenty-four hours for a-bromovalerophenone). The reaction flask was immersed in ice water during the reaction and stirring was continued for one-half to three-quarters of an hour after the addition of the bromo compound. Cold, concd. hydrochloric acid was then added very slowly along with some finely cracked ice until the mixture was acidic. If it became warm the product turned very dark in color and a larger proportion of tar was produced. At this point the reaction mixture was orange or red due to the presence of some bromo ketone that had not reacted and to the formation of certain tarry by-products. These were extracted with ether from the water layer and the bromo ketone recovered. The water layer was evaporated to dryness in *vacuo*, treated with a little chloroform and evaporated to dryness again to assist in removing the moisture from the rather hard mass. After standing in a vacuum desiccator for a day, the residue was extracted several times with fresh portions of chloroform and each time the insoluble crystals of methylamine hydrochloride were filtered. The chloroform solution was then evaporated until it was very concentrated, and acetone was added to cause the crystallization of the amino ketone hydrochloride. Recrystallization was carried out by dissolving in a small amount of alcohol, filtering, and adding about twice the volume of acetone in small portions.

In the condensation of chloro-acetophenone with methylamine, the reaction was carried out in essentially the same way as the one just described for the bromo ketones except that the chloro-acetophenone was added in the form of a powder and allowed to react with the alcoholic methylamine for a period of five to six hours.

For the preparation of the alkylamino ketones in which a group larger than methyl was attached to the nitrogen, a slightly different procedure was used. A 50% aqueous solution of the amine was cooled down carefully to 5–10° in an ice-bath and previously cooled bromo ketone was added slowly with mechanical stirring in the ratio of 1 mole of bromo ketone to 2 moles of amine. The reaction product was allowed to stand and to come to room temperature and the stirring continued until no layer of unreacted bromo ketone separated upon standing. The reaction mixture was then cooled and an excess of concd, potassium hydroxide solution was added slowly with stirring, the temperature not being permitted to rise above 15–20". The amino ketone and excess alkylamine separated and were extracted with ether and the ether solution was washed with water.

---

[6] Schmidt, Ber., 22,3251 (1889).

Upon evaporation of the ether and then warming the residue in *vacuo* to a temperature not over 40°, the excess alkylamine was removed. The residual amino ketone was dried with solid potassium hydroxide, taken up in dry ether, cooled thoroughly and dry hydrogen chloride passed in with stirring. In the course of a few minutes the hydrochloride of the amino ketone began to crystallize.

These hytlrochlorides were purified by first digesting with hot acetone and filtering. This helped to remove the color. The hydrochlorides were crystallized from ethyl acetate containing a small amount of ethyl alcohol (3–10%, depending upon the product being prepared), or from alcohol by addition of some acetone as described under the crystallization of the amino ketone hydrochlorides.

In the condensation of chloro-acetophenone with *n*-butylamine, the powdered chloro compound was added to 2.5 times the quantity of anhydrous n-butylamine over a period of seven hours and stirring continued ior three hours more. The reaction flask was cooled well during this time. The reaction product was worked up in the same manner as previously described for the condensation of various amines other than methylamine with the halogenated ketones.

If any decomposition occurred during the formation of the amino ketones, the hydrochlorides invariably separated as oils which crystallized only with great difficulty. In one or two instances it was found possible to vacuum distil the amino ketone base in an atmosphere of nitrogen, but ordinarily this procedure is not to be recommended because some decomposition always takes place.

In condensing bromobutyrophenone with di-*n*-butylamine, the reaction was carried out by adding the bromo ketone to the amine in the proportion of 1 to 3 moles, respectively. Stirring was continued and no attempt was made to cool the reaction mixture. The crystals of di-*n*-butylamine hydrobromide were filtered and washed with ether. The ether solution was worked up as previously described. The hydrochloride separated as a red, sirupy mass. After drying it in a vacuum desiccator, it was dissolved in a little dry acetone and by adding small amounts of ether a solid product was obtained and purified.

Reduction of Amino Ketones to Amino Alcohols.—The amino ketones were dissolved in ordinary ethyl alcohol in the proportion of 0.1 mole of ketone to 50–100 cc. of solvent and 0.1 g. of platinum oxide[9] was added. The reductions were carried out under a pressure of 30–40 pounds and the calculated amount of hydrogen was always absorbed. The rate of reduction depended upon the purity of the amino ketone hydrochlorides. In general the time ran from twenty minutes to six hours in the compounds studied. The products were removed from the reaction mixture merely by filtration of the catalyst and evaporation to a concd. solution. They were recrystallized either by dissolving in absolute alcohol and adding acetone to the hot solution to the point where precipitation just started, or from ethyl acetate containing a few per cent. of ethyl alcohol. The products were generally pure after one crystallization and the yields amounted to about 90%.

Summary

A series of homologs of *d,l*-ephedrine has been prepared in which the alkyl group on the nitrogen has been varied from methyl to n-amyl; a series in which the alkyl group on the β-carbon has been replaced by H, ethyl and n-propyl and two compounds in which the alkyl groups are present on the nitrogen.

Blood sugar is increased as the alkyl group on the nitrogen is made larger; blood sugar is decreased as the alkyl group on the @-carbonis increased in size; the ketones showed a similar action; the dialkylamino compounds produced no physiological action.

The only homolog which gave a dependable increase in blood pressure was the a-phenyl β-methylamino-ethanol.

THE REPLACEABILITY OF CERTAIN METHYLENE GROUPS AND THE RELATION OF CONSTITUTION TO THE STABILITY OF A C=C LINKAGE

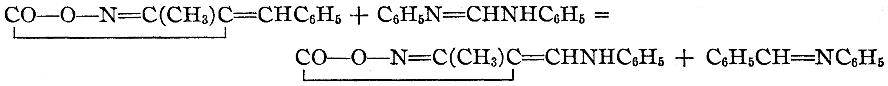
H. V. MOYER[1] AND F. B. DAINS

RECEIVED JUNE 4, 1928 PUBLISHED AUGUST 4, 1928

In a previous series of papers,[2] it has been shown that the methylene hydrogen in many compounds when heated with the substituted formamidines could be readily replaced by the anilidomethylene grouping, thus synthesizing a C=C bonding.

$$>CH_2 + RN{=}CHNHR = >C{=}CHNHR + RNH_2$$

An exception was noted in the case of methylisoxazolone, which gave only tarry products with diphenylformamidine. Further experiments showed, however, that the benzal derivative reacted easily and smoothly with the formamidine, yielding the anilidomethylenemethylisoxazolone, as follows:



$$CO{-}O{-}N{=}C(CH_3)C{=}CHC_6H_5 + C_6H_5N{=}CHNHC_6H_5 = CO{-}O{-}N{=}C(CH_3)C{=}CHNHC_6H_5 + C_6H_5CH{=}NC_6H_5$$

The reaction was unusual since it involved the separation of carbon from carbon and the formation of another C=C linking. It seemed worth while to investigate this further and the following paper is a preliminary study of the types of compounds which lend themselves to such an interchange.

$$R_2C{=}CHC_6H_5 + R'N{=}CHNHR = R_2C{=}CHNHR + R'N{=}CHR'$$

Thus far the replacement has been successful only in the case of the aldehyde (RCH=) derivatives of certain heterocyclic rings, namely: isoxazolone, pyrazolone and rhodanine (thiazolidone) and is probably confined to those compounds in which the benzal group can be removed easily by hydrolysis with dilute acids or heating with phenylhydrazine.

$$R_2C{=}CHR' + HOH = R_2CH_2 + RCHO$$
$$R_2C{=}CHR' + C_6H_5NHNH_2 = R_2CH_2 + C_6H_5NHN{=}CHR'$$

With open chain derivatives such as benzalphenyl cyanide or nitrobenzalacetylacetone it was found impossible to break the double bonding and introduce an aminomethylene grouping.

Experimental

The Aldehyde Derivatives of 3-Phenylisoxazolone and Diphenyl Formamidine

4-Benzal-3-phenylisoxazolone was readily formed when molar quantities of benzaldehyde and the isoxazolone were heated for a few minutes at the melting point of the mixture. The benzal derivative (**5** g.) and diphenylformamidine (**4** g.) were heated at 145° until the mixture melted and then at 120° for forty-five minutes. From the reaction product was isolated **2.5** g. of the 4-anilidomethylene-3-phenylisoxazolone,[2b] which was identified by a mixed melting point and analysis.

Anal. Calcd. for $C_{16}H_{12}O_2N_2$: N, **10.61.** Found: N, **10.88.**

In order to ascertain the effect of other aromatic aldehyde groupings, the piperonal-, anisal-, m-nitrobenzal- and cinnamylidenephenylisoxazolones were heated with diphenylformamidine under similar conditions. In all cases the aldehyde grouping was replaced by the anilidomethylene radical. It should be noted that this is the only instance in which the unsaturated cinnamylidene group has been replaced. Later experiments with the cinnamic aldehyde[3] condensation products of other ring compounds gave only tarry products. Negative results were obtained with the furfuralphenylisoxazolone.

Diphenylformamidine with the Aldehyde Derivatives of Various Pyrazolones

The experimental work has shown that the methylene hydrogen as well as the benzal groups in the substituted pyrazolones can be replaced, though the ease is determined somewhat by the nature of the substituents in the ring. Thus from the benzal and piperonal derivative of 1-phenyl-3-methylpyrazolone,  $CONC_6H_5N{=}C(CH_3)C{=}CHR$, at 140°, the 4-anilidomethylenepyrazolone (m. p. 154°)[4] was obtained. The ease with which the aldehyde bonding can be broken was shown by the fact that when the piperonalpyrazolone was heated in alcohol solution with phenylhydrazine, piperonalphenylhydrazone and methylphenylpyrazolone were isolated and identified.

1,3-Diphenylbenzalpyrazolone gave at **160°** the anilinomethylene derivative (m. p. **140°**) alone. This is of advantage since the diphenylpyrazolone with diphenylformamidine yielded both the **140°** compound and *bis*-diphenylpyrazolone (m. p. **247°**).[4,5]

Anal. Calcd. for $C_{31}H_{22}O_2N_4$: N, **11.62.** Found: N, **11.87.**

3-Hydroxy-1-phenyl-4-benzalpyrazolone,[6]  $CO{-}N(C_6H_5)N:C(OH)C{=}CHC_6H_5$, was prepared by heating benzaldehyde and the pyrazolone at 130° or, better, by simply refluxing the components in alcohol solution for an hour. The dark red needles melted at 275°.

Anal. Calcd. for $C_{16}H_{12}N_2O_2$: N, **10.60.** Found: N, **10.87.**

It was heated with diphenylformamidine first at **210**" and then at 180° for thirty minutes. From the reaction product was isolated the 1-phenyl-3-hydroxy-4-anilinomethylenepyrazolone, which separated from boiling acetic acid in yellow needles melting at 272–273°. It was soluble in dilute potassium hydroxide and was precipitated unchanged by acids.

Anal. Calcd. for $C_{16}H_{13}O_2N_3$: N, 15.05. Found: N, 15.34, 14.85.

Corresponding results were obtained on heating the anisalpyrazolone (m. p. 250°)[7] with the formamidine. As a check the same anilinomethylene compound, m. p. 272–273°, was synthesized from the hydroxyphenylpyrazolone by heating with the formamidine at 160°.

3-Phenyl- **and 3-Methyl-4-benzalpyrazolone,** $CONHNC(R)C{=}CHC_6H_5$.—These pyrazolones differ from the preceding in having the N in position 1 unsubstituted. Both were unchanged after heating with the diphenylformamidine, a result which would seem to show that the double bond becomes more stable as the positive nature of the ring is increased.

3-Methyl-4-anilinomethylenepyrazolone, $CONHN{=}C(CH_3)C{=}CHNHC_6H_5$.—The 3-methylpyrazolone with a free CH_2 grouping reacted only with difficulty. Finally, heating at 200° with a large excess of the formamidine produced a yellow compound melting at 204° which corresponded to the above.

Anal. Calcd. for $C_{11}H_{11}N_3O$: N, 20.9. Found: N, 21.68.

Benzalthiazolidone Derivatives

3-Phenylrhodanine, which illustrates another type of heterocyclic ring, the thiazole, possesses a reactive methylene grouping. Its benzal derivative, $S{-}CSNC_6H_5COC{=}CH{-}C_6H_5$ (m. p., 192°)[8] reacted in like manner with the formamidine at 200° in a sealed tube, yielding the 5-anilinomethylene compound (m. p. 247°).[9]

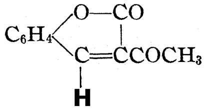
The cinnamylidenephenylrhodanine (m. p. 223°)[10] was unaffected at temperatures below 200°. Above this point, only decomposition products were obtained.

Anal. Calcd. for $C_{18}H_{13}NOS_2$: N, 4.33. Found: N, 4.36.

Benzaldi-o-Tolylthiazolidone, $SC(NHC_7H_7)NC_7H_7COC{=}CHC_6H_5$.—The only essential difference between the rhodanine and this compound is in having the S at position 2 replaced by a tolylimino grouping. The change has, however, increased the positive character of the molecule so that the heating at 220° for five hours with the formamidine gave only negative results.

Benzylidene Derivatives in Which the Methylene Carbon Is Not Part of a Ring

To illustrate this type, there were chosen benzalbenzylcyanide, *m*-nitrobenzalacetylacetone and cinnamylidene-acetylacetone. In no case did heating with the formamidine afford any evidence of breaking the C=C linking, although the free methylene compounds reacted readily with the amidine. The same negative result was obtained with acetylcoumarine,



which contains a C=C bonding due to aldehyde condensation with acetoacetic ester.

[10] Andreash and Zipser found 217°, *Monatsh.*, 24, 513 (1903).

Benzalacetophenone (Anil Formation with the Ketone Oxygen).—The experiments with benzalacetophenone, while they showed the stability of the double bonding, led to another interesting result. Molar quantities of the ketone and formamidine were heated at temperatures ranging from 130–150°. From the reaction product was isolated in not over 5% yield a compound which crystallized from alcohol in white needles and melted at 168°. Had the reaction involved the substitution of the benzal group, the compound $C_6H_5COCH{=}CHNHC_6H_5$ (m. p. 141°) should have resulted.[11] The 168° product gave the following results on analysis.

Anal. Calcd. for $C_{21}H_{17}N$: C, 89.1, H, 6.00, N, 4.9; mol. wt., 283. Found: C, 88.94, 89.0; H, 6.31, 6.15; N, 4.92, 4.93; mol. wt. 270, 286.

This corresponded, as was proved, to the anil of benzalacetophenone, $C_6H_5CH{=}CHC(NC_6H_5)C_6H_5$. The compound was unsaturated and gave on hydrolysis with dilute sulfuric acid, aniline, acetophenone and benzaldehyde, which indicated that the benzal group had not been removed. The mechanism of the reaction is doubtless the following

$$C_6H_5CH{=}CHCOC_6H_5\ 4\ RN{=}CHNHR \longrightarrow C_6H_5CH{=}CHC(NR)C_6H_5 + HCONHR$$

The isolation of p-bromoformanilide in one case where di-*p*-bromodiphenylformamidine was used points to this interpretation.

Direct Synthesis of the **Phenylimide.**—A 10% yield followed when the ketone and freshly distilled aniline were heated at 175° for four hours, but the yield was raised to 80% by using a dehydrating agent.

Thus benzalacetophenone (20 g.), aniline (8.8 g.) and anhydrous sodium acetate (20 g.) were thoroughly mixed and heated at 175° for three hours. The molten mass was poured into a large volume of water and the oily liquid which separated crystallized from alcohol and then from benzene.

As an additional confirmation of this synthesis, p-chloro-aniline and p-toluidine were used in place of aniline with equal success.

***p*-Chlorophenylimide** of Benzalacetophenone, $C_6H_5CH{=}CHCN(C_6H_4Cl)C_6H_5$, separates from alcohol in white needles which melt at 167°.

Anal. Calcd. for $C_{21}H_{16}ClN$: Cl, 11.16, N, 4.41. Found: Cl, 11.07; N, 4.30.

p-Tolyliminobenzalacetophenonehas a melting point of 170°.

Anal. Calcd. for $C_{22}H_{19}N$: N, 4.71. Found: N, 4.78, 4.81.

Action of Bromine on the **Phenyl Imino** Derivative.—Bromine added to the anil in carbon bisulfide on chloroform solution yielded a precipitate that blackened at 160° and decomposed at 240°.

Analysis showed it to be a mixture, but that addition had mainly taken place on the nitrogen was proved by the fact that one of the hydrolysis products was p-bromoaniline. This is in accord with the fact that in a grouping $C{=}NC_6H_5$, bromine adds to the nitrogen and then rearranges to the p-bromo derivative.

Summary

1. An aromatic aldehyde condensed with the methylene hydrogen of an isoxazolone was readily replaced by an anilinomethylene group, yielding a new C=C bonding.

2. The same reaction occurred with the benzalpyrazolones with a phenyl group in the 1-position, but not when this position was unsubstituted.

---

[11] Claisen and Pischer, Ber., 20,2192 (1887).

3. Benzyl cyanide and the benzalacetylacetone were found not to react with the formamidine, though the free CH_2 derivatives did.

4. With benzalacetophenone and the formamidine the anil resulted—a product that was obtained in 80% yield on heating the ketone with aniline and sodium acetate.

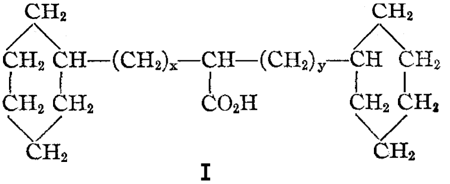
DI-(CYCLOHEXYLALKYL) ACETIC ACIDS. XIV[1]

BY LETHA A. DAVIES[2] AND ROGER ADAMS

RECEIVED JUNE 4, 1928 PUBLISHED AUGUST 4, 1928

In previous papers it has been demonstrated that when a cyclohexyl group is substituted at the end of a straight-chained aliphatic acid of certain molecular weight, the product is an effective bactericide *in vitro* toward *B. leprae*, whereas the corresponding straight-chained acid with the same number of carbon atoms is ineffective. It has been shown further that if the carboxyl group is removed from the end of the chain to a position nearer to the ring, the effectiveness of the isomeric acid is increased. As a consequence it seemed advisable to prepare a few di-(cyclohexylalkyl) acetic acids for testing, in which the carboxyl group is in the favored position. It is thus possible to determine whether a second ring structure would enhance the bactericidal properties. The compounds prepared are of the general formula represented by I where "x" is 1, 2, 3 or 4 and where "y" is 0, 1, 2 or 3. They were made in the usual way by introducing first one cyclohexylalkyl group into malonic ester and then a second, followed by saponification and heating of the malonic acid.



I

The bacteriological results in Table I indicate that no particular ad-

vantage is gained by the introduction of the second ring. In fact, the two compounds which have 20 carbon atoms are, like most of the other molecules studied which contain that number of carbon atoms, comparatively inactive.

FURYLANGELIC ACID[1]

BY ALBERT S. CARTER

RECEIVED JUNE 8, 1928 PUBLISHED AUGUST 4, 1928

In proving the structure of furfural, Baeyer[2] studied the condensation of furfural and sodium acetate, yielding furylacrylic acid in a manner exactly analogous to the condensation of benzaldehyde to yield cinnamic acid. Upon reduction, furylacrylic acid gave furylpropionic acid, which upon treatment with bromine and subsequent oxidation by silver oxide was converted into a so-called *furonic* acid, having the structure indicated by the formula $HOOCCH{=}CHCOCH_2CH_2COOH$. This was reduced by hydriodic acid to yield a dibasic acid identified as pimelic.

In the same general manner used to prepare furylacrylic acid, Baeyer[3] successfully prepared a so-called furylangelic acid from sodium butyrate and furfural, to which he assigned the structure $C_4H_3OCH{=}CHCH_2CH_2COOH$. Tonnies[4] reported the conversion of furylangelic acid into furylvaleric, butyrofuronic and finally azelaic acids in a manner analogous to the conversion of furylacrylic into pimelic acid, The azelaic acid thus obtained did not agree exactly in melting point with any of the known isomers of the formula $C_9H_{16}O_4$, but approximated most nearly that of n-azelaic acid. The literature definitely states that the resulting acid possesses a normal chain. The structure $C_4H_3OCH{=}CHCH_2CH_2COOH$ does not agree with the present conception of the course of the Perkin condensation, for in the light of the formation of a-methylcinnamic acid from benzaldehyde and sodium propionate and other similar condensations, we should be led to expect that Baeyer's furylangelic acid would have the structure represented by $C_4H_3OCH{=}C(C_2H_5)COOH$. This would lead to the formation of a-ethylpimelic acid instead of n-azelaic acid in the course of the reactions carried out by Tonnies, but this ethylpimelic acid has been prepared[5] and found to differ from the product which Tonnies reported.

Furylangelic acid was prepared and found to be identical with the product obtained by Baeyer. By treatment with ozone and hydrolysis of the ozonide, the products included carbon dioxide, propionic acid and possibly a-ketobutyric acid. It is impossible to obtain these products

---

[1] From an investigation, carried out under the direction of Professor Richard Fischer, which constituted a part of a thesis presented by A. S. Carter to the Graduate School Faculty of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

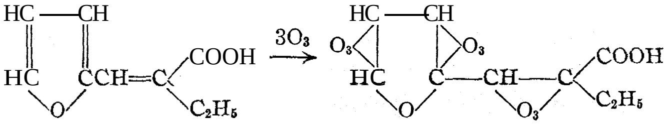
[2] Baeyer, *Ber.*, 10, 355, 395, 1358 (1877).

[3] Baeyer, *Ber.*, 10, 1364 (1877).

[4] Tonnies, *Ber.*, 12, 1200 (1879).

[5] Carter, THIS JOURNAL, 50, 1967 (1928).

from Baeyer's formula for furylangelic acid (δ-furylallylacetic acid), but they might, however, be the expected products from a-ethyl-@-furylacrylic acid, as shown below. This evidence indicates that furylangelic acid is an ethylacrylic acid derivative and the ozone oxidation proceeds as follows



the ring breaking to form HCOOH, CHOCHO and CHOCOOH, and the side chain giving $C_2H_5COCOOH$, which subsequently decomposes to form C_2H_5COOH, CO_2 and H_2O. The evidence throughout the remainder of this paper substantiates this view.

The products of permanganate oxidation of furylangelic acid included furoic acid, acetic acid and propionic acid, and from a study of the oxidation it was concluded that it could be understood only through the use of the ethylacrylic acid structure for furylangelic acid, oxidizing at the side-chain double bond to give ketobutyric acid, which decomposed in two ways to form acetic acid and propionic acid.

In an endeavor to correlate these facts with those of l'onnies, his work was repeated as exactly as possible. Having established the structure of furylangelic acid as possessing a branched chain, it was considered improbable that any means of reduction and ring opening could yield n-azelaic acid.

Reduction of furylangelic acid gave furylvaleric acid, which was undoubtedly the same as that obtained by Tonnies, though no analytical results or physical data can be found by which his product might be recognized. The composition of this product indicated that the reduction consisted in the addition of one molecule of hydrogen, which would be expected to enter at the most vulnerable point, namely, the double bond in the side chain. The reduction would then be analogous to the reduction of cinnamic to hydrocinnamic acid.

Furylvaleric acid was converted into butyrofuronic acid through the use of bromine and subsequent oxidation with silver oxide

$$C_4H_3OC_4H_6COOH \xrightarrow[H_2O]{Br_2} OCHCH{=}CHCOC_4H_6COOH + 2HBr \xrightarrow{Ag_2O}$$
$$HOOCCH{=}CHCOC_4H_6COOH$$

The product of this reaction was carefully purified and found to possess a melting point slightly higher than that recorded by Tönnies, but analysis indicated the same compound. The name given to this acid is misleading. In accord with his structure of furylangelic acid, butyrofuronic acid would be heptene-1-one-3-dicarboxylic acid-1,7; in accord with the structures established in this paper it should be heptene-1-one-3-dicarboxylic acid-1,5.

Upon hydriodic acid reduction of butyrofuronic acid, *n*-azelaic acid was not obtained. Instead, the products of the reduction were ethylpimelic acid and heptanone-3-dicarboxylic acid-1,5. The results of this work seem to warrant the conclusion that an acid melting at 117° similar to azelaic acid cannot be obtained by the method of hydriodic acid reduction employed. The melting point of the butyrofuronic acid used by Tonnies might indicate that it was impure and this might lead to the explanation of his different results. To speculate upon the hydriodic acid reduction; in the light of such anomalous results as the reduction of dibenzylcarbonyl to the phosphoric acid ester of the corresponding alcohol, as obtained by Grabe[6] and Johnson and Hodge,[7] it would not be highly improbable to expect the reduction of butyrofuronic acid to ethylacetone diacetic acid (heptanone-3-dicarboxylic acid-1,5) and the corresponding hydroxy compound which Tonnies found to be unstable, as intermediate reduction products. Heptanone-3-dicarboxylic acid-1,5 was evidenced by the products obtained by reduction at 190° for four hours; further reduction might next produce the hydroxyl group and subsequent decomposition of this acid take place, thus accounting for the water-insoluble resin and the low yields of the final product, ethylpimelic acid, mentioned in the experimental part of this paper.

Marckwald[8] subjected furylacrylic acid to the action of dry hydrogen chloride in alcoholic solution and obtained a diethyl ester of acetone diacetic acid. In a manner similar to this, the diethyl ester of heptanone-3-dicarboxylic acid-1,5 was prepared, which upon hydrolysis yielded the previously unprepared acid. Marckwald was unsuccessful in carrying out a similar reaction upon furylpropionic acid; the same failure to obtain results was found when the reaction was applied to furylvaleric acid. It is probable, therefore, that the double bond plays an important part in this reaction, which is essentially the addition of two molecules of water to furylangelic acid.

Heptanone-3-dicarboxylic acid-1,5 was successfully reduced to ethylpimelic acid by means of hydriodic acid. In all, fifteen reductions were made on butyrofuronic acid and heptanone-dicarboxylic acid and in no case was an acid similar to azelaic obtained, proving conclusively that furylangelic acid has the furylethylacrylic structure indicated by its oxidation products.

Experimental Part

Furylangelic Acid.—Forty g. of dry sodium butyrate, 40 cc. of freshly distilled furfural and 100 g. of butyric anhydride were heated under an air condenser for eighteen hours at 135–160°. The product, while warm, was washed out of the reaction flask

---

[6] Grabe, Ber., 7, 1624 (1874).

[7] Johnson and Hodge, THIS JOURNAL, 35, 1014 (1913).

[8] Marckwald, Ber., 20, 2811 (1887); 21, 1398 (1888).

with 450–500 cc. of water, was neutralized with sodium carbonate and then treated for two or three hours with absorbent charcoal without boiling. Upon filtration, most of the tar and much of the color was removed; this was then again treated with charcoal, boiled for twenty minutes, allowed to settle and filtered, giving a light yellow solution. Boiling the solution during the first treatment causes the solution of some of the tar, which is otherwise carried down with the charcoal in the cold. Boiling the solution for twenty minutes during the second treatment was found to replace satisfactorily steam distillation of the excess furfural from the reaction mixture. Ice was then added and the free acid precipitated with dilute sulfuric acid. An excess of sulfuric acid is to be avoided, for it tends to bring out remaining furfural, contaminating the product. The cold solution was filtered by suction and the furylangelic acid dried; yield, 45–48 g. (80%) of crude, slightly colored product melting at 85–90". For much of the work this crude acid could be used without further purification but it was readily purified by dissolving in ethyl alcohol and precipitating with ice water or by crystallization from hot petroleum ether. The pure substance melted at 95.5–97° after drying at 40° in vacuum for six hours; it was soluble in alcohol, chloroform, hot petroleum ether and slightly in hot water.

Anal. Subs. 0.1500: CO_2, 0.3577; H_2O, 0.0806. Calcd. for $C_9H_{10}O_3$: C, 65.06; H, 6.02. Found: C, 65.04; H, 5.94.

The melting point recorded above is higher than that observed by Baeyer (87–88°). The melting point of the crude acid before purification checked more closely that of Baeyer. Two stereoisomeric forms are possible. Liebermann[9] isolated two forms of furylacrylic acid which were found to melt at 103 and 82–86°.

It was found impossible to obtain satisfactory yields of furylangelic acid using acetic anhydride as the condensing agent, as furylacrylic acid was the predominant product of the reaction in every case.

Ozone Oxidation of Furylangelic Acid.—Ten g. of dry furylangelic acid was dissolved in 200 cc. of dry chloroform in a tall cylinder, packed in ice and subjected to 5% ozonized oxygen at the rate of 10 liters per hour for four hours. The substance became yellow and then darkened to a brown with a definite green fluorescence and a brown, oily product separated on the sides of the tube. The ozonide was a thick, brown, tarry mass, insoluble in water and only partially soluble in chloroform, with a strong pungent odor resembling acetic acid. The chloroform was removed under diminished pressure after transferring the product to a 500-cc. flask. The ozonide was hydrolyzed by refluxing for three hours with 300 cc. of water. The product consisted of an acid solution and a tar from which nothing could be resolved. The acid solution was neutralized with dilute sodium hydroxide and evaporated to 2 cc. under diminished pressure. This solution was made acid with hydrochloric acid and a small amount of insoluble tar filtered off; the filtrate was treated with 1 cc. of a solution containing one part of phenylhydrazine to eight of a 50% solution of acetic acid. After standing for several hours, an oily hydrazone precipitated out, which was filtered off and recrystallized from chloroform; m. p. 138–142°. Upon standing for a few days, this hydrazone became liquid and underwent decomposition. Its behavior and properties resembled the phenyl hydrazone of a-ketobutyric acid, melting[10] at 144–145° which is probably the primary product of the hydrolysis.

It was found that the hydrolysis product was much more strongly acid if a small quantity of ferric chloride was added before hydrolyzing. The tar was filtered from this solution; it was made alkaline with ammonium hydroxide and again filtered to remove

[10] Wislicenus, *Ann.*, 246, 333 (1888).

ferric hydroxide. The solution was treated with ammoniacal silver nitrate and warmed to 40–50° for six hours; the resulting reduced silver was filtered from the warm solution, leaving a more completely oxidized product which was free from formaldehyde. This was made strongly acid with phosphoric acid, filtered and distilled to a volume of 30 cc. The acid distillate was redistilled and used for Duclaux determinations of the acid present. The values determined on two runs were 11.4, 11.2, 11.4 and 11.6, 11.6, 11.6 on the first three 10-cc. fractions. These values indicate propionic acid, which was checked by the preparation of propiono-p-toluide from the sodium salts obtained by evaporating the neutralized distillates from the Duclaux determinations.

Permanganate Oxidation.—Ten g. of furylangelic acid was dissolved in 150 cc. of water containing 10 g. of sodium hydroxide; this was rapidly titrated with saturated potassium permanganate (about 680 cc.), the manganese dioxide was filtered off and the solution was boiled down to a volume of 100 cc. Upon acidifying the solution with sulfuric acid, a white precipitate resulted, which was filtered off, dried and identified as furoic acid.

Anal. Subs. 0.2000: CO_2, 0.3916; H_2O, 0.0635. Calcd. for $C_5H_4O_3$: C, 53.57; H, 3.57. Found: C, 53.40; H, 3.53.

The acid solution was still found to reduce permanganate, so 100 cc. of the saturateti permanganate solution was added and the mixture distilled until salts began to crystallize out. The distillate was redistilled after addition of 10 cc. of sulfuric acid and an equal volume of permanganate, leaving about 20 cc. in the distilling flask to insure that no sulfuric acid was in the product. This was used for Duclaux determination of the acids present, the first four fractions giving the following values: 9.9+, 9.9—. 9.8—, 9.7+. These values do not check either propionic acid or acetic acid, but fall between them. The neutral solutions were evaporated and the resulting sodium salts were used for the preparation of *p*-toluides. The melting point of the resulting toluide was 104–120°, indicating a mixture. This was dissolved in 3 cc. of hot benzene and, upon cooling, aceto-*p*-toluide, melting at 146–147°, was obtained and a more soluble toluide remained in the benzene, which was recrystallized from petroleum ether, giving a product melting at 120–125°, probably indicating propiono-p-toluide (m. p. 123–124.5°).

Upon carrying out a similar run in which the furylangelic acid was dissolved in hot, concentrated sulfuric acid, considerable carbon dioxide was evolved during the addition of the oxidizing agent and no furoic acid was left at the end, indicating that the furane ring had been oxidized. The acid distillate, however, gave the same toluides and Duclaux values as had been found in the case of the basic oxidation. If phosphoric acid was substituted for sulfuric acid, the Duclaux values were lower, that is, 8.0, 8.2, 8.5, and the relative amount of the propiono-p-toluide obtained was very small. This evidence seems to indicate that acetic and propionic acids are both formed from some intermediate oxidation product, probably ketobutyric acid, for it was found that propionic acid was not oxidized to acetic acid under the conditions of this work.

Furylvaleric Acid.—Fifty grams of furylangelic acid was suspended in 2 liters of water and 800 g. of 3% sodium amalgam was added; frequent small additions of sulfuric acid hastened the action of the amalgam. The basic solution was separated from mercury, filtered and acidified with sulfuric acid, giving an oil which was collected in ether, dried over sodium sulfate and finally, upon evaporation of the ether, gave 50 g. of an oily acid (98% of the theoretical). This acid was distilled under diminished pressure; b. p. about 174° at 46 mm.

Anal. Subs. 02000: CO_2, 0.4698; H_2O, 0.1274. Calcd. for $C_9H_{12}O_3$: C, 64.3; H, 7.14. Found: C, 64.05; H, 7.08.

Butyrofuronic Acid.—By means of violent mechanical stirring, 4.5 g. of furylvaleric acid was suspended in one liter of water. To this was added 4.5 g. of bromine dissolved in water; stirring was stopped and the brominated mixture was immediately poured upon washed silver oxide, freshly precipitated from 28.5 g. of silver nitrate. Again the product was mechanically stirred and heated in a water-bath at 35–40° for two hours. The silver was precipitated with hydrochloric acid, filtered and the butyrofuronic acid extracted with ether. Continuous ether extraction for twenty-four hours was necessary because of the solubility of butyrofuronic acid in water. Evaporation of the ether gave brown crystals which were purified by dissolving in water, boiling with absorbent charcoal and evaporating to dryness in a vacuum desiccator over calcium chloride. This product was further purified by precipitating from warm ether by means of petroleum ether. Butyrofuronic acid was soluble in water, alcohol, warm chloroform and ether; m. p. 149–150° (Tonnies gives 140–142° with previous softening); yield about 1 g. (18–19%).

Anal. Subs. 0.1350: CO_2, 0.2669; H_2O, 0.0714. Calcd. for $C_9H_{12}O_5$: C, 54.0; H, 6.00. Found: C, 53.90; H, 5.88.

Reduction of Butyrofuronic Acid.—One g. of butyrofuronic acid, 8 g. of hydriodic acid (sp. gr. 1.70) and 0.5 g. of red phosphorus were sealed in a Pyrex bomb tube and heated at 195–200° for six hours. Upon opening the tube there was slight pressure and an inflammable gas escaped; the contents were decolorized with sulfurous acid and extracted with ether Evaporation of the ether left brown, tarry material, a part of which was soluble in hot water. This portion was precipitated from hot water three times, giving a colorless product which was further purified by precipitation from hot benzene. This entire oily mass crystallized upon the introduction of a crystal of ethylpimelic acid and proved to be identical with ethylpimelic acid (heptane-dicarboxylic acid-1,5), melting at 41-43°, and the silver salt corresponded to silver ethylpimelate.

Anal. Subs. 0.2000: AgCl, 0.1430. Calcd. for $C_9H_{14}O_4Ag_2$: Ag, 53.73. Found: Ag, 53.81.

The temperature and the duration of heating were varied in a number of runs but in no case was a product melting at 117° obtained. By adding only 0.3 g. of phosphorus and heating for four hours, a very small amount of heptanone-3-dicarboxylic acid-1,5 was recognized in the product.

Heptanone-3-dicarboxylic Acid-1,s.—Thirty g. of furylangelic acid was dissolved in 100 cc. of 95% alcohol and subjected to dry hydrogen chloride until a turbid solution was obtained (twenty-five minutes). Continuing the current of hydrogen chloride, this was refluxed on a water-bath for one hour, then treated with the gas for two hours longer, during which period it was allowed to cool. The alcohol and hydrogen chloride were distilled off on a water-bath, leaving a thick, brown oil possessing a pleasant aromatic odor. This ester was shaken with an equal volume of saturated sodium carbonate solution, collected in a small volume of ether and fractionated under diminished pressure. The major portion of the product distilled at 198–200° (25 mm.), giving 45 g. (96%) of colorless ester. Free heptanone-3-dicarboxylic acid-1,5 was obtained by refluxing with 150 cc. of 20% potassium hydroxide solution until the hydrolysis was complete. This solution was acidified with sulfuric acid and continuously extracted with ether for a period of forty-eight hours. Evaporation of the ether gave 32.5 g. (92.4%) of crystalline acid from 45 g. of the ester. Heptanone-dicarboxylic acid was readily obtained in a high degree of purity by recrystallizing from hot benzene; m. p. 83–84.5°. The silver salt was prepared and analyzed.

Anal. Subs. 0.3000: AgCl, 0.2061. Calcd. for $C_9H_{12}O_5Ag_2$: Ag, 51.9. Found: Ag, 51.7.

Heptanone-dicarboxylic acid was soluble in water, ether, acetone, chloroform and hot benzene; insoluble in cold benzene and petroleum ether; it crystallized in small white rosets from the sirup resulting by evaporation of a water solution.

Reduction of Heptanone-3-dicarboxylic Acid-1,5.—As before in the reduction of butyrofuronic acid, **9** g. of the acid was reduced by means of 1.8 g. of phosphorus and 60 cc. of hydriodic acid for eight hours at 190–200°. The product, extracted from the reduction mixture after decolorizing with sulfur dioxide and purifying by precipitation from hot water and benzene, consisted of **1** g. of colorless liquid which crystallized upon the introduction of a crystal of ethylpimelic acid. Analysis and melting point indicated that the reduction product was identical with that obtained from butyrofuronic acid, namely, ethylpimelic acid. The analysis of the silver salt gave the following results.

Anal. Subs. 0.5000: AgCl, 0.3601. Calcd. for $C_9H_{14}O_4Ag_2$: Ag, **53.73.** Found: Ag, **54.20.**

Summary

1. A method has been developed whereby furylangelic acid can be produced in yields of over 80% of the theoretical from furfural, sodium butyrate and butyric anhydride.

2. The structure of furylangelic acid and the course of the Perkin reaction when applied to furfural and butyric acid have been established through the isolation and identification of the products of oxidation of furylangelic acid.

3. Furylvaleric acid has been prepared and the ring opened by bromination and oxidation to yield heptene-1-one-3-dicarboxylic acid-1,5.

4. Butyrofuronic acid has been reduced to heptane-dicarboxylic acid-1,5 and heptanone-3-dicarboxylic acid-1,5.

5. The previously unprepared heptanone-3-dicarboxylic acid-1,5 and its ethyl ester have been prepared from furylangelic acid, and this product has been reduced to heptane-dicarboxylic acid-1,5.

THE ACIDIC AND BASIC CATALYSIS OF ACETYLATION REACTIONS

BY JAMES B. CONANT AND GEORGE M. BRAMANW

RECEIVED JUNE 18, 1928 PUBLISHED AUGUST 4, 1928

The acetylation of hydroxy compounds by means of acetic anhydride is frequently catalyzed by the addition of sulfuric acid, sodium acetate or pyridine. Since acetic acid is often the initial solvent and is always formed by the reaction, the behavior of these catalysts in this solvent may afford the clue to the explanation of their action. Sulfuric acid is obviously an acid catalyst which furnishes hydrogen ions in excess of those provided by acetic acid itself. Sodium acetate and pyridine are examples of basic catalysts, since it has been shown[1] that these substances are strong bases in acetic acid.

The development of methods of studying the hydrogen ion activity

---

[1] **Hall** and **Conant,** THIS JOURNAL, 49,3047 **(1927).**

of glacial acetic acid solutions[1] makes possible a further investigation of the influence of the acidity or basicity of the medium on the rate of acetylation. The results presented in this paper are in the nature of a preliminary survey of the field. They are limited by the accuracy of the present methods of determining hydrogen ion activities in glacial acetic acid and, in their interpretation, by our inadequate knowledge of the physical chemistry of the behavior of acids, bases and salts in this solvent. Furthermore, it was not found possible to obtain precise measurements of the rate of any of the acetylation reactions we studied. In spite of these limitations the results clearly show the fundamental factors which affect the speed of acetylations with acetic anhydride. This suggests wide possibilities in regard to controlling such reactions for preparative and analytical purposes. We shall report experiments along these lines at another time.

The Rate of Acetylation of β-Naphthol

After some experimentation with a variety of substances, β-naphthol was chosen for the rate measurements. It is readily acetylated by acetic anhydride with the formation of a crystalline acetate which is insoluble in water and resistant to hydrolysis by cold water. The β-naphthol and a four-fold excess of acetic anhydride were allowed to interact in glacial acetic acid solutions of definite acidity. The extent of the reaction was determined by diluting with water, filtering off the mixture of β-naphthol and o-naphthyl acetate on a Gooch crucible, washing with water and saponifying the residue with standard sodium hydroxide. Experiments with mixtures of pure β-naphthyl acetate and β-naphthol showed that the precipitation by water was not complete. We, therefore, standardized our procedure by operating always with such volumes that the recovery of the acetate was 70 ± 5% as shown by numerous blank runs with varying proportions of β-naphthol and β-naphthyl acetate dissolved in acetic acid. In calculating the extent of the reaction, we corrected the actual titration figures on the assumption that only seven-tenths of the acetate was recovered. The correctness of this procedure was demonstrated by the fact that the final constant value for the amount of acetate formed in each buffer was 100 ± 10% on the corrected basis. The necessity for this correction as well as the difficulty of the uniform precipitation and washing make the method only an approximate one, as shown by the figures exhibited below. A qualitative check of some importance was afforded by the determination of the melting point of the product. The acetate melts at 68°, β-naphthol at 122°, while a 50–50 mixture when precipitated from acetic acid by water melts at 48–51°. The melting points of the products showed the general correctness of the results of the analytical procedure, Analytical Procedure.—In starting each experiment, 5 cc. of a 0.5 molar solution of 0-naphthol in glacial acetic acid was placed in a tube in a thermostat at 25°; 5 cc. of the buffer solution (see Table I) was then added. One cubic centimeter of acetic anhydride was added rapidly and the mixture shaken; the time was taken from this point (with a stop watch if necessary). The tube was closed by a cork or by sealing off the glass and allowed to stand in the thermostat for the allotted time. The contents were then added to 100 cc. of water and the mixture was shaken rapidly. The coagulated precipitate was filtered off on a Gooch crucible, pressed on the filter and washed with 100 cc. of water. The crucible was then transferred to a 250-cc. wide-mouthed flask, containing 25 cc. of alcohol and 25 cc. of 0.1 N sodium hydroxide. The mixture was heated for ten minutes on the steam-bath under a reflux condenser attached to a soda lime tube. The excess of sodium hydroxide was titrated with 0.1 N hydrochloric acid using phenolphthalein as the indicator; the end-point is difficult to ascertain because of the color of the solution. The following results, obtained with a 0.2 molar benzamide solution, 0.4 neutralized with sulfuric acid, as the buffer, are typical.

TABLE I

TYPICAL RESULTS

Time, minutes	Percentage reacted By titration	Percentage reacted Corrected	$k \times 10^2$	Melting point of product, °C.
5	17	24	4.6	
10	25	35	4.4	
15	31	44	3.8	
20	36	51	3.5	55
25	52	74	5.4	
30	62	88	7.0	
40	68	97		63
50	68	97		
60	67	96		68
80	71	102		
140	70	100		

The results are summarized in Table II. The values of k given are the reaction velocity constants calculated from the monomolecular formula using natural logarithms and the time in minutes. Only experiments in which the extent of the reaction was between 10 and 85% were used in calculating k; the number of such experiments is given in the fourth column. In addition, there were always a number of experiments for longer periods of time to show that the reaction proceeded essentially to completion and thus to check our analytical procedure. The $P_{\mathrm{H}}^{(\mathrm{HAc})}$ values were determined by means of the chloranil electrode as previously described; they agreed within 0.2 of a unit of the values predicted from the titration curves. Solutions 5 and 6 were intended to be identical but actually varied 0.3 in $P_{\mathrm{H}}^{(\mathrm{HAc})}$; this slight difference was reflected in the rate measurements. The use of buffer solutions containing magnesium acetate partially neutralized with perchloric acid (Nos. 7, 9, 10) was suggested to us by Dr. N. F. Hall as a result of his further study of the behavior of acids and bases in glacial acetic acid.[2] Primary and secondary

---

[2] To be published shortly.

amines and even urea were not suitable materials for preparing buffer solutions for our work since they are rapidly acetylated by acetic anhydride. Even benzamide and acetanilide are acted upon slowly, but not at a rate which seriously affects the validity of the results given in Table II.

TABLE II

RATE OF ACETYLATION OF β-NAPHTHOL IN GLACIAL ACETIC ACID BUFFER SOLUTIONS AT 25°

Concn. of β-Naphthol, 0.22 molar; of acetic anhydride, 0.88 molar

The most detailed recent studies of acid and base catalysis in aqueous solutions have been carried out by Lowry[3] and by Bronsted[4] in connection with the investigation of the mutarotation of glucose. The results of these two investigators show that in this process both an acid and a base (in Bronsted sense of the terms) are involved. If the acetylation of β-naphthol by acetic anhydride is subject to the same fundamental laws, the catalysts which would be effective would be the solvated hydrogen ion (the acetonium ion $CH_3COOH_2^+$), undissociated acid molecules, the acetate ion (or other ion of a weak acid) and relatively strong basic molecules such as pyridine. Just as the hydrated hydrogen ion and the hydroxyl ion are usually the most effective catalysts in aqueous solution, so in glacial acetic acid the solvated hydrogen ion and the acetate ion would

---

[3] Lowry, J. *Chem. Soc.*, 1927, 2554.

[4] Brönsted and Guggenheim, THIS JOURNAL, 49, 2554 (1927).

be expected to be of predominant influence. The molecules of acetic acid, like those of water, may act as either acid or basic catalysts by virtue of their ability to donate or receive a proton with the formation of the acetate and acetonium ions, respectively. The effectiveness of these catalysts would be expected to be expressed by an equation such as the following

$$k = k_o + k_{\mathrm{H}^+}C_{\mathrm{H}^+} + k_{\mathrm{Ac}^-}C_{\mathrm{Ac}^-} + k_{\mathrm{B}}C_{\mathrm{B}} \qquad (1)$$

In this equation, k is the specific reaction constant as measured, k_o the constant in pure acetic acid, k_{H^+}, k_{Ac^-}, k_{B}, the constants characteristic of the solvated hydrogen ion, the acetate ion and any strongly basic ion and C_{H^+}, C_{Ac^-}, C_{B} the concentrations of these acids and bases. The effect of very weak acids and bases has been neglected since the recent work of Bronsted shows that, at least in certain cases, the value of each catalytic constant is closely related to the strength of the acid or base.

Unfortunately we have no certain information in regard to the concentrations of the ions in the case at hand so we cannot substitute the proper values in Equation 1. However, we have found that our experimental results may be formulated in terms of the hydrogen ion activity of our solutions by means of an equation similar to Equation 1. This empirical equation is as follows:

$$k \times 10^2 = 0.005 + 0.1\,a_{\mathrm{H}^+} + \frac{10^{-5}}{a_{\mathrm{H}^+}} + 2.0\,C_{\mathrm{Pyridine}} \qquad (2)$$

In this equation a_{H^+} denotes the hydrogen ion activity referred to an aqueous solution of $P_{\mathrm{H}} = 0$ as the reference state as in the previous work; it is defined experimentally as $\log a_{\mathrm{H}^+} = -P_{\mathrm{H}}^{(\mathrm{HAc})}$.

The values of k calculated according to Equation 2 are given in the last column of Table II. In Fig. 1, where log k is plotted against $P_{\mathrm{H}}^{(\mathrm{HAc})}$, the curve of Equation 2 omitting the last term is shown. For solutions 1 to 8 only the second term of Equation 2 is involved and there is, therefore, a straight line relationship between log k and a_{H^+}. With solution 14 only the third term is significant and the factor of 10^{-5} was obtained by a consideration of this point. The value of k_0 (0.005) was found empirically as that necessary to give the proper values with those solutions in which both the second and third terms are small. The introduction of the last term in the cases of the solutions containing pyridine is necessary to correspond to the increased catalytic activity; that such a term should appear would be expected from Bronsted's theory.

It is obvious that the factors 0.1 and 10^{-5} in the second and third terms of Equation 2 are not k_{H^+} and k_{Ac^-}, but include also a factor which relates the activity of the hydrogen ion, in the one case to the concentration of the acetonium ion ($CH_3COOH_2^+$) and in the other case to the concentration of the acetate ion. If in a 0.2 M solution of perchloric acid $C_{\mathrm{H}^+} = 0.2$, k_{H^+} is about 10^4 and if in a 0.2 M solution of sodium acetate $C_{\mathrm{Ac}^-} = 0.2$,

$k_{Ac^-} = 0.1$. It is extremely unlikely that such a simple state of affairs is actually the case even in the strong acid and basic solutions in glacial acetic acid; the assumption, however, may not be very greatly in error. It is interesting that k_B for pyridine (2.0) was found to be only about twenty times the value of k_{Ac^-} (0.1) derived on this simple assumption. It is impossible to estimate, at present, the concentration of the solvated hydrogen ion in solutions 2–15 except on the simple assumption that there is a direct proportionality between C_{H^+} and a_{H^+}, as has been done in writing Equation 2. To evaluate the catalytic activity of the other components of these buffer solutions will require work of a greater accuracy than that presented in this paper.

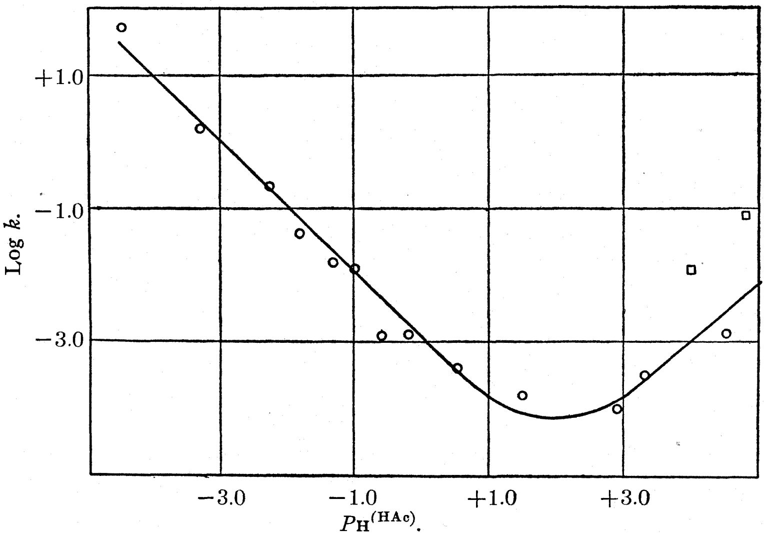

Fig. 1.—The rate of acetylation of β-naphthol in glacial acetic acid solutions. The smooth curve corresponds to Equation 2 with the omission of the last term. The experimental values are shown by the circles; the squares indicate the experiments using pyridine.

From the preparative point of view, it should be noted that the results reported in Table II cover a very wide range in the rates of reaction. Thus, in the perchloric add solution (No. 1) the time required for 50% reaction is less than six seconds as compared with five days in the slowest reaction (No. 11) and ten minutes with a 3 molar pyridine solution. It is thus possible by choosing the proper buffer solution to regulate quite closely the rate of the reaction between acetic anhydride and hydroxy compounds.

Summary

Measurements have been made of the rate of acetylation of β-naphthol by acetic anhydride in glacial acetic acid solutions of definite hydrogen ion

activity. The rate varies nearly a million-fold and is dependent on the acidity or basicity of the medium. The maximum rate is at $P_H^{(HAc)}$ -4.5, the minimum at about $P_H^{(HAc)}$ $+2.0$; over this range the rate is approximately proportional to the hydrogen ion activity. Between $+2.0$ and $+5.0$ the rate increases again showing that the process is one which is subject to both acid and basic catalysis.

CAMBRIDGE 38, MASSACHUSETTS

NOTE

A Simpler Derivation of the Cook Formula for the Determination of the Acetyl Value of Fats and Oils.—It is now generally conceded that the André–Cook[1] method of determining the acetyl number is more accurate and more rapid than the older method of Lewkowitsch.[2] The André–Cook method consists merely in determining the saponification value of the oil before and after acetylation. The acetyl value is then calculated by means of the formula

$$A = \frac{S' - S}{1 - 0.00075S}$$

where A is the acetyl value, and S and S' are the saponification values before and after acetylation. The derivations of this formula given by André and by Cook are rather involved.

In this note the same formula is derived by a simpler method. Let x represent the weight of acetylated oil which will contain 1 mole (59 g.) of *acetate* radical. Then x g. of acetylated oil will yield one mole of acetic acid on hydrolysis, and this quantity of acetic acid will require 1 mole or 56,000 mg. of potassium hydroxide for neutralization. Therefore, the acetic acid from 1 g. of acetylated oil will require $56{,}000/x$ mg. of potassium hydroxide, and

$$A = \frac{56{,}000}{x} \text{ or } x = \frac{56{,}000}{A} \qquad (1)$$

By definition of x it is obvious that x g. of acetylated oil was derived from a quantity of original oil which contained 1 mole (17 g.) of hydroxyl radical. The gain in weight during the acetylation of this quantity of oil was 59—17 or 42 g. Therefore x g. of acetylated oil was derived from $(x-42)$ g. of original oil.

Since A is equal to the number of mg. of potassium hydroxide needed to neutralize the acetic acid from 1 g. of acetylated oil, Ax mg. of potassium hydroxide will be needed for the acetic acid from x g. of acetylated oil. Similarly $S'x$ mg. of potassium hydroxide will be needed to saponify x g. of acetylated oil; and $S(x-42)$ mg. will be needed to saponify $(x-42)$ g. of

---

[1] André, *Bull. soc. chim.*, [4] 29, 745 (1921); Cook, THIS JOURNAL, 44, 392 (1922).

[2] Lewkowitsch, *J. Soc. Chem. Ind.*, 16, 503 (1897).

original oil, which is equivalent to x g. of acetylated oil. In other words, x g. of acetylated oil require $S(x-42)$ mg. of potassium hydroxide to react with the glycerol esters, Ax mg. to react with the acetate esters and $S'x$ mg. for complete saponification. Therefore

$$S(x - 42) + Ax = S'x \tag{2}$$

Substituting (1) in (2)

$$S\left(\frac{56{,}000}{A} - 42\right) + A\,\frac{56{,}000}{A} = S'\,\frac{56{,}000}{A}$$

Multiplying by $A/56{,}000$

$$S(1 - 0.00075A) + A = S'$$

Solving for A

$$A = \frac{S' - S}{1 - 0.00075S} \tag{3}$$

Equation (3) is identical with the Cook formula.

Das Periodische System in Neuer Anordnung mit Tabellen über Fünfzehn Physikalische Konstanten in Anordnung nach der Ordnungszahl der Elemente und nach der Grosse der Konstanten. (The Periodic Table in a New Form with Tables of Fifteen Physical Constants Arranged According to the Atomic Numbers of the Elements and the Magnitude of the Constants.) By DR. DARWIN O. LYON. Franz Deuticke, Leipzig and Vienna, 1928. vi + 40 pp. Illustrated. 17.5 X 26 cm. Price, unbound, M 8; bound, M. 10.

In an introduction the author first discusses rather broadly the origin and structure of matter. Next there is a cursory presentation of the Thomsen-Bohr arrangement of the elements followed by a brief discussion of several other arrangements of the elements particularly spiral ones. Special attention is devoted to magnetic relationships.

In the concluding section there are thirteen diagrams where curves are drawn connecting thirteen physical properties such as density, melting point, specific heat, electrical conductivity, entropy, etc., plotted against atomic numbers. There is then a large table where the numerical values of all these properties and the atomic numbers and atomic weights are arranged in fifteen columns with increasing values downward.

There is a clear tendency for the elements to occur at about the same level in the various columns of this table, although almost every element shows marked and violent irregularities. The most regular of all the elements is tin (No. 50) which comes at almost precisely the same level in all the columns except that for the melting points. It is not clear, however, that this marked regularity would persist if data for these properties were available for all the elements, or *a fortiori* if still other physical properties were similarly listed.

A final table lists the numerical values of these properties in the order of the atomic numbers.

ARTHUR B. LAMB

The Phase Rule and its Applications. By ALEXANDER FINDLAY, M.A., D.Sc., F.I.C., Professor of Chemistry, University of Aberdeen. Sixth edition, revised and largely rewritten. Longmans, Green and Company, 55 Fifth Avenue, New York, 1927. xv + 326 pp. 165 figs. 14 X 22 cm. Price $3.50.

In this sixth edition the author has undertaken a more thorough revision than in any of the preceding new editions. It is evident that a careful consideration has been given to the many recent advances in the wide field covered by this treatise.

To accomplish this thorough revision the author has made somewhat extensive alterations in the general framework of the book. The introductory chapters on systems of one component have been rewritten from a general and systematic rather than a specific point of view; the chapters on systems of two components have also been rewritten and considerably enlarged. A discussion of the nature of the equilibria in intensively dried systems and of Smits' theory of allotropy has been added as well as an entirely new chapter on the applications of equilibrium diagrams.

It is a tribute to the utility and excellence of this treatise that new editions of it have been in such constant demand. We predict a similar popularity for this latest edition—which, by the way, is aptly dedicated to Wilder D. Bancroft.

ARTHUR B. LAMB

Lehrbuch der Organischen Chernie. (Textbook of Organic Chemistry.) By JULIUS VON BRAUN, Ph.D., Professor and Director of the Chemical Institute of the University of Frankfort. S. Hirzel, Konigstrasse 2, Leipzig, Germany, 1925. xxii + 508 pp. 18 × 25.5 cm. Price, unbound, 22 M.; bound, 24 M.

This comprehensive text of organic chemistry is divided into four parts: (I) Introduction, (II) General, (III) Special and (IV) Historical. The chapter headings demonstrate in a general way the manner in which the subject has been presented.

(I). The introduction comprises a description of the analysis, principal characteristics and investigational methods of organic compounds.

(II). The general part contains the following chapters: (1) Methane and its Closest Derivatives; (2) General Survey of the Formation of Organic Compounds; **(3)** Hydrocarbons; (4) Halogen Compounds; (5) Metallo-organic Compounds; (6) Sulfonic Acids; (7) Nitro Compounds; (8) Reduction Products of Nitro Compounds; (9) Phosphorus, Arsenic, Antimony, Bismuth, Silicon and Boron Derivatives; (10) Hydroxyl Compounds; (11) Carbonyl Compounds; (12) Carboxyl Compounds; (13) Heterocyclic Compounds; (14) Summary and Critical Discussion (methods for determining constitution, value of physical properties for constitution, rearrangements, etc.).

(III). The special part is divided as follows: (1) Proteins; (2) Carbohydrates; (3) Fats; (4) Purines; (5) Alkaloids and Synthetic Medicinals; (6) Terpene Compounds and Rubber; (7) Resins, Styrols, Tannins, Ferments; (8) Dyes.

(IV). The historical part takes up the development of the theories of organic chemistry from the earliest time.

It will be noticed in the general part that the subject is developed by discussing in detail the character, formation and reactions of each functional group in turn. The first chapter in this part deserves special comment because it introduces immediately to the new student almost all of the common functional groups. Thus, after discussing methane, it is shown how this is converted to methyl chloride, the latter in turn to methyl alcohol. Then follow dimethyl ether, the dimethyl esters of inorganic acids, nitromethane, methylamine, dimethylamine, trimethylamine, dimethylhydrazine, tetramethyl ammonium hydroxide, methyl mercaptan, methyl sulfide, methyl sulfonic acid, zinc methyl, methyl magnesium iodide, formaldehyde, formic acid, formamide, hydrogen cyanide.

All of the chapters include a description of both aromatic and aliphatic compounds, and a comparison of the formation and reactivity of the corresponding groups in these two classes is carefully discussed. The heterocyclic compounds are left to a special chapter on account of the many unusual reactions in this field.

The fourth part is an excellent summary of the historical development of organic chemistry and is particularly to be recommended to the average student.

The book covers an extraordinarily large number of individual reactions and topics and it is difficult to see how it could be used in an introductory course in organic chemistry as this subject is usually taught in the various universities of the United States. It could be used as a text in a second course, and would unquestionably be a valuable reference book to one who has some knowledge of organic chemistry and who desires to have the outstanding facts about many of the fields of modern interest and importance. The author has made no attempt to include a discussion of the commercial applications of organic compounds or of industrial processes.

This book should certainly be added to the list of those which the student with some knowledge of organic chemistry, and which the teacher of this subject, should have at their disposal.

HOMOGENEOUS GAS REACTIONS AT HIGH CONCENTRATIONS.
I. DECOMPOSITION OF HYDROGEN IODIDE

BY GEORGE B. KISTIAKOWSKY

RECEIVED MARCH 12, 1928 PUBLISHED SEPTEMBER 5, 1928

Kinetic studies of homogeneous gaseous reactions have revealed in a number of cases a perfect agreement between the predictions of the mass action law as deduced from the stoichiometric equation of the process and the observed influence of concentration on the reaction velocity. It has been generally assumed that, in these cases, the observed reactions directly follow a collision of two molecules in the case of bimolecular and of three molecules in the case of trimolecular reactions. There exist, however, many reactions which follow a more complicated course even in the small concentration interval investigated and the postulation of intermediary processes seems to be necessary for their kinetic interpretation. Moreover, the mechanism of bimolecular reactions may not be quite as simple as it appears, although this cannot be definitely established by the existing experiments. It is possible that experiments on a larger scale of concentrations would reveal deviations from the simple bimolecular law. Hibben[1] found, for example, that the decomposition of nitrous oxide is no longer bimolecular at very low concentrations. This deviation is due, apparently, to the predominance of a heterogeneous wall reaction and is therefore in no direct relation to the mechanism of the homogeneous reaction. The increase of relative probability of a wall reaction with increasing mean free path of the gaseous molecules is of course inherent in all bimolecular gaseous reactions and may considerably complicate their investigation at very low concentrations. Conversely, reactions which are homogeneous at ordinary concentrations will very probably remain so at higher concentrations and their investigation in this region, therefore, should not meet the difficulty mentioned above. Here, however, the homogeneous rate itself may become influenced by factors, the effect of which is negligible under ordinary experimental conditions ("atmospheric pressure" and below) owing to an increasing probability of three-

[1] J. H. Hibben, *Proc. Nat. Acad. Sci.,* 13,626 (1927).

and poly-molecular collisions or, speaking more generally, owing to the close proximity of the molecules. A hypothesis concerning a retarding effect of "three body" collisions on the rate of bimolecular reactions which the writer had in mind when starting these experiments has not been substantiated and its discussion therefore appears to be unessential; the experiments, however, offer one the possibility of drawing certain conclusions concerning the mechanism of bimolecular processes and should, therefore, be of some interest in connection with the theory of gaseous reactions.

The decomposition of hydrogen iodide was chosen as the object of study partly from considerations of an experimental nature, partly because this reaction has been most thoroughly investigated at ordinary concentrations and is known to have no complicating side reactions.

The rate of hydrogen iodide decomposition, the rate of its formation from molecular iodine and hydrogen and the position of the gaseous equilibrium have been extensively investigated by Bodenstein[2] over a wide range of temperatures (283–508°). He obtained good agreement between the rate and the equilibrium measurements, showing furthermore that the rate of decomposition is bimolecular—at least in the somewhat narrow concentration interval (around 0.042 mole per liter) investigated—and that this reaction is homogeneous in glass vessels. The more recent experiments of Taylor,[3] who found the rate of decomposition to be influenced by extensidn of the surface of the Pyrex glass used by him, can hardly affect Bodenstein's last conclusion, since his velocity constants are throughout considerably larger than those of Bodenstein. Furthermore, from Bodenstein's values of $d \ln k/dT$, a constant heat of activation[4] is calculable, whereas Taylor's results give a heat of activation decreasing with temperature. His experiments only show, therefore, that, in addition to the homogeneous decomposition, a wall reaction can be created by a suitable choice of the material for the containing vessels. Quite recently, Lewis and Rideal[5] doubted the simple bimolecular character of the reaction, suggesting that the decomposition is caused by free iodine atoms and finding that the rate (and similarly the position of the equilibrium) is influenced by minute quantities of water vapor. Bodenstein and Jost[6] pointed out, however, that phosphorus pentoxide, used by Lewis and Rideal as the drying agent, reacts at the temperature of their experiments with hydrogen iodide and probably causes all the observed effects. The experiments of Lewis and Rideal, therefore, do not prove the active influence of water vapor on the reaction velocity, but, as Bodenstein and

Jost conclude, there is on the other hand no experimental evidence available contradicting the existence of such influence.

Experimental Details

The method chosen for the purpose of the present investigation was the static one and was in principle very similar to that used by Bodenstein. Sealed vessels filled with hydrogen iodide were heated in a thermostat for a desired length of time and their contents later analyzed.

Since, however, the details of both methods are somewhat different and the technique of rate measurements on gases at pressures up to about 500 atmospheres is not yet quite developed, the more important details will be here briefly described.

Gas Preparation.—Hydrogen iodide was prepared by passing a mixture of hydrogen and iodine through a heated furnace. It was distilled once in a vacuum to free it from larger quantities of iodine and was stored in a glass vessel cooled by liquid air.

Preparation of Gas Samples.—In order to fill the experimental vessels with hydrogen iodide they were sealed (through a graded seal) to a larger glass bulb (about 200 cc.) provided with a Daniels[1] glass membrane manometer and a dry inner ground glass stopper, magnetically operated, which connected it through a trap and, further, through a greased stopcock with the hydrogen iodide container. The only greased stopcock in direct connection with the filling bulb was at the end of a long capillary (to prevent decomposition of larger quantities of hydrogen iodide) and connected it through a mercury vapor trap to a mercury diffusion pump. After thorough evacuation of the system some hydrogen iodide was distilled into the intermediary trap with the pump still working. This operation resulted always in a slight decomposition due to the passage of hydrogen iodide through the greased stopcock but the iodine formed remained during the subsequent operations in the trap on account of its low vapor pressure. The stopcocks to the container and to the pump were now closed and hydrogen iodide in the trap was slowly warmed up until a desired pressure (from 50 to **300** mm.) was created in the system. Then the inner glass stopper was closed and the trap and one of the experimental vessels were simultaneously cooled by liquid air. Experiments showed that practically no hydrogen iodide diffused from the large bulb through the stopper but that all condensed in the vessel. After about two minutes the stopcock to the pump was opened again and a few minutes later the vessel, which had been filled, was sealed off. It was found impossible to prevent slight decomposition of hydrogen iodide, particularly during the sealing off; the liquid hydrogen iodide, after the vessels were warmed up, was always slightly colored by iodine. Analysis of the contents of those vessels, which were somewhat more than usually dark colored and thus were considered unsuitable for experiments, showed that the free iodine content of these was not greater than 0.02%. The amount of iodine present initially in other vessels must, therefore, be lower than this figure. The experimental vessels were made of fused quartz, since the only other possible material—Pyrex glass—has been shown by H. A. Taylor to be catalytically active. The vessels were of cylindrical shape of some 50 cc. volume (2 × 15 cm.) for low pressure experiments, of about 8cc. volume (0.8 × 15 cm.) for medium pressures and of about **3.3** cc. (0.5 × 15 cm.) and 0.7 cc. (0.2 × 20 cm.) for high pressures. The 3.3cc. vessels (two of them) used initially were found to be impractical. On account of their very thick walls (10 mm.) the quartz showed signs of considerable inner strain, manifested from time to time by small cracks in the surface. One of these vessels exploded

---

[7] Daniels and Bright, THIS JOURNAL, 42, 1131 (1920).

a few minutes after cooling, the other during the first experiment after about five minutes of heating in the thermostat. The hydrogen iodide concentrations were in both cases only about one-fifth of those which the smaller vessels with the same ratio of internal diameter to wall thickness (1:2) were later found to withstand.

One end of each vessel was drawn to a fine tip, the other to a capillary about **0.5** mm. in diameter used in sealing the vessels to the filling system. The volume of all vessels, determined by weighing, varied slightly from experiment to experiment on account of the impossibility of sealing off the capillaries at exactly the same length. The errors so introduced are negligibly small for the larger vessels; for the small ones they were partly corrected for, the length of the capillary being measured each time and also the average area, the volume thus determined being added to the main volume. The errors introduced through the somewhat irregular shape of the capillaries may amount to as much as **0.5%** of the total volume.

Conduct of the Reaction.—For heating the vessels a large lead-bath thermostat, electrically heated, was used. The temperature, measured by a Chromel-Alumel thermocouple, was read on a potentiometer to 0.2°. The thermostat contained an efficiently working stirrer, an additional knife heater and a mercury thermoregulator. Due to a special design this latter was very sensitive; it responded to a sudden change of temperature of **0.5**" within ten seconds and the periodic variations of the temperature in the thermostat did not amount to more than **0.2".** During longer periods of time, however, the temperature of the thermostat, when left without attention, showed a slow drift amounting sometimes to as much as **1.5**" in twenty-four hours. The insertion of the cold quartz vessels into the thermostat lowered its temperature by a few degrees and several minutes were required for the temperature to become stationary again. In the later part of the work this inconvenience was avoided by heating the thermostat before each experiment to an appropriately higher temperature, so that even initially the temperature was within **0.5°** of the average.

To obtain a rapid cooling, the vessels, after taking them out of the thermostat, were immediately put into a steel pipe attached to a carbon dioxide tank and were cooled by a stream of cold gas. Two minutes were found to be sufficient (except for the 3.3cc. vessels) to bring them below room temperature.

Analysis.—The analysis was initially beset with considerable difficulties They were overcome by applying a cotton pad soaked in liquid air to one side of the vessel[8] and breaking the fine tips in distilled and degassed water under a specially designed small gas receiving apparatus. The rush of evaporating hydrogen iodide was so violent, however, that sometimes a fraction of it escaped from the receiver and more than one analysis was ruined in this way. It was fortunate that escaping hydrogen iodide immediately formed a fog in the air and so was easily detected. The tip of the capillary at the other end of the vessel was finally broken off and the vessel washed out with a degassed potassium iodide solution. For the subsequent titration of iodine and hydrogen iodide a standard solution of sodium thiosulfate approximately **0.1** N and two potassium hydroxide solutions **0.1** and **0.03 N** were used. Before each titration a **0.01** or **0.005 N** solution was freshly prepared from the standard thiosulfate by dilution. All titrating solutions were checked at regular time intervals according to the usual standard methods. For the iodine determination a certified micro buret was used almost exclusively. The other volumetric apparatus was recalibrated. The volumetric determination of free hydrogen, which, as a check, proved to be so useful to Bodenstein, had to be abandoned here on account of considerable complications resulting in the method of analysis

---

[8] The simpler procedure of freezing one end of the vessels failed, hydrogen iodide melting first at the far end of the narrow and relatively thin-walled capillary and the resulting expansion cracking the quartz.

adopted. However, Bodenstein had to use this determination only in order to correct errors in analysis due to a reaction of hydrogen iodide with the alkaline constituents of his soft glass vessels. Pure quartz, which was used in the present work, is very unlikely to react in this way and therefore the omission of the hydrogen determination is more or less admissible (see, however, later pages)

Calculation of Results

By integrating the equation

$$-\frac{d[HI]}{dt} = k[HI]^2 - k_1[I_2][H_2] \tag{1}$$

Bodenstein has derived an expression which gives the velocity constant k of the decomposition reaction as a function of the time t, the fraction decomposed, x

$$x = \frac{I_2}{I_2 + {}^1/_2HI} \tag{2}$$

and of the fraction decomposed at equilibrium ζ. The equation is

$$k = \frac{\log\left[\frac{\frac{\zeta}{2\zeta - 1} - x}{\zeta - x}(2\zeta - 1)\right]}{0.8686\,\frac{1-\zeta}{\zeta}\,t} \tag{3}$$

This equation is valid for experiments in which pure hydrogen iodide was present initially. The reaction of hydrogen iodide being bimolecular, the constant k of the above equation is still proportional to the concentration and must therefore be divided by this latter in order to obtain a bimolecular velocity constant independent of concentration. The measurements of the equilibrium between gaseous hydrogen iodide, iodine and hydrogen at total concentrations not far from 0.04 mole per liter have been summarized by Bodenstein in the following interpolation formula for the equilibrium decomposition, ζ

$$\zeta = 0.13762 + 7.221 \times 10^{-5}t + 2.5764 \times 10^{-7}t^2 \tag{4}$$

where t is the temperature in centigrade degrees. Prom this equation the equilibrium decomposition can be calculated for every temperature.

Equation *(3)* shows immediately that the closer the observed decomposition is to that at equilibrium, the more sensitive will the calculated value of the velocity constant k be to small errors or to changes in the equilibrium constant. For this reason the time of heating in the following experiments was always chosen so as to give only a small and almost uniform decomposition. Such a decision, however, in conjunction with the bimolecular character of the reaction, limited the choice of convenient temperatures to the lower part of the range investigated by Bodenstein.

Experimental Results

Table I gives the results of rate measurements at an average temperature of 321.4°. The temperature of each experiment is **a** graphical average of all readings during the time of heating. The constant k given in the seventh column has been calculated by means of Equation (3), using for ζ

the value 18.745% computed from Bodenstein's interpolation formula and counting the time in seconds. In order to obtain the constant k_0 of the last column, the k's were divided by the initial concentration of hydrogen iodide expressed in moles per liter (sixth column) and were reduced to the same temperature, 321.4°, by using a value 1.061 as the temperature coefficient of the rate at 321° per degree, calculated from Bodenstein's data. The table reproduces actually the results of all the experiments made which were not interrupted by an explosion of the vessel or by a failure in the analysis of the contents. A group of seven experiments in vessels which, contrary to the usual procedure, were not heated and degassed thoroughly during the evacuation process previous to filling, have been recorded separately in Table II. All these experiments, scattered throughout the range of concentrations investigated, yield values of k_0 considerably larger than the rest of the experiments and indicate, therefore, the presence of some additional catalytic decomposition. Supporting this view is an observation made occasionally when degassing the reaction vessels, that microscopic amounts of some yellow substance—possibly of mercuric iodide—were deposited in the colder parts of the apparatus.

Experiments with Specially Dry Hydrogen Iodide.—In order to investigate how far the rest of the experiments represented the true velocity of decomposition of pure hydrogen iodide and were not influenced by the presence of some unknown impurities (water), the filling apparatus was modified at the end of the present work. The stopcock and the capillary leading to the pump were removed and replaced by a wide tubing with a constriction for sealing off; between the trap, mentioned in the description of the apparatus, and the hydrogen iodide container were introduced three additional traps with inner glass seals at both ends of the line. Freshly prepared hydrogen iodide was used. All the separated (by the inner seals) parts of the system were baked out in a vacuum at 450400' for ten hours. The quartz part of the apparatus with the reaction vessels sealed to it was heated to a somewhat higher temperature than the rest. Hydrogen iodide was distilled four times in a vacuum from a bath of melting carbon disulfide ($-112°$), only the first fraction being used each time and the rest being sealed off after cooling. Unfortunately the glass membrane manometer failed to work after the heating and the pressure of hydrogen iodide in the filling system had to be guessed. The result was that too much was filled into two of the vessels and they exploded on heating; the remaining two experiments are Nos. 14 and 23 of the first table. Hydrogen iodide prepared in this way must have been not only extremely dry but also incomparably freer from all foreign matter than the quality normally used. Incidentally, it contained only very small quantities of free iodine and appeared to the eye absolutely colorless. This was secured by allowing a long time for complete condensation of hydrogen iodide before the vessels were sealed off.

The Influence of Temperature.—Table III represents nine experiments made at a lower temperature. The value of ζ used in the calculation of the constants k was computed from Bodenstein's data to be $\zeta = 18.247\%$. The bimolecular constants k_0 of the last column have been corrected to the mean temperature of 300.0".

Equilibrium Measurements.—Table IV gives the results of equilibrium measurements at 321.4°. The analysis of these experiments was particularly difficult on account of large amounts of non-condensable hydrogen present and a considerable number were rendered useless by losses of hydrogen iodide. The number of experiments offered is somewhat limited also because the quartz vessels did not seem to withstand well the long heatings necessary to attain equilibrium. Numerous explosions which, of course, ruined the rather costly quartz vessels were the unpleasant result.

Table IV

Errors

Influence of Impurities.—Before discussing the theoretical significance of the experiments made, it is well worth while to consider in detail the possible errors. Table II shows quite plainly that hydrogen iodide decomposition is rather sensitive to the presence of impurities. Whether the observed catalytic acceleration is really due to the mercuric iodide noticed or is due to oxygen occluded in quartz and driven off in most of the experiments by heating cannot be decided. It is important to note that the results of Table I very probably represent the true velocity of decomposition of pure hydrogen iodide, as is best demonstrated by the complete agreement between the main body of the results and those of experiments Nos. 14 and **23** made with unquestionably pure and dry hydrogen iodide.

Accidental Errors.—The mean of the first 14 experiments up to 0.5 mole per liter concentration (the reasons for this limitation will be seen from a later discussion) is $k_0 = 3.95 \times 10^{-6}$ with an average deviation of single values amounting to 3.1% and with a probable error of the mean itself of 0.73%. But, aside from one or two values with larger deviation—and these are very likely due to unobserved small losses of hydrogen iodide or of iodine (in the broken tip of the capillary)—the average deviation is even much smaller. It is fully accounted for by unavoidable errors in buret readings and other uncertainties of the analysis and of volume determinations and also by errors made in averaging the temperature;

these latter may amount easily for longer time intervals (overnight) to **0.3'** and will therefore account for about 2.0% deviation in the constants, k_0. All this shows that the rate measurements gave completely reproducible results.

Systematic Errors.—The calculated probable error of the mean does not include, however, systematic errors. The more important of these are: **(1)** Incorrect titers of solutions used and errors in the calibration of the volumetric apparatus. Assuming an error of 0.5% to be thus involved in each titration, we are on the safe side. This gives a possible error of **1.5%** in k_0, since iodine determination enters here in the first power, that of hydrogen iodide as the square. *(2)* More important still is the error in determination of the absolute temperature of the thermostat. The Chromel-Alumel thermocouple was calibrated in boiling water, mercury and sulfur. As the result of these determinations, repeated several times with almost identical results, a three-constant equation has been calculated which gives the temperature of the thermostat, designated in Table I as **321.4** to 321.6°. Independent check of the temperature was made by means of a platinum resistance thermometer and a high-precision Mueller type bridge. The first determination—in an early part of the work—yielded **321.2';** the second one, made somewhat later, **321.3'.** Attributing a statistical weight unity to the thermocouple determination and a weight **2** to the mean of the platinum thermometer temperatures, the final mean temperature is calculated to be 321.4° with an uncertainty of not more than **0.3'** or with an error in the k_0 not exceeding 2%.

Errors at **High** Concentrations.—The experiments at higher concentrations of hydrogen iodide are, of course, equally subject to all these errors and, in addition, to two others which will now be considered. The time intervals required for the heating up and for the cooling down of the vessels have been neglected so far, the "true" time of heating being equated to the actual time of immersion in the thermostat. This source of error will obviously affect the results more considerably the shorter the time of immersion. Therefore, four experiments, represented in Table V, have been made of only very short duration; the "true" time of heating has then been calculated after assuming an appropriate velocity constant

TABLE V
THE CORRECTION OF HEATING TIME

k_0 (see the latter part of the article) for each experiment. The difference between the mean "true" and the actual immersion time amounts to only twenty-three seconds, the iodine initially present and the decomposition during the cooling apparently more or less compensating the slower rate during the warming up period. Therefore, the systematic error of time determination even in the shortest experiment (No. 45, Table I, 1140 seconds) amounts to only 2% and a correction of the results in Table I in this respect was considered unnecessary. The other error may arise from a change in the equilibrium decomposition due to the non-ideal character of the gases at high concentrations. The observed deviation of the decomposition velocity under these conditions from the normal course is rather in favor of such possibility. Table IV, containing the equilibrium measurements, could also be interpreted as supporting it. A closer comparison shows, however, that there is no systematic change of equilibrium decomposition with concentration of hydrogen iodide but rather a steady, although a slow, increase with time of heating for about equal concentrations. Different interpretations of the effect can be offered. (1) The time of heating was possibly too short. The last column of the table gives, however, the calculated times at which the equilibrium should be reached within 1% (that is, $x = 0.18558$ for $\zeta = 0.18745$) and shows that this time is throughout much shorter than the actual time of heating. It would remain so even if the equilibrium decomposition was shifted to $\zeta = 0.22000$ (this last calculation of course, was made with a suitably modified value of k_0). (2) The equilibrium mixture becomes inhomogeneous, liquid iodine being separated. Unfortunately a calculation of the iodine vapor pressure at 321° would be of no value since the composition of a liquid phase under the experimental conditions is unknown. Another consideration, however, will help. If a condensation does take place, there must be a critical concentration of hydrogen iodide with which at equilibrium a saturation concentration of iodine obtains. Above this, the extent of decomposition would increase very rapidly with increase of initial concentration of hydrogen iodide. No evidence of such behavior, at least in the concentration range investigated, can be found in Table IV. (3) Hydrogen is slowly consumed in the walls of the quartz vessels. The vessels showed, however, no visible signs of any change on the inner surfaces and so a reduction of silica appears improbable. It is more likely that hydrogen under high pressure is slowly diffusing through quartz. That helium diffuses through quartz even at room temperature has been shown by Elsey[9] and it is well known that at temperatures considerably higher than 320° quartz is quite permeable to hydrogen. The presence of such a diffusion process would not only account for the observed slow shift in the equilibrium decomposition but would also indi-

[9] H. M. Elsey, THIS JOURNAL, **48**, 1600 (1926).

cate that the true decomposition values at high concentrations are somewhat lower than the figures recorded in Table IV and, hence, either about equal to or slightly lower than Bodenstein's value, $\zeta = 0.18745$, obtained for concentrations not in excess of 0.08 mole per liter. The velocity constants k_0 in the upper range of concentrations represent therefore in all probability either the true or slightly smaller values.

Kinetic Interpretation of the Results

For convenience in the following discussion the results of the first table have also been represented in Fig. 1. The ordinates give the velocity constant k_0, the abscissas the initial concentration of hydrogen iodide plotted on a logarithmic scale. The constants k_0 obtained at the mean temperature, 300.0" (Table 111), have also been plotted on Fig. 1 (as large circles) after having been multiplied by a factor of 3.85. This graphical representation will be of value in showing that the bimolecular velocity constant k_0 (the range 0.02 to 1.0 mole/liter) is quite independent of the size of the vessels used. Since, however, the surface–volume ratio of the different quartz vessels varied by at least a factor of 10, it means that the decomposition velocity measured was at least almost exclusively that of the homogeneous reaction. The experiments with dried hydrogen iodide mentioned earlier show, furthermore, that it was the true velocity of decomposition uninfluenced by the presence of impurities. Possibly even more convincing in this respect is a comparison with Bodenstein's results. His empirical interpolation formula for the velocity constant k_0[10] yields for the temperature 321.4° a value 1.10 X 10^{-5} (mole/22.4 liters, minutes). Converted to our units (mole/liter, seconds) the value is 4.12×10^{-6}. The same value 4.12 is obtained when for the calculation of the reaction velocity at 321.4° the equation

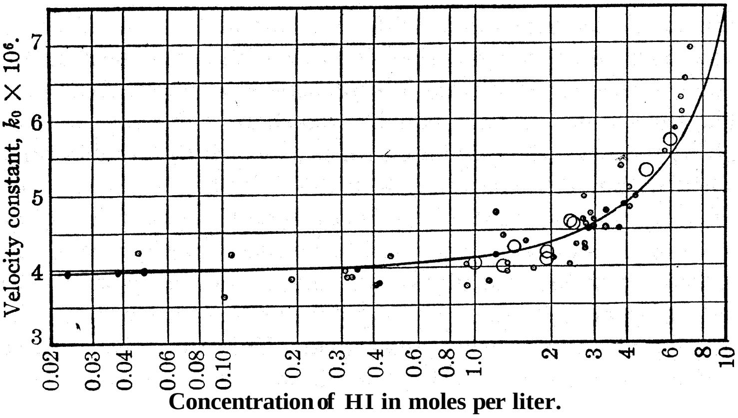

Fig. 1.—The bimolecular velocity constant of HI decomposition.

[10] Bodenstein, Z. physik Chem., 29,295 (1899).

$$\ln \frac{k_{T_1}}{k_{T_2}} = A\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \tag{5}$$

and the two nearest values (302 and 356°) of Bodenstein are used. The agreement between Bodenstein's and the present values is quite unusually good. The difference amounts to only 4% and is thus even within the limits of the maximum possible error estimated for these experiments alone, although about the same error *(5%)* must be inherent in Bodenstein's measurements. In consideration of the fact that he used soft glass vessels instead of pure quartz and that his method of filling the vessels (and therefore the amount of impurities) was quite different from ours, such agreement is the best proof that in both cases the true homogeneous rate has been measured.

Fig. 1 shows quite clearly that the velocity constant, k_0, which remains unchanged in a wide range of concentrations, starts to rise from about 1 mole per liter, reaching a value higher by more than 50% for the concentration of 7 moles per liter. Furthermore, as the values of k_0 at 300.0° indicate, the slope of the rise is essentially independent of the temperature; the temperature coefficient of the reaction rate at different concentrations therefore is the same.[11] The most natural explanation of this rise, that does not involve a postulate of some tri- or of still higher order molecular processes, is that the reaction rate is strictly proportional to the number of bimolecular collisions, but that the number of these latter is not proportional to the square of the concentration, provided the concentration is rather large. Indeed, van der Waals[12] has already shown that the equation for the total number of collisions

$$Z = 2\sqrt{\pi}\, N^2 \sigma^2 \sqrt{\frac{RT}{M}} \tag{6}$$

(N the number of molecules per unit volume of the only kind present, σ their diameter, M the molecular weight, R the gas constant and T the absolute temperature) is only a first approximation and that the next step in refining it is the multiplication of it by a factor

$$\frac{1}{1 - Nb} \tag{7}$$

The constant b has been found to be equal to four times[13] the volume of a molecule assumed to be a sphere. The same correction of course must be applied to the constants k_0 in order to retain the proportionality between the collision number and the reaction velocity. In Fig. 1 the curve has been drawn with a value of Nb equal to 47 cc. per mole or with σ =

---

[11] It is appropriate to point out that the factor 3.85, by which the constants at 300.0" have been multiplied, is within 1% of the temperature coefficient of the rate between 300.0 and 321 4° determined from Bodenstein's data.

[12] J. D. van der Waals, "Over de continuiteit van den gas-en vloeistoftoestand," Leiden, 1873.

[13] O. E. Meyer, "Die kinetische Theorie de Jase," Breslau, 1899.

3.33×10^{-8} cm. This value of b fits best the numerous experiments between $c = 2.5$ and $c = 4.5$ moles per liter concentration. The experiments at very high concentrations are unsuitable for the determination of b because, as Jaeger[14] pointed out, even the corrected collision equation is only an approximation and must fail when Nb approaches unity. The experiments in the region $c = 0.9$ to $c = 2.5$ moles per liter show somewhat too large irregular deviations to be used for the calculation of b. They yield, however, a mean ($k_0 = 4.14 \times 10^{-6}$; $c = 1.31$ moles/liter), which is within 1% of the curve[15] drawn. The introduction of the quantity b into the expression for the collision number is equivalent to the introduction of the volume correction b into the equation of state of van der Waals. The other correction "a" which takes care of the attracting forces between the molecules has, however, a different influence on the form of the collision equation. As Sutherland[16] has shown, only the apparent diameter of the molecules is increased by forces of attraction, whereas, at least as long as only forces acting between two (colliding) molecules are considered, the number of collisions remains proportional to the square of the molecular concentration. No more general calculations taking care of the influence on the collision frequency of forces exerted by other neighboring molecules are recorded in the literature.

The agreement of the value of a obtained ($a = 3.3 \times 10^{-8}$ cm.) with that calculated by Rankine[17] from viscosity data, $a = 3.5 \times 10^{-8}$ cm., is rather good.

Summarizing, the conclusions arrived at can be stated as follows. The decomposition of hydrogen iodide is kinetically strictly bimolecular; Bodenstein's measurements of the reaction velocity seem to be very accurate; an exact value for the velocity constant at 321.4° and a fairly accurate value of the molecular diameter[18] have been obtained.

Activation Energy and Collision Area.—With these data on hand an investigation of the mechanism of activation[19] and reaction can now be attempted. The writer has repeated the graphical determination of the

---

[14] G. Jaeger, *Sitz. Akad. Wien*, 105 (2A), 111 (1896).

[15] The larger deviations of these experiments arise partly from uncertainties in the analysis of the very small amounts of iodine formed in the small 0.7cc. vessels. The two experiments with the 3 28cc. vessel (Nos. 24 and 26) have not been included in the above average. It is very doubtful whether the "true" time of heating coincides with the time of immersion in the thermostat so well for this large and very thick walled vessel, as it does for the small 0.7cc. vessels.

[16] Sutherland, *Phil.* Mag, 36, 507 (1893).

[17] Rankine, *Trans. Faraday Soc.*, 17,719 (1922).

[18] The probable error in this latter is somewhat uncertain. It is easy to show, however, that a change of b by 25% (therefore a change in σ by about 8%) completely destroys the agreement between calculation and experiments in Fig. 1.

[19] For the following considerations compare, for instance, C. N. Hinshelwood, "The Kinetics of Chemical Change in Gaseous Systems," Oxford, 1926

activation energy[4] from the temperature coefficient data of Bodenstein. The values of ln $k_0 - {}^1/_2 \ln T$, from the equation

$$\ln k = {}^1/_2 \ln T - E/RT + C \tag{8}$$

have been plotted on a large scale against $1/T$. All values of Bodenstein from 508 to 302° lie on a straight line with maximum deviation not exceeding 5% in the value of k (not ln k). The slope yields for E, 44,300 cal.[20] In order to estimate the probable limit of error of this figure, we may assume that the velocity constants at 508 and 302° are wrong each by 20%—a rather exaggerated error in view of the agreement earlier demonstrated. The upper limit of E under these conditions is calculated to be 45,900 cal. Assuming that the reaction occurs on each collision in which the energy of both molecules exceeds the above value, we may calculate the rate of hydrogen iodide decomposition at 321.4°.

$$k_0c^2 = 2Z\, e^{-E/RT} \tag{9}$$

Z, the total number of collisions per cc. per second at unit concentration (1 mole per liter), is calculated to be 2.82×10^{31}, if $\sigma = 3.3 \times 10^{-8}$ cm. The exponential with $E = 45{,}900$ cal. is equal to 1.28×10^{-17}, so that the number of molecules reacting, which is twice the number of effective collisions, is calculated to be at least 7.25×10^{14}. This must be compared with the experimentally determined number ($k_0 = 3.95 \times 10^{-6}$) 2.39×10^{14}. The agreement obtained cannot be considered as quite good because, it must be remembered, the calculated reaction velocity represents the lower limit, still consistent with Bodenstein's measurements of the temperature coefficient, and should probably be raised by a factor close to 2.

As has been frequently pointed out, Equation 9 holds strictly only if the energy of activation of the colliding molecules is assumed to be distributed in two degrees of freedom only. It is of some interest to consider another possible source of activation energy: the total kinetic energy of relative motion of colliding molecules.

In such a case the number of collisions (therefore half the rate of decomposition) with the relative kinetic energy larger than a given one is expressed not by Equation (9) but by[21]

$$k_0c^2 = 2Z\left(1 + \frac{E}{RT}\right) e^{-\frac{E}{RT}} \tag{10}$$

To calculate the theoretical reaction velocity of hydrogen iodide decomposition with Equation 10 it must be first noted that the temperature coefficient of the reaction rate is given now by

---

[20] The value of k_0 at 283° is considerably off the straight line (by some 20% in k) and its inclusion would *decrease* the average activation energy. The deviation is possibly due to a wall reaction becoming marked at this low temperature. Since we are interested here in the upper limit of ϵ only, the value of k at 283° has been neglected.

[21] Tolman, "Statistical Mechanics with Applications to Physics and Chemistry," The Chemical Catalog Company, New York, 1927.

$$\frac{d \log k_0}{dT} = \frac{1}{2T} + \frac{E}{RT^2} - \frac{1}{T} \tag{11}$$

(the term $(1 + E/RT)$ being substituted in Equation (10) with a sufficient degree of accuracy by E/RT) and that therefore RT must be added to the previously determined value of E.

The upper limit of E at 321° now becomes 47,100 cal., and from this and Equation 10 the *minimum* number of effective collisions is calculated to be 4.45×10^{15}, the rate therefore to be 8.9×10^{15}. The experimentally determined value was 2.4×10^{14}.

Without going into further calculation it may be pointed out here that the discrepancy between the calculated and experimental rates will be still considerably increased if the assumption is made that all forms of energy present in a diatomic molecule, that is, energy of translation, of rotation and of oscillation, contribute to the activation of hydrogen iodide.[22] The only error which could have entered into the calculations of the theoretical reaction rate (provided the theory of activation is correct generally) lies in the assumption that the diameter of the reacting molecules or, better, their effective cross section, is the same as the kinetic cross section of an average molecule. And, since the calculated rate was found to be greater than the observed, it means that the effective cross section of molecules in collisions leading to reaction is considerably smaller than the average. If only two degrees of freedom are acting in the activation, the effective cross section is still not far from the normal—probably one-half to one-fourth of it. But if we assume that at least three—the translational—degrees of freedom are responsible for the activation, the effective cross section of reacting molecules must be smaller than 0.03 of the normal. This result is rather striking because, as has been shown repeatedly,[23] atoms (and probably also molecules) in the state of electronic excitation have cross sections considerably greater than the calculated kinetic averages for normal atoms. Some light on the process of activation in thermal reactions could possibly be obtained by similar studies of the cross sections of molecules excited to higher oscillation and rotation quantum states by absorption of light in their infra-red absorption bands. At present very little can be said definitely as to the origin of the small effective cross sections of the activated molecules. They may be due to a "steric factor"[24]—the

---

[22] For the form of equations determining the number of collisions with energy greater than a given one, as a function of the number of degrees of freedom, see Herzfeld, "Die Kinetische Theorie der Wärme," Braunschweig, 1925; Hinshelwood, Proc. *Roy. Soc., London,* **113A,** 230 (1926); Fowler and Rideal, *ibid.,* **113A,** 570 (1926); O. K. Rice and H. C. Ramsperger, THIS JOURNAL, 49, 1617 (1927).

orientation of the molecules in the moment of their collision—or to some other causes. Prior to deciding this question, it is necessary to know the exact origin of the activation energy.

The Molecular Volume Factor in the Velocity Experiments.—The experiments here described offer—at least in principle—the possibility of solving this last problem. A more careful consideration of the meaning of the term Nb which, according to the suggested interpretation, caused the observed increase of the velocity constant at high concentrations, will show that this quantity is somewhat different from the ordinary Nb entering the van der Waals equation of state. In this equation b determines, so to speak, that part of the total volume of a gas which, being occupied by the rest of the molecules, is excluded from the space which can be occupied by an average molecule. Therefore, b of van der Waals is determined by the nearest distance to which the centers of two average molecules can approach each other, that is, by the sum of their radii. In contrast to this the experiments on reaction rate describe not the behavior of average molecules but the behavior of certain[25]—activated—molecules; Nb, therefore, represents that fraction of the total volume which is excluded to these particular molecules, is thus determined by the nearest distance to which the center of an activated molecule can approach the center of an average molecule in an average collision. The knowledge of this distance will make possible at least an indirect conclusion as to the forms of energy sharing in the thermal activation. If it is the kinetic energy we may expect[15] that b, determined from the rate measurements, will be somewhat smaller than the usual b at the same temperature. On the other hand it is quite likely that increased energy of rotational and vibrational degrees of freedom[26] increases somewhat the dimensions of the molecules and should be therefore manifested by a larger volume correction in the rate experiments. Unfortunately, the present state of knowledge of the exact volume of average molecules of hydrogen iodide at the temperature of the experiments here recorded as also possible errors in b, determined, from the rate measurements, make a successful comparison rather improbable.

[25] The case is equivalent to the case of a mixture of two kinds of molecules, although we must assume that there is a continuous exchange of individual molecules, of which each has a chance to be either activated or deactivated. Provided the concentration of one (the "activated") kind is negligibly small, the volume correction for it is given by $4N[4/3\pi((r' + r)/2)^3]$, r' and r being the radii of both kinds, whereas for the other kind (the "average") the correction is $4N(4/3\pi r^3)$. In reality molecules in different (higher) rotational or oscillational quantum states or molecules with different velocities are probably capable of reaction on collision with a suitable other molecule. The above calculation gives, therefore, only their average cross section.

[26] A Sommerfeld, "Atombau und Spectrallinien," Vieweg und Sohn, Braunschweig, 1924.

In conclusion the writer wishes to thank Professor Hugh S. Taylor for his active interest and encouragement during the course of this work.

Summary

1. The decomposition of gaseous hydrogen iodide has been investigated at concentrations from 0.02 to 7 moles per liter.

2. The rate of decomposition is bimolecular in the whole range of concentrations investigated and is not influenced by extreme drying.

3. At higher concentrations a correction taking care of the volume of the molecules in the expression for the number of bimolecular collisions must be introduced in order to retain the bimolecular character of the reaction rate.

4. Calculations of the reaction rate from the data on the activation energy show that the effective cross section of activated molecules in collisions leading to reaction are smaller than the average kinetic cross section of molecules.

5. A way of deciding which forms of molecular energy are contributing to the activation process has been indicated from considerations on the nature of the volume correction obtained from the rate measurements here recorded.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. VII. THE ELECTRIC MOMENTS OF CERTAIN DIPHENYL DERIVATIVES. THEIR RELATION TO THE SEVERAL STRUCTURES

BY JOHN WARREN WILLIAMS[1] AND ARNOLD WEISSBERGER[2]

RECEIVED APRIL 16, 1928 PUBLISHED SEPTEMBER 5, 1928

A study of the chemical properties of diphenyl and its derivatives has led to interesting speculations concerning the structures of the various molecules. For the purpose in hand it is considered unnecessary to review the work which has been done in this field; it will be sufficient simply to state the conclusions given in two more recent publications These articles contain numerous references to previous investigations.

Adkins, Steinbring and Pickering,[3] as a result of their studies, conclude that the non-formation of the anhydrides is due to the fact that in the dinitro and dihydroxy acids the rings are extended as in the conventional formula, while in the amino or benzidine type of acids the rings are super-

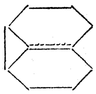
imposed. Kuhn and Albrecht,[4] discussing the same question, "come to the conclusion that it is not possible to explain diphenyl and its derivatives by means of a single space formula." In the case of the *p,p'*-disubstituted diphenyl compounds, two types of formula are discussed, as follows. (1) A formula in which the axes of the two benzene rings lie in a straight line. (2) A formula in which the axes of the two benzene rings make an angle with each other or are directed parallel to each other, as indicated in the following diagram.



In the previous papers of this series,[5] the use of electric moment data for the solution (in many cases at least) of problems of chemical structure has been suggested. The purpose of this article is to demonstrate the utility of these data as applied to the question of the structure of certain derivatives of diphenyl.

Experimental

The electric moments of the molecules in question, as well as that of *p*-phenylenediamine, which is necessary for the discussion, have been determined from dielectric constant and density data of their dilute solutions in benzene at 25°. The limited solubility of the diphenyl derivatives in benzene requires that the difference in dielectric constant between the solution and that of the solvent be determined with a high degree of accuracy. For this purpose an apparatus shown diagrammatically in Fig. 1 was built.

It differs from that previously described[6] in that it consists of three distinct circuits, two of which are oscillators and the other a receptor. The heterodyne principle was used as before; in fact, the method of making a dielectric constant measurement was very similar to that previously described. The dielectric constant of benzene was assumed to be 2.2820; that of the solutions was determined by noting the change in capacitance produced when the solution was substituted for the solvent between the plates of the measuring condenser. In the tables the dielectric constants have been expressed to four significant figures only. A fifth and doubtful figure was used in the calculation of the molar polarization of the solution, and therefore in the calculation of the molar polarization of the solute molecule. The uncertainty in the molar polarization of the solute molecule, P_2, is of the order of magnitude of 5%.

All substances used for the measurements reported were subjected to a careful purification by the usual methods of crystallization or distillation or both. The melting points of the various solutes were determined, and in no case was the observed melting point different by more than 1° from that given in the literature.

The results of the experimental determinations are given in Tables I and II. The symbols used in the earlier articles have been retained throughout; therefore their significance need not be repeated here.

TABLE II

ELECTRIC MOMENTS OF SOLUTE MOLECULES AT 25°

Molecule	P_2	P_2''	P_2'	$\mu \times 10^{18}$
p-Phenylenediamine	37.5	35	2.5	0.3[a]
4,4'-Dichlorodiphenyl	63	63	0	0
4,4'-Dinitrodiphenyl	65	65	0	0
4,4'-Diaminodiphenyl	100	60	40	1.3
4,4'-Diethoxydiphenyl	150	75	75	1.9

[a] Moment indistinguishable from zero by the method used.

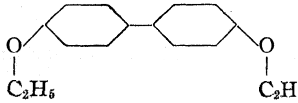
Discussion

In the discussion of these results it is necessary to consider the data not only for the particular derivatives of diphenyl but also for the corresponding derivatives of benzene. The data for *p*-dichlorobenzene,[7] *p*-dinitrobenzene[5] and hydroquinonediethylether[8] are available in the literature; that of *p*-phenylenediamine is reported above.

With regard to the structure of the several derivatives of diphenyl, the following statements may be made.

(1) Since the electric moments of the compounds *p*-dichlorobenzene and 4,4'-dichlorodiphenyl, and of *p*-dinitrobenzene and 4,4'-dinitrodiphenyl, are zero, and since the introduction of a single Cl atom or NO_2 group into the benzene nucleus causes a highly unsymmetrical molecule," the conclusion is definite that in the case of the compounds 4,4'-dichlorodiphenyl and 4,4'-dinitrodiphenyl the rings of the diphenyl nucleus are co-axial. They are represented diagrammatically in the following sketches.

(2) The electric moments of the compounds hydroquinonediethylether and 4,4'-diethoxydiphenyl (1.7 and 1.9 × 10^{-18} e. s. u., respectively) must be considered to be of the same order of magnitude. The reason why hydroquinonediethylether gives a finite moment has been discussed previously.[8,9] Since the magnitude of the moment of the corresponding diphenyl derivative is the same, it is highly probable that its structure is similar. The conclusion to be drawn from these considerations is, again, that the benzene rings are extended. This structure is suggested in the following diagram.



---

[7] Smyth and Morgan, THIS JOURNAL, 49, 1030 (1927).

[8] Williams, *Physik.* Z.,, 29, 271 (1928). In this connection see also Williams, THIS JOURNAL, 50, 2350 (1928).

[9] Weissberger, *Physik. Z.*, 29, 272 (1928).

In this connection it may be pointed out that until more accurate experiments are available for this and similar substances, the possibility of a slight deformation from the extended position is not excluded.

(3) The electric moment data for the compounds *p*-phenylenediamine and 4,4′-diaminodiphenyl distinctly indicate a collapsed or folded structure for the latter substance, in benzene solution, at least.[10] The electric moment of the similar benzene derivative is zero; thus there is no tendency for the NH_2 groups to be bent from the plane of the benzene ring. 4,4′-Diaminodiphenyl has a comparatively large moment, $\mu = 1.3 \times 10^{-18}$ e. s. u. If the benzene rings of the diphenyl were extended, as has been shown to be the case for the dichloro, dinitro and diethoxy derivatives, there can be little question that a moment indistinguishable from zero would have resulted for the benzidine molecule as well.

Thus the electric moment data reported in this article indicate the truth of the statement quoted above from the article of Adkins, Steinbring and Pickering, namely, that in the dinitro and dihydroxy derivatives of diphenyl the rings are extended as in the conventional formula, while in the amino or benzidine type the rings are folded. They are also in accord with the conclusions of Kuhn and Albrecht. It is evident, however, that these data are insufficient to establish the general truth of these conclusions; therefore the work is being continued.

The authors take pleasure in thanking Professor P. Debye for facilities placed at their disposal, for his kindly interest in the work and for the inspiration he has given it.

Summary

1. Dielectric constant and density data at 25° have been obtained for benzene solutions of *p*-phenylenediamine, 4,4′-dichlorodiphenyl, 4,4′-dinitrodiphenyl, 4,4′-diethoxydiphenyl and 4,4′-diaminodiphenyl. The electric moments of the various solute molecules have been calculated from these data.

2. The electric moment data have been shown to indicate the truth of statements made by Kuhn and by Adkins with regard to the structure of certain derivatives of diphenyl. In the case of the dinitro and dihydroxyl derivatives, the rings of the nucleus are extended. In the case of the amino derivative the rings cannot be extended.

THE OXIDATION POTENTIAL OF THE PENTAVALENT–TRIVALENT COLUMBIUM SYSTEM. II

BY SAMUEL J. KIEHL AND DAVID HART

RECEIVED APRIL 30, 1928 PUBLISHED SEPTEMBER 5, 1928

Introduction

During our study of the reduction of columbic acid at a mercury electrode[1] the behavior of the reduced columbium upon reoxidation to the pentavalent state indicated that the trivalent columbium might possess a rather high reducing potential. Consequently, inasmuch as the literature contained no potential measurements whatever upon the pentavalent–trivalent columbium system, it was deemed worth while to make a study of this phase of the chemistry of columbium.

Apparatus

On account of the oxidation of a reduced columbium solution by contact with the air, it was necessary to devise and construct an hermetically sealed apparatus in which measurements could be made and solutions could be introduced, withdrawn and transferred. In an apparatus described below, which provided an atmosphere of hydrogen, the measurements were made. Platinum electrodes were first tried but the results were so inconstant and non-reproducible that, as with Forbes and Bartlett[2] in their measurement of the stannic–stannous potential and Forbes and Richter[3] in their determination of the chromic–chromous potential, they were abandoned and the mercury electrodes were employed instead. Forbes and Bartlett and Forbes and Richter concluded from their experimental work that with the mercury electrodes results were more quickly obtained, irregularities due to surface energy of the electrode were less pronounced and deviations due to traces of oxygen in the system were almost eliminated. Besides, mercury has, as an important and as an additional property in its favor, a free surface upon which hydrogen has a high overvoltage. Also it does not appreciably react with sulfuric acid of the concentrations used in these experiments when the solutions are at room temperature.

Mercury Electrode.—The mercury electrode employed in the measurement of oxidation potentials is shown in Fig. 1. It consists of a wide-mouthed bottle of 250cc. capacity, closed with a rubber stopper provided with seven holes through which, respectively, pass a glass tube with a

sealed-in platinum wire to make contact with the mercury on the bottom of the cell, a glass tube to furnish a stream of hydrogen, two burets to introduce the reduced and unreduced solutions, respectively, a glass tube leading into a bottle to act as a water seal to release the excess of hydrogen, a glass tube for the withdrawal of an analytical sample, and finally a glass tube to act as a salt bridge connecting the solution to be measured with the saturated calomel cell.

The instruments, the arrangement and the method used to measure the electromotive force were described by Hansen and one of us.[4]

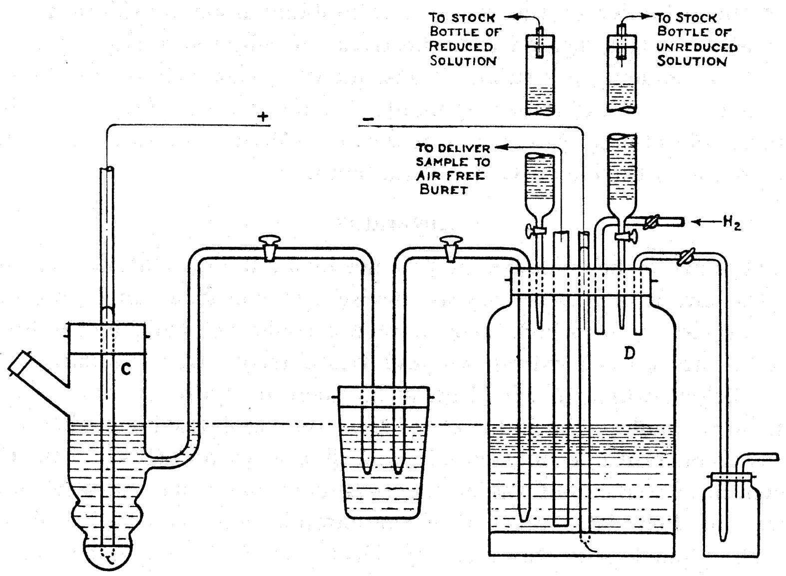

Fig. 1.

Experimental

Preparation of Solutions.—Solutions containing both pentavalent and trivalent columbium were prepared as follows. A solution of approximately 0.025 M Cb_2O_5 in the desired concentration of sulfuric acid was prepared and reduced completely to the trivalent state by the method previously described by us.[1] About one-half of this reduced solution was transferred to a stock bottle and rwxidized to the pentavalent state by passing purified air through it until the blue color disappeared. The excess oxygen was removed by a stream of hydrogen. This procedure insured the same sulfate concentration in the reduced as in the unreduced solution. This solution furnished the pentavalent columbium used below in the measurements.

Before the required amounts of the two solutions were introduced into bottle D, Fig. 1, the air was swept out by a stream of hydrogen. The whole system, including stock bottles, pipet for withdrawal of samples and titrating system used previously by us,[1] was connected hermetically and operated in an atmosphere of hydrogen. After the complete apparatus was ready, measured quantities of the solutions of trivalent

---

[4] Kiehl and Hansen, This journal, 48,2802 (1926).

and pentavalent columbium sufficient to make a total of 100 cc. and to give the required reduction were introduced into bottle D of Fig. 1 through the burets connected to the stock bottle5 In this manner the approximate amount of reduction was secured.

The bottle D was connected to the saturated calomel–saturated potassium chloride half-cell C by a glass-stoppered siphon tube leading through an intermediate solution of saturated potassium chloride at 25° The value of this electrode at 25° according to Fales and Mudge[5] is 0 5266 volt The system was placed in a Freas electrically regulated thermostat at 25° and the electromotive force measurements were made by the null method with the standard apparatus previously mentioned. Wherever rubber connections were employed, they were covered with collodion.

After several hours, the potential assumed a value which remained constant within ±0.0003 of a volt, provided no leakage of air occurred. This was considered to be the potential of the combination at equilibrium for this particular system. Furthermore, this value remained the same whether the solution was stirred or not, whereas violent fluctuations occurred if the solution was stirred before a constant value was obtained. For further assurance of the equilibrium potential a trace of mercuric chloride, a test generally used, was introduced into the system. The trivalent columbium reduced the mercuric mercury to the mercurous condition and free mercury, a reaction which lowered the potential considerably. The original potential before the introduction of the mercuric chloride was restored after it stood for a short time unless equilibrium was not reached

After the equilibrium potential was recorded, 25 cc. of the equilibrium solution was delivered into a 250cc. Erlenmeyer flask previously swept by hydrogen and the amount of reduced columbium was determined by a standard potassium permanganate solution as heretofore.[1] The value thus obtained, in general, agreed closely with the amount of reduced solution originally added, so practically no oxidation had taken place during the transfer of solutions.

After each electromotive force measurement, the bottle D was thoroughly cleaned and dried. Fresh mercury prepared by the method of Hulett[6] was then introduced to serve as the electrode for the next measurement.

Tables I, II and III contain the results obtained with 0.024 molar solutions of Cb_2O_5 in approximately three molar, six molar and ten molar sulfuric acid, respectively.

[b] Referred to sat. calomel–sat. KCl electrode as zero

[c] $K = [Cb^{+++}]e/[Cb^{+++++}]e$.

[d] 0.002 *M* $KMnO_4$ was employed in these titrations.

The Effect of a Change of Total Columbium Content.—In Tables I, II and III the total columbium content was the same in each case. To determine what effect a change in the concentration would make, a solution of one-half the total concentration used above was prepared in a **3** *M* sulfuric acid solution. The results recorded in Table IV show that in solutions of such low concentrations of columbium in the presence of such high concentrations of sulfuric acid there is but little change in the normal oxidation potential.

Table V contains the data from which the curves in Fig. 2 were constructed. It contains the ratio of the concentrations, the logarithm of the ratio and the corresponding electromotive force measurement for the three different acid concentrations, respectively.

Discussion

In all the electrical potential measurements the probable error found experimentally was plus or minus one-half millivolt. The observed voltage represents the average of several readings taken after the system had reached equilibrium.

The potential was referred to a saturated calomel–saturated potassium chloride cell as zero to which it became progressively more negative as the acid concentration increased. With a large negative potential trivalent columbium may be classed, therefore, as a strong reducing agent within the range of our experiments.

By assuming that the degree of ionization and the activity were the same for both states of columbium, calculations of the normal oxidation potential tabulated in Tables I, II, III and IV were made by use of the[7] well-known equation

$$E = E_0 - \frac{RT}{nF} \times \ln \frac{C''}{C'}$$

developed from the Nernst formula. When the ratio of the concentrations was unity, the observed potential became the normal potential

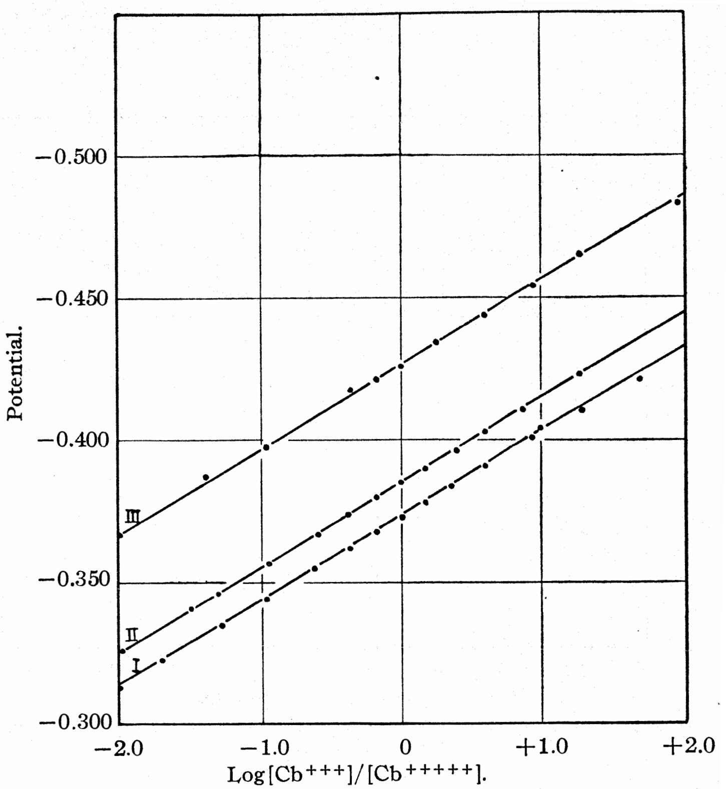

Fig. 2.—I, 0.024 *M* Cb_2O_5 in 3.14 *M* H_2SO_4; II, 0.024 *M* Cb_2O_5 in 5.91 *M* H_2SO_4; III, 0.024 *M* Cb_2O_5 in 9.87 *M* H_2SO_4; temperature, 25°.

By this value the valence of three for the reduced form determined by us[1] was confirmed. At 25° the final equation used for the calculations was

$$E = E_0 - 0.0295 \log \frac{[Cb^{+++}]}{[Cb^{+++++}]}$$

By use of the formula

$$\log K = \frac{E_0}{0.0295}$$

derived from the above relations, the average value of equilibrium con-

stants for the system in three sulfuric acid concentrations, 3.14 M, 5.91 M and 9.87 M were found to be, respectively, 2.3×10^{-13}, 8.9×10^{-14} and 3.6×10^{-15}.

During the process of measurement, the potentials at extreme reduction were made and the extent of reduction determined by titration in the usual manner. In the 3.14 M, 5.91 M and 9.87 M sulfuric acid, respectively, the average corresponding potentials were −0.4580, −0.4795 and −0.5090, with the values of 99.87, 99.94 and 99.83% in order for the determined reduction.

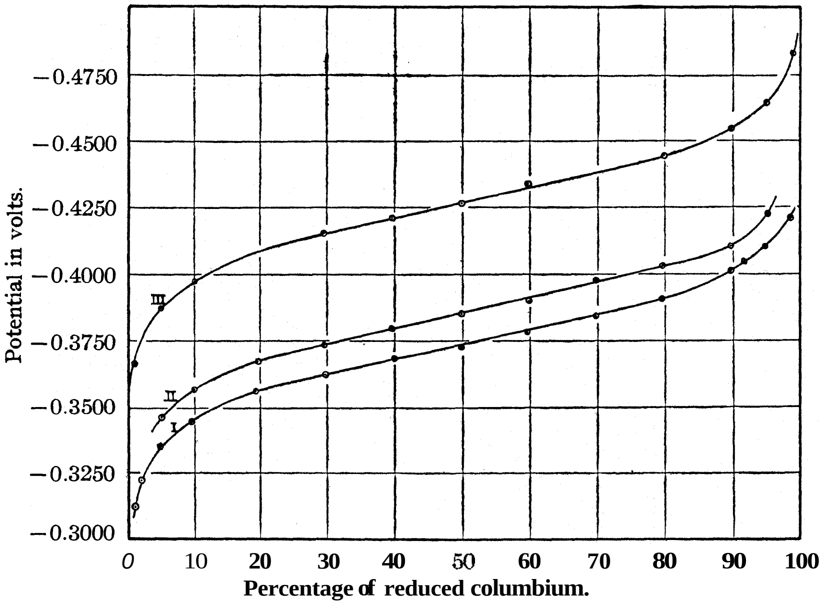

Fig. 3.—I, 3.14 M H_2SO_4; II, 5.91 M H_2SO_4; III, 9.87 M H_2SO_4; 0.024 M Cb_2O_5; temperature, 25°.

In Fig. 2 the data collected in Table V were used to construct nearly straight lines, the slopes of which are very nearly identical for the three acid concentrations and agree very closely with that of the ideal, 0.0295. The slopes for the system in the three acid concentrations were calculated also. Their average values were, respectively, for 3.14 M sulfuric acid, 0.0294; for 5.91 M sulfuric acid, 0.0293 and for 9.87 M sulfuric acid 0.0296. The plotted values were, respectively, 0.0298, 0.0295 and 0.0300 approximately.

When the percentage of reduced columbium is plotted against the corresponding potential, a set of curves set forth in Fig. 3 was obtained. These curves are similar in form and character to those obtained by Peters[7] in the ferric-ferrous system.

Summary

1. The oxidation-reduction potentials of the pentavalent-trivalent columbium system were measured with a mercury electrode in an atmosphere of hydrogen at 25°. Three concentrations of sulfuric acid, 3.14 M, 5.91 M and 9.87 M were used. The concentration of columbium in Tables I, II, III and V expressed as Cb_2O_5 was 0.024 M. In Table IV it was 0.012 M.

2. The trivalent columbium was found to be a strong reducing agent which increased markedly as the concentration of acid increased.

3. A valence of three was confirmed for the reduced state.

4. The average calculated normal electrode potentials for the three concentrations of acid, respectively, are: -0.3730, -0.3849 and -0.4261.

PHOTOCHEMICAL STUDIES. VII. THE PHOTOCHEMICAL DECOMPOSITION OF FORMIC ACID LIQUID AND VAPOR

BY W. N. HERR AND W. ALBERT NOYES, JR.

RECEIVED MAY 3, 1928 PUBLISHED SEPTEMBER 5, 1928

The fact that formic acid decomposes under the influence of ultraviolet radiation has been known for many years. Thiele[1] found that the product of photochemical decomposition of the anhydrous acid was largely carbon dioxide, together with small amounts of oxygen, carbon monoxide and other gases. Berthelot and Gaudechon[2] state that long wave lengths (250 to 350 mμ) cause the formation of water and carbon monoxide, while shorter wave lengths cause the formation of carbon dioxide and hydrogen. Allmand and Reeve,[3] in a recent careful investigation of the photochemical decomposition of formic acid in aqueous solution, find that wave lengths below 350 mμ are effective and that practically the only gas formed is carbon dioxide. They think that the hydrogen (which would be formed simultaneously) is used in reducing formic acid to formaldehyde and other products. These authors also made accurate studies of the quantum efficiency and found the latter to be nearly independent of concentration but to depend on the wave length, being greater for short wave lengths.

Little work has been done on the photochemical decomposition of formic acid vapor. Ramsperger and Porter[4] have made a study of the absorption spectrum. They find that two types of molecule, HCOOH and $(HCOOH)_2$, exist in the vapor state and that each absorbs below about

260 mμ. They exposed vapors of formic acid to radiation from the quartz mercury arc lamp until decomposition was complete. Under these conditions carbon monoxide and water formed 64% of the mixed products and carbon dioxide and hydrogen 36%. No details of the method of analysis and no measure of the quantum efficiency were given. Bates and Taylor[5] have studied the photochemical decomposition of formic acid vapor sensitized by excited mercury. They find that the sensitized reaction proceeds much more rapidly (400 times) than the unsensitized reaction and that of the products uncondensed by liquid air, 76% were carbon monoxide and 24% hydrogen.

Other work has been done but need not be mentioned at this time.

I. Experimental Procedure and Results

A. Decomposition of the Vapor.—The formic acid used in these experiments was prepared by the method of Schlesinger and Martin[6] by drying with boron trioxide. In part of the experiments phosphorus pentoxide was used as the drying agent. The formic acid used was outgassed after it had been admitted to the vacuum line. The line was first thoroughly flamed out with the highest vacuum obtainable and the formic acid distilled in with liquid air. The line was again evacuated with the formic acid frozen. The formic acid was then distilled from one trap to another and the evacuation repeated. This was continued until the amount of gas removed by a Toepler pump into a volume of 210 cc. was less than 10^{-4} mm. No excess liquid was present except in two of the preliminary runs.

After exposure to the radiation the formic acid was condensed with liquid air and the decomposition products remaining in the gas phase were removed by the Toepler pump. These consisted entirely of hydrogen and carbon monoxide. The formic acid was then distilled with liquid air and the free gas removed by the Toepler pump. This process was repeated until distillation liberated a negligible amount of gas. Carbon dioxide snow and ether ($T = -77°$) was then substituted for liquid air and the process repeated. Under these conditions carbon dioxide (and small amounts of water vapor) were removed by the Toepler pump.

Monochromatic light was not used in these experiments. The light intensities were measured by a thermopile calibrated by a standard source of radiation furnished by the Bureau of Standards. A perforated sheath was placed over the mercury arc lamp to approximate a point source of radiation. The light was made into a slightly diverging beam by means of a quartz lens, passed through a quartz cell 2 cm. in thickness containing water and then through a tube 92 cm. in length fitted with transparent quartz ends. The intensity was measured when the vapor was in the tube and when the vapor was condensed in liquid air The difference gave the deflection due to the light absorption. The area of the spot was not very definite due to the fact that monochromatic light was not used, since the index of refraction of the quartz in the lens varies with wave length.

Water absorbs practically all of the infra-red beyond 1.4μ. The infra-red intensity of a quartz mercury arc lamp is relatively low. In addition, while the authors were unable to find any data on formic acid vapor, most simple organic compounds in the vapor state do not possess infra-red absorption bands between 1.4μ and 0.7μ. The error due to infra-red

---

[5] Bates and Taylor, THIS JOURNAL, 49,2438 (1927).

[6] Schlesinger and Martin, *ibid.*, **36,** 1589 (1914).

should not exceed 10%. Prom a consideration of the absorption spectrum and the energy distribution of the quartz mercury arc lamp as determined with a quartz spectrograph, the average wave length absorbed by the vapor was taken to be 250 ± 10 mp.

The average of ten determinations gave 6.6×10^{12} molecules uncondensed by liquid air formed per erg absorbed or 0.52 molecule per quantum with an average deviation from the mean of 0.16. In addition 0.39 molecule (with an average deviation of 0.10) not condensed by carbon dioxide snow and ether but condensed by liquid air was formed per quantum. The measurement of the light intensity was the most probable source of error since it involved the difference between two quantities. It would seem, however, that the quantum efficiency of the decomposition of the vapor is on the average less than unity.

B. Decomposition of the Liquid.—It is exceedingly difficult to measure the decomposition of anhydrous liquid formic acid because some thermal decomposition is unavoidable. However, the gas formed by thermal decomposition is uncondensed by liquid air, while the main gas formed by photochemical decomposition is condensed by liquid air but not at $-77°$. This agrees with the statement made by Allmand and Reeve for solutions, that the main gas evolved by photochemical decomposition is carbon dioxide.

Light intensity measurements were made by placing the thermopile In front and in back of the cell. By use of the change in area of the beam in traversing the **cell** and the decrease in deflection due to the empty cell, it was found that 15% of the radiation from the arc lamp (after passage through 2 cm. of water) was absorbed by 3.1 **cm. of** liquid formic acid. The average wave length is taken as 300 mp since the mercury line of greatest intensity in the region of strong absorption is at **313** mμ. The coefficient k in the equation $I = I_0^{-kl}$ (l is thickness in cm.) increases from 0.42 at 300 mp to about 1.5 at 250 mp (Measurements made with rotating sector in conjunction with quartz spectrograph.) Seven determinations gave 0 **46** molecule condensed by liquid **air but** uncondensed by carbon dioxide snow and ether per quantum absorbed with an average deviation of 0.16.

Five runs with light transmitted by Pyrex glass were made. From a consideration of the absorption coefficients of the liquid and the fact that of the ultraviolet lines transmitted by Pyrex glass by far the most intense are at **366** mμ and **313** mp, the average wave length was taken as **330** mμ The average number of molecules of gas condensed by liquid air but not at $-77°$ formed per quantum absorbed was 0.14 with an average deviation of 0 04.

Allmand and Reeve found the quantum efficiency for decomposition of formic acid in solution to be about 2.7 at 260 mμ and 1.0 at 300 mp. A very rough calculation shows that the quantum efficiency is about 1.1 on the average for those wave lengths transmitted by quartz but not by Pyrex glass. Since the average wave length in this case is nearer 300 mμ than 250 mμ, the quantum efficiency is not greatly different from that found by Allmand and Reeve for solutions.

II. Discussion of Results

The results of Ramsperger and Porter[4] and of Bates and Taylor[5] indicate that formic acid may decompose either directly or through the agency of excited mercury into carbon monoxide and water or into carbon dioxide and hydrogen. If these two primary reactions occur, measurement of the number of molecules of hydrogen and carbon monoxide together (both uncondensed by liquid air) would give an indication of the number of molecules of formic acid vapor decomposed. One run was made in which hydrogen to a pressure of 0.2 mm. was added. Normally, with the light intensity used, a pressure increase (with liquid air around the trap) of 0.03 mm. would have been observed. Actually the pressure change was negligible but showed, rather, a slight diminution. This may indicate that hydrogen is capable of reducing formic acid under the conditions of the experiment with formation of a product condensed by liquid air.

From the data of Ramsperger and Porter[4] it can be shown that at 25° and a total pressure of 39 mm. (the approximate conditions in the above experiments) over 95% of the pressure is exerted by the bimolecular form. Since the absorption coefficient of this form is higher than fot the monomolecular form, nearly all of the radiation is absorbed by $(HCOOH)_2$. While sufficient resolution was not used by Ramsperger and Porter to make an analysis of the absorption spectrum of the vapor, the absorption seems to be continuous and to increase in intensity with frequency. Whether a definite low frequency limit to the absorption exists or not cannot be ascertained. The heat of dissociation of the bimolecular form is about 14,000 calories per mole. This would correspond to a wave length of 2μ. This wave length may be absorbed. The ultraviolet absorption may cause the dissociation of the bimolecular form as follows: $(HCOOH)_2 = HCOOH + HCOOH^*$, where $HCOOH^*$ represents an activated molecule. The monomolecular form should then absorb at slightly longer wave lengths in the ultraviolet than the bimolecular form, since the heat of dissociation is small compared to the total energy absorbed. The activated molecule may decompose either directly or upon collision. Little information can be obtained on this point from the absorption spectrum measurements. While the error in the above experiments may be fairly large, the low value of the quantum efficiency indicates that direct dissociation probably does not result.

The question now arises as to whether all of the products found by Ramsperger and Porter[4] and by Bates and Taylor[5] result from the primary reaction. In solution and in the anhydrous liquid only one type of decomposition seems to result. The following possibilities may be considered.

(*a*) The monomolecular form may decompose in one manner and the bimolecular form in another. This would necessitate a large quantum efficiency for the decomposition of the monomolecular form and a relatively small one for the decomposition of the bimolecular form. Increase in the percentage of the monomolecular form by lowering of the pressure from **39** mm. to 18 mm. did not affect appreciably the ratio of gas uncondensed by liquid air to that condensed by carbon dioxide snow and ether.

(b) The activated molecules may decompose in two manners for the reasons given by Bates and Taylor.[5]

(c) The primary decomposition may be into carbon dioxide and monatomic hydrogen. The heat of the reaction is small (of the order of four thousand calories) and the production of monatomic hydrogen is possible. Production of formaldehyde might result by the action of the monatomic hydrogen on another molecule of formic acid. The formaldehyde might then decompose. By this mechanism the quantity of hydrogen should be equal to the quantity of carbon monoxide unless the hydrogen were partially used up. Formaldehyde was tested for but not found in the condensed formic acid vapor remaining after the gases had been removed by a Toepler pump with carbon dioxide snow and ether around the trap. The small amount of carbon monoxide in the gases given off from solutions[S] indicates that formaldehyde, if formed, does not decompose rapidly in solution due to the screening effect of the formic acid or to polymerization. Evidence is not satisfactory on these various points.

(d) It is possible that the bimolecular form might decompose directly into formaldehyde, carbon dioxide and water, the formaldehyde decomposing into carbon monoxide and hydrogen. The excess of carbon monoxide over hydrogen found by previous observers could be explained by reducing action of the hydrogen.

It seems not impossible, therefore, that the primary reaction in both liquid and vapor state may lead to the formation of carbon dioxide. While the errors in the determination of the quantum efficiencies are large, they are of the same general magnitude.

If the activated state for the vapor is the same as for the liquid, one might expect the heat of vaporization to be related to the effective frequencies for decomposing the liquid and vapor by the formula $AH = Nh(\nu_1 - \nu_2)$, where A H is the heat of vaporization, h is Planck's constant and ν_1 and ν_2 are the frequencies necessary to cause decomposition of the liquid and vapor, respectively. It is not possible to test this formula accurately with the present data due to difficulty in choice of frequency but we may say qualitatively that the formula does not give the wrong order of magnitude.

The authors wish to express their appreciation to Mr. W. E. Vaughan for aid in performing part of these experiments.

Summary

1. The number of molecules of gas uncondensed by liquid air formed per quantum absorbed has been determined for the photochemical decomposition of both liquid and gaseous formic acid. A similar determination of the number of additional molecules uncondensed by carbon dioxide snow and ether has been made.

2. The quantum efficiency increases with frequency in the case of the liquid. The vapor absorbs only at short wave lengths and variations of frequency were not made.

3. Possible mechanisms for the reaction have been discussed.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. VIII. THE ELECTRIC MOMENT AS A VECTOR QUANTITY

BY JOHN WARREN WILLIAMS[1]

RECEIVED MAY 14, 1928 PUBLISHED SEPTEMBER 5, 1928

Electric moment data for a number of molecules, organic and inorganic in nature, have been presented in the previous papers of this series.[2] The moments have been calculated from dielectric constant and density data for suitable binary mixtures, using the Debye modification of the Clausius–Mosotti Law. The purpose of the present article is to give the results of further experimental work in this field and to suggest the significance of these data.

The apparatus used for the determination of the dielectric constants of the binary mixtures was designed and constructed especially for the purpose by the author. It has been very briefly described in a previous article.[2e] Dielectric constant and density determinations were made at 25°, using a carefully regulated thermostat and observing the usual precautions for precision work. In every case the solvent used was benzene.

Purification of Materials

All substances used for the measurements herein reported were subjected to a careful purification. For that purpose the customary methods of crystallization or distillation or both were resorted to. It is considered unnecessary to give the outline of the method for each particular substance—suffice it to say that in no case did the observed physical constants,

---

melting point or freezing point, differ appreciably from those given in the standard tables.

Results

The results of the experimental determinations and calculations are given in Table I. The symbols of the previous articles have been retained throughout. In the interest of a saving of space the dielectric constant and density data for the binary mixtures have been omitted; they are in all respects similar to those previously given. Their accuracy is fully as great in practically every case.

Table I

Electric Moment Data for Solute Molecules

Molecule	P_2	P_2''	P_2'	$\mu \times 10^{18}$

[a] Previously reported in a preliminary note, Williams, *Physik. Z.*, 29, 271 (1928).

[b] The author takes this opportunity to thank Dr. A. Weissberger of the Chemisches Laboratorium der Universitat, Leipzig, for the preparation and purification of these chemicals.

The polarization due to the deformation of the molecule, P_2'', was calculated by taking the sum of the atomic refractions or by means of the familiar Lorenz-Lorentz formula. In either case the molar refraction is obtained. That this method of procedure leads to a slight inaccuracy is well known;[2a] however, it does not in any way interfere with the significance of the results as discussed below.

Discussion

The molecules for which electric moment data are presented above are derivatives of benzene of one form or another. They are discussed in the order of an increasing number of substituent atoms or groups of atoms. The simplest case is, of course, that in which only one of the hydrogens of the benzene is replaced. Since benzene itself is a non-polar substance, any such substitution of an atom or group will cause the formation of a polar molecule. Sufficient electric moment data are now available to indicate that an atom or group when introduced into a molecule may be considered as a vector and acting in a certain direction. For example, the introduction of an OH group into methane, ethane, propane or benzene gives a moment of magnitude, $\mu = 1.7 \times 10^{-18}$ e.s.u., while the NO_2 group substituted into benzene gives a moment of magnitude, $\mu = 3.9 \times 10^{-18}$ e.s.u. This statement must not be understood to mean that the moment of any compound formed by the substitution of an atom or group into methane will be exactly the same as the moment formed when the same atom or group is substituted into benzene or other non-polar molecule; the idea to be conveyed is that each atom or group is characterized by a more or less definite moment. There are many ways in which the vector value of this moment may be somewhat altered, since when such an atom or group is introduced the number of electrons present in the molecule is changed and internal compensations may take place. If such a group be introduced into the benzene nucleus (which for the purpose of discussion is considered as two-dimensional) it is natural to assume that the vector will act in the direction of the plane. On the basis of this assumption an approximate moment may be assigned to each of nine atoms or groups from the data of this and the previous articles.[2] The data are taken entirely from electric moment data for derivatives of benzene.

When two of these groups are substituted into benzene, the second in various positions with respect to the first, it is possible to assign an electrical character to each of these groups, the only limitation being that one of the groups must be used as a reference. In the table given below the CH_3 group is considered to be positive in nature. It was shown[3] from the data for the nitrotoluenes that if the CH_3 group has one kind of electrical effect, the NO_2 group must have the opposite kind of electrical effect. If, on the other hand, the data for the chloronitrobenzenes[4] are considered, it is seen that the electric moment of the molecule becomes smaller and smaller as the second substituent moves from the ortho through the meta to the para position. This indicates that the Cl atom and the NO_2 group have like electrical effects—also, if the CH_3 group is positive, then both must be negative. In this manner charges and approximate values have been assigned to the atoms or groups given in Table II.[5]

TABLE II

CHARACTERISTIC MOMENTS OF ATOMS OR GROUPS

Group	Moment	Group	Moment
NO_2	−3.9	OCH_3	−1.2
 $C(H){=}O$	−2.8	C—OH	−0.9
OH	−1.7	CH_3	+0.4
Cl	−1.5	NH_2	+1.5
Br	−1.5		

---

[3] Williams, *Physik. Z.*, 29, 174 (1928).

[4] Höjendahl, *Nature*, 117, 892 (1926).

[5] The classification of the NH_2 group was made possible by the kindness of Dr. Hojendahl who communicated the results of unpublished data on the nitranilines.

To this point **Höjendahl**[4] and Smyth and Morgan[S] have discussed their data in a similar manner.

These data are of interest in connection with an article by Thomson[7] written before these and similar data were available. Considering the case when both substituents are of the same kind, this author concludes that "neglecting the deflection of the two doublets due to their action on each other that: 1. If the second constituent goes into the para position the resultant moment is zero. 2. If it goes into the ortho position the resultant moment is

$$(I^2 + I^2 + 21^2 \cos 60°)^{1/2} = \sqrt{3I}$$

3. If it goes into the meta position the resultant moment is

$$(I^2 + I^2 + 2I^2 \cos 120°)^{1/2} = I$$

where I = moment characteristic of the atom or group."

The results of recent researches[4,6,8] on disubstituted benzenes of this type have in every case been treated in the manner suggested above, assuming always that the vectors which represented the groups acted in the plane of the benzene ring. It was found that the experimental data could without serious difficulty be represented by the formulas of Thomson or their equivalent. However, the fact that hydroquinone diethyl ether and hydroquinone diacetate have rather large dipole moments indicates clearly that the simple assumption of no interaction between the two groups cannot always be made. It is becoming more and more evident that as the substituted groups become longer or more complex the greater is the interaction between them—in other words, it is only in the case of the substitution of atoms and smaller groups that the vectors may be considered to act approximately in the plane of the benzene ring, and that when sufficient data are accumulated the cases where there is appreciable interaction will be in the majority. It is only because the simplest substances have been investigated first that the para disubstituted benzenes have previous to this article appeared always to have moments indistinguishable from zero.

Thomson further considers the case in which the second substituent is not the same as the first. In this case the "moment of the molecule if the second substituent goes into: (1) the para position is $I - I$; (2) the ortho position is $(I^2 + I'^2 + II')^{1/2}$; (3) the meta position is $(I^a + I^2 - II')^{1/2}$; where I' = moment characteristic of the second atom or group." As in the case of two like substituents, it is found that in certain cases (atoms and smaller groups) the assumption of vectors directed in the plane of the benzene nucleus does not lead to any appreciable difficulty. This is rather nicely illustrated in the case of para chloro-

Errera, *Physik. Z.*, *27*, *764 (1926)*.

bromobenzene tabulated above, which gives a moment indistinguishable from zero. The moments of chlorobenzene ($\mu = 1.52 - 1.55 \times 10^{-18}$) and bromobenzene ($\mu = 1.51 \times 10^{-18}$) are very nearly alike, so that when one vector acts in opposition to the other a cancellation results. Other cases of this type have been sufficiently discussed. However, it is becoming more and more apparent, as before, that this is true only in the cases where simple substituents are present in the benzene nucleus, and that as the substituent groups become more complex the effect of the interaction between the groups becomes more pronounced. As evidence for this statement Table III has been prepared. It contains data for several substituted nitrobenzenes. The moment has in each cast. been calculated in the manner suggested by Thomson.

TABLE III

ELECTRIC MOMENT DATA POR PARA DISUBSTITUTED BENZENES

	Molecule	Observed moment	Calculated moment
1.	$NO_2C_6H_4CHO$	2.4×10^{-18}	1.1×10^{-18}
2	$NO_2C_6H_4COOH$	3.5×10^{-18}	3.0×10^{-18}
3.	$NO_2C_6H_4NH_2$	7.1×10^{-18}	5.4×10^{-18}
4.	$NO_2C_6H_4Cl$	2.5×10^{-18}	2.4×10^{-18}
5.	$NO_2C_6H_4CH_3$	4.5×10^{-18}	4.3×10^{-18}

It is at once evident that in the case of the first three molecules there is appreciable interaction between the substituents. The data for the last two molecules, cases in which the second substituent (Cl or CH_3) is of simpler type, have been included only for purposes of comparison. Other tables might be prepared from data now available which would illustrate the same point.

To summarize: it would appear that when two atoms or groups of atoms (like or unlike) are substituted into the benzene nucleus, the assumption that there is no interaction between them can be made only when the groups are of very simple type. In general the vectors characterizing the groups *cannot* be considered to act in the direction of the plane of the benzene ring, so that in any vectorial considerations a three dimensional rather than a two dimensional molecule must be considered.

In the above discussion the various molecules have been considered as derivatives of benzene. Recent data of the author indicate that in the case of the substitution of certain groups (OH and OCH_3, for example) the role played by the benzene nucleus may become insignificant and that the molecules are best treated from another point of view. These data are reserved for a later communication.

The data for the symmetrical trisubstituted derivatives of benzene are of interest in connection with the question of the structure of the benzene nucleus. If the Korner formula[9] were the correct one, a finite electric

---

[9] **Korner,** *Gazz. chim. ital.*, **4, 444 (1874). See also** Huggins, THIS JOURNAL, **44, 1607 (1922); 45,264 (1923).**

moment for every like trisubstituted compound of the symmetrical type should result. The same supposition may be made in the cases of the formulas of Baeyer[10] and of Ladenburg.[11] The evidence is conclusive that in the case of mesitylene and symmetrical triethylbenzene no such moment results. The same is true in the case of symmetrical tribromobenzene, where a moment indistinguishable from zero has been reported by Höjendahl.[4] In a previous article Williams and Schwingel[2d] reported a value, $\mu = 1.08 \times 10^{-18}$, for symmetrical trinitrobenzene, but stated that from theoretical considerations a zero value should have resulted. However, a value of such magnitude should be distinguishable from zero;[2] therefore this substance was reinvestigated with extreme care. The result given in Table I was kindly communicated to me by Mr. Schwingel from the Laboratory of Physical Chemistry, University of Wisconsin as the result of careful measurements on trinitrobenzene which had been "recrystallized from benzene ten times and dried *in vacuo* at 35° to constant weight." A repetition of the work by the author in this Laboratory gave a result 5% higher. Therefore the original result is essentially correct and it indicates that symmetrical trinitrobenzene has a finite electric moment. The explanation is, without doubt, to be found in a consideration similar to that given to the disubstituted compounds. The interaction between the groups causes them to be extended (only slightly in this case) above the plane of the benzene nucleus.

There can be no doubt that measurements of this type, made at a single temperature and using benzene as a solvent, will indicate a finite moment for *sym.*-trinitrobenzene. However, in order to remove any question, it would be desirable to supplement these measurements by others at different temperatures.

Concerning the data for phloroglucinol triacetate there can be no question. This substance, a symmetrically trisubstituted benzene, has a comparatively large dipole moment, the explanation of which is to be found in a strong interaction between the groups. The case is exactly analogous to that of hydroquinone diethyl ether and hydroquinone diacetate[12] and will not be discussed further at this point.

In the case of the trisubstituted benzenes, then, it is predicted that as the groups which are substituted into the benzene nucleus become more complex, the greater will be the interaction between them. This point is now being investigated more thoroughly by the author.

In the above discussion the phrase "the plane of the benzene ring" has been more or less frequently used, although it has not been directly proved that the six carbon atoms of the benzene nucleus are in one plane.

---

[10] Baeyer, Ann., 245, 103 (1888).

[11] Ladenburg, *Ber.*, 2, 140 (1869).

[12] In this connection see also Williams, *Physik.* Z., 29, 271 (1928).

It is claimed that the data presented cannot be explained by the use of such a formula as that suggested by Korner, Baeyer or Ladenburg and that they can be accounted for by the assumption of a plane formula. The results are strongly indicative of the latter type of arrangement.

Smyth and Morgan,[6] from a consideration of their electric moment data for certain of the disubstituted benzenes conclude that "it appears logical to suppose that the benzene nucleus is a regular hexagon with all the carbon and hydrogen atoms in the same plane, although substitution may possibly distort the hexagon to a somewhat puckered ring." The results of the present investigation must be considered to strengthen materially the argument in favor of the plane ring, particularly in view of the limitations which must be placed upon any conclusions drawn from considerations of the disubstituted compounds. The limitations are, briefly, (1) the fact that any para like-disubstituted benzene forms a symmetrical molecule cannot be considered as proof for a special configuration of the benzene nucleus,[3] and (2) the effect of the interaction between groups which is emphasized in this article is certain to obscure the treatment.

The results of this article are also of interest in connection with those recently reported by Ebert and v. Hartel[13] for molecules of the type CX_4. Certain molecules of this type, CCl_4, CH_4, $C(CH_2Cl)_4$, and also from unpublished data of the author, $C(NO_2)_4$ and $C(CH_2Br)_4$ have zero moments and therefore are symmetrical, while others, such as $C(OCH_3)_4$, $C(OC_2H_5)_4$ and $C(CH_2OOCCH_3)_4$ are characterized by finite electric moments ($\mu = 0.8$, 1.1 and 2.6×10^{-18}, respectively). From these data as well it would appear that as the length or complexity of the substituent group is increased, the interaction between groups is increased. Thus electric moment data for molecules of the types $1,4—C_6H_4X_2$, $1,3,5—C_6H_3X_3$ and CX_4 are now available which indicate that in the case of simpler substituents (X) a symmetrical molecule is formed, but that as the substituent becomes more and more complex the effect of interactions between the groups becomes prominent and asymmetrical molecules result.

It would be desirable to have the x-ray diagrams in the cases of the molecules of the types $1,4—C_6H_4X_2$ and $1,3,5—C_6H_3X_3$ which give finite electric moments. One might expect in the case of compounds of the latter type, for example, that the ends of the substituted groups would be found in a plane above that of the benzene nucleus and that it should be possible to compare the results of such studies as these, that is, data concerning the structure of the molecules in the dissolved state, with their structure in the solid state as determined by x-ray analysis. However, at the present writing such a comparison is possible in but very few cases. It must be pointed out, too, that in certain of these cases, at least, the results are

---

[13] Ebert and v. Hartel, *Naturwissenschaften*, 15, 668 (1927).

in direct conflict with each other, so that it cannot be said that such a comparison is always possible. This fact has been briefly discussed in another place.[14]

Conclusion

It appears from the data of this and previous articles that for both aliphatic and aromatic compounds an interaction between groups in a molecule is a common phenomenon. Thus formulas such as those of Thomson for the case of disubstituted benzene derivatives, which neglect the deflection caused by the interaction of two or more groups in a molecule, cannot be of general utility. In most cases the vectors characteristic of the groups must be considered to be acting in space rather than in a plane, making a three-dimensional analysis necessary.

The writer acknowledges with pleasure his indebtedness to Professor P. Debye for apparatus placed at his disposal and for the interest shown and counsel given by him during the progress of the work.

Summary

1. Dielectric constant and density data at 25° have been obtained for benzene solutions of bromobenzene, benzaldehyde, *p*-nitrobenzaldehyde, *p*-nitrobenzoic acid, *p*-chlorobromobenzene, hydroquinone diethyl ether, hydroquinone diacetate, mesitylene, *sym.*-triethylbenzene, *sym.*-trinitrobenzene and phloroglucinol triacetate. From these data the electric moments of the various solute molecules have been calculated and presented in a table.

2. It has been shown that an atom or group when substituted into a molecule is characterized by a more or less definite electric moment. This moment can be considered to be a vector quantity to which it is possible to assign an electrical character by making a simple assumption with regard to the electrical character of one group.

3. Interaction between groups in a molecule appears to be a common phenomenon; therefore the dipole moment of a molecule which contains several groups can be calculated in general only provided the vectors characteristic of the groups be considered to be acting in space.

4. The data are strongly indicative of a formula for benzene in which the six carbon atoms lie in one plane.

5. The possibility of comparing the molecular structure of molecules in the dissolved state, as indicated by electric moment data, with their structure in the solid state, as determined by x-ray analysis is briefly discussed.

THE MEASUREMENT OF THE ELECTROKINETIC POTENTIAL ON PROTEINS BY THE STREAMING POTENTIAL METHOD[1]

BY DAVID R. BRIGGS[2]

RECEIVED MAY 14, 1928 PUBLISHED SEPTEMBER 5, 1928

It has been shown by various investigators that chemically inert particles suspended in a protein solution take on the electrokinetic properties of the protein. Loeb[3] demonstrated this fact with collodion particles suspended in solutions of gelatin and of other proteins. Freundlich and Abramson[4] have recently shown that quartz particles act in the same manner. Svedberg and Tiselius[5] used this phenomenon as a means for measuring cataphoretically the mobility of egg albumin and therefrom its ζ-potential at various hydrogen ion concentrations. Abramson[6] repeated their work, using a simplified method and showed that an extremely dilute solution of the protein (10^{-3} g. per liter or less) could be used and that it was to be preferred to the more concentrated solutions.

The author has shown[7] that the electrokinetic potential, that is, the ζ-potential, may be accurately determined by the streaming potential method upon diaphragms of various materials, for example, of paper pulp, built up between two perforated gold electrodes, provided the specific conductivity of the liquid, as it exists within the diaphragm, is determined. An application of this method for measuring the ζ-potential on proteins at various PH values seemed desirable because of the ease and accuracy with which such measurements may be made.

Method

It was found that finely ground quartz powder could be made into a diaphragm between the two perforated gold plates in a manner already described for paper pulp.[7] Surface conductance, that is, increased conductivity of the liquid when in contact with the diaphragm material, was found to be relatively unimportant for such a crystalline diaphragm even when conductivity water was used for the interstitial liquid. When dilute electrolyte solutions were present in the diaphragm, surface conductance was found to be negligible and the specific conductivity factor, K,

in the streaming potential formula could be taken as that of the solution in bulk.

Through such a quartz diaphragm could be forced a dilute solution of fairly pure commercial egg albumin from which had been separated the water-insoluble fractions. After an amount of solution which contained approximately 0.2 g. of albumin had passed through the diaphragm (the diaphragm contained 17.5 cc. of quartz powder), the quartz surface was found to be saturated with the protein and the diaphragm then acted as though it were a protein diaphragm. Subsequently, solutions of various hydrogen ion concentrations and containing approximately 10^{-3} g. of the protein per liter were forced through the diaphragm and the ζ-potential was determined in the usual manner. Svedberg and Tiselius used 1% egg albumin solutions of 0.02 M buffer mixtures of acetic acid and sodium acetate. Abramson used the very dilute protein solutions in the 0.02 *M* buffer mixtures. Such concentrations of electrolytes cannot be used in streaming potential measurements because the electrical conductivity of such solutions is so great as to prevent entirely the building up of a measurable potential across the ends of the diaphragm. The solutions used in the present work were 0.0004 *M* in hydrochloric acid and lithium chloride, a concentration great enough to eliminate surface conductance in the diaphragm and yet low enough to allow for the formation of a streaming potential which was easily measurable. After 50 cc. of any of the solutions had passed through the diaphragm (requiring about twenty minutes) equilibrium had been attained and the measurements could be taken. The PH of the solutions used was determined electrometrically.

Experimental

The application of the streaming potential method to the determination of the isoelectric points and the effects of ions upon the ζ-potential on water–soluble proteins, is well illustrated by the data presented in this paper. Egg albumin was used as the protein in order to make a comparison with the data offered by Abramson.[6]

The ζ-potential is calculated according to the formula

$$\zeta = \frac{HK}{P} \cdot \frac{4\pi\eta}{\epsilon}$$

where H is the streaming potential set up across the ends of the diaphragm at pressure P, K is the specific conductivity of the liquid as it exists inside the diaphragm and which, in this case, is equal to that of the liquid in bulk and η and ϵ are, respectively, the viscosity and the dielectric constant of the liquid, which may be taken as those of water for such dilute solutions of electrolytes and protein as are those used. The ζ-potential will be given in volts when H, P and K are given in millivolts, cm. of mercury, and reciprocal ohms, respectively, and multiplied by the factor 1.0596×10^2.

In Table I are shown the PH values of a series of 0.0004 M mixtures of hydrochloric acid and lithium chloride, in which was dissolved the egg albumin in a concentration of 10^{-3} g. per liter. Such solutions have no buffer capacity and may vary a few hundredths of a PH from solution to solution of the same concentration of electrolyte. Because of this variation the PH was determined individually for every solution used.

TABLE I

SHOWING PH OF MIXTURES OF LITHIUM CHLORIDE AND HYDROCHLORIC ACID WHERE NUMBERS OF CC. INDICATED ARE DISSOLVED IN A LITER OF THE DILUTE PROTEIN SOLUTION

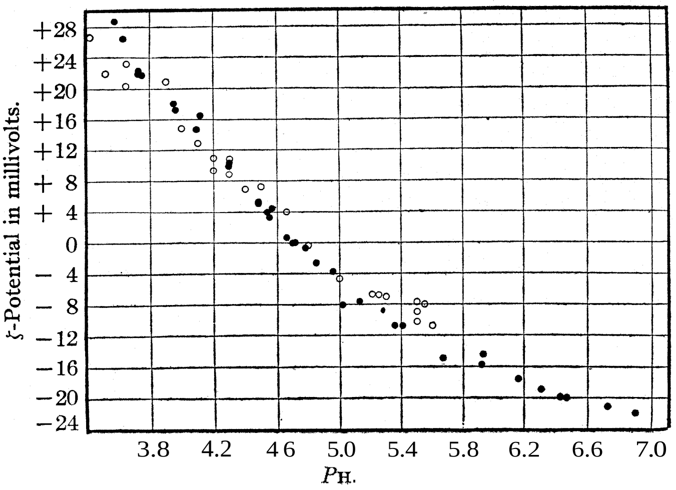
Fig. 1 shows the values given in Table II in comparison with those obtained by Abramson for the same protein by the cataphoretic measurements. It will be noted that through the range of PH between 3.8 and 5.2 there is shown a remarkable agreement between the values of the ζ-



●, By streaming potential method; ○, by cataphoresis, measurements by Abramson.

Fig. 1.—The variation of the ζ-potential with PH on egg albumin.

potential as obtained by the two methods. Through this range the ζ-potential is influenced almost entirely by the hydrogen and hydroxyl ion concentrations of the solution. Beyond this range on either the alkaline or acid side, the values obtained in the 0.0004 *M* solutions diverge to a greater extent from zero potential than those measured in 0.02 M solutions. The higher concentrations of the other ions begin to show their effect toward reducing the ζ-potential soon after that function moves away from the zero value in either direction, but this effect is very small compared to that of the H^+ and OH^- ions until the hydrogen ion concentration has moved out of the above mentioned range. While this divergence between the two curves is primarily a concentration effect, it is not entirely unlikely that the kind of ion used may also have some influence. Recent work by the author[8] has shown that the lithium ion reduces the ζ-potential on a negatively charged surface to a less extent, at any given concentration, than does the sodium or the potassium ion. It was for this reason that lithium chloride was used in the present experiment instead of the more common alkali chlorides. The chloride ion, likewise, should have a greater effect toward lowering the ζ-potential at a positively charged surface than the acetate ion, which may account for the fact that the two curves lie together for a longer range of PH on the acid side of the isoelectric point than they do on the alkaline side.

Incidentally, the streaming potential method for measuring the ζ-potential offers an accurate means for determining the isoelectric point on a water-soluble protein. The solution, which is being streamed through the diaphragm covered with the protein, may be adjusted to a hydrogen ion concentration such that there is no streaming potential set up. The PH of this solution can then be accurately determined, this PH being the isoelectric point of the protein. By such a procedure it is possible to determine this point to within the experimental error of the PH determination.

Further work is being done both upon proteins and upon other colloidal materials which are peptized in water or in dilute acid, alkali or alcohol solutions, and which have a marked effect upon lowering the interfacial tension, such as saponin and lecithin. It is not improbable that the electrokinetic properties of many dyestuffs and other organic compounds may be similarly studied.

Summary

1. The streaming potential method of measuring electrokinetic potentials has been applied in a study of egg albumin by utilizing the property of the protein to adsorb onto a quartz surface so as to give that surface the properties of the protein.

---

[8] Briggs, *J. Phys. Chem.*, 32, October, 1928.

2. Data, upon comparison with the work of Abramson with the same protein on quartz surfaces but by the cataphoresis method, show excellent agreement between the values of the ζ-potential obtained by the two methods between P_H 3.8 and P_H 5.2. Divergence of the values of ζ-potential beyond this range is explained by the differences in the concentration of the electrolyte utilized in the two experiments and probably, to some extent, by the differing effects of the ions used.

DIPHENYLCARBAZIDE AS A TEST FOR CHROMIUM

BY NORMAN M. STOVER

RECEIVED JUNE 1, 1928 PUBLISHED SEPTEMBER 5, 1928

A search of the literature has revealed a number of organic reagents which have been used for the detection and estimation of chromium when present as chromate or dichromate. Of these organic compounds, diphenylcarbazide, $CO(NHNHC_6H_5)_2$, seemed very promising. Cazeneuve[1] used this reagent to detect chromic acid in a dilution of 1:1,000,000. Brandt[2] proposed the use of diphenylcarbazide as an inside indicator in the titration of iron with potassium dichromate, while more recently Snoddy[3] has made it the basis of a colorimetric method for estimating small amounts of chromium in fats. Scott[4] mentions the use of this reagent in detecting chromium as chromate.

Since the test is very simple to carry out and the reagent produces a distinctive violet or reddish-violet color with exceedingly small amounts of dichromate, it seemed desirable to compare the sensitivity of diphenylcarbazide with that of the ether—hydrogen peroxide test usually employed in qualitative analysis and to determine the best conditions under which the test might be applied.

Experimental Work

I. Tests with Potassium Dichromate

Solutions of potassium dichromate containing varying amounts of chromium were first tested with diphenylcarbazide and also by the ether–hydrogen peroxide method in order to determine which method was the more sensitive. Further, the tests with diphenylcarbazide were carried out in solutions acidified with different. acids, namely, sulfuric acid, acetic acid and citric acid.

---

[1] Cazeneuve, *Bull. soc. chim.*, [3] 23, 592, 701, 76R (1900).

[2] Brandt, *Z. anal. Chem.*, **45**, 95 (1906).

[3] Snoddy, *J. Oil Fat Ind.*, **2**, 20 (1925).

[4] Scott, "Standard Methods of Chemical Analysis," D. Van Nostrand Co., New York, 1918, p. 132

The reagent was made by dissolving 0.2 g. of diphenylcarbazide in 10 cc. of glacial acetic acid and diluting to 100 cc. with 95% ethyl alcohol. The solution remains colorless for about one day, but thereafter gradually turns to a slightly reddish-brown color, even when kept in a brown bottle. This change in color, however, did not seem to render the reagent less sensitive.

The following procedure was used. A stock solution of potassium dichromate was made up to contain 10 mg. of chromium per cc. This solution was then diluted to a definite concentration as required and that volume pipetted out which gave four times the amount of chromium needed for the test at that particular dilution. This solution of potassium dichromate was treated with 4 cc. of 6 *N* ammonium hydroxide, diluted to 100 cc. and divided into four equal portions. One portion was acidified with 6 *N* sulfuric acid, an excess of about 2 cc. being added, followed by the addition of 3 to 5 cc. of ether and 3 cc. of 3% hydrogen peroxide solution. The mixture was shaken vigorously and the appearance of the ether layer noted. The three remaining portions were slightly acidified with sulfuric acid, acetic acid and citric acid, respectively, and 2 cc. of the diphenylcarbazide reagent was added to each. The solutions were allowed to stand for ten minutes before recording the formation of a red or reddish-violet color. When using 2 cc. of the reagent a deep red color is produced with relatively large amounts of dichromate while with small amounts of dichromate the solution assumes a distinctly violet color, the intensity of which varies with the amount of dichromate present. The 25cc. portions of solutions tested contained from 0.04 mg. to 0.00005 mg. of chromium, these concentrations representing 1 part in 625,000 and 500,000,000, respectively. A duplicate series of tests was carried out, the results of the two series being almost identical. It was found that the highest dilutions giving positive tests were as follows: for the ether–hydrogen peroxide method, 1 part of chromium in 1,250,000; for diphenylcarbazide, 1 part in 100,000,000 to 250,000,000 when using sulfuric acid, 1 part in over 71,000,000 when using acetic acid, and 1 part in 12,500,000 when in the presence of citric acid. These results indicate that diphenylcarbazide affords a much more sensitive test than does the ether–hydrogen peroxide method and that diphenylcarbazide is more sensitive when used in the presence of sulfuric acid than in the presence of either acetic or citric acid.

A series of blank tests was next run in duplicate on solutions containing 10 mg. of zinc, or 5 cc. of 3% hydrogen peroxide or both the zinc and hydrogen peroxide, and when acidified with 2 cc. of either 6 N sulfuric, hydrochloric or acetic acid. The final volume of each solution was between 25 and 30 cc. The zinc used was in the form of zinc nitrate. In every case a negative test was obtained upon adding 2 cc. of the reagent.

These blank tests were made on solutions containing zinc and hydrogen peroxide because these two substances might be present in a solution at the point of testing for chromium in the usual qualitative procedure.

Also, since the color produced by the reagent is probably due to oxidation by chromate or dichromate, it was thought that the nitrate ion in acid solution might itself cause a color change. The nitrate ion, of course, would normally be present in a solution at this point in the qualitative procedure if nitric acid were used to acidify the filtrate from the sodium hydroxide–sodium peroxide treatment preliminary to removing aluminum. Accordingly, three solutions were made as follows: (1) 25 cc. of water, 1 cc. of 6 *N* ammonium hydroxide and sulfuric acid until acid; (2) same as (1) but with 1 g. of sodium nitrate added; (3) same as (1) but with 1 g. of ammonium nitrate added. Two cc. of reagent was added to each solution. No color developed in any of the solutions.

II. Tests with Chromic Nitrate

The diphenylcarbazide reagent having been found to be very sensitive to dichromate ions, it was thought advisable to determine the sensitivity toward solutions obtained by starting with chromic ions and subjecting them to the usual Group III procedure of qualitative analysis. For this purpose chromic nitrate solutions containing definite amounts of chromium were used, while the procedure followed was that given by Reedy[6] for the analysis of Group III. After precipitating aluminum hydroxide, the filtrate (about 50 to 60 cc.) was cooled and divided into two equal portions. One part was acidified with acetic acid and 2 cc. of the diphenylcarbazide reagent added. The other portion, which would normally be used for the test for zinc, was tested for dichromate by the ether–hydrogen peroxide method already described under the tests with potassium dichromate. A comparison of the two tests for chromium was thus made from the same solution at the same time. It was found that the highest dilution giving a positive test with diphenylcarbazide was 1 part of chromium in approximately 1,666,000, while a dilution of 1 part in 250,000 failed to give a positive test by the ether–hydrogen peroxide method. Although the diphenylcarbazide reagent is again shown to be more sensitive than the ether–hydrogen peroxide method, it is to be noted that a smaller amount of chromium was detected when originally present as dichromate than when present as chromic ions and the latter put through the usual Group III procedure of qualitative analysis.

Another series of tests similar to those just described for chromic nitrate was carried out, but with 10 mg. each of aluminum, zinc and iron added to each solution tested. The aluminum was added in the form

---

[6] Reedy, "Elementary Qualitative Analysis," McGraw-Hill Book Co., New York, 1924.

of the ammonium alum, the zinc as zinc nitrate, and the iron as ferric nitrate. The procedure was the same as when using chromic nitrate alone. The results obtained were almost the same as those obtained when using chromic nitrate alone, indicating that little or no chromium was lost during the precipitation and removal of other cations that might normally be present.[6]

It should be mentioned why, in the tests made on solutions originally containing chromic ions, acetic acid was used instead of sulfuric acid to acidify the solutions prior to adding diphenylcarbazide. In performing blank tests on the individual cations used in the various mixtures above, namely, aluminum, zinc and iron, several slight positive tests were obtained when using sulfuric acid to acidify the solutions before adding diphenylcarbazide, although the salts used were supposedly free from chromium. When the same blank tests were repeated, using acetic acid instead of sulfuric acid, no positive tests were obtained. The slight positive tests given when using sulfuric acid may have been due to very minute traces of chromium in the salts used, together with the fact that diphenylcarbazide is extremely sensitive when used in sulfuric acid solutions. Hence, acetic acid was to be preferred.

Acetic acid has the added advantage in that it is the acid used to acidify the solution prior to adding potassium ferrocyanide in making the test for zinc by this method. Thus the filtrate from the aluminum precipitation has only to be acidified with acetic acid, divided into two parts, one part treated with diphenylcarbazide to test for chromium and the other portion with potassium ferrocyanide for zinc.

The use of diphenylcarbazide possesses two other advantages.

1. It involves adding only one solution, whereas the ether–hydrogen peroxide method requires two. 2. It dispenses with the use of ether, which is usually regarded as a source of danger when used by beginning students in chemistry, due to its inflammability.

Summary

1. The sensitivity of diphenylcarbazide toward dichromate ions has been compared with the sensitivity of the ether–hydrogen peroxide method, the diphenylcarbazide proving to be much more sensitive.

2. The advantages offered by the use of diphenylcarbazide in place of ether and hydrogen peroxide have been pointed out.

A STUDY OF SUPERACID SOLUTIONS. III. THE TITRATION AND DILUTION CURVES OF BASES DISSOLVED IN ACETIC ACID[1]

BY NORRIS F. HALL AND TYRRELL H. WERNER

RECEIVED JUNE 2, 1928 PUBLISHED SEPTEMBER 5, 1928

In the first papers of the present series[2] it was shown that the chloranil electrode, when combined with a suitable salt-bridge and reference electrode, is very well adapted to the study of titrations in glacial acetic acid. Titration curves were there reproduced for a number of bases in 0.2 *M* concentration. The acid used was sulfuric acid. Here we propose to study the effect of changes in the acid, the concentration and other conditions on the titration curves of bases. The increased precision of the newer measurements permits a more complete study of the form of the titration curves, and also of certain related questions, such as the variation in hydrogen-ion activity when solutions of various bases in acetic acid are diluted.

Effect of the Solvent

The general relationships between acids and bases, while essentially similar in a variety of solvents, may also exhibit significant differences. This has been more or less clearly stated or demonstrated by a number of investigators such as Franklin,[3] Brönsted,[4] Hildebrand,[5] Folin[6] and others. No really precise and comprehensive study of the question appears to have been made, however, and such an investigation is under way in this Laboratory, with the aid of both electrometric and colorimetric methods.

Our preliminary results indicate that certain other solvents may be as superior to acetic acid as the latter is to water, in the titration of certain bases, but that few if any solvents can be found which have all the advantages of acetic acid for a general survey. The first important characteristic of a solvent is the size of the "break" in the titration curve of a given base at a given concentration in that solvent when titrated with a given acid.[6a]

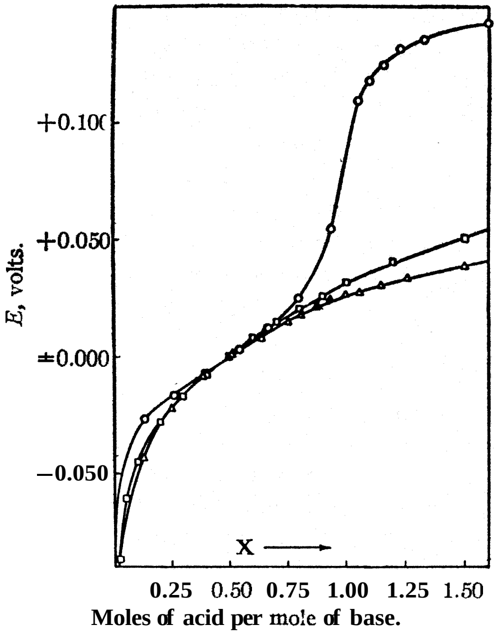
This point is emphasized in Fig. 1, which shows the character of the curves when 99.5% acetic acid, commercial absolute ethyl alcohol, and water are used, respectively, as solvents in the titration of a 0.1 M solution of a weak base, acetoxime ($K_B = 6.5 \times 10^{-13}$).[7]

In each case 100 cc. of the 0.1 M solution of the base was prepared and titrated with a solution of perchloric acid (approximately 1.0 M) in the appropriate solvent, except that in the alcohol titration a 1 M solution of perchloric acid in acetic acid was used for the titrating solution. The quinhydrone electrode was employed and the potentials were measured against the saturated calomel half-cell through a glass-stoppered joint, using a quadrant electrometer. The point where $\Delta E/\Delta V$ has a maximum value was taken as the point of complete neutralization in every case. The exact form of the curves is not significant in this particular case, as it may be affected by electrode and liquid junction errors.

The curves have been shifted vertically as a whole by adding a constant to the observed potentials, so as to bring the points of half neutralization into coincidence in the three cases (in order to mask the grosser differences of liquid junction potential). It is plain that this base, which is so weak as to give no break at all in either water or alcohol, gives a break of 0.1 volt when dissolved in acetic acid. This large break is due to the exceptionally high hydrogen-ion activity of solutions of perchloric acid (and some others) in acetic acid (and certain other solvents). Solutions of this sort have been called "superacid."[2]



○, CH_3COOH; □, C_2H_5OH; △, H_2O.

Fig. 1.—Effect of the solvent in the titration of a weak base (acetoxime) with perchloric acid.

Aside from this "superacidifying" character, other properties of the solvent are of importance. In particular it must dissolve appreciable quantities of the bases selected for study, and also of the salts of these bases with the titrating acid, if the titration curves are not to be complicated by the appearance of precipitates. In the main, acetic acid meets

[7] Lundén, Ladolt-Barnstein, "Tabellen."

this requirement very well, although there are numerous exceptions, as noted in a later paper.

Choice of the Titrating Acid

In the earlier work sulfuric acid was used in all the titrations, although it was remarked that the acidity of equivalent solutions of perchloric acid was apparently higher and although the titration curves showed that the second as well as the first hydrogen of sulfuric acid occasionally entered into reaction (especially with the stronger of the bases). Further, there are certain bases which have insoluble sulfates or acid sulfates but whose perchlorates are soluble. For these reasons it seemed desirable to make a comparative study of the two acids, and as hydrochloric acid also might be supposed to present certain advantages, it was included in the preliminary survey.

This was conducted as follows. Five bases were selected with strengths fairly evenly distributed over the measurable range. Three equal portions of 0.05 M solutions of each of these in acetic acid were titrated, respectively, with 1.0 M $HClO_4$, 1.0 M H_2SO_4 and 1.0 M HCl (all in acetic acid), and the curves plotted in the usual way. Fig. 2 gives the results of the titrations.

The six families of curves are plotted on the same vertical scale with the same zero. The horizontal scales are the same but the zero is shifted in each case 0.5 unit to the right. The abscissa is the fractional neutralization. The ordinate is the measured potential of a cell such as that sketched in Fig. **3,** and constituted as follows

Pt	$C_6Cl_4O_2$ (Sat.) $C_6Cl_4(OH)_2$ (Sat.) **Base** (Cb) **Acid** (Ca)	LiCl Cx	KCl Sat	KCl Sat. HgCl Sat.	Hg
	in HAc		in H_2O		

The convention

$$(P_{\mathrm{H}})^{\mathrm{HAc}} = \frac{E - 0.566}{0.0591} \text{ at } 25^\circ$$

(where E is the electromotive force of the cell, regarded as positive when the platinum is positive to the mercury) was used as in the earlier papers,[2] to which the reader is referred for experimental details. The following changes may be noted in the technique. The early difficulties with electrode poisoning were almost completely absent, perhaps because the electrodes were always ignited before every new run. We did not warm the solutions to saturate them with chloranil, as we found that stirring for ten minutes at 25° was uniformly effective. The acetic acid used was in all cases the P. W. R. analytical reagent. The perchloric acid was prepared as described below (footnote 9). The hydrochloric acid was prepared by passing the pure gas, dried with sulfuric acid, into acetic

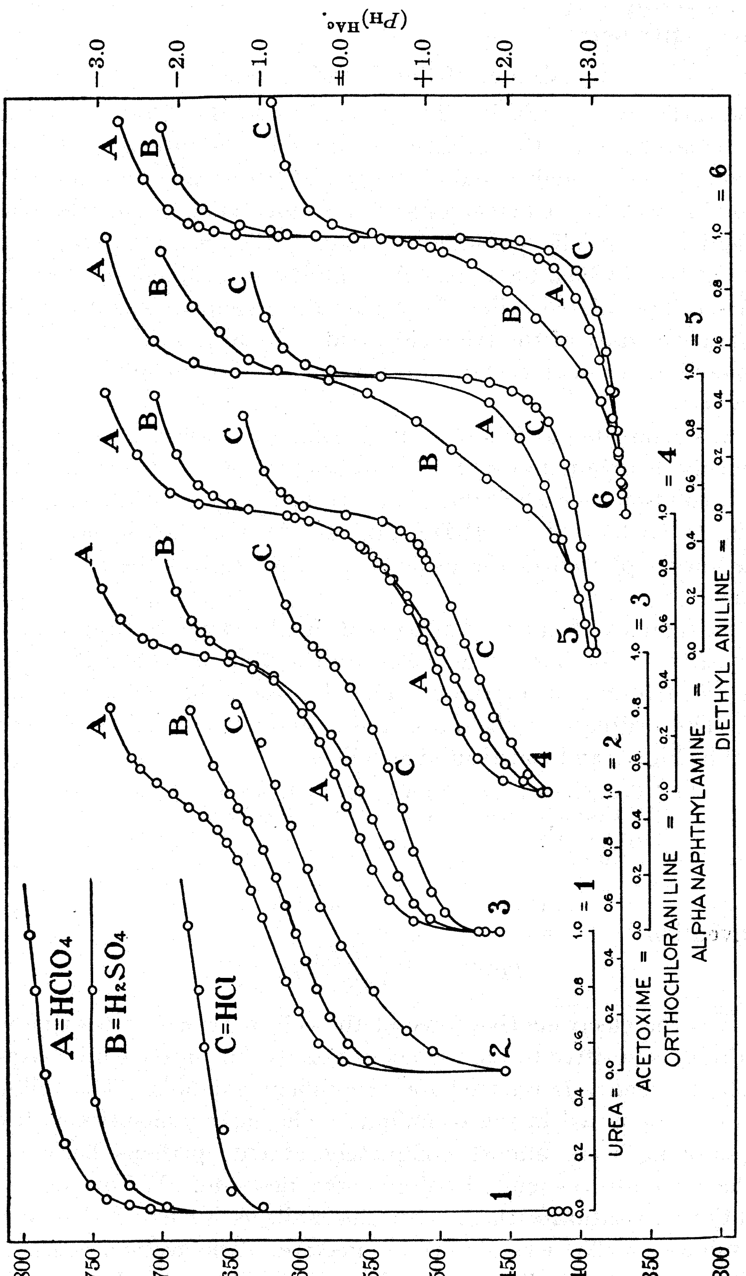


Fig. 2.—Comparison of $HClO_4$, H_2SO_4 and HCl as titrating acids. Abscissas are moles of acid added per mole of base.

acid until the proper concentration was reached or exceeded, and then diluting if necessary. The other materials were of the same nature, as described in the earlier paper.

Beginning in the upper left hand corner of Pig. 2, the first family of curves is not one of titration curves but simply represents the effect of adding the three acids to the pure solvent in amounts corresponding to those used in the other cases (titrations). These curves show clearly that equal concentrations of the three acids are far from being equally "acid." The individual character of strong acids, masked in water by the relatively basic solvent, is here permitted to exhibit itself. It is further apparent that certain bases which would give no break at all with hydrochloric acid could be titrated quite satisfactorily with perchloric acid. The next family of curves (titrations of urea) brings out just this phenomenon. This base is so weak that even in acetic acid it gives no break with hydrochloric acid and only a slight bend with sulfuric acid, while with perchloric acid the break, though slight, is clearly marked. The next two bases, acetoxime and o-chloro-aniline, are appreciably stronger, as shown by the increasingly negative potential of their half-neutralization points, and with them first two, and then all three of the acids give a good break.

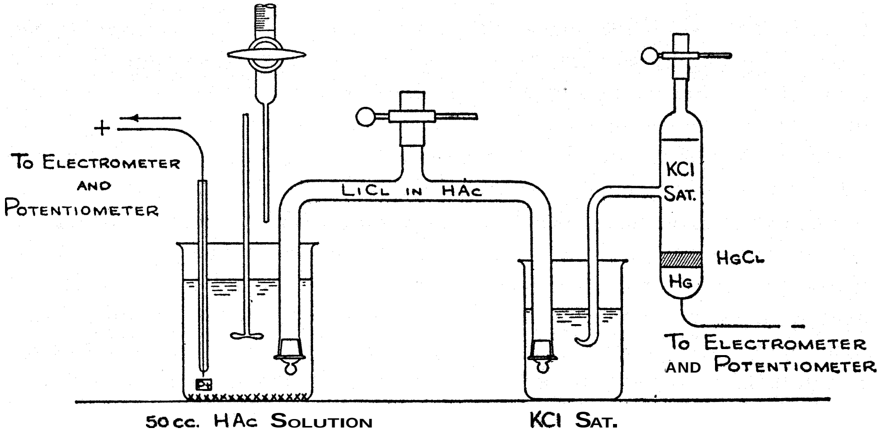

Fig. 3.—Cell for titrations in glacial acetic acid using the chlorauil electrode.

The three curves are also coming closer together as potentials are reached which lie far below those characteristic of the acids alone, but at the same time the sulfuric acid curve (B) is rising rather more rapidly over the range from 50 to 95% neutralization, due to a quite different cause. This is clearly apparent in the case of the much stronger base α-naphthylamine (No. 5). Here the break is in all three cases very pronounced—the form of the curves A and C recalls those characteristic of strong bases in water, by comparison with the weak base types 2, **3** and 4, and the sulfuric acid curve, B, has bent sharply upward at the halfway point and lies far above the other two. This is of course due to the fact that the base is now strong enough to react with the second hydrogen of sulfuric acid, and the sulfate thus formed is progressively converted to the acid salt as the neutralization proceeds. An essentially similar state of affairs is shown by Curve 6 (diethylaniline). This base has a K_B in water of about 4×10^{-8},[8] and therefore behaves in this solvent like a strong base (in respect to its titration curve) as will be more explicitly shown below. The break (with perchloric acid) from 50 to 150% neutralization, is about six PH units, while with hydrochloric acid it is about two units less.

Only one base (cocaine) has been found whose curve obtained under comparable conditions lies appreciably (as much as 15 millivolts) below that of diethylaniline, while many substances known to be stronger bases, such as diphenylguanidine, triphenylguanidine and triethylamine, have curves practically coincident with the diethylaniline curve. On the other hand, some stronger bases such as eserine, strychnine, ammonia, quinine, quinidine, nicotine, brucine, cinchonine, dimethylamine, diethylamine and piperidine give curves that lie from 5 to 30 millivolts *above* it. It seems probable, in view of all the data at hand, that the curve of diethylaniline represents the limiting value (at this concentration) for a normal base which is "strong" as regards its titration in the solvent and that all bases with curves lying appreciably above this value are definitely not completely "strong," but that minor variations of 15–30 millivolts about this limiting value are to be attributed to unknown chemical influences and not to differences in base strength. The individual behavior of particular bases will form the subject of a later communication.

It is obvious from these diagrams that perchloric acid is far preferable to the other two as far as its purely electrical character is concerned in the titration of bases of all measurable strengths. There are, however, other considerations involved.

A great many of the bases we have studied have rather insoluble perchlorates (pyridine, K, Rb, NH_4, nicotine, brucine, cinchonine, cinchonidine, pamido-acetophenone, arylcarbinols, etc.) or sulfates or acid sulfates (Na, Li, Ca, Sr, Ba, Pb, β-naphthylamine, dianisal acetone, semicarbazide, *-bromo-aniline, etc.). We have not tried hydrochloric acid in all of these cases but it seems probable that the chlorides of many of these bases are much more soluble, so that hydrochloric acid might be used in a comparative study of certain (of the stronger) bases which give curves of irregular form when titrated with perchloric or sulfuric acid. On the other hand, the partial pressure of hydrochloric acid from

---

[8] Pring, *Trans. Faraday Soc.*, 19, 705–10 (1923–24); Bourgeaud and Dondelinger, Bull. *soc. chim.*, [4] 37, 277 (1925).

acetic acid solutions is so large that a 1.0 *M* solution fumes about as strongly as 16 *M* hydrochloric acid in water, so that aside from their unpleasantness in use the solutions of this acid are variable in composition, due to the high rate of escape of hydrochloric acid.[9] On the whole it seemed best to use perchloric acid whenever possible, changing to the other acids for particular substances or classes of substances.

The Effect of Concentration

The curves given in the first paper were all obtained at a single concentration (0.2 M), and it was recognized that the observed potentials were in general influenced by concentration changes to a greater degree than is the case in aqueous solutions. We have therefore made a few experiments to determine the nature of this effect. In water the effects of concentration change are as follows. When a strong base such as sodium hydroxide is titrated with a strong acid in a series of concentrations each of which is one-tenth that of the preceding one, the titration curves obtained are all essentially similar and parallel, and are spaced about one P_H unit apart (see Fig. 4A). On the other hand, when a weak base such as ammonia is titrated with a strong acid the titration curves for different concentrations lie very much closer together and presumably almost intersect at the mid-point. In acetic acid as solvent the phenomena are notably different. The curves for a "strong" base are usually quite similar in shape to those determined in water, but the effect of a tenfold dilution is to move the curve only about one-half of a P_H unit instead of a whole one. On the other hand, the effect of dilution is very much greater on a weak base titration curve than it is in water. These relationships are exhibited in Figs. 4 and 5.

Fig. 4A shows calculated curves for the titration of aqueous sodium hydroxide with hydrochloric acid. In drawing these curves the volume has been assumed constant during the titrations and no account has been taken of the change of hydrogen-ion activity coefficient with change in the composition of the solution as the titration proceeds. The activity coefficients of the pure sodium hydroxide solutions were taken from the data of Harned,[10] and the curves are plotted on the assumptions that *(a)* the

---

[9] We have found that in making up perchloric acid, by adding an approximately 8 N aqueous solution to the theoretical quantity of chilled acetic anhydride and diluting with acetic acid to 1 *M*, it is important that there be no excess of acetic anhydride left in the solutions, as otherwise high and irregular potentials are observed. These are due to the action of acetic anhydride on hydrochloranil. A thermal method has proved useful in gaging the exact proportions of acetic anhydride and aqueous perchloric acid to be used. After the two components are mixed in nearly correct proportions, it is found that adding a small amount of one of the components produces a temperature rise. This component is then added until further additions are without thermal effect and the mixture is then diluted with acetic acid to the desired concentration.

[10] Harned, THIS JOURNAL, 47, 676–689 (1925).

Ph of 0.0001 *N* NaOH is 10.00, (b) the activity coefficients of the two ions of sodium hydroxide are equal at each concentration and (c) the activity coefficient of 0.001 N NaOH can be calculated from the limiting equation of Debye and Hückel. On the scale of the diagram, the changes in the shape and relative position of the curves introduced by these approximations are negligible.

The curves in the right-hand half of the diagram reproduce the results of actual titrations of solutions of diethylaniline of the concentrations indicated, in glacial acetic acid. The titrating mixture was a solution of perchloric acid in acetic acid. The concentration of this solution was 2.0 *M* in the lowest two curves, 0.2 M in the middle curve, 0.02 M and 0.002 *M* in the two upper curves. The lowest curve is corrected for the volume change during titration, on the assumption that the measured e.m.f. is 0.018 volt too high when the concentration is halved. Corresponding corrections to the other curves would be negligible and were not applied. The curves show that between 0.02 and 0.002 *M* the $(P\mathrm{H})^{\mathrm{HAc}}$ of the solution changes approximately as the *square* root of the concentration of unneutralized base, while at both higher and lower concentrations the change in $(P\mathrm{H})^{\mathrm{HAc}}$ is greater, approaching that found in water solutions. These rather surprising results suggested the investigations reported below (Figs. 6, 7 and 8).

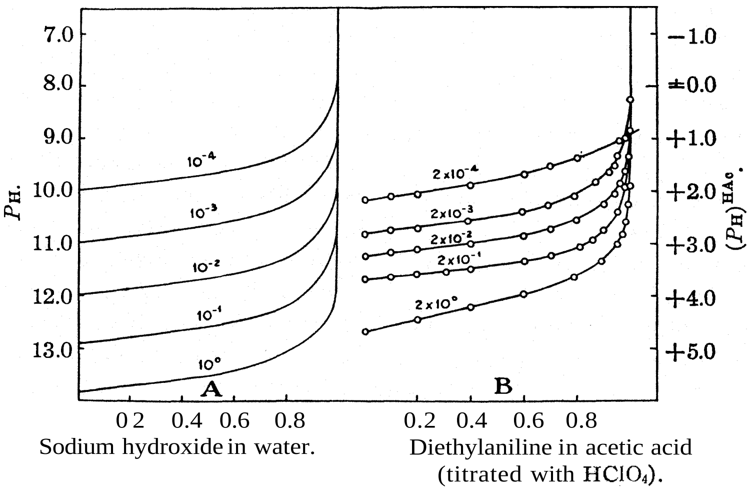

Fig. 4.—Titration curves of "strong" bases. Effect of concentration. Abscissas are moles of acid per mole of base.

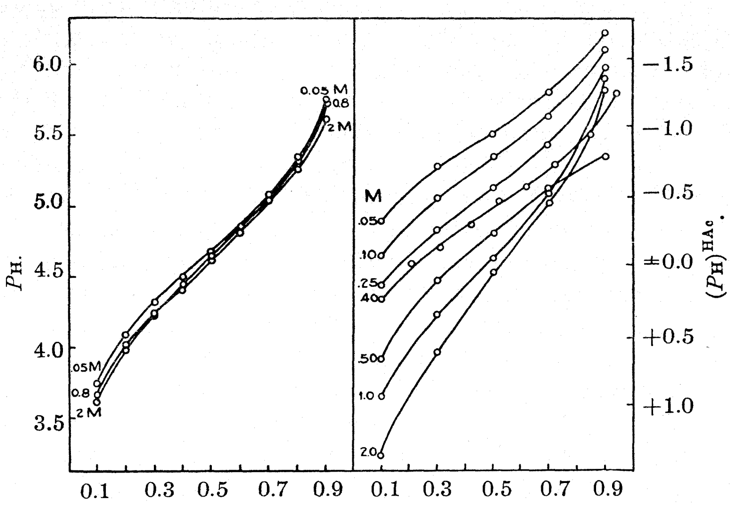
In Fig. 5 are reproduced somewhat similar curves for "weak" electrolytes in the two solvents. As we know of no complete data on a weak base in aqueous solution, we decided to use the results of Cohn and his collaborators[11] on acetic acid. These investigators[12] report the values of $-\log \gamma$ for solutions containing varying proportions of acetic acid and sodium acetate at a number of fixed concentrations of total acetate. As $-\log \gamma$ is essentially the measure of the deviation of the actual titration curves from the theoretical curve whose mid-point is at $P_K = 4.73$, it is a simple matter to construct the actual titration curves from their data. This has been done for three concentrations of total acetate: 2 M, 0.8 M and 0.05 M. It is evident that the curves lie close together and do not greatly deviate from the ideal shape.



A. Acetic acid titrated with sodium hydroxide in water.

B. Urea titrated with $HClO_4$ in acetic acid.

Fig. 5.—Effect of concentration change on titration curves of weak electrolytes in water and in acetic acid. Abscissas indicate fractional neutralization.

On the right-hand side of Fig. 5 are found similar curves reproducing our measurements on the titration of urea with perchloric acid in acetic acid solution. Here it is seen that a corresponding concentration change produces an enormously greater effect than in water. Only one of the curves (that for 1.0 M urea) follows closely the theoretical form; the others are either too steep (2 M) or too flat (all others). At the point of 10% titration the change in $(P_H)^{HAc}$ is approximately one unit between 0.5 M and 0.05 M. At 90% titration it is two-thirds of a unit. Between 0.1 M and 1 M the corresponding changes are one unit and one-third of a unit.

Taken in conjunction with Fig. 2, these results show clearly that both the nature of the titrating acid and the concentration used have much

---

[11] Cohn, Heyroth and Menkin, This Journal, **50,** 696–714 (1928).

[12] Ref. 11, p. 711.

more effect on the PH of mixtures of a weak base and its salt in acetic acid than is the case in water. The extrapolation involved in computing the dissociation constants of bases will therefore be much greater and more uncertain in the former solvent. Accurate values even of the relative strength of bases will evidently only be obtainable under carefully regulated conditions.

The Form of the Titration Curves

In the course of the earlier work it was noted that the curves there obtained (in the titration of 0.2 M bases with sulfuric acid) showed fair approximation to the theoretical form for a weak electrolyte.[13] As can be seen from the present results (Fig. 2 above) sulfuric acid tends to act to some extent as a dibasic acid even with fairly weak bases, and it therefore seemed best to re-examine the question of the exact form of the curves, using perchloric acid, which is free from this particular complication. A concentration was therefore selected (0.05 M) at which the peculiarities of individual substances should be less marked than at 0.2 M, while the buffer capacity of the solutions should still be adequate and the potentials definite and reproducible. Eight bases were then chosen which did not have insoluble perchlorates and which showed a regular gradation of base strength over the measurable range. These were titrated at the stated concentration with 1 M perchloric acid and the resulting potentials are reproduced in Fig. 6. The experimental values have not been corrected for the change in volume during titration because (a) the percentage volume change is the same in all the curves, (b) it is not yet clear just how great the correction should be in all cases and (*c*) as the volume change is only 5% at 100% neutralization, the correction is probably at most 0.06 log 1.05 = 0.001 volt, or within the experimental error.

The strongest of the bases, guanidine, is a diacid base, and was therefore studied in 0.025 M concentration. All the others were 0.05 *M*. In preparing the sodium acetate solution, the calculated amount of metallic sodium was quickly weighed out and added to the acetic acid. The top curve, marked "solvent," shows the potentials obtained when pure acetic acid is treated with amounts of the titrating acid corresponding to similar points on the curves below. The measured potentials, except those of the top curve, were steady and closely reproducible on successive trials. However, each curve records the results of a single titration only, except the top one where the potentials are mean values taken from a number of runs, with a mean deviation from the mean of about 0.01 volt. The curves show a clear gradation in character as one goes to progressively weaker bases and the break can be traced as far at least as to urea, even at this low concentration.

---

[13] Ref. 2, p. 3053, Fig 2.

In order to save space, and because the uncertainty of the liquid junction potential throws doubt upon the absolute significance of the numerical results obtained, these will in general be reported only in the form of diagrams. It seems desirable, however, to give a clearer indication of the precision of the numerical values, and accordingly the titration data for some of the stronger bases are reproduced in Table I. These data with others are shown graphically in Figs. 2, 6, 7 and 8.

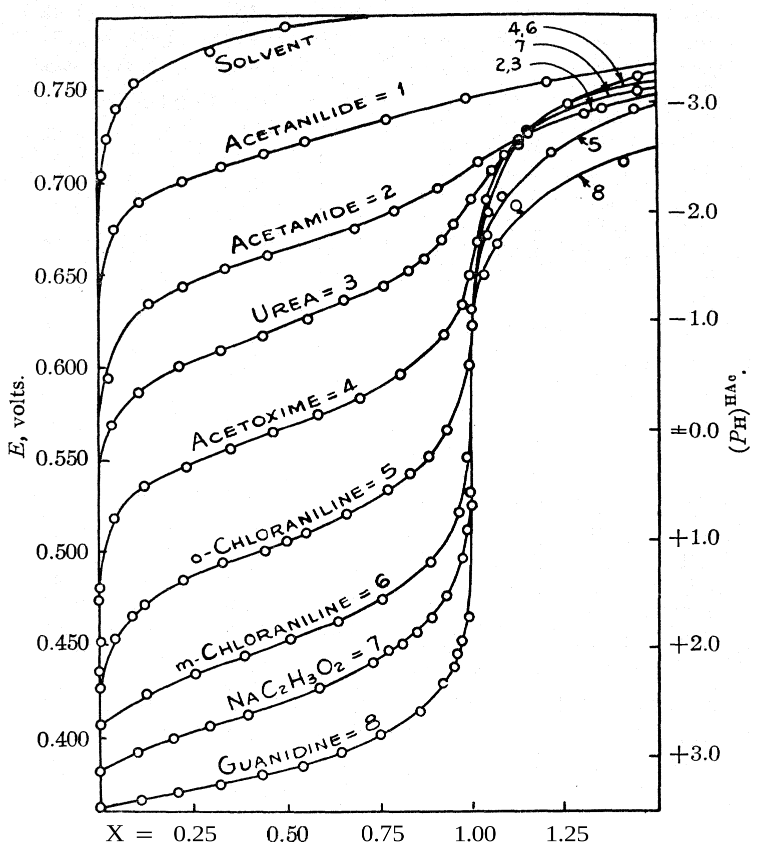


Fig. 6.—Titration of 0.05 N bases in glacial acetic acid with perchloric **acid.** Abscissas show fraction of base neutralized.

In Table I the first column (100X) gives the percentage neutralization. (The point where $\Delta E/\Delta V$ [the change of potential with volume of titrating acid] has a maximum value is taken in every case as the point of complete neutralization.) Col. 2 is the observed e.m.f. of the cell constructed as shown in Fig. **3** and described on p. 2369. The third column gives the negative logarithm of the fractional part of the original base remaining unneutralized. The fourth column is the $(P_H)^{HAc}$ value calculated accord-

ing to the convention stated on p. 2369. The fifth column gives the sum of the third and fourth. An idea of the precision of the measurements may be obtained from the constancy of this sum for diethylaniline and guanidine—two bases which are "strong" in their titration behavior that is, which act in this respect like sodium hydroxide in water. This is not true of the other bases, which are weaker, and for which the values in the fifth column of Table I show a definite trend. These points will be further discussed on p. 2380.

To test the approximation of the curves of Fig. 6 to theoretical forms, one may employ various types of logarithmic plotting. Thus if X is the fraction of the base neutralized, one may plot e.m.f. against log $X/(1 - X)$. On such a plot the titration curve of a base which obeys the mass law without correction is a straight line having a slope of 59 millivolts for a unit change in the logarithm of the ratio.

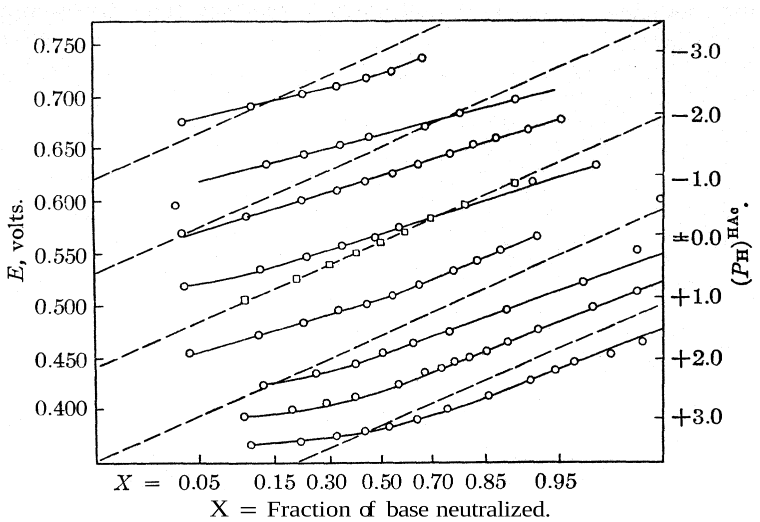

Fig. 7.—Logarithmic titration curves of bases in acetic acid titrated with perchloric acid. True abscissa = log $[X/(1 - X)]$.

In Fig. 7 this type of plotting is applied to the data of Fig. 6. The curves for the different substances lie in the same order and relative position as in that figure. The diagonal broken lines reproduce for comparison the slope which would be shown by bases which obeyed the mass law without correction. For comparison also we have taken the data of Cohn, Heyroth and Menkin[11] for acetic acid in water at the concentration 0.05 M, and arbitrarily placed the mid-point of this curve so that it falls upon the most centrally located broken line. The data at other points are then represented by squares. It is seen that in this case the deviations of the points from the theoretical slope are scarcely appreciable.

In the cases of all the substances dissolved in acetic acid, however, the deviations are considerable. The lines show a curvature which steadily increases with the strength of the base, and in all cases the slope is less than the theoretical.

It is thus evident that none of the bases act when titrated exactly as do weak electrolytes in water. On the other hand, the lowest curves in Fig. 6 are surprisingly similar to those given in water by *strong bases.*

In a further test of this point, a different type of logarithmic plotting may be employed. If the electromotive force is plotted against the logarithm of $1 - X$ (the unneutralized fraction), a curve of the strong base type will be a straight line. Thus in water the titration of sodium hydroxide with hydrochloric acid gives a straight line on such a plot. This is generally attributed to the essentially complete dissociation of NaOH and NaCl, the essentially constant value, within the range, of the activity coefficient of the hydroxyl ion and the fact that $a_{\mathrm{H}^+} \times a_{\mathrm{OH}^-} =$ Const. $= Kw$.

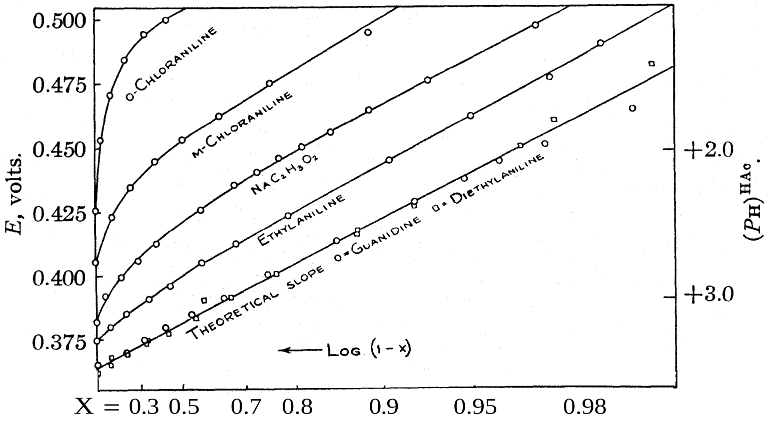

Fig. 8.—Logarithmic titration curves of bases in acetic acid. X = fraction of base neutralized. Abscissa = $-\log (1 - X)$.

If now this method of plotting is applied to the four lowest curves of Fig. 6, and to the titration of ethylaniline and diethylaniline under the same conditions (as shown, for example, in Fig. 2, 6A), Pig. 8 is obtained. Here the lowest line has the theoretical slope (for strong bases) of one PH unit (59 millivolts) per unit change of log $(1 - X)$, and has been adjusted vertically so as best to fit the points for the two bases diethylaniline and guanidine. The other lines are fitted as well as possible to the experimental points without regard to theory. All these latter exhibit a curvature which rapidly increases as the bases become weaker. This sort of plotting is a sensitive test for "strong base" behavior and shows that diethylaniline and guanidine have titration curves of the strong base type within the experimental error of 2 or 3 millivolts, as may also be seen from the constancy of the values in Col. 5 of Table I.

A possible inference from these results would be that the acetates of diethylaniline and guanidine are completely dissociated, while those of the other bases are incompletely dissociated. However, such a view encounters difficulties when one reflects that the dielectric constant of acetic acid is rather low (possibly about 10 at 25°)[14] and that, therefore, the attraction between univalent ions should be enormously greater than in water, so that there should be in this solvent no electrolytes which are strong in the sense in which this term is used in water; that is, in the sense that their ions at appreciable concentrations act like point charges almost unaffected by the surrounding ion atmosphere.

It seemed desirable, in seeking further light on this question, to abandon titration curves and to study the effect of dilution on solutions of the pure bases. This is, of course, the classical procedure followed by Ostwald and all his successors who have tested the applicability of the dilution law to electrolytic solutions—principally in water. These studies have nearly all been made with the aid of conductivity measurements. In non-aqueous solutions the conductivities are frequently very low and the effects of impurities proportionately great, so that significant results are only obtainable by this method at the price of extreme care and effort. There is available, however, another convenient method of following the course of electrolytic dissociation on dilution. If an electrode is available which is responsive to changes in the activity of one of the ions formed by the dissociating substance, and if the activity coefficient of this ion can be estimated at the various concentrations employed, dissociation can be studied by e.m.f. measurements as satisfactorily as by conductivity. Apparently this method has been surprisingly little used. On account of its many advantages, we decided to use the chloranil electrode in studying the form of the dilution curves of bases.

The Form of the Dilution Curves of Bases

If the hydrogen-ion activities of solutions of a base in water are measured over a large concentration range, and a plot is made of e.m.f. (or P_H) against the logarithm of the normal concentration of the base, the points for each substance should lie very nearly on a straight line with a slope of one (P_H) if the base is completely dissociated, while if its dissociation obeys the law of concentration effect, the slope should always be less than one, and there should be a considerable range where the points lie on a line with a slope of $^1/_2$.[15]

Fig. 9 shows theoretical curves for bases of varying strength in a solvent having an ion activity product of 10^{-14} (water at 25°). In drawing the

---

[14] Landolt, Bornstein, "Tabellen," 5th ed., p. 1037, Suppl. 557.

[15] For a strong base, $a_{H^+} = \frac{K_w}{C_B}$ $\therefore P_H = P_w + \log C_B$, $\frac{\partial P_H}{\partial \log C_B} = 1$. For a weak base $K_B = \frac{a_{BH^+} \times a_{OH^-}}{a_B}$, $a_{BH^+} \cong a_{OH^-}$, $a_B \cong C_B$ and $a_{H^+} = \frac{K_w}{a_{OH^-}}$. $\therefore \frac{K_w^2}{a^2_{H^+}} \times \frac{1}{C_B} = K_B$, $2P_w - 2P_H + \log C_B = P_B$ and $\frac{\partial P_H}{\partial \log C_B} = {}^1/_2$.

curves account has been taken both of the dissociation of the solvent where that is appreciable and of the cases where the concentration of the undissociated base is not substantially equal to that of the total base. It is seen that the strong base curve has a unit slope while there is a range where each weak base curve has a slope of $^1/_2$. We could find no complete set of data to compare with these curves and, indeed, it would be difficult if not impossible to make the necessary measurements at the lower concentrations. A few measurements on a single strong base (NaOH) and a single weak base (NH_3) are reported by Michaelis[16] (for 18°) and these have been included. It is obvious that their behavior is typical of the classes to which they respectively belong.

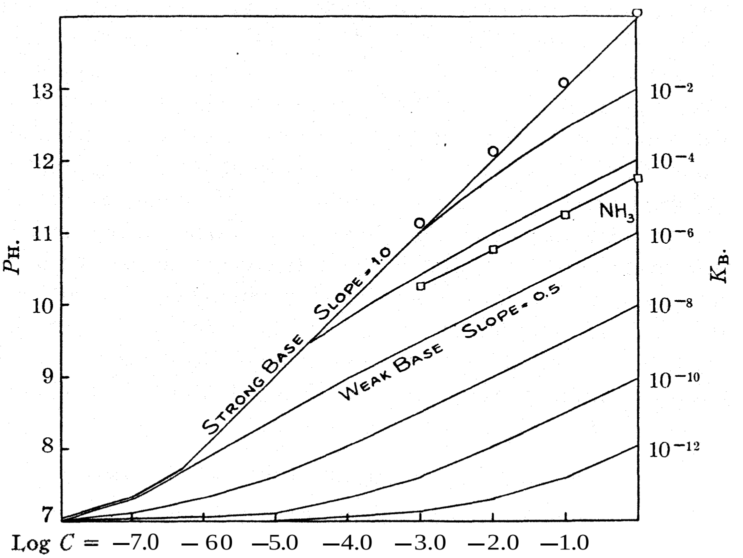

Fig. 9.—PH–Dilution curves of bases in H_2O. Theoretical curves drawn for t = 25°. Data from Michaelis at t = 18°. ○ = NaOH; □ = NH_3.

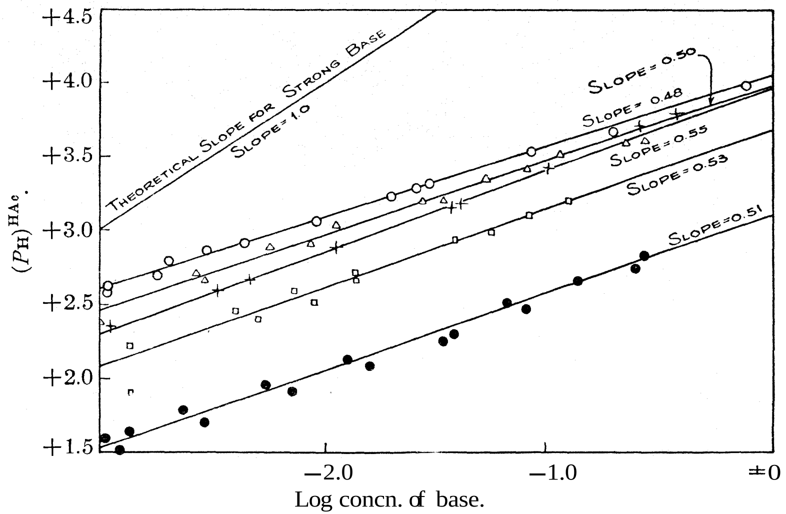
In applying this method to acetic acid solutions, we proceeded as follows: a rather concentrated solution of the base was first prepared (2 or 3 M) and from this two or three other solutions, each of which was one-tenth as concentrated as its predecessor. Fifty cc. of pure acetic acid was then measured out and its $(P\mathrm{H})^{\mathrm{HAc}}$ determined in the usual way. Then measured volumes of the most dilute solutions of the base (up to a volume of 5 cc.) were run into the acetic acid, and the new $(P\mathrm{H})^{\mathrm{HAc}}$ values determined. After 5 cc. had been added, the procedure was repeated with more concentrated solutions of the base. In this way the concentration

---

[16] Michaelis, "Hydrogen-Ion Concentration," Williams and Wilkins Co., Baltimore, Md., 1926, p. 24.

at each stage could be computed with sufficient accuracy on the assumption that the volumes were additive and it was therefore possible to plot $(P_{\rm H})^{\rm HAc}$ against the logarithm of the concentration. Fig. 10 is such a plot for two thoroughly "strong"[17] bases (diethylaniline and guanidine) and three that are appreciably "weaker" (pyridine, sodium acetate and *o*-chloroaniline). The potentials are less reproducible in these dilute solutions of pure bases than in the case of the titrations; nevertheless, most of the points fall on a straight line between concentrations of 1 *N* and 0.001 N, and these lines have very nearly the theoretical slope (for a weak base) of 0.5. At lower concentrations the measurements are not reproducible



○, Diethylaniline; +, pyridine; □, sodium acetate; △, guanidine; ●, *o*-chloro-aniline.

Fig. 10.—$(P_{\rm H})^{\rm HAc}$–Dilution curves of bases in acetic acid.

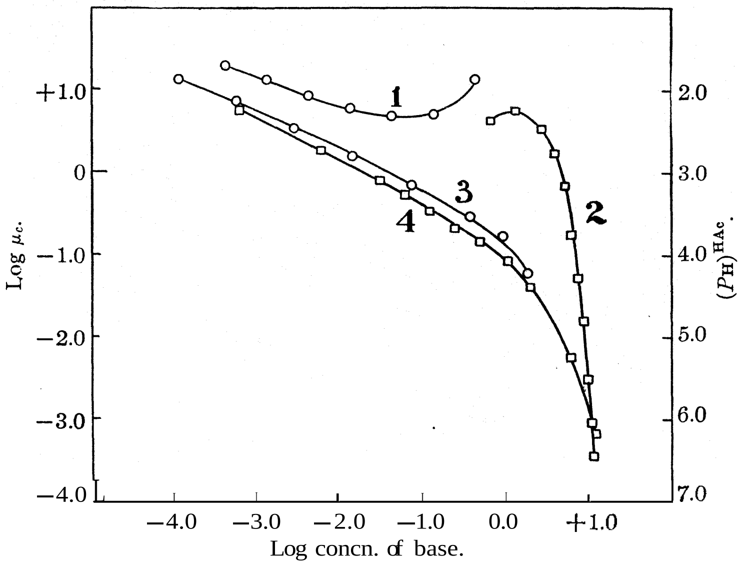
but seem to indicate an increase in the slope, as would be expected. At higher concentrations good measurements are very easy to make but their interpretation is obscure due to the individual peculiarities of concentrated solutions (see Fig. 11) and possibly to deviations of the volumes from additivity. A few measurements on still weaker bases indicated that their points fell on lines parallel to and below those given in Fig. 10. These data seem to constitute a convincing demonstration that in acetic acid bases which behave during titration like strong bases are nevertheless actually quite regular in their conformity to the requirements of the law of concentration effect, and are not to be regarded as completely dissociated in the sense in which this term is used of aqueous electrolytes.

It is evident that the electromotive force method constitutes a powerful

---

[17] As regards their titration curves.

tool for investigating the effect of concentration on the properties of solutions in non-aqueous solvents. This problem has been the subject of very numerous studies by the conductivity method but the results have been so complex and difficult to interpret that the interest of many investigators in this field has perhaps somewhat cooled in recent years. It is not too much to hope that this interest may be revived as the value of the electromotive force method becomes more widely appreciated. Thus it may be found that certain anomalies in the conductivity results, which make a considerable demand on auxiliary hypotheses such as those of association, solvation, etc., may not appear at all in the electromotive force measurements. A diagram (Fig. 11) will illustrate this idea. The molar conductances of solutions of potassium acetate and of pyridine in acetic acid have been determined over a considerable concentration range by Völmer[18] and by Patten.[19] When their values of μ_c are plotted against the concentration, both curves are anomalous, that for potassium acetate showing a minimum and that for pyridine a maximum value of the molar conductance. In Fig. 11 is given such a plot of their results except that logarithms of the molar conductance (μ_c) and of the concentration are



1, Potassium acetate—log μ_c; 2, pyridine—log μ_c; 3, potassium acetate—$(P_H)^{HAc}$; 4, pyridine—$(P_H)^{H*}$.

Fig. 11.—Comparison of effect of dilution on conductivity (Curves 1 and 2) and on hydrogen-ion activity (Curves 3 and 4) of bases dissolved in acetic acid.

---

[18] B. Volmer, *Z. physik Chem.*, *29*, *187* (1899).

[19] H. E. Patten, *J. Phys. Chem.*, *6*, 554–600 (1902).

used as ordinates and abscissas, respectively (Curves 1 and 2). On the same diagram and with the same abscissa are plotted our values of log $a_{H^+} = -(P_H)^{HAc}$ (right-hand ordinate) ior the same substances over a much greater concentration range. The resulting curves (3 and 4) show no evidence whatever of the anomalies mentioned but steadily fall as the concentration of the base increases and are, of course, straight lines with a slope of $-{}^1/_2$ over a large part of the range, as stated above.

It is evident therefore that the form of the conductance functions is complicated in comparison to that of the activity functions, as a result of secondary effects of uncertain nature. Similar anomalies are shown by the conductance functions of sulfuric and hydrochloric acids in the same solvent, and again our (unpublished) activity data give no indication of their existence.

The Liquid Junction Potential

The significance of the results hitherto reported depends in large measure on the (assumed) constancy of the liquid junction potential when the concentration and composition of the solutions are varied, though not directly on the absolute value of this potential. Thus it might be supposed that the failure of the curves of Fig. 7 to approach more closely the theoretical form was due to systematic variations in the junction potential. It is perhaps impossible entirely to exclude this possibility. Nevertheless we feel that the following are strong arguments in favor of the essential constancy of this potential in all our measurements.

(1) The agreement of the individual points with the theory is so good in the case of the data of Table I and the lowest curve of Fig. 8 that there can hardly be any appreciable liquid junction error involved, yet these data cover much the same range of acid–base ratio and of acidity as the curves of Fig. 7.

(2) The similar consistency of the *dilution* curves of Fig. 10 seems to show that *concentration* changes from 1.0 N to 0.001 N are practically without effect on the liquid junction. We therefore feel that the effective constancy of this potential throughout all our measurements, while not definitely proved, is rendered very probable.

The following aspects of the data reported demand further elucidation: (I) the abnormally small effect of dilution on the "strong" base curves (Fig. 4B); (2) the abnormally large effect of dilution on the "weak" base curves (Fig. 5B); (3) the failure of the weak base curves to conform to the theory (Fig. 7); (4) the fact that bases which are clearly "weak" (Fig. 10) should nevertheless behave like "strong" bases when titrated (Fig. 8).

Among the factors which may be suggested as responsible for these anomalies are the following: (1) the low value of the dielectric constant of the solvent with the correspondingly large effect of interionic attractions on the activity coefficients of the ions, so that interionic association is always considerable; (2) large differences in the extent of solvation of the various ionic and molecular species present in the solutions. Thus it seems probable that association with the solvent is very complete in the case of the stronger bases but very incomplete in the pure solutions of the weaker bases.

In the absence of independent information concerning the colligative properties of such solutions as we have studied, it seems undesirable at present to elaborate further mechanical hypotheses to account for their observed peculiarities.

Summary

Diagrams and tables are given which show the effect of the following influences on the shape of the titration curves of bases dissolved in acetic acid: the nature of the titrating acid, the concentration and the strength of the base. It is shown that the weaker bases give anomalous titration curves while the curves of bases which act like strong bases in water conform to the theory of such titrations. The effect of dilution on the hydrogen-ion activity of solutions of bases is studied by the electromotive force method, and it is shown that even the "strongest" bases are truly weak electrolytes in this solvent. It is shown that these results practically demonstrate the effective constancy of the liquid junction potential between saturated aqueous potassium chloride and the various acetic acid solutions used. The value of the electromotive force method in studying the effect of dilution on dissociation is emphasized in the discussion.

A LEAD–MERCUROUS IODIDE VOLTAIC CELL

BY WARREN C. VOSBURGH

RECEIVED JUNE 4, 1928 PUBLISHED SEPTEMBER 5, 1928

The results of measurements of voltaic cells with mercurous iodide electrodes are not very concordant. Gerke[1] has calculated the electromotive force of the cell

$$\text{Hg} \mid \text{Hg}_2\text{I}_2 + \text{HI}\ (a = 1) \mid \text{HI}\ (a = 1) \mid \text{H}_2(\text{Pt}) \qquad (1)$$

from the results of Bugarsky[2] and from the results of Oeholm,[3] obtaining the values 0.0432 v. and 0.0414 v. at 25°, respectively. Cohen and Bruins[4]

---

[1] Gerke, *Chem. Reviews*, 1, 385 (1925).

[2] Bugarsky, *Z. anorg. Chem.*, 14,145 (1897).

[3] Oeholm, *Acta Soc. Scientarum Fennicae*, 41, 1 (1913); *C. A.*, 7,2718 (1913).

[4] (a) Cohen and Bruins, *Z. physik. Chem.*, 93, 53 (1918); (b) see also, Yoshida, *J. Chem. Soc. Japan*, 48,435 (1927).

found for the cell

$$Cd(Hg) \mid CdI_2, \text{ sat.} \mid CdI_2, \text{ sat.} + Hg_2I_2 \mid Hg \qquad (2)$$

the value $E_{25} = 0.41712$ v.[5]

From this and the value calculated by Gerke[1] for the cell

$$Cd(Hg) \mid CdI_2 \text{ sat.} + HI\ (a = 1) \mid H_2\ (Pt) \qquad (3)$$

the value $E_{25} = 0.0403$ v. can be calculated for Cell 1. The electromotive force of Cell 3 was calculated from some results of Obata[6] with which some later results of the author[7] were in good agreement. A third value for Cell 1 given by Gerke, namely, $E_{25} = 0.0404$ v., was calculated from some results obtained in this investigation. It is in good agreement with the value calculated from the results of Cohen and Bruins. Ishikawa and Shibata[8] have determined the electromotive force of the cell

$$Zn(Hg) \mid ZnI_2 \mid ZnI_2 + Hg_2I_2 \mid Hg;\ E_{25} = 0.5243 \text{ v.} \qquad (4)$$

By combining their value with values for the cells

$$Ag \mid AgI + HI\ (a = 1) \mid HI\ (a = 1) \mid H_2\ (Pt);\ E_{25} = 0.1501 \text{ v.}^1 \qquad (5)$$

$$Zn(Hg) \mid ZnI_2 \mid ZnI_2 + AgI \mid Ag;\ E_{25} = 0.3987 \text{ v.}^9 \qquad (6)$$

the value $E_{25} = 0.0245$ v. is found for Cell 1, which is in poor agreement with the other values.

The purpose of this investigation was to measure accurately the electromotive force at various temperatures of the cell

$$Pb(Hg) \mid PbI_2 \mid PbI_2 + Hg_2I_2 \mid Hg \qquad (7)$$

Preparation of Materials

Mercury.—The mercury was purified by passing commercial redistilled mercury through a column of mercurous nitrate solution and redistilling at least once under reduced pressure in a current of air.

Lead Amalgam.—The lead amalgam was made electrolytically from purified mercury and either twice recrystallized lead nitrate or lead chloride made from recrystallized lead nitrate. Four different preparations were used. One contained 12.7% of lead and the other three contained 10% of lead.

Cadmium Amalgam.—The cadmium amalgam was prepared electrolytically from purified mercury and thrice recrystallized cadmium sulfate. It contained 10% of cadmium.

Lead Iodide.—The lead iodide was made by adding slowly a solution of recrystallized potassium iodide to a hot solution of twice recrystallized lead nitrate. The lead iodide so obtained was washed by decantation and preserved under water. Several different preparations were made in the course of the work, all by the same method.

Cadmium Iodide.—Two lots of cadmium iodide were prepared. No. 1 was prepared by recrystallizing C. P. cadmium iodide twice, the second time from redistilled water.

---

[5] The measurements of Cohen and Bruins were made at temperatures between 16 and 24°. The value $E_{25} = 0.41712$ v. was obtained by an extrapolation which, however, introduces an uncertainty of less than 0.1 mv.

[6] Obata, *Proc. Phys. Math. Soc. Japan,* [3] **3,** 64, 136 (1921).

[7] Vosburgh, THIS JOURNAL, 49, 2228 (1927).

[8] Ishikawa and Shibata, *Bull. Chem. Soc. Japan,* 1, 169 (1926).

[9] Webb, *J. Phys. Chem.,* 27, 448 (1923).

No. 2 was prepared by allowing C. P. cadmium metal to react with a solution of C. P. iodine.[10] The solution was stirred continuously and iodine was added occasionally. The cadmium iodide so prepared was recrystallized twice, the second time from redistilled water.

The cadmium iodide to be introduced into the cells in the solid form was heated for five days at 150° to convert it into the stable form.[11]

Mercurous Iodide.—The mercurous iodide was prepared by precipitation. A solution of recrystallized potassium iodide was added slowly with mechanical stirring to a solution of twice or thrice recrystallized mercurous nitrate containing nitric acid. It was washed by decantation with either water or a very dilute potassium iodide solution and was preserved under water. Some of the preparations stood for several months under water before being used. The concentrations of the reacting substances varied in the different preparations but were of the order of **0.1** M.

Preparation **1** was made as described, redistilled water being used. It was digested on a hot-plate for two hours with water. Air was excluded during the precipitation by a current of nitrogen.

Preparation 2 was made similarly but without exclusion of air. Toward the end of the precipitation some orange-colored precipitate presumably containing mercuric iodide was formed. The addition of more mercurous nitrate converted it into the yellow mercurous iodide. In the subsequent preparations care was taken to keep the mercurous nitrate present in excess throughout the precipitation The mercurous iodide was washed by decantation, first with mercurous nitrate solution and then with very dilute potassium iodide solution.

Preparation **3** was a portion of No **2** which was digested on a hot-plate at nearly boiling temperature for about seven hours under a very dilute potassium iodide solution.

Preparations **4, 5** and **6** were precipitated in the cold, the first from solutions more concentrated than usual and the second from solutions more dilute. During the precipitation of No. **4** air was excluded and the solution was stirred with a current of carbon dioxide. Preparations 4, **5** and 6 were not digested

Preparation **7** was a portion of No. 6 which was digested for three days on a steam-bath in the dark.

Preparation 8 was prepared by the usual method but using redistilled water and with concentrations of about 0.2 M. It was digested for four days on a steam-bath in the dark.

Preparation of the Cells

The cells were set up in glass H-vessels. For the earlier cells[12] vessels of the type used by Vosburgh and Eppley[13] or that used by the author[14] for portable Weston cells were used. These vessels were hermetically sealed when the cells were made. For Cells **511–526**[15] vessels of the same type but of different dimensions were used. They were about **18** cm. long and **5.5** cm. wide. The inside diameter of the tubes was 12–**15** mm. The cells set up in these vessels were closed by means of paraffined corks.

[14] Vosburgh, **J.** *Optical Soc. Am.*, **9, 66 (1924).**

[15] Made at the State University of Iowa.

A paraffined cork disk was pushed into the top of each leg of the vessel to a distance of 2 or 3 cm. and then covered with a layer of paraffin about 1 cm. thick. Finally, the openings of the tubes were closed by corks shellacked on the outside.

In setting up the mercurous iodide electrodes the procedure was that used by the author for setting up the mercurous sulfate electrodes of Weston Cells.[16] The mercurous iodide, with which was mixed lead iodide and in Cells 511–522 ground cadmium iodide crystals also, was washed first in a Gooch crucible and then by decantation in an atmosphere of nitrogen or carbon dioxide with the solution to be used in the cells. It was then transferred to the cell vessels out of contact with air. The mercurous iodide layer was at least 1 cm. deep. On top of it was placed some lead iodide and in Cells 511–522 some cadmium iodide crystals also.

The lead iodide electrodes were made by introducing first lead amalgam and then a paste of the electrolyte and either lead iodide or a mixture of lead iodide and cadmium iodide. In setting up Cells 511–522, in which the latter mixture was used, special precautions were taken to prevent oxidation of the lead amalgam.

In a number of cells a saturated solution of lead iodide in redistilled water was the electrolyte. This gave sufficient conductance so that the electromotive force could be measured accurately within a tenth of a millivolt. However, most of the cells so made were less constant and less reproducible than the others. In other cells a 0.01 *M* or 0.02 M potassium iodide solution was used as the electrolyte. An iodide solution has the advantage of dissolving mercuric iodide, so when the mercurous iodide mixture is washed with an iodide solution, any mercuric iodide present tends to be washed out The most reproducible cells were made with cadmium iodide solution as the electrolyte.

The cells were nearly always made in duplicate Duplicates usually agreed within a few hundredths of a millivolt. In the best cells made, Cells 517–522, the difference between duplicates was within 0.01 mv

The cells were mounted on wooden racks and the platinum wires leading from the cell electrodes were connected to copper terminals by means of fine copper wire which was soldered to both. Usually the negative electrodes were connected to a common terminal. while the positive electrodes were connected to separate terminals insulated from each other and from the wood by hard rubber or glass. In measuring the cells, copper lead wires from the potentiometer were clipped to the terminals of the rack by copper test clips. The racks of cells were immersed in an oil thermostat capable of being regulated to within 0.01° of the desired temperature.

Electromotive Force Measurements

Apparatus.—The electromotive forces were measured by means of a Leeds and Northrup Type K potentiometer. Two different potentiometers were used in the course of the work. The first was used only with the less reproducible cells with the very dilute solutions for electrolytes. The second, used for the measurement of the more reproducible cells with cadmium iodide electrolytes, was calibrated by the method described by the manufacturers.[17]

The standards used in the measurements recorded in Tables I and IV were those used in previous investigations.[16] The standards used in the measurements recorded in Tables II, III and V were nine others of equal quality, seven of which had been directly compared with the first stand-

---

ards. Three saturated Weston Cells set up at the State University of Iowa agreed with these seven cells, which had been carefully carried from Newport to Iowa City, within 0.002%. Two years later a portable saturated Weston Cell obtained from the Eppley Laboratory agreed with the standards within 0.002%.

Measurements at 25°.—Measurements were made occasionally over a considerable period of time to show the constancy of the electromotive force before the values were accepted as final. Some of the cells had electromotive forces lower than the normal at first. Among these were Cells 511–522. The electromotive forces increased as time went on till finally a constant value was attained. Fig. 1 shows the change undergone by four of the cells. It is to be noted that constancy of electromotive force was not attained by Cells 511–512 until a month after they were set up. Thus, electromotive force measurements made soon after cells are set up cannot always be relied upon to give correct values.

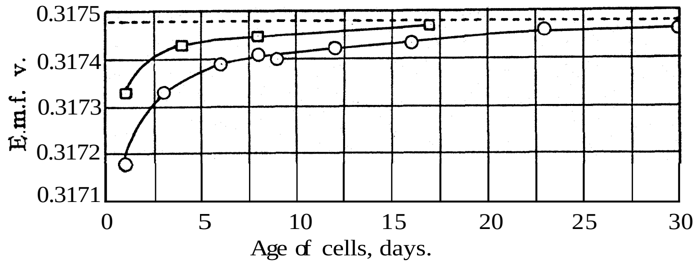

Fig. 1.

Tables I and II give the electromotive forces of the cells after constancy was attained. The time intervals are the periods of time which elapsed between the preparation of the cells and the measurements in question. Table I gives measurements of the cell

$$\mathrm{Pb(Hg)} \mid \mathrm{PbI_2,\ sat.} + x\,\mathrm{M\ KI} \mid x\,\mathrm{M\ KI} + \mathrm{PbI_2} + \mathrm{Hg_2I_2} \mid \mathrm{Hg} \qquad (8)$$

and Table II gives the results of measurements of the cell

$$\mathrm{Pb(Hg)} \mid \mathrm{PbI_2,\ sat.} + \mathrm{CdI_2,\ sat.} \mid \mathrm{CdI_2,\ sat.} + \mathrm{PbI_2\ sat.} + \mathrm{Hg_2I_2} \mid \mathrm{Hg} \qquad (9)$$

[a] The electrolyte for these cells was prepared by treating a 0.01 M sulfuric acid solution with an excess of solid lead iodide and filtering.

TABLE II

CELL: Pb(Hg) | PbI_2, SAT. + CdI_2, SAT. | CdI_2, SAT. + PbI_2, SAT. + Hg_2I_2 | Hg

Cells	Hg_2I_2 no	Electromotive force at 25° 1 month, v.	2, v.	3, v.	4, v.
511–512	4	0 31746	0.31748	0.31749	0.31740
513-514	5	.31768	,31769	.31768	.31766
515–516	6	.31754	.31755	.31756	....
517–518	7	.31746	.31747	.31748	.31748
519–520	8	.31747	,31747	.31748	.31748
521–522	8	.31748	.31748	.31748	.31749

It is quite evident that the cells with the cadmium iodide electrolyte (Table II) were superior to the other cells both in reproducibility and constancy. Of the former the best were Cells 517–522. These were all made with mercurous iodide which had been digested on a steam-bath under water with the object of bringing it to a stable physical condition. This practice has been shown[18] to be of value also in the preparation of mercurous sulfate for standard cells. The good agreement of Cells 517–522 makes it probable that the materials used were in a stable physical state. Most of the materials used for Cells 521–522 were different preparations from those used for the other four cells and if anything were better purified. Cells 513–514 were 0.2 mv. higher in electromotive force than most of the others, and it is to be concluded that the mercurous iodide preparation used was not in its most stable physical form.

To check the values of Cohen and Bruins[4"] and Yoshida[4b] for Cell 2 and to compare the mercurous iodide which the former authors prepared, from mercury and iodine with that prepared by precipitation, 4 cells like Cell 2 were set up. The procedure used was enough like that described above for the lead–mercurous iodide cells to need no further description. The electromotive forces are given in Table III. It is evident that the agreement with the cells of Cohen and Bruins and also those of Yoshida is very good.

TABLE III

CELL: Cd(Hg) | CdI_2, SAT. | CdI_2, SAT. + Hg_2I_2 | Hg

Cells	Hg_2I_2 no.	Electromotive force at 25° 1 month, v.	2, v.	3, v.	3.6, v.
520–524	7	0.41702	0.41701	0.41704	0.41704
525–526	8	.41701	.41698	.41700	.41700

Temperature Coefficients.—The cells of Table I were measured at 5° intervals of temperature between 15 and 40°. The measurements were made along with some measurements at the same temperatures of Weston standard cells and the details as to temperature regulation and general procedure have already been published.[19] The lead–lead iodide cells

---

[18] Ref. 16, p. 1267.

[19] Vosburgh, J. Optical *Soc. Am.*, 12, 512 (1926).

did not show the hysteresis which the Weston cells showed, and so came to equilibrium more quickly, especially after a decrease in temperature. Table IV shows the differences between the electromotive forces at 25° and those at the other temperatures.

TABLE IV

VARIATION OF ELECTROMOTIVE FORCE WITH TEMPERATURE

		$E_t - E_{25}$				
Cells	E_{25}, v.	15°, mv.	20°, mv	30°, mv.	35°, mv.	40°, mv.
410411	031766	– 125	– 062	061	1.26	1.94
431–402	,31780	–1.22	–.57	.61	1.26	1.94
433434	,31783	–1.44	– 73	.67	1.36	2 07
436-437	,31764	–1 42	– 70	.63	1.30	1 96
439440	.31727	– 129	–.65	.63	1.29	1.93

The effect of temperature changes on Cells 517–522 and 523–526 was also determined. The temperature was changed successively from 25 to 20, 30, 35, 40, 35, 30 and 25°, while the standards were maintained at 25° in a separate thermostat. Temperatures were measured by a thermometer certified by the Bureau of Standards, and are probably accurate to ± 0.03'. The results are given in Table V.

TABLE V

VARIATION OF ELECTROMOTIVE FORCE WITH TEMPERATURE

		$E_t - E_{25}$						
Cells	E_{25}, v	20°, mv.	30°, mv.	35°, mv.	40°, mv.	35°, mv.	30°, mv.	25°, mv.
517–518	0.31748	–0.61	0.65	1.28	1.93	1.30	0.67	0.01
519–520	,31748	– .63	.66	1.28	1.93	1.29	.65	.00
521–522	.31749	– .66	.65	1.27	1.91	1.29	.64	.00
523–524	.41704	–1.93	1.79	3.60	5.41	3.57	1.74	–.10
525–526	.41700	–1.88	180	3.61	5.42	3.59	1.77	–.04

If $E_{25} = 0.31748$ v. is taken as the best value for Cell 7, the electromotive force between 15 and 40° is given by the equation

$$E_t = 0.31748 + 0.000129\ (t-25)$$

within the limits of error of measurement in the case of Cells 517–522 and within the limits of reproducibility in the case of the cells of Table IV.

A small lag in the attainment of equilibrium was noticed in the case of Cells 517–522. Usually two or three days were required for the attainment of constancy, although the electromotive force was usually within 0.04 mv. of its final value one day after an increase in temperature of 5°.

For Cell 2 the electromotive force between 25 and 40° is given by the equation

$$E_t = 0.41702 + 0.000360\ (t-25)$$

The agreement is not good at 20°, perhaps because sufficient time was not allowed for equilibrium. Equilibrium was attained rapidly after an increase in temperature, but rather slowly after a decrease, and the measurements made after a decrease in temperature are to be considered less reliable than those made after an increase.[20] Both Cohen and Bruins[4a] and Yoshida[4b] gave as the temperature formula for Cell 2 an equation for a curve instead of a straight line. However, the above formula agrees with the experimental values of Cohen and Bruins within 0.1 mv., and if the first term on the right-hand side of the equation (the value at 25°) were increased by 0.1 mv., the formula would agree with all but one of their experimental values within 0.01 mv.

Discussion

The difference between the electromotive forces of Cells 2 and 7 should give the electromotive force of the cell

$$\mathrm{Cd(Hg)} \mid \mathrm{CdI_2,\ sat.} \mid \mathrm{CdI_2,\ sat.} + \mathrm{PbI_2} \mid \mathrm{Pb(Hg)} \qquad (10)$$

Subtracting $E_{\text{Cell } 7} = 0.31748 + 0.000129\ (t - 25)$ from $E_{\text{Cell } 2} = 0.41702 + 0.000360\ (t - 25)$, the value

$$E_t = 0.09954 + 0.000231\ (t-25)$$

is obtained for Cell 10 as compared with

$$E_t = 0.0996 + 0.000235\ (t-25) - 0.0000002\ (t-25)^2$$

previously found by the author,[7] which is in good agreement with the results of Obata[6] for the same cell. The agreement between the two formulas is within the experimental error of the latter. Thus, the results for Cells 2, 7 and 10 are consistent among themselves, and as the values for Cells 2 and 10 agree with those of other observers, it is probable that the value given for Cell 7 is correct.

From the results for Cell 7 the free energy change, entropy change and heat of reaction can be calculated for the reaction

$$\mathrm{Pb(s)} + \mathrm{Hg_2I_2(s)} \longrightarrow \mathrm{PbI_2(s)} + \mathrm{2Hg(l)}$$

If the electromotive force of Cell 7 is added to that of the cell[21]

$$\mathrm{Pb} \mid \mathrm{Pb^{++}} \mid \mathrm{Pb(Hg)};\ E_t = 0.0057 + 0.000016\ (t-25) \qquad \mathbf{(11)}$$

the electromotive force of the cell

$$\mathrm{Pb} \mid \mathrm{PbI_2,\ sat.} \mid \mathrm{PbI_2,\ sat.} + \mathrm{Hg_2I_2} \mid \mathrm{Hg} \qquad \mathbf{(12)}$$

is found to be $E_t = 0.3232 + 0.000145\ (t - 25)$. Therefore, for the above reaction $\Delta F_{25} = -14{,}915$ cal., $AS = 6.69$ cal. per degree and $AH = -12{,}920$ cal.

For the heat of formation of lead iodide Braune and Koref[22] found thermochemically $\Delta H_{20} = -41{,}850$ cal., and Gerke[21] found electrochemically $\Delta H_{25} = -41{,}859$ cal. From the latter value and from the heat of reaction of lead and mercurous iodide, the heat of formation of mercurous iodide is found to be

$$\mathrm{2Hg(l)} + \mathrm{I_2(s)} \longrightarrow \mathrm{Hg_2I_2(s)};\quad \Delta H_{25} = -28{,}939 \text{ cal.}$$

---

[20] In showing hysteresis only after a decrease in temperature these cells resemble Weston cells. The latter, however, have abnormally high values after a decrease in temperature while the former show abnormally low values.

[21] Gcrke, THIS JOURNAL, 44, 1703 (1922).

[22] Braune and Koref, *Z anorg Chem.*, 87, 180 (1914).

This agrees with the value of Varet,[23] A H = —28,850 cal., and less well with the value of Nernst,[24] *AH* = —28,400 cal., but does not agree with the value of Thomsen,[25] *AH* = —31,100 cal.

The electromotive force of Cell 2 (Table V) can be combined with the electromotive force of the cell[26]

$$Cd \mid Cd^{++} \mid Cd(Hg);\ E_t = 0.0505-0.000244\ (t-25) \qquad (13)$$

to give the electromotive force of the cell

$$Cd \mid CdI_2, \text{sat.} \mid CdI_2, \text{sat.} + Hg_2I_2 \mid Hg;\ E_t = 0.4675 + 0.000116\ (t-25) \qquad (14)$$

From this it can be calculated that for the reaction

$$Cd(s) + Hg_2I_2(s) \text{ --+ } CdI_2(s) + 2Hg(l)$$

$\Delta F_{25} = -21{,}575$ cal., $\Delta S_{25} = 5.35$ cal. per degree and $\Delta H_{25} = -19{,}979$ cal. If the above value for the heat of formation of mercurous iodide is taken as correct, the heat of formation of cadmium iodide is found to be

$$Cd(s) + I_2(s) \longrightarrow CdI_2(l);\ \Delta H_{25} = -48{,}918 \text{ cal.}$$

Thomsen[27] found *AH* = —48,830 cal.

Summary

The following cells were set up and their electromotive forces measured at 25° and at five degree intervals between 20 and 40°:

$$Pb(Hg) \mid PbI_2 + x\ M\ KI \mid x\ M\ KI + PbI_2 + Hg_2I_2 \mid Hg$$
$$Pb(Hg) \mid PbI_2 + CdI_2, \text{sat.} \mid CdI_2, \text{sat.} + PbI_2 + Hg_2I_2 \mid Hg$$
$$Cd(Hg) \mid CdI_2, \text{sat.} \mid CdI_2, \text{sat.} + Hg_2I_2 \mid Hg$$

The electromotive force of the first two was found to be $E_t = 0.31748 + 0.000129\ (t - 25)$ volts. The two cells agreed within the limits of reproducibility of the first, which was the less reproducible of the two.

The electromotive force of the third was found to be $E_t = 0.41702 + 0.000360\ (t - 25)$ volts, which is in good agreement with the results of Cohen and Bruins and Yoshida for the same cell.

From the electromotive forces of the cells the free energy and entropy changes and heats of reaction for the corresponding reactions were calculated. From the latter and a reliable value for the heat of formation of lead iodide the heats of formation of mercurous iodide and cadmium iodide were calculated to be

$$2Hg(l) + I_2(s) \longrightarrow Hg_2I_2(s);\ \Delta H_{25} = -28{,}939 \text{ cal.}$$
$$Cd(s) + I_2(s) \longrightarrow CdI_2(s);\ \Delta H_{25} = -48{,}918 \text{ cal.}$$

THE USE OF PICRIC ACID AS AN ARTIFICIAL STANDARD IN THE COLORIMETRIC ESTIMATION OF SILICA

BY E. J. KING AND C. C LUCAS

RECEIVED JUNE 11, 1928 PUBLISHED SEPTEMBER 5, 1928

The determination of small amounts of silica in natural waters has been shown to be of industrial value as well as scientific interest. Diénert[1] has shown the importance of the silica content of ground waters in relation to their origin. In his studies of town water supplies, Thresh[2] noted an inverse relationship between the silica content of the water and the action of dissolved oxygen on lead pipes. The possible biological importance of silica was commented on by Richter,[3] who observed that artificial cultures of marine organisms thrived in glass vessels but that very poor development occurred in paraffined containers.

Atkins[4] investigated the possibility of a lack of silica being a limiting factor in the multiplication of phytoplankton.

Since the gravimetric determination of traces of silica in water is both long and tedious, Diénert and Wandenbulcke[5] proposed a colorimetric method based on the production of a highly colored yellow silico-molybdic acid. When dilute silica solutions are treated with an acid and ammonium molybdate, a color develops which exactly matches that of dilute picric acid solutions. Diénert and Wandenbulcke proposed an artificial standard of 36.9 mg. of picric acid per liter as being equivalent to 50 mg. of silica per liter. The permanence of the picric acid solution renders it a more desirable standard than the relatively unstable silicate solutions which might be used. The procedure consists in adding 2 cc. of a 10% solution of ammonium molybdate and 4 drops of 50% (by volume) sulfuric acid to 50 cc. of solution. The yellow color which develops reaches its maximum in less than ten minutes and remains constant for some time. Appropriate dilutions of the picric acid standard are made and the solutions are compared in a colorimeter or in Hehner tubes.

Atkins[4] followed the above procedure in his studies of the silica content of natural waters and used the 36.9 mg. picric acid standard. Thresh and Beale[6] regard the colorimetric method as being as accurate as the

[6] J. C. Thresh and J. F. Beale, "The Examination of Waters and Water **Supplies,**" 1925, London.

gravimetric, but recommended the use of 40 mg. of picric acid per liter as a standard equal to 50 mg. of silica per liter.

As a result of a series of colorimetric determinations of the silica content of marine waters on the west coast of Canada, in which unusually high values were obtained, the picric acid standards used were suspected of being at fault. This led to a careful comparison of the color intensities given by picric acid and silicate solutions. For this purpose a standard solution was made containing 40 mg. of vacuum dried, C. P., picric acid per liter. This solution was found to have considerably more color than that developed in a solution containing 50 mg. of silica per liter when treated with ammonium molybdate and sulfuric acid.

Standard picric acid solutions containing 40 mg. per liter were prepared from various makes of C. P. picric acid, all of which were dried to constant weight in a vacuum desiccator. Solutions made from picric acid recrystallized from water, from ethyl alcohol and from benzene had the same depth of color as the other standard solutions. This seemed satisfactory evidence that the picric acid solutions used had a definite and constant color value.

Merck's pure silica was dried in a muffle furnace at red heat to constant weight. The material was cooled in a desiccator and weighed rapidly to avoid any possible adsorption of moisture. An excess of anhydrous sodium carbonate (Kahlbaum) was mixed in a platinum crucible with 0.2000 g. of silica and cautiously heated to fusion. The melt was cooled, dissolved in distilled water and made up to 200 cc. Five cc. of this solution when diluted to 100 cc. gave a concentration of silica of 50 mg. per liter. When treated with ammonium molybdate and sulfuric acid, a color was again obtained which was much less intense than that of the 40 mg. picric acid standard.

Pure silica was prepared by treating washed sea sand with calcium fluoride and concentrated sulfuric acid. The silicon tetrafluoride which was produced was passed into distilled water and the hydrated silica formed by hydrolysis was collected on a filter, washed and dehydrated in a muffle furnace. A silicate solution made from this material developed the same intensity of color as the former solution.

The color values of these silicate solutions when read against the 40 mg. picric acid standard in a Duboscq colorimeter are given in the accompanying table.

TABLE I

COLOR VALUES OF 50MG. SILICATE SOLUTIONS AGAINST 40MG. PICRIC ACID STANDARD

	Silicate solns. prepared from	Reading of test, mm.	Reading of standard, mm.
(1)	Commercial silica dust	10.0	6.3
(2)	Powdered quartz	10.0	6.3
(3)	Commercial silica dust	10.0	6.4
(4)	Merck's pure silica	10.0	6.4
(5)	Silica from silicon tetrafluoride	10.0	6.4

A stock solution (containing approximately 1 mg. of silica per cc.) made from Baker's C. P. $Na_2SiO_3 \cdot 9H_2O$ was tested colorimetrically. Five cc. of this solution, diluted to 100 cc., when treated with acid and molybdate developed a color of such intensity that with the test set at 10.0 mm. the standard read 6.0 mm.

Two hundred-cc. portions of the stock solution were analyzed gravimetrically with the following results: silica from 200 cc. of stock solution, (1), 0.1874 g.; (2), 0.1867 g.

Since by analysis the stock solution was only 93.6% of its stated concentration, the dilute solution prepared from it was also under strength to the same degree. Consequently, a solution containing 50 mg. of silica per liter when set at 10.0 in the colorimeter would give a standard reading of 6.0 mm. X 100/93.6 = 6.4 mm.

From the foregoing figures it would appear that a picric acid solution, to show equal color to that given by a 50 mg. per liter silica solution treated with the reagents, should contain 0.64 X 40 = 25.6 mg. of picric acid per liter. A solution of this concentration was prepared and found to have the same intensity of color as that given by the silica solution when matched in a Duboscq colorimeter or in Hehner tubes.

It was thought that the discrepancy between our results and those of other workers might lie in their having used commercial picric acids. Since considerable amounts of water are added to picric acid by the manufacturers to eliminate the possibility of explosion in transit, care must be taken to dry the material thoroughly before attempting to use it in quantitative work. Possibly the earlier workers neglected to take this precaution. To test this point crystals were taken from the top of a freshly opened bottle of Baker's picric acid. A solution of the proper color value required 36 mg. per liter of these crystals, but when dried to constant weight in a vacuum desiccator over calcium chloride only 26 mg. per liter was necessary. Samples of picric acid from different bottles had widely varying moisture contents and even in the same bottle the moisture content at different levels varied considerably. While most reputable brands of picric acid when dried to constant weight give solutions of maximum color value, recrystallization from benzene according to the method of Benedict[7] may be resorted to if the purity of the sample is in doubt.

Summary

The intensity of the yellow color given by a silicate solution containing 50 mg. of silica per liter when treated with the reagents of Diénert and Wandenbulcke is equivalent to that of a solution of picric acid containing 25.6 mg. of vacuum-dried, C. P. picric acid per liter.

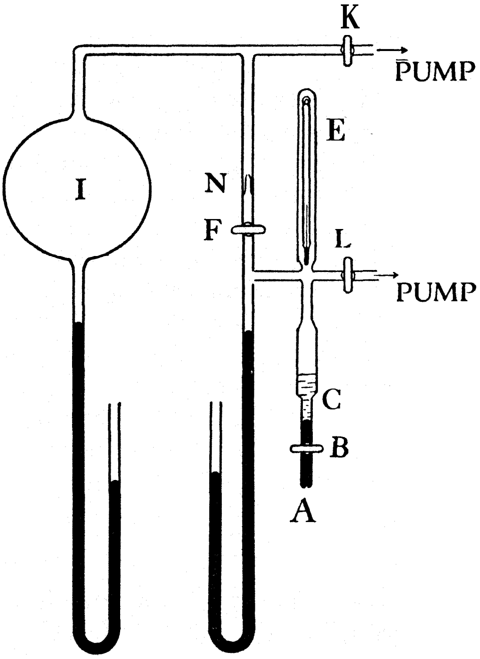
MOLECULAR WEIGHTS OF SATURATED VAPORS BY THE EFFUSION METHOD

BY HENRY EYRING

RECEIVED JUNE 25, 1928 PUBLISHED SEPTEMBER 6, 1928

The application of the method of effusion in measuring the molecular weights of gases has been carefully studied by a number of investigators[1] since Graham first announced it. The success of the procedure depends upon accurate time and pressure measurements and upon the selection of an orifice of dimensions which reduce viscosity effects to a minimum. Under such circumstances molecular weights having an accuracy of 1% for gases of rather different properties are attainable.



Pig. 1.

It seemed desirable to devise a rapid method of estimating the molecular weight of organic vapors if certain obvious difficulties could be overcome. The final all-glass apparatus which satisfactorily accomplishes this purpose was constructed as shown in Fig. 1.

The operations consist simply in evacuating the whole apparatus with a Hyvac pump, then admitting liquid into the vessel at B. The stopcock is then opened and the time taken with a stopwatch for the pressure in the receiving chamber to rise to some predetermined pressure. The same operations are repeated with air, care being taken to adjust stopcock B so that the pressure of air remains constantly equal to the vapor pressure of the liquid whose molecular weight is to be determined. The following data were obtained using purified isopropyl alcohol: time for air, 140 seconds; time for isopropyl alcohol, 202 seconds. Then the molecular weight of isopropyl alcohol = $(202/140)^2$ 28.8 = 60. The

---

[1] Bunsen, "Gasometry," p. 198; J. N. Edwards, "Technologic Papers of the Bureau of Standards," No. 94.

whole determination can be conducted in less than a half-hour and involves no weighings. The apparatus is simple, involves no washing and can be permanently attached to the wall. The method can be applied to gases and to all vapors with vapor pressures greater than that of water without using a cathetometer. This range of course can he extended to lower vapor pressures by making more accurate pressure measurements or by raising the temperature.

If the pressure in the receiving chamber is permitted each time to rise to one-half the vapor pressure (pressure on side containing liquid) exactly the same calculation as was used to compare it with air can be used to intercompare liquids of different vapor pressures without the calibration run. In Table I this method has been styled Method 2 to distinguish it from the procedure in which the time for each vapor is compared directly with the time for air called Method 1. Thus it took **227** seconds for benzene to build up a pressure equal to half its vapor pressure while it took **317** seconds for carbon tetrachloride. Assuming a molecular weight of benzene of **78** we have for carbon tetrachloride $(317/227)^2\ 78 = 152$. The advantage of Method No. 2 is the elimination of the comparison run with air effectually cutting the time of a determination in two. The disadvantage is that the vapor pressure must be accurately measured and exactly one-half the vapor pressure (or some other convenient fraction) be taken as the pressure rise in the receiving chamber. If a large number of determinations are to be made, undoubtedly the second method, using a cathetometer or mounted telescope, is most satisfactory. Under such circumstances successive determinations can be made in about fifteen minutes.

The following times obtained for air to reach a pressure in the receiving chamber of one-half the constant pressure maintained on the sending side show this time to be independent of the sending pressure.

Pressure in cm..................	73.35	57.35	44.00	24.80
Time of half press. incr., sec.......	163.0	164.3	163.3	165.5

The independence of time of this "half pressure increase" follows from kinetic theory. Equation (315) of Jeans, "The Dynamical Theory of Gases," may be slightly modified to give

$$dn = \frac{(p_0 - p)}{\sqrt{2\pi MRT}} A\,dt = \frac{V_r dp}{RT}$$

where dn is the number of moles effusing through an orifice of A square centimeters per dt seconds; $p_0 - p$ is the vapor pressure minus the pressure in the receiving chamber, that is, the effective pressure; M is the molecular weight; R is the gas constant in ergs per degree; T is the absolute temperature and V_r is the volume of the receiving chamber.

Whence

$$dt = \frac{V_r}{A}\sqrt{\frac{2\pi M}{RT}}\,\frac{dp}{p_0 - p}$$

and

$$t = 2.303\,\frac{V_r}{A}\sqrt{\frac{2\pi M}{RT}}\,\log\frac{p_0}{p_0 - p} = \frac{V_r}{A}\,6.37 \times 10^{-4}\sqrt{\frac{M}{T}}\,\log\frac{p_0}{p_0 - p}$$

For $p = p_0/2$, we have

$$M = T\,t_0^2\left(\frac{A}{V_r}\right)^2 1572^2\left(\frac{1}{0.310}\right)^2$$

From this it is seen that the time for the pressure in the receiving chamber to reach one-half the sending pressure (or any other fraction) is independent of the sending pressure. The formulas for the preceding calculations of molecular weights follow immediately from the deduction above, since when the temperature T is constant, $M = Kt_0^2$. The cross sectional area of the orifice was calculated by taking $V_r = 2656$ cc.; $T = 296°$; $t_0 = 164$; whence A was found to equal 0.00097 sq. cm. or 0.097 sq. mm.

Orifices of platinum were found unsatisfactory, presumably because of flaps which changed the sizes of the openings. Glass orifices considerably smaller in cross section introduced errors due to viscosity. One orifice prepared by sending a large spark through the glass gave satisfactory results for the molecular diameter of hydrogen assuming viscous flow but entirely unsatisfactory results for its molecular weight using the relationship above. Apparently the leak was through a large number of small cracks.

The orifice shown in Fig. 1 at *N* was made by blowing a thin round bulb on 6 mm. glass tubing. A hot glass rod was then used to pull a small capillary out from the bulb which was then broken off flush with the bulb surface, giving an opening of 0.1 sq. mm., approximately. With an orifice of this size the receiving chamber should have a volume of about two and one-half liters to give a convenient time of efflux

Certain details of operation seem necessary for the success of a determination. After evacuating the system, F and K are closed and a weighing bottle containing mercury and the liquid is placed at **A** and mercury drawn up until it reaches the stopcock B. The apparatus is re-evacuated, I, being then closed. The weighing bottle is then lowered slightly and B opened until sufficient liquid is drawn into the apparatus. The weighing bottle is raised, mercury again being drawn up until any liquid in the neighborhood of the stopcock B has been displaced. In this wav there was no difficulty in keeping a stopcock, lubricated with ordinary stopcock grease, from leaking with any organic liquids. Using either a pinch clamp on rubber tubing or a stopcock lubricated with phosphorus pentoxide proved unsatisfactory.

After introducing the liquid the stopcock F was turned at the same time a stop watch was started. The vapor pressure was kept at the desired pressure by occasionally warming the liquid C with the hand. When air is being run it can be kept very accurately at the desired pressure by occasionally partially closing **A** with the finger.

Some typical results are given below.

In addition to these experiments Mr. P. B. Tuttle made determinations on a number of substances not listed here, obtaining satisfactory results. The vapor from the constant boiling mixture of hydrochloric acid at 73.8

[a] Assumed in determining constant.

cm. pressure gave a molecular weight of 22, showing the absence of association.

It has been customary to explain the high specific heat of saturated (wet) steam by assuming it to be due to the presence of large molecular aggregates.[2] Such aggregates might be due to a mechanical suspension of water or to associated molecules. The values obtained for saturated water vapor at room temperature give no indication of association. This seems consistent with results obtained by others using different methods.

The investigation of any supposedly associated vapors should yield interesting results. The simultaneous determination of successive vapor pressures and molecular weights of mixtures of organic liquids as the mixed vapors pass through the orifice N should be of value in analysis.

Summary

A method for the rapid determination of molecular weights of saturated vapors has been outlined. No appreciable association of saturated water vapor, of the vapor from constant boiling hydrochloric acid nor of organic vapors was observed.

THE MECHANISM OF HOMOGENEOUS GAS REACTIONS. I. THE EFFECT OF BLACK BODY RADIATION ON A MOLECULAR BEAM OF NITROGEN PENTOXIDE[1]

BY F. O. RICE, H. C. UREY AND R. N. WASHBURNE[2]

RECEIVED JUNE 27, 1928 PUBLISHED SEPTEMBER 5, 1928

The homogeneous unimolecular character of the decomposition of nitrogen pentoxide first studied by Daniels and Johnston[3] has now been thoroughly established by a large number of investigations.[4] However, in spite of a large amount of theoretical work,[5] the mechanism of the reaction cannot be regarded as well understood. The attempts to explain the mechanism of the nitrogen pentoxide decomposition in common with other reactions are based upon the Arrhenius hypothesis of active and inactive molecules. There is only one exception to this, namely, the form of the radiation hypothesis in which it is assumed that the molecule absorbs a quantum of light and decomposes in a single act. The velocity of the reaction would therefore be proportional to the density of radiation capable of decomposing the molecule. Since the density of this radiation increases exponentially with the reciprocal of the absolute temperature, the temperature coefficient of the reaction is satisfactorily explained. On the basis of all other hypotheses it seems necessary to assume a process of activation in order to account for the temperature coefficient. Our difficulties arise when we attempt to devise a process of activation, for this must be much more rapid than the observed chemical reaction. We may conveniently summarize the various proposals that have been made, as follows.

1. The Simple Radiation Hypothesis.—This can be represented by

$$AB + h\nu \longrightarrow A + B$$

Or we may have a process of activation of the type

$$AB + h\nu \longrightarrow AB'$$

followed by the reaction

$$AB' \longrightarrow A + B$$

$$AB' + AB \longrightarrow A + B + AB$$

$$AB' + AB \longrightarrow 2A + 2B$$

[3] Daniels and Johnston, THIS JOURNAL, **43,** 53 (1921).

[4] A summary of these is given by Rice and Getz, *J. Phys. Chem.*, **31,** 1572 (1927).

[5] Most of these references are included in a review of the radiation hypothesis, Daniels, *Chem. Reviews*, **5,** 39 (1928).

In the last two examples the velocity of the reaction will fall with decreasing pressure.

It should be pointed out, however, that nitrogen pentoxide does not absorb in the region such that $Nh\nu$ is equal to the heat of activation as calculated from the temperature coefficient of the reaction.

2. The Elaborated Radiation Hypothesis.—On the basis of this hypothesis nitrogen pentoxide for example is supposed to absorb successive quanta such that the total is equal to the heat of activation. Nitrogen pentoxide has a very strong absorption band at 5.81 μ such that absorption of five of these quanta would give the heat of activation. It should be pointed out, however, that the coefficient of absorption of compounds (including nitrogen pentoxide) would have to be many orders higher than ever observed to account for the observed rates of chemical reactions. It must also be noted that infra-red radiation does not increase the rate of chemical reactions.[6]

3. Radiation Hypothesis with a Chain Mechanism.—On the basis of this hypothesis it is assumed that the molecule of nitrogen pentoxide activated by radiation starts a chain of successive reactions which results in the final decomposition of many molecules. This suggestion will not explain the decomposition of nitrogen pentoxide for reasons given under (2) and in addition any chain mechanism appears to be improbable because the energy change for the entire reaction is very small; it would be necessary to assume that one of the products of a decomposing nitrogen pentoxide molecule carried all the energy of activation and others none and farther that this energy would be completely transferred to another nitrogen pentoxide molecule and not to any other molecules. This appears to be very improbable.

4. Sir J. J. Thomson Hypothesis.—On the basis of this hypothesis[7] it is assumed that a molecule of nitrogen pentoxide may acquire energy of activation from the surrounding medium by some other means than radiation or collisions with other molecules. He postulates that the amount of energy possessed by a molecule may fluctuate with the time and that only on the average is energy conserved. He assumes that the probability that a molecule will acquire a certain energy is an exponential function of its internal energy. Our experiment throws no light on this hypothesis.

5. Activation by Molecular Collisions.—On the basis of this hypothesis, a molecule of nitrogen pentoxide is assumed to obtain its energy of activation by collision with another molecule. In this case the rate of activation is proportional to the number of collisions and should therefore

---

[6] Hibben, THIS JOURNAL, 50, 937 (1928) The paper contains the references to previous work.

[7] Thomson, *Phil.* Mag., [7] 3,241 (1927).

be proportional to the square of the concentration. In order that the reaction may be experimentally unimolecular it is necessary to assume that the rates of activation and deactivation are very rapid compared to the rate of the reaction and further that the rate of decomposition of the activated molecules is a truly unimolecular process which is independent of collisions of the activated molecules; thus the probability of decomposition of an activated molecule per unit time is no greater during collision than during the time between collisions. This last condition seems to be supported by the fact that nitrogen pentoxide decomposes at the normal rate when dissolved in liquids, with the exception of nitric acid.4 This exception is due probably to the formation of a complex compound.

Attempts have been made to test this hypothesis by conducting experiments at low pressures which should at sufficiently low pressures change the order of the reaction from unimolecular to bimolecular and decrease the absolute rate. The experiments that have been published so far are contradictory.[8] We are unwilling to discuss these papers because some work in this Laboratory by Miss E. Wilson has yielded results differing from both these papers. Preliminary measurements show that the rate falls off even at pressures of several mm.

The difficulty of deciding the mechanism of the decomposition of nitrogen pentoxide or any other reaction lies perhaps in the fact there are three processes occuring simultaneously in reactions as ordinarily studied. These three processes are *(a)* absorption and emission of radiation, (b) intermolecular collisions and (c) collisions with the walls of the vessel. It is the purpose of this series of papers to separate these three effects and study them independently. The first effect may be isolated from the other two by allowing a molecular beam of nitrogen pentoxide to pass through a furnace, within which approximately black body radiation is maintained. Similar work has been done by Kröger[9] using iodine and by Lewis and Mayer, and Mayer[10] using pinene. They report no reaction in either case. The results of our investigation are in accord with these results; no detectable decomposition occurred.

The second effect may be isolated by allowing two beams to impinge as was done by Kroger for cadmium and iodine and cadmium and sulfur. Undoubtedly this is impractical in the case of nitrogen pentoxide because in the first place the total number of collisions is small and only a very minute fraction of these would result in active molecules.

The third factor may be isolated by allowing the beam to impinge

on a heated surface from which it is reflected to a surface cooled to liquid air temperatures. Mr. I,. A. Staib has undertaken experiments of this character in this Laboratory. Such experiments offer the possibility of determining the life of excited molecules providing it happens to be of the order of magnitude of the time of flight from the activating to the collecting surfaces. This point, however, will be discussed in greater detail in a following paper.

Apparatus and Methods

Molecular **Beam** Apparatus.—The apparatus with which the final experimental work was done (see Fig. 1) was made of Pyrex glass. The nitrogen pentoxide evaporates from the storage reservoir (not shown) and enters the beam chamber, C, through the 3 mm. hole, a, in the end of the delivery tube, B; 9 millimeters above a is the rough defining hole, b, which is 4 mm. in diameter. The final defining hole, c, 1 mm. in diameter, is 10 millimeters above b. The holes b and c are in the center of glass disks which were sealed into the apparatus when it was constructed. This eliminates the possibility of any nitrogen pentoxide entering the furnace chamber other than through c. The beam of nitrogen pentoside issuing from the chamber C passes through the furnace, D (described in detail below), and is condensed on the liquid-air cooled surface E. This surface is the base of the cylindrical tube, F, which is introduced into the apparatus by means of a ground-glass joint at G. This facilitates the removal of the sample for analysis at the completion of an experiment. The surface, E, which is 2.6 cm. in diameter, is surrounded by a collar 1.3 cm. high which serves as an auxiliary condenser to reduce losses that would occur if the molecules did not condense upon the first collision with E.

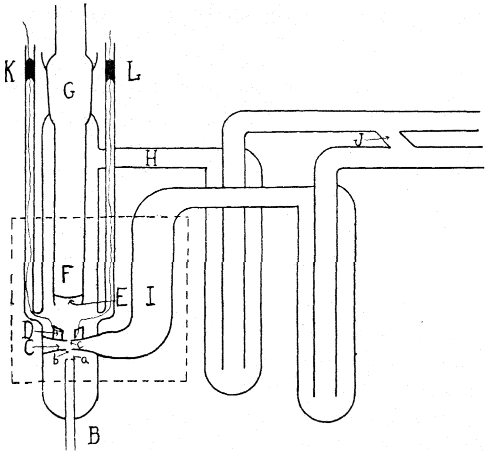

Fig 1.—Molecular beam apparatus.

The apparatus is evacuated through H and I, which lead to separate liquid-air traps and Stimson two-stage diffusion pumps. The two branches are connected at J to eliminate any circulation of gases through the region C should the diffusion pumps not be working with equal efficiency. A single Nelson oil pump was used as a fore pump. Pressures were measured with a McLeod gage with which pressures of 10^{-5} mm. of mercury could be read accurately, and those in the 10^{-6} order were estimated within 10%.

Furnace.—The furnace D used as a source of black body radiation (see Fig. 2) was made from a piece of Pyrex tubing 1.2 cm. long with an inside diameter of 8.8 mm. It is suspended by three glass prongs, a, from platinum stirrups, b, fused in the glass collar D which rests upon the plate containing the final defining hole. The furnace is heated electrically with a platinum wire (0.14 mm. dia.) wound spirally about it in a groove made for that purpose. Electrical current is supplied through heavy platinum leads and tungsten seals at K and L (Fig. 1). The groove, which encircles the furnace ten times, was etched into the glass with hydrofluoric acid. The distance between successive spirals is 1 mm. The furnace was firmly mounted on a spool-like core which could be fitted into the chuck of a lathe. The glass was coated with a thin layer of wax in which a spiral was cut with a needle-like tool mounted in the tool carrier. By adjusting the latter for a screw pitch of 24 turns to the inch, a very uniform spiral was obtained. The furnace was then immersed in hydrofluoric acid for five minutes. Longer immersions were found to widen the groove too much. By repeating the above process five times a sharply defined groove about 0.2–0.3 mm. deep was obtained, a depth sufficient to prevent the wire from slipping off the furnace when heated. The furnace was then wired and in the finished furnace 8 complete winds (*23.2* cm.) were effective in heating. Current input was measured by a milliammeter and voltmeter.

The portions of the apparatus which had to be at liquid-air temperatures are included within the dotted lines in Fig. 1. This cooling was finally effected by covering the glass with lead foil to increase thermal conduction and circulating liquid air from a container above the apparatus through a ten foot length of rubber tubing, which had been wound snugly about the two branches of the apparatus. The whole region was heavily insulated with asbestos and cotton to make the cooling more efficient. To maintain circulation of the liquid air through the rubber tubing a gentle suction was applied at the free end. If suction is not applied moisture condensing from the air soon plugs the tube with the result that the temperature of the apparatus rises. Tests made with a large test-tube wound with rubber tubing in this way showed that temperatures of about −170° could be maintained. The reservoir is heavily insulated with felt, the liquid air level being indicated by a wire attached to a cork float. A very fine wire gauze in the bottom of the reservoir prevents ice crystals from entering the rubber tube and plugging it. This method of cooling was found entirely satisfactory aside from the fact that about *700* cubic centimeters of liquid air was required per hour.

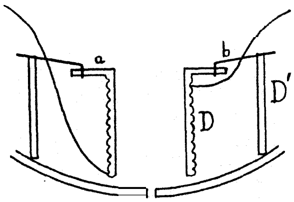

Fig 2.—Furnace.

The final experiments were made with the supply of nitrogen pentoxide at a temperature of −60 ± 1°. This temperature was maintained by surrounding the reservoir with toluene contained in a Dewar flask. The Dewar flask was likewise surrounded by a larger one containing carbon dioxide snow and ether. As the inner Dewar was not very highly evacuated, heat was conducted from it nearly as fast as absorbed from the apparatus. The temperature of the toluene was measured with a pentane thermometer and controlled by the addition of small pieces of carbon dioxide snow or with a nichrome heating wire. Aside from frequent stirring, little attention was needed to maintain the desired temperature.

In experiments in which the crystals were kept at the temperature of carbon dioxide snow and ether or liquid ammonia, the nitrogen pentoxide reservoir was merely immersed in a Dewar flask containing the desired substance. When liquid ammonia was used, the gas was kept from entering the room by bringing a metal funnel-like cap down over the flask. The funnel was connected to a suction pump and such a rapid flow of air maintained that no odor of ammonia could be detected.

The nitrogen pentoxide was prepared in the same manner as described by Rice and Getz.[4] Before distilling the crystals into the reservoir of the molecular beam apparatus they were raised to room temperature and all visible traces of nitrogen tetroxide removed by passing dried air over them. The use of ozone for purification of the nitrogen pentoxide was omitted to preclude the possibility that traces of it might be collected with the sample and subsequently oxidize the alkaline nitrite solution. The traces of nitrogen dioxide which were always present could be corrected for by the blank runs, that is, experiments in which the furnace was not heated.

Experimental Procedure

The experimental procedure can best be described by a brief outline of the steps involved in an actual determination. A phosphorus pentoxide tube is sealed to the projection of the storage bulb of the molecular beam apparatus. The main supply of nitrogen pentoxide is then connected to this tube and a third drying tube is sealed in at this junction and air drawn through it over the crystals, which are at room temperature, until visible traces of nitrogen dioxide are removed. The lower end of the reservoir is now surrounded with carbon dioxide snow and ether and about 3–4 g. of nitrogen pentoxide condensed by evacuating the system. The lower ends of the liquid-air traps are immersed in liquid air to prevent mercury vapor from distilling back into the reservoir during the process. The main supply of crystals and the drying tubes are then removed and the reservoir is immersed in the toluene bath described above. To remove the greater portion of the nitrogen dioxide formed in the above transfer the diffusion pumps are started and the toluene is kept at $-35°$ for about one and one-half hours. During this time the furnace is heated to 300–400° to drive off adsorbed gases. Finally the tolurne is cooled to $-60°$ and liquid air is then introduced into the liquid-air reservoir and the collecting tube F. In about one and one-half hours the molecular beam apparatus comes to liquid-air temperature. The burners under the diffusion pumps are turned down and air, which passes through soda lime, calcium chloride and phosphorus pentoxide is admitted. The collecting tube is removed while a current of air is forced through the apparatus to prevent the diffusion of moisture into it. The opening is immediately closed with an inverted beaker having a rubber collar which fits tightly about G. The collecting tube is washed off and dried, by warming in a flame and wiping with a linen cloth before putting it back into the apparatus. The burners under the diffusion pumps are lighted, liquid air is poured into the collecting tube and the fore pump started. In four minutes the pressure in the apparatus drops to 1×10^{-5} mm. of mercury and in six minutes to less than 1×10^{-6}. Readings of the current input and the pressure are taken frequently during the runs. At the end of the desired time the sample is removed and dissolved in dilute potassium hydroxide (1 cc. of 0.001 *N* KOH made up to 20 cc.). The collecting surface and collar are thoroughly rinsed into the solution and the tube is dried as above before returning to the apparatus. The experiments were carried out in series of from five to nine runs each.

Analytical Methods.—The nitrite content was determined by a method described in a bulletin of the American Public Health Association[11] and the nitrate content by the method of Chamot, Pratt and Redfield.[12] These methods make it possible to determine 0.001 mg. of nitrite nitrogen and 0.1 mg. of nitrate nitrogen to within 2–3%.

Calculations

Before the experiments which have been described were undertaken, it was necessary to make preliminary calculations on the amounts of nitrogen pentoxide which would pass through the defining holes of our molecular beam apparatus, the time the molecules are in the furnace and the furnace temperature required to secure measurable decomposition.

---

[11] "Standard Methods of Examination of Water and Sewage," American Public Health Association, 1920.

[12] Chamot, Pratt and Redfield, THIS JOURNAL, 33, 366, 381 (1911).

Stern[13] in his work on molecular beams has used pressures in the high pressure chamber such that the mean free path of the molecules is of the same order of magnitude as the width of his slit. Kroger and Lewis and Mayer have used much more intense beams and Johnson[14] has studied the intensities and sharpness of such beams as functions of the pressure. We found in this work that higher pressures than those used by Stern resulted in the freezing up of the defining holes. Since nitrogen pentoxide and nitrogen dioxide can be determined quantitatively in very small amounts, it was unnecessary to use beams of high intensity. It was found empirically that when the nitrogen pentoxide chamber was held at a temperature of −60°, a satisfactory beam was secured. The calculated vapor pressure at this temperature is 0.042 mm. using the formula of Russ and Pokorny;[15] assuming that the nitrogen pentoxide molecule has the same diameter as the benzene molecule, the mean free path would be 0.3 mm., which is only one-tenth of the diameter of the first defining hole. The amount of nitrogen pentoxide passing through the last defining hole can easily be shown to be

$$p\sqrt{\frac{M}{2\pi RT}} \times \frac{2A_1A_2}{d^2} \qquad (1)$$

where A_1 and A_2 are the areas of the defining holes, d is the distance between the holes and p is the pressure in dynes per sq. cm. The calculated amounts of nitrogen pentoxide passing the slit system per hour is 1–2 mg., which is about ten times the amount actually secured. This discrepancy may be due to a considerable error in calculating the vapor pressure of nitrogen pentoxide, to the fall in pressure along the tube leading from the storage chamber to the first defining hole and to a considerable time lag in the warming up of this tube from liquid air temperature to −60°.

We shall now calculate the fraction of the nitrogen pentoxide molecules which should decompose during their flight through the furnace, assuming that the probability of decomposition per unit time is the same in the beam as that observed when the gas decomposes in bulk. In making this calculation we shall use the following symbols: T = temperature of furnace; T' = temperature of N_2O_5 chamber; $K(T)$ = probability of decomposition per unit time at temperature T, that is, the velocity constant of the reaction; n_v = number of molecules having velocities lying between v and $v + dv$; n = total number of molecules of all velocities; x = coordinate along the axis of the furnace.

The number of molecules having velocities lying between v and $v + dv$ which decompose during the time dt is

$$K(T)\, n_v\, dt \qquad (2)$$

---

[13] Stern, *Z. Physik*, 39, 761 (1926).

[14] Johnson, *Phys. Rev.*, 31, 103 (1928).

[15] Russ and Pokorny, *Monatsh.*, 34, 1027 (1913).

Now

$$n_v = 4\pi\left(\frac{M}{2KT'\pi}\right)^{3/2} e^{-\frac{mv^2}{2KT'}} v^2\, \mathrm{d}v \tag{3}$$

and changing to the variable x instead of t by the relation $\mathrm{d}x = v\mathrm{d}t$ we have

$$\mathrm{d}n = -K(T)n4\pi\left(\frac{M}{2KT'\pi}\right)^{3/2} e^{-\frac{mv^2}{2KT'}} v^2\, \mathrm{d}v\, \frac{\mathrm{d}x}{v} \tag{4}$$

Integrating and remembering that $K(T)$ is a function of x, the position in the furnace, we have

$$\int\frac{\mathrm{d}n}{n} = 4\pi\left(\frac{m}{2KT'\pi}\right)^{3/2}\int e^{-\frac{mv^2}{2KT'}} v\, \mathrm{d}v \int -K(T)\mathrm{d}x \tag{5}$$

This gives

$$\ln\frac{n}{n_0} = \frac{\sqrt{2m}}{\sqrt{KT'\pi}}\int_0^l -K(T)\mathrm{d}x \tag{6}$$

Since we have taken x to be the coordinate along the axis of the furnace, this calculation applies only to those molecules passing directly along the axis. Molecules passing at an angle traverse a longer path and pass through a part of the furnace having a higher temperature. Since the results are negative, we shall assume that all the molecules pass along the axis; this approximation would merely reduce somewhat the theoretical decomposition. The last integration has been made graphically by calculating temperatures along the axis of the furnace; the velocity constants corresponding to these temperatures were then calculated from the formula $k = 4.98 \times 10^{13}\, e^{-\frac{24{,}700}{RT}}$ and plotted against corresponding values of x.

The temperature of the furnace was determined by placing a thermocouple against its inner wall. This gave a temperature of 793°K., which is a minimum value since heat was conducted away from the wall through the lead wires. We also suspended the thermocouple in the center of the furnace. It registered a temperature of 523°K., but a calculation of the amount of radiant energy falling on the thermocouple and that conducted away through the lead wires shows that this temperature must be far too low. In calculating the temperatures along the axis we assume that Pyrex glass radiates 0.9 as much energy per second as a black body. This makes the effective wall temperature of the furnace $793 \times 0.9^{1/4} = 771$°K. The temperature of a point on the axis distant x cm. from one end of the furnace is equal to the effective temperature of the furnace wall multiplied by the fourth root of the fraction of the solid angle subtended by the furnace at this point, divided by 4π. This is

$$771\left[\frac{l-x}{2\{(l-x)^2+r^2\}^{1/2}} + \frac{x}{2(x^2+r^2)^{1/2}}\right]^{1/4} \tag{7}$$

This gives a temperature of 718°K. and 634°K. for the center and ends of the furnace, respectively, and 10^6 for $\int_0^l K(T)\mathrm{d}x$; substituting the numerical values in Equation (6) we find for n/n_0 the value 10^{-27}, which means that only one molecule in 10^{27} should remain undecomposed. We performed additional experiments at higher temperatures which we estimated roughly from the relative power input; the effective wall temperatures were 806°K. and 846°K., that is, **35** and 75° higher than the temperature at which the detailed calculations have been made. We attempted to use the change of resistance with temperature of the furnace winding as a measure of its temperature but found this to be erratic. We attribute this to the conductivity of the Pyrex glass furnace, which was heated to its softening point.

In all these calculations we have used the least favorable assumptions and approximations so that the calculated decomposition should be less than if these assumptions and approximations were not made.

Experimental Results

The greater portion of this research was done with the furnace walls at 793°K. as determined by the thermocouple; this temperature is that used in the calculations given in the preceding section. Three runs were made at 806°K. and one at 846°K. as determined by the increased power input. These results are summarized in Table I. The percentages of nitrogen peroxide obtained are the same as in the original material, as shown by separate analysis. There is no indication of any decomposition whatsoever in the beam.

Discussion of Results

We have passed a beam of nitrogen pentoxide molecules through a furnace containing approximately black body radiation under such conditions that there was no intermolecular collision or collisions with the walls. The temperature of the furnace was such as to give practically complete decomposition if nitrogen pentoxide reacted at the rate secured by extrapolating the known experimental values obtained in the bulk decomposition to these higher temperatures. Since no decomposition occurred we have proved that infra-red radiation does not decompose nitrogen pentoxide molecules and there appears to be no special mechanism of absorption alone that can explain away this experiment. It may be pointed out that chains cannot occur in a molecular beam; consequently this experiment does not disprove the hypothesis which assumes a chain mechanism started by absorption of radiation.

It is convenient at this point to consider the probability of absorption of a quantum of light by a molecule passing through the furnace. This calculation is not essentially different from previous considerations showing that the coefficient of absorption of nitrogen pentoxide or other molecules would have to be very much larger than the observed values in order to account for the observed rate of decomposition. An approximate value for this coefficient for nitrogen pentoxide may be calculated from observations made by Warburg and Leithäuser;[16] for the region of the strongest absorption band, namely, 5.81μ, they find that the intensity is decreased to 0.7 of its initial value by passing through a column 30 cm. long containing nitrogen pentoxide at 0.5 mm. of mercury. This gives approximately 6.7×10^{-19} for the coefficient of absorption per molecule, *a*,. This is related to the Einstein probability coefficient, $B_{i \longrightarrow j}$, for a transition from a state i of lower energy to a state j of higher energy by the absorption of light of frequency v under the influence of unit energy density lying between the frequencies v and v + dv by the approximate formula,[17] $B_{i \longrightarrow j} = c/h\nu \int \alpha_\nu d\nu$, where the integral is to be extended over the whole range of absorption. As a further approximation we take the coefficient *a*, as constant over the region of the half width of the line; from Warburg's curve this half width is about 0.3μ. The $\int \alpha_\nu d\nu$ then becomes $c\alpha_\nu$ AX/X^2 and $B_{i \longrightarrow j}$ is 1.6×10^{17}. We have then for the rate of absorption of energy $dN/dt = -Nu_\nu B_{i \longrightarrow j}$; now assuming that each absorption results in decomposition we have $\ln (N_0/N) = u_\nu B_{i \longrightarrow j} t$. The mean life of the molecules is, therefore, $1/B_{i \longrightarrow j} u_\nu$; substituting the numerical value for $B_{i \longrightarrow j}$ and for u_ν the density of black body radiation of frequency v at a temperature of 900°K., we secure the value 9 seconds for the mean life. Since the molecules in this experiment are in the furnace for about 4×10^{-5} secs., only a negligible fraction could even absorb radiation of this strongest absorption band. Similar calculations

[17] See Tolman, "Statistical Mechanics," The Chemical Catalog Co., Inc., New York, 1927, p. 175.

using the absorption coefficients where an electron transition is involved, such as in the dissociation of bromine into a normal and an excited bromine atom, show that such dissociations could not be effected in a molecular beam using the most intense sources of light available. Thus the experiments of Kröger, Lewis and Mayer, Mayer and the present investigation are in entire agreement with the theoretical expectations.

Summary

1. In reactions as ordinarily studied there are three factors influencing the decomposition, namely, the absorption and emission of radiation, intermolecular collisions and collisions with the walls. Methods have been discussed for separating these three factors and studying them independently.

2. We have completed experiments on the effect of radiation alone on nitrogen pentoxide by passing a molecular beam of this substance through a furnace containing approximately black body radiation. Even at the lowest temperature only one molecule in 10^{27} should have escaped decomposition if black body radiation alone caused the decomposition under ordinary conditions. We could detect no decomposition in any experiment.

3. We have calculated the probability of absorption of radiation by the nitrogen pentoxide molecule and find the experimental result in agreement with theory.

TRANSFERENCE NUMBERS OF IONS IN SOLID SODIUM CHLORIDE AT HIGH TEMPERATURES

BY T. E. PHIPPS AND R. T. LESLIE

RECEIVED JUNE 30, 1928 PUBLISHED SEPTEMBER 5, 1928

For a large number of solid salts it has been shown that the relation between the electrical conductance and the absolute temperature may be represented by an equation of the form:

$$\ln k = A/RT + C \tag{1}$$

where k is the specific conductance, A is a heat quantity designated as the heat of liberation of the ions from the lattice, and R is the gas constant. It has been found, however, that this relation is not linear over the whole temperature range for sodium and potassium chlorides, bromides and iodides. Ussataja and Hochberg[1] have observed this deviation for sodium chloride above 500° and have attempted to apply an equation of the form

$$\ln k = AT + C \tag{2}$$

---

[1] Ussataja and Hochberg, *Z. Physik*, **46,** 88 (1927).

above this temperature. Phipps, Lansing and Cooke[2] and Phipps and Partridge[3] have investigated the above salts and have found that the relation between log k and $1/T$ is linear but that the curve shows two slopes. The upper is slightly greater than twice the lower slope for the halides of sodium and potassium mentioned above. The curve for sodium chloride is shown in Fig. 1. On account of the difficulty of measurement in the transition range, due probably to polarization effects, it is not certain whether the change in slope is gradual or abrupt.

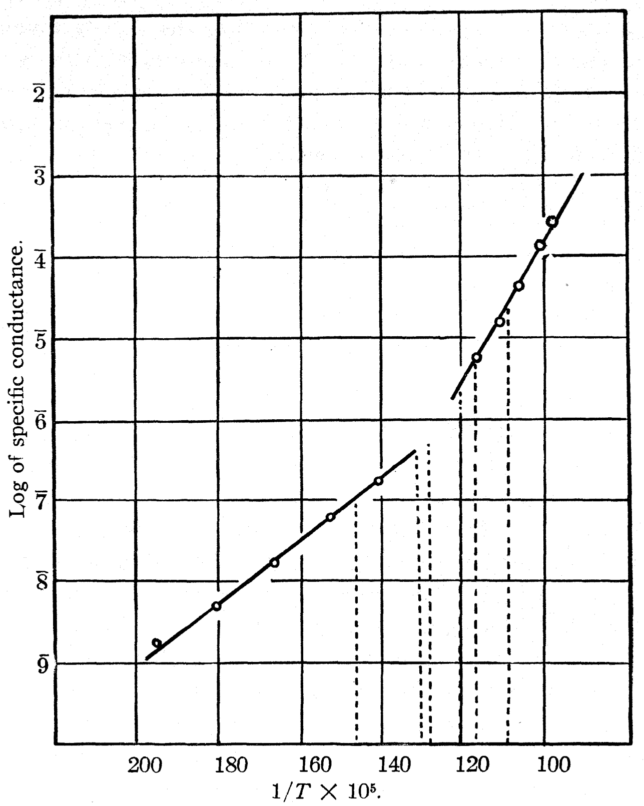

Fig. 1.—Temperature-conductance curve of solid sodium chloride. Dotted lines mark temperatures at which transference experiments were run.

Tubandt's[4] transference experiments upon salts of the less polar type such as the halides of silver and lead have indicated uni-ionic conduction in practically all cases. For these same halides a single slope is observed

---

[2] Phipps, Lansing and Cooke, This Journal, 48,112 (1926).

[4] Tubandt, *Z.* anorg. *allgem. Chem.,* 115,105 (1921).

when log k is plotted against $1/T$. The existence of two slopes in the conductance curves for the more polar halides of sodium and potassium led Phipps, Lansing and Cooke[2] to make the suggestion that there may be a change in the mechanism of conduction in the latter case as the temperature is raised, perhaps from uni-ionic to bi-ionic conduction. Smekal[5] interpreted the two-slope behavior just mentioned as supporting the "imperfect lattice" theory, the lower slope being determined by the heat of liberation of "Lockerionen" (that is, ions freer to move due to their position on the "inner surfaces" of the imperfect lattice) while the upper slope is determined by the heat of liberation of the "Gitterionen" (that is, the ions on the interior of units which are small enough to be considered as perfect). Smekal's conclusion rests upon the transference experiment of von Seelen[6] in which it was found that only the sodium ion moved in sodium chloride at 400°. This, however, is below the temperature at which the conductance curve changes slope.

Transference experiments were undertaken to determine if possible whether or not uni-ionic conduction persists at high temperatures in solid sodium chloride. The results may be briefly stated as follows. Transference by the chloride ion is negligible up to approximately 510°. At higher temperatures the chloride ion assumes an important part in the conduction.

Experimental

It has been suggested that the nature of the electrodes determines the mechanism of conduction. Thus Le Blanc and Kroger[7] have attributed the transference number of unity for silver in silver iodide, as observed by Tubandt,[4] to the fact that Tubandt used silver electrodes which provided a "follow-up" ion for the silver but not for the iodide ions of the lattice. In the present investigation it did not seem possible to design an electrode reversible for the chloride ion for use with sodium chloride at high temperatures. A metallic sodium anode and a nickel cathode were used. If Le Blanc and Kroger are correct in their surmise, the movement of the sodium ion would be favored by this choice of electrodes. In spite of the fact that the conditions might be considered adverse to the movement of the chloride ion, the results showed conclusively that the chloride ion took part in the conduction at high temperatures.

The chief difficulty encountered in the work was in the devising of a satisfactory sodium electrode. The final form of the apparatus which **was** used is shown in Fig. 2. The transference cell proper consisted of a block of rock salt, G, into which a hole was drilled to form a cup for the sodium, and three or four thin plates of salt upon which this cup rested. The cup constituted the anode portion and the plates the cathode portion. Attempts were made at first to use open cups, but the sodium spattered while

[7] Le Blanc and Kroger, *Z. Electrochem.*, 30,253 (1924).

being introduced and evaporated too rapidly during the run. To obviate these difficulties a salt cover having two small holes, one for the introduction of the sodium and the other for the nickel electrode wire, was finally used. The nickel electrode rested on the cover of the anode cup as may be seen in Fig. 2 (detail). This formed a direct path through the salt to the nickel cathode. However, calculation showed that not more than 3% of the current could have passed by this path instead of through the sodium in the cup. Even if the nickel electrode should force movement of the chloride ion at the expense of the sodium ion, an uncertainty of at most 0.03 in the transference number of either ion would result from this shunt around the sodium. It is thought that the actual error introduced here is much less than 0.03.

The cups were about a centimeter in cross section and two centimeters high, while the plates were from a quarter to a half a square centimeter in area and a tenth of a centimeter thick. The parts were smoothed with fine emery paper. It was found in this connection that fitting together of raw cleaved surfaces resulted in excessive sticking and faulty cleavage at the end of the experiment. All parts were given a preliminary heating to about 400°, cooled in a desiccator and weighed before the experiments.

The lower part of the frame, E, in which the crystals were held was constructed entirely of nickel in order to withstand the sodium vapor. The nickel plate cathode, H, was removable so that it could be washed separately from the rest of the frame, and the washings analyzed for salt in case the crystals stuck to it. This frame was suspended from the negative terminal in such a way that it could be removed to facilitate mounting the crystals before the run.

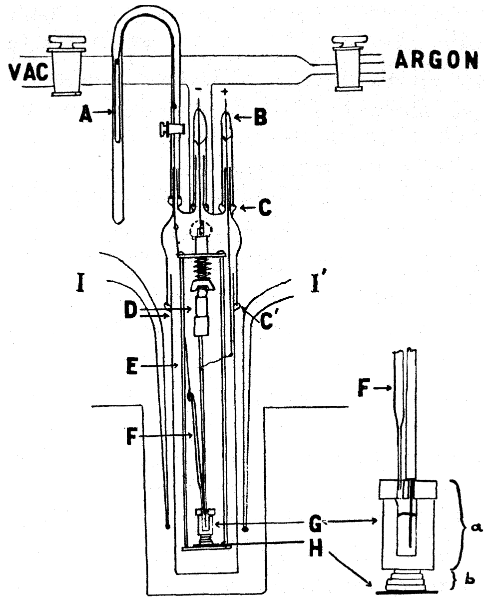

Fig. 2.—Apparatus used in determining transference numbers. A, brass counterpoise; B, tungsten-to-glass seals; C, C′, sealing wax seals; D, quartz; E, nickel frame; F, pyrex capsule filled with sodium; G, rock salt transference cell; H, removable nickel; I, I′, thermocouples; a, anode portion; b, cathode portion.

The tube inclosing the whole apparatus was of quartz to allow visibility during the introduction of the sodium into the anode cup and to withstand the high temperatures. The tube was considerably attacked by the sodium vapor at the high temperatures and became coated with the usual brown deposit of silicon together with a layer of soda glass, which had to be removed by treatment with hydrofluoric acid after each run. Failure to do this led to cracking of the tube when it was next heated. The quartz tube was joined at C′ with a sealing wax seal to the Pyrex cap shown in Fig. 2.

The glass capsule, F, was filled with sodium by the method described by Gibson and Phipps[8] and was suspended in the position shown in the figure with the brass counterpoise, A, drawn up and clamped by means of the stopcock.

---

[8] Gibson and Phipps. This Journal, **48,312** (1926).

To start the run the apparatus was evacuated to 10^{-5} or 10^{-6} mm. of mercury, and the temperature of the furnace surrounding the quartz tube was raised to about 150°. This caused the sodium to melt and run out of the capsule into the cup. The stopcock holding the counterpoise was then opened so that the capsule was drawn up into the cool part of the tube where it was not attacked by the sodium vapor. The stopcock to the vacuum pump was then closed and the apparatus filled with argon to about two atmospheres' pressure. This decreased the rate of evaporation of the sodium. Before the argon entered the apparatus it was passed through an alloy of sodium and potassium and through forty centimeters of magnesium perchlorate trihydrate in a vacuum-tight, all-glass train which was joined to the argon tank by a copper-to-glass seal.

The temperature was then brought up to the desired point and regulated automatically by a potentiometer, contact galvanometer and stick-relay system which was actuated by the thermocouples, I, I′, shown in the figure. This regulator had been previously calibrated in a blank run by inserting a Pt, Pt-Rh thermocouple in the position occupied by the crystals in an actual run. Regulation was found to be within a degree.

The total current through the crystals was measured by a silver coulometer and was kept below a milliampere to prevent heating. At high temperatures the sodium evaporated rapidly from the cup and it was necessary to determine by trial how long the run could be continued without losing all of the sodium.

The cathode crystals were colored blue in all of the runs above 410° except in the experiments where artificially grown sodium chloride plates were used, in which case a brown color resulted. All of the other parts remained colorless. The amount of sodium which diffused into the cathode plate was doubtless negligible, as shown by the work of Phipps and Mason.[9] Its presence could not have given rise to metallic conductance since only the end crystal was colored. A layer of metallic sodium was generally found between the cathode crystal and the nickel plate. Much of the sodium liberated at this interface distilled to the cooler parts of the apparatus.

Immediately after the apparatus was opened the cup and the cover were separated from the salt plates. The two parts were dropped as quickly as possible into separate portions of absolute alcohol and the sodium allowed to dissolve. The crystals were then rinsed with alcohol, the rinsings being added to the proper washings, and dried at 130° for several hours. The cup and cover were weighed together as anode portion. The plates remained stuck together and were weighed as cathode portion.

The possibility of serious error due to faulty cleavage made necessary the following rather elaborate procedure. To determine the cleavage

---

[9] Phipps and Mason, *Ill. Acad. of Science*, **18,304 (1925).**

error in the weight of the anode and cathode crystals, the plate next to the cathode was first split off and the remaining block of crystals again weighed. The change in weight due to transference should have occurred in this first plate. The next plate in order was then split off and the remainder weighed. This was continued until all the plates had been separated. The group of plates which included the plate next to the anode cup and which changed weight the least is shown in Table I as "middle section." In some experiments this middle section showed a change in weight and in such cases it was assumed that the change was entirely due to faulty cleavage between the middle section block and the cathode plate. Accordingly, such change was included in the change in weight of the cathode plate. However, part or all of this change of weight might have arisen from faulty cleavage between the anode cup and the middle section. The change in the transference number which would result if the change in weight of the middle portion were ascribed entirely to faulty cleavage between the anode cup and the middle section is shown in parentheses after each transference number in Table I.

The alcohol washings from the anode and cathode portions were analyzed separately and the weights of these portions were corrected for the salt which had dissolved. This correction was not apportioned among the plates in finding the change in the middle section because it was suspected that most of the salt in the alcohol washings came from the plate next to the cathode as a result of the rather violent reaction between the layer of sodium and the alcohol at this surface. In fact the alcohol washings from the cathode crystal and the nickel cathode nearly always showed small chips of undissolved salt at the bottom in amount considerably exceeding the solubility of the salt in absolute alcohol. These chips undoubtedly came from the cathode–cathode crystal interface and comprised by far the greater part of the sodium chloride in the washings. This will explain the very large correction of the cathode crystals for weight lost in washings, which in an extreme case (No. 14, Table I) amounted to 5 mg. That the middle plates contributed practically nothing to the alcohol washings was proved by the fact that in nearly every run at least one plate in the middle section was found after the washing to check to a tenth of a milligram with its original weight. The error in imputing the solubility losses of the middle plates to the cathode plate affects the transference numbers indirectly if at all by affecting the magnitude of the possible cleavage errors (the values in parentheses, Table I). The weight of the cathode portion was further corrected for the salt which stuck to the nickel cathode. The nickel frame and the inside of the quartz tube were also washed and the salt found was added to the weight of the cup and cover. This was justified by the fact that the exposed area of the anode cup and cover was about ten times that of the cathode portion so that the error caused by attributing all of this salt to evaporation from the anode is less than the uncertainty due to cleavage. At the highest temperature, 655°, the error in the transference number which might have resulted from this approximation was 0.01 unit.

Results

The pole reactions may be written

$$\mathrm{Na} \longrightarrow \mathrm{Na}^+ + \ominus \text{ anode}$$
$$\mathrm{Na}^+ + \ominus \longrightarrow \mathrm{Na} \text{ cathode}$$

On the passage of C equivalents of current through the cell there is a net loss of $C(1 - t_+)$ equivalents of sodium and $C\,t_-$ equivalents of chlorine, that is to say, $C\,t_-$ equivalents of sodium chloride from the cathode portion.

[a] (Loss in 1) − (4).

[b] (Gain in 3) + (5) + (6).

[c] Figures in parentheses are corrections which would result in t_- if changes in weight of middle section were calculated as due to sticking of the cup to the middle section rather than as a change due to transference.

[d] + Frame and tube.

An equal gain should be observed at the anode. To obtain the value of the transference number, the net loss in weight of the cathode portion or the net gain of the anode portion is reduced to equivalents and divided by the total number of equivalents of current passed.

The results of ten out of thirty-nine runs are given in detail in Table I and summarized in Table II. The missing runs suffered mishaps chiefly from the following causes: (1) poor temperature control, (3) leaks or breaks in the vacuum line causing oxidation of the sodium and serious contamination of the crystals, *(3)* failure of the sodium to run out of the capsule into the anode cup in sufficient quantity, (4) complete evaporation of the sodium from the cup, (5) faulty cleavage after the runs, (6) failure to take complete data (thus in the earlier runs the loss of sodium chloride in the alcohol washings was not determined), (7) cracking of the crystals on heating up the apparatus at the beginning of the run, (8) the use of too high a potential across the cell, causing arcing.

TABLE II

SUMMARY OF TRANSFERENCE NUMBERS

655	36	.27	.28	.28
	39	...	.28	

[a] In this case the negative value is probably due to the fact that small errors in manipulation and weighing were of great importance on account of the small amount of current transferred.

Best results were obtained from the cathode portions. In three cases satisfactory checks were obtained from analysis of both anode and cathode portions. The complete removal of the sodium from the anode cup was difficult, and even with the best vacuum conditions and the purest argon the anode cover showed a small amount of black contamination, presumably from the interaction of oxidized sodium with the nickel. This made it impossible in most cases to get a satisfactory determination of transference numbers from the weight of the anode cup.

Material from four sources was used. Sample 1, which was the same material used by Phipps, Lansing and Cooke in the determination of the conductance curves, was natural halite from Navarre, Michigan. Sample 2 was a second specimen from Navarre, Michigan. Sample **3** came from Heilbronn, Germany. In run No. **33** (Table I) the anode cup was made from Sample 3, while the plates were grown from a melt. The material of the melt was Mallinckrodt's "Reagent Quality" sodium chloride, thrice recrystallized from conductivity water. It is apparent from the data that the source of the sodium chloride had no appreciable effect upon the transference numbers.

Discussion

From a consideration of all the sources of error it is concluded that the transference numbers summarized in the last column of Table II are accurate to ±0.05 unit. At 580°, where the greatest number of determinations was made, the mean value of five determinations is 0.36 for the chloride ion. It appears certain that there is a change in the mechanism of electrolytic conduction through the salt very near to the temperature at which the extrapolated slopes of the conductivity curve shown in Fig. 1 intersect.

The decrease in the value of t_- with increasing temperature in the upper range was unexpected. It might have been due to leakage of the current through the sodium vapor at the high temperature, which increased with the temperature. Saha and Sur[10] have stated that the specific resistance of sodium vapor at 900° is about 13,000 ohms. At 600" calculation shows that conduction through the vapor would be insignificant compared with conduction through the salt. It seems more probable that the direct current produces a polarization of the crystal, which reacts upon the mechanism of conduction so as to affect unequally the mobilities of the two ions of the lattice. It is perhaps predictable from the behavior of the transference numbers that with very small currents passing for long periods of time the transference number of the chloride ion would approach 0.50. If this is correct, the absolute values of the transference numbers given in Table II have little significance except as an indication of the degree of polarization of the crystal under the stated conditions, From the point of view of the lattice theory the significant fact appears to be that at sufficiently high temperatures both ions of the sodium chloride lattice acquire the freedom which only the sodium ion possessed at lower temperatures. Similarity between the conductance curves (log k vs. $1/T$) of the chlorides, bromides and iodides of sodium and potassium indicates that this phenomenon is general among uni-univalent polar salts. The fluorides may prove exceptional.

Summary

Transference experiments were performed on sodium chloride at temperatures varying from 410 to 655", using a reversible sodium anode and a nickel cathode.

The fraction of the current carried by the chloride ion is practically zero between 410 and 510°. Between 558 and 655° chloride ion carries a

---

[10] Saha and Sur, *Quart. J Indian Chem. Soc.*, **1**, 10 (1924).

considerable part of the current. It is significant that the temperature region in which the change from uni-ionic to bi-ionic conduction occurs is the same as the temperature region in which the slope of the conductance curve (log k vs. $1/T$) doubles its value.

In the temperature range 558 to 655° the fraction carried by the chloride ion appears to decrease with increasing temperature. This is thought to be a polarization effect.

THE SOLUBILITY OF ALUMINUM BROMIDE IN CARBON DISULFIDE

BY H. H. KAVELER AND C. J. MONROE

RECEIVED JULY 11, 1928 PUBLISHED SEPTEMBER 5, 1928

Carbon disulfide as a solvent of inorganic salts was first studied by Arctowski,[1] who found the mercury halides slightly soluble, but the common inorganic salts insoluble. Kohler[2] found that aluminum bromide and iodide are rather soluble. Qualitative data of various investigators on the solubilities of various salts in this solvent have been compiled by Walden.[3]

As aluminum bromide dissolves in carbon disulfide to the extent that various inorganic salts dissolve in water, quantitative determinations of its solubilities at various temperatures were made.

Preparation of the Reagents

The carbon disulfide was purified by the method of Sidot,[4] with modifications of Arctowski, as follows. Commercial carbon disulfide was shaken with mercury until the surface of the metal was no longer tarnished and was then distilled from anhydrous calcium chloride. It was kept in contact with phosphorus pentoxide until ready for use, when it was decanted into a dry flask containing a little paraffin, from which it was distilled out of contact with air. The product, which had a sweet, pleasant odor, was used immediately.

Aluminum bromide was prepared from the purest commercial aluminum and C. P. bromine purified by distilling from chromic acid and from potassium hydroxide and potassium bromide.

As the extreme solubility of the salt made it desirable to prepare as much as 700 g. at one time, a somewhat different apparatus than that of Kohler, Richards,[5] and others was used, as shown in Fig. 1.

A combustion tube (*c*), of 12 mm. diameter and 1 meter length, resting in an electric furnace (E), was fused onto a train of three 750cc. distilling flasks. It was charged

with 100 g. of the metal, cut into small strips, and was heated to 400°, at which temperature a stream of dry hydrogen saturated with bromine was passed over the hot aluminum. The product was most rapidly formed when a reaction between the hydrogen and bromine to form hydrogen bromide proceeded with the production of flashes of light, the hot metal being a good catalyst for this reaction, which normally proceeds at a higher temperature.

When about 80% of the metal was used up, the introduction of bromine was stopped. The salt, carried by the escaping gas into the first flask, was then refluxed in a slow stream of hydrogen and distilled, at a pressure of about 15 mm., into the second, and then the third flask. The product is a white, highly crystalline compound. Its melting point has been reported to be 97.1°.[6]

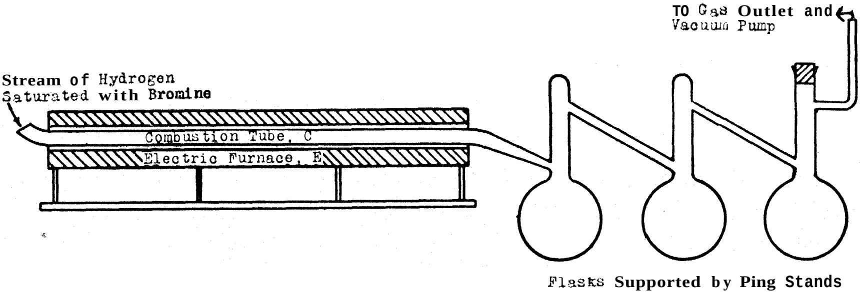

Fig. 1.—Arrangement for preparing quantities of aluminum bromide.

Determination of the Solubility

After sealing off the third distilling flask from the others, the desired amount of disulfide was added to the bromide while dry hydrogen was passed into the side neck. The sample tube was inserted and the flask shaken in a thermostat. At temperatures below 70°, an hour was found to be sufficient time for equilibrium to be attained. At higher temperatures, more than twelve hours was allowed for establishment of equilibrium, due to a polymorphic transformation of the solute.

Below 30°, an ordinary glass tube served as a delivery tube for taking samples. Since at higher temperatures the highly concentrated solutions would deposit crystals when forced into a sampling tube cooler than the bath, a delivery tube had to be used which could be kept at the temperature of the thermostat. A glass sampling tube was wound with nichrome wire and sealed inside of a larger tube to prevent the wire from coming in contact with the solution (see Fig. 2). This was calibrated, under the conditions at which it was to be used, with the aid of a small thermometer suspended inside the delivery tube, a temperature–current curve being obtained. With this device samples at the high temperatures could be taken with the same accuracy as at the low temperatures.

---

[6] The melting point of aluminum bromide has been reported (a) as 97.1° by Kendall, Crittenden and Miller, THIS JOURNAL, 45, 963 (1923), and (b) as 90.5° by Biltz and Voigt, *Z. anorg. Chem.*, 126, 39 (1922).

A convenient aspirator was made from two 500cc. leveling bottles, filled with mercury, the raising or lowering of one causing pressure to be applied or withdrawn quickly, while the same dry air is kept in contact with the solutions.

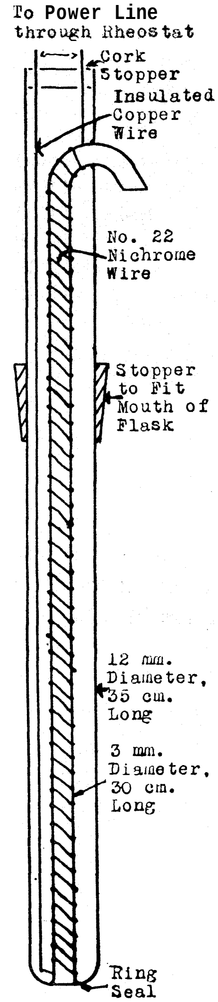

Fig. 2.—Device for sampling saturated solutions at constant temperatures.

The end of the delivery tube was placed in a bell jar filled with dry air to prevent fuming during the taking of a sample.

As aluminum bromide dissolves in carbon disulfide with the absorption of heat, and in water with the evolution of a large quantity of heat, addition of water to a sample, preliminary to analysis for bromide by the Volhard method, resulted in local, violent reaction, even when the temperature was far below zero. Addition of a third liquid, as ethyl alcohol, which forms with the first two a one-phase region, resulted in the violence of the reaction being reduced to such an extent that the method could have been used, although a small amount of hydrogen bromide was still lost. It was found that the complex $AlBr_3 \cdot 2C_6H_5NO_2$ was readily formed below 20°,[7] and that it reacted with water very quietly, with no loss of hydrogen bromide, so the following method of analysis was adopted.

(1) The weighing bottle containing the weighed sample was set into 100 cc. of water in a 600cc. beaker and 15–25 cc. of pure, anhydrous nitrobenzene added to the sample. (2) Pour hundred cc. of water, cooled to about 10°, was poured into the beaker. (3) With the weighing bottle covered with water, the mixture in it was stirred until all the aluminum bromide had reacted to form the complex. (4) The bottle was tipped, allowing water to run in slowly, the white, gummy complex going into solution with a hissing noise. (5) After stirring, the aqueous solution was decanted into a volumetric flask. (6) The residual emulsion of nitrobenzene, carbon disulfide and water, which retains some of the salt, was washed with water until the emulsion broke, when no detectable amount of bromide remained with the organic liquids. (7) The volume of the combined aqueous solution was made up to a standard liter, an aliquot part taken and titrated for bromide

[7] This compound, along with others of the benzene series, was reported by Menschutkin; see Seidell, "Solubilities of Inorganic and Organic Compounds," D. Van Nostrand Co., New York, 1919, pp. 21–24.

by the Volhard method, and the percentage of aluminum bromide in the original sample calculated.

Using this method of analysis, as much as 80 **g.** of the anhydrous salt were put into solution without difficulty.

Discussion of Results

The exceptionally high solubility of this salt in carbon disulfide is in accordance with several rules[8] derived from a study of solutions of electrolytes in other solvents.

TABLE II

SOLUBILITIES IN CARBON DISULPIDE

Salt	M. p., °C.	Heat of fusion, cal./mole[a]	Soly. in CS_2 in mole % at 25
KCl	772	6450	Insoluble (0 002)
KBr	748	(3040)	Insoluble
KI	(about 748)	(3820)	Insoluble
AgCl	455	3500	Insoluble
AgBr	430	2370	Insoluble
$HgCl_2$	265	5490	0.0147
$HgBr_2$	235	5010	0.0489
HgI_2	250	3280	0.0638
$AlCl_3$	195	(3450)	Slightly soluble
AlI_3	191	(4280)	Rather soluble
SnI_4	145.3	4180	Rather soluble
$AlBr_3$	97.1	2790	32 3

[a] The heats of fusion in parentheses were calculated, the others and the melting points were taken from standard tables. The salts are arranged in the order of their solubilities.

---

[8] Hildebrand, "Solubility," The Chemical Catalog Company, Inc., New York, 1924, p. 166.

(a) Aluminum bromide is unique in that it has a melting point and a heat of fusion much lower than the same values for almost any inorganic salt. (Some salts have lower melting points, but much higher heats of fusion; others have lower heats of fusion but much higher melting points.) Table II shows that the solubilities of salts in carbon disulfide are in accordance with the rule of greater molal solubility the lower the melting point and heat of fusion.

(b) Solvation tends to increase solubility. The color of the saturated solutions varied from a red at low temperature to an almost opaque black at 85°, possibly due to molecules of $x\mathrm{AlBr_3}y\mathrm{CS_2}$ being formed.

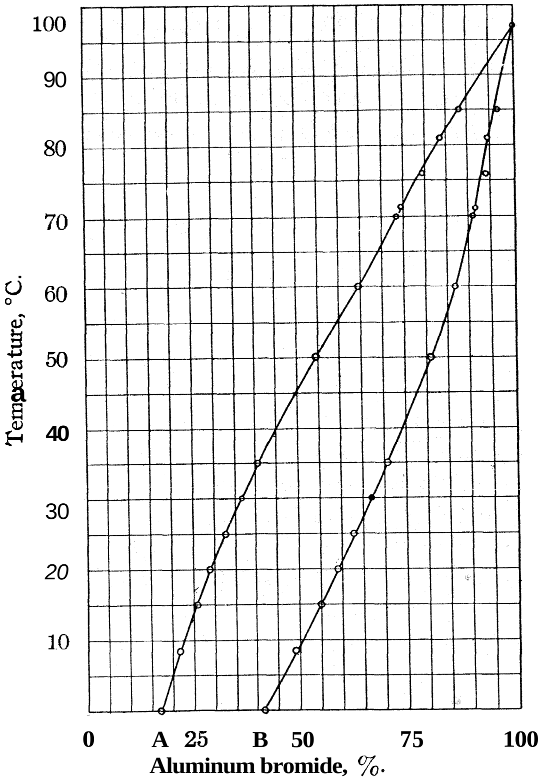

Fig. 3.—Curve A, mole %; curve B, weight %.

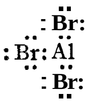
(c) The solubilities of the various salts in Table II are roughly in accordance with the rule that equal polarity of solvent and solute tends to increase solubility, although aluminum chloride, which has about the same polarity as aluminum bromide, is insoluble in carbon disulfide.

(d) On the basis of the Lewis theory,[9] the electronic structure of aluminum bromide is



$$\begin{array}{c} \ddot{\mathrm{:Br:}} \\ \mathrm{:\ddot{Br}:\ddot{Al}} \\ \mathrm{:\underset{..}{Br}:} \end{array}$$

The Al atom, not having the maximum number of electrons, may obtain a pair from a bromine atom of another molecule, with resultant polymerization and increased solubility (Kohler,[2] by the boiling point rise method, found the salt had the formula Al_2Br_6 in carbon disulfide), or may obtain the desired electrons from an atom of sulfur, with resultant solvation and increased solubility (see rule b), in accordance with the rule that the existence, in one of the components, of an atom without the maximum number of surrounding electrons or atoms promotes the solubility.

---

[9] Lewis, This Journal, 38, 762 (1916).

The ideal solubility[10] of aluminum bromide is 38 mole % at 20°, and 88 mole % at 85°, calculated using the approximate Raoult's law equation

$$\log N = -(L_f/4.58)\,(1/T - 1/T_m)$$

The experimental data show a negative deviation from this law at low temperature and almost perfect agreement at high temperature, typical of the behavior of many binary systems.[11]

The solubility–temperature curve shows a change of slope between 70 and 71°, indicating the existence of two crystalline modifications of the solute, confirming the thermal method report[6]'' on a polymorphic transformation at 70.1'.

The Conductivity of CS_2–$AlBr_3$ Solutions

Dilute solutions were found to have conductivities more than a thousand times that of pure carbon disulfide, although the solvent, due to its low dielectric constant, is a poor ionizing agent.

Summary

1. A method for the synthesis of quantities of aluminum bromide is described.

2. A method for sampling saturated solutions at constant temperature is described.

3. A new method for the analysis of anhydrous aluminum bromide has been found.

4. Quantitative data on the solubility of the salt in carbon disulfide have been obtained.

5. Solutions of aluminum bromide in carbon disulfide have been found to be appreciably conducting.

6. The existence of polymorphic forms of aluminum bromide has been confirmed by the solubility method.

NOTES

Note on the Formation of Ammonia from Active Nitrogen and Active Hydrogen.—Professor A. Koenig and E. Elod have called my attention to experiments in which they mixed hydrogen and nitrogen, after each gas had been activated separately in a discharge.[1] They did not find ammonia, contrary to results obtained by me.[2] This apparent discrepancy can be explained easily by the conditions of their experiments. One explanation is suggested by Koenig and Elod themselves, namely, that at the much higher pressures employed by them (10–15 mm. compared to 0.04–0.1 mm. in my experiments) the atomic hydrogen had recombined before reaching the mixing point. This explanation is supported by recent work.[3] Another effect contributing to the discrepancy is that ammonia is decomposed by active hydrogen.[4] At the high pressures of active nitrogen and due to the comparatively long gas exit tube, all of the ammonia (if a trace did form) must have been destroyed. In my experiments more favorable conditions obtained, the condensable gases being frozen out at liquid air temperature immediately following and in close proximity to the mixing chamber. Even so, the ammonia yields were undoubtedly somewhat reduced in the passage of this short space.

A Modified Confirmatory Test for Aluminum.—The confirmatory test for aluminum given by Noyes[1] is not quite satisfactory for class exercise, for the test requires much practice and great dexterity on the part of the students. For this reason, Otto[2] sought to improve this cobalt aluminate test.

Noyes' procedure[1] is as follows. The ammonium hydroxide precipitate is dissolved in nitric acid and to the solution a few cc. of water and drops of cobalt nitrate solution are added, in addition to the ammonium hydroxide solution to reprecipitate the aluminum. The precipitate is washed free from sodium salt as completely as possible. The filter paper is then rolled with the precipitate, a platinum wire wound around it and the

filter heated until the carbon is burned off. A blue residue shows the presence of aluminum.

The modification introduced in the test by the authors is that the precipitate produced in the reprecipitation is filtered through a filter paper with a few asbestos fibers at the cone of the filter. Instead of the filter paper, the asbestos fibers which hold the precipitate are burned, hooked in a platinum wire. Blue beads over the asbestos indicate the presence of aluminum.

In this proposed modification, several advantages are obtained. The presence of 0.2 mg. of aluminum is easily detected. The presence of sodium salt with the precipitate does not interfere in the test; thus, complete removal of sodium salt by washing is not necessary. Washing is necessary when a filter is used, for sodium salt will fuse with the filter and lessen the delicacy of the test. The modified test is satisfactory even when the aluminum precipitate is not washed at all. The ignition to produce the blue cobalt aluminate takes a shorter time. A longer ignition does not interfere with the result, as in the case of filter paper, which drops to pieces if ignited too long.

6-ALDEHYDO-COUMARIN AND DYES DERIVED FROM IT

BY RAJENDRANATH SEN AND DUKHAHARAN CHAKRAVARTY

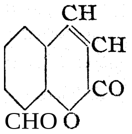
RECEIVED JUNE 6, 1927 PUBLISHED SEPTEMBER 5, 1928

Richard Stoermer and Ed. Oetker[1] first obtained 6-aldehydo-coumarin (melting at 189°) as an intermediate product in the synthesis of coumarin-6-carboxylic acid from 6-acetoxymethylcoumarin, but it was never prepared in quantity and no work appears to have been done with it. In the present case *p*-coumaric aldehyde or 6-aldehydo-coumarin has been prepared in quantity by the application of Reimer and Tiemann's reaction on coumarin (the yield being about 3.5 g. of the aldehyde from 16 g. of coumarin).

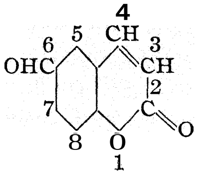
The application of Reimer and Tiemann's reaction on coumarin may be expected to lead to the formation of two aldehydes, the aldehyde group occupying the ortho position in one (I) and para position in the other (II) with reference to the lactonic oxygen atom; but it has been possible to isolate only one aldehyde in the pure condition, which is found to be identical with 6-aldehydo-coumarin, melting at 187–189°.

---

[1] Stoermer and Oetker, ***Ber.***, 37, 192–203 (1904).



I



II

In every preparation it has been found that in addition to the p-coumaric aldehyde, which is rather sparingly soluble in alcohol, another by-product is obtained instead of the expected o-aldehyde or 8-aldehydo-coumarin, in fairly large yield, which is readily soluble in alcohol but which, on account of its ready transformation into the resinous state, is extremely difficult to purify. After going through a long and laborious process of purification, which necessarily involves much loss of the substance, a small quantity of a solid product has been isolated from this resinous by-product, which softens at 174° with decomposition. It is soluble in alkalies, forming a deep red solution, and the lactonic ring in the substance seems to be rather unstable, as it is broken up when kept for some time in contact with cold sodium bicarbonate solution. It does not respond to the ordinary tests of an aldehyde. It appears to be very probable that the o-aldehyde is actually formed and subsequently undergoes some sort of transformation in the presence of the caustic alkali. This substance is still under investigation.

The introduction of an aldehyde group into the benzene nucleus of coumarin seems to affect the stability of the lactonic ring as is shown by the comparatively ready solubility of 6-aldehydo-coumarin in caustic alkalies. The aldehyde also differs from coumarin in the following respects. While coumarin forms a greenish-yellow solution in caustic alkalies, the aldehyde gives a slightly reddish solution. The solubility in water and organic solvents in general is also diminished.

The only derivatives of p-coumaric aldehyde prepared by Richard Stoermer and Ed. Oetker[1] were an oxime and a semicarbazone. The aldehyde, prepared by the present method, gives the identical oxime (melting at 223°) and semicarbazone (sintering at 305°) and also a hydrazone with phenylhydrazine (melting at 207°), which was not prepared before. The aldehyde alsp undergoes benzoin condensation in the usual manner, giving a product which may be called coumaroin. The aldehyde readily responds to Claisen's reaction and dicoumaral[2] acetone ($C_9H_5O_2\text{-}CH{=}CHCOCH{=}CHC_9H_5O_2$) and coumaral acetophenone ($C_9H_5O_2CH{=}CHCOC_6H_5$) have been obtained by its condensation with acetone and acetophenone, respectively. Dicoumaral acetone is yellow and coumaral acetophenone is colorless; this is probably due to the presence of a larger number of ethylene linkages and C=O groups in the former.

[2] The radical [$C_9H_5O_2CH{=}$] of 6-aldehydo-coumarin may be called "Coumaral."

Several interesting azo-methine dyes have been obtained by the condensation of 6-aldehydo-coumarin with (1) mono-amines such as *p*-toluidine, *β*-naphthylamine, *p*-nitraniline and amino-azobenzene, (2) diamines such as benzidine, o-, *m*- and p-phenylenediamines and **(3)** such dyes as rosaniline, chrysoidine and safranine, which contain free amino groups. These azo-methine dyes are usually hydrolyzed by warming with dilute acids.

One molecule of a mono-amine ordinarily reacts with one molecule of the aldehyde. One molecule of o-, *m*- or p-phenylenediamine reacts with two molecules of the aldehyde; but with benzidine and chrysoidine only one molecule of aldehyde condenses, the presence of the free amino groups being proved by diazotization. With rosaniline and safranine the reaction goes normally, one molecule of the former reacting with three molecules of the aldehyde and one molecule of the latter reacting with two molecules of the aldehyde. It is interesting to note that the replacement of the NH_2 groups in p-nitraniline, amino-azobenzene and the dyes rosaniline and safranine markedly diminishes the intensity of color, owing perhaps to the elimination of the auxochromic effect of the NH_2 groups. It is curious that although coumaral-chrysoidine, $C_6H_5N{=}NC_6H_3(NH_2)$-$N{=}CHC_9H_5O_2$, contains chromophoric groups, $N{=}N$, $CH{=}N$ and the auxochromic group NH_2, yet it produces a much yellower shade on silk and wool than chrysoidine.

By the condensation of the aldehyde with dimethylaniline in the presence of zinc chloride or hydrochloric acid as the condensing agent, tetramethyldiaminodiphenylcoumarylmethane, $C_9H_5O_2CH(C_6H_4N(CH_3)_2)_2$, has been obtained, This leuco-base, on oxidation with lead dioxide in the usual manner, gives a fine deep bluish-green dye (coumaral green), which is of much interest on account of the presence of the lactone ring associated with the basic group $N(CH_3)_2$, the compound being soluble both in acids and alkalies.

Pyronine dyes have been obtained by condensing the aldehyde with diethyl-*m*-aminophenol and also with such hydroxy compounds as resorcinol, hydroquinone and gallic acid in the presence of sulfuric acid (sp. gr. 1.84) at a temperature of 120–130° in the manner described by Sen and Sinha.[3] a- and @-naphtholsgive colorless, phthalein-like compounds under similar conditions.

It has been noticed, however, in the course of these condensations, that the $C{=}O$ group in the lactone ring of coumarin, which was observed to react in the presence of zinc chloride by Sri Krishna[4] and also by Sen and Guha Sarkar,[5] reacts with the hydroxy compounds in the presence of concd.

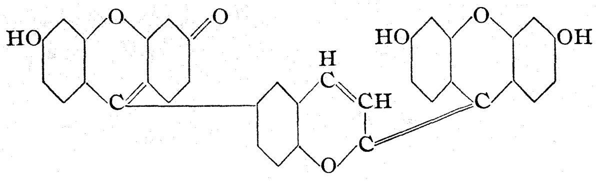
[5] Sen and Sarkar, THIS JOURNAL, 47, 1079 (1925).

sulfuric acid also in many cases at much lower temperature than when zinc chloride is used as the condensing agent.

Thus resorcinol-coumarein[4] is found to be readily obtained by condensing coumarin with resorcinol in the presence of sulfuric acid (sp. gr. 1.84) at a temperature of 120–130° on the oil-bath. Hence in the condensation of 6-aldehydo-coumarin with the aromatic hydroxy compounds like resorcinol under similar conditions the C=O group in the lactone ring as well as the aldehyde group reacts. Therefore the compound with resorcinol is given the structure of tetraresorcinol-coumarein (III).

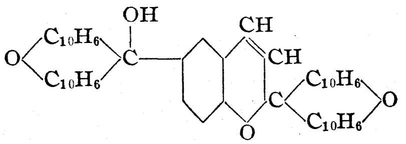


III

Silk and wool are dyed bright orange shades by the potassium salt of this compound.

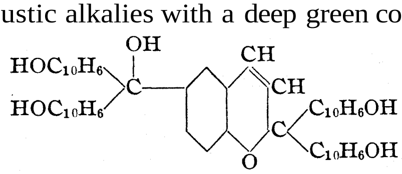
The condensation products with hydroquinone and resorcinol can be very readily brominated in an alcoholic medium; the former giving a tetrabromo and the latter a hexabromo derivative; silk and wool are dyed dark brown shades by the former and beautiful dark red shades by the latter.

a- and β-naphthol condense with the aldehyde, giving rise to phthalein-like bodies. The β-naphthol compound is completely insoluble in alkali and the analytical result corresponds to the following formula (tetranaphthol-coumarein): (IV)



IV

but in the case of a-naphthol, two different compounds are obtained;[5] one (IV) insoluble in caustic alkali (ortho condensation) and the other (V) soluble in caustic alkalies with a deep green color (para condensation)



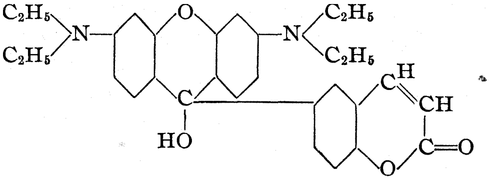
V

but the second product has not been obtained in a sufficiently pure condition for analysis.

The condensation product of 6-aldehyde-coumarin and gallic acid is, as expected, tetragallic acid coumarein, which is a polygenetic dye, wool being dyed a dark brown shade on chrome mordant, a reddish-brown shade on aluminum mordant and a dark olive shade on iron mordant.

Qualitative experiments show that the compound with o-cresotinic acid also exhibits polygenetic character, wool being dyed a pink shade on aluminum mordant and a light blue shade on chromium mordant.

The condensation product of the aldehyde with diethyl-*m*-aminophenol, which may be called coumaral-rhodamine (VI) is a fine bluish-violet dye, soluble both in acids and alkalies. It is interesting to note that unlike the other hydroxy compounds already mentioned, only 2 moles of diethyl-*m*-aminophenol condense with 1 mole of the aldehyde; the C=O group of coumarin itself failing to react with diethyl-m-aminophenol under these conditions.



VI

A comparative study of the colors of coumaral green and coumaral rhodamine and the analogous compounds from benzaldehyde is interesting. Thus while malachite green and benzaldehyde-rhodamine (rosamine) produce green and bluish-red shades, respectively, on silk and wool, the analogous compounds with 6-aldehydo-coumarin produce beautiful bluish-green and bluish-violet shades. The latter compounds differ from the former in the presence of an additional lactonic ring, which is perhaps responsible for this marked change in color.

Experimental

Preparation of **6-Aldehydo-Coumarin.**—Sixteen grams of coumarin is dissolved with 27 g. of caustic soda in 40 cc. of water and heated on the boiling water-bath with a reflux condenser for eight to nine hours with frequent addition of chloroform (20 cc. in all), keeping the temperature at 80° initially for three hours. The deep red solution is heated on the water-bath to drive away the excess of chloroform and when cooled is filtered and acidified with concentrated hydrochloric acid. A liquid separates out which solidifies on keeping.

The precipitate is filtered off, washed with water and extracted with a mixture of alcohol and ether (8:1) after slight warming. The insoluble white residue is filtered off rapidly at the pump and washed with alcohol. This is the 6-aldehydo-coumarin. It is finally crystallized from 80% alcohol; yield about 3.5 g.; a white, needle-shaped crystalline solid, slightly soluble in cold water and in cold alcohol, moderately soluble in cold benzene and practically insoluble in ether, readily soluble in chloroform, acetone and glacial acetic acid, m. p. 187–189°.

The alcoholic solution, which remains after the separation of the aldehyde, is evaporated to drive away the alcohol and ether, when a pasty semi-solid substance remains. This is then washed with benzene and ether in order to remove coumarin and a certain portion of the tarry matter produced. The residue is again dissolved in alcohol and gradually poured with constant stirring into water acidified with hydrochloric acid. After repeated treatment in this manner (at least ten or twelve times), a product is isolated which is a pale yellow solid and decomposes at 174–175°, the decomposed product melting at 205–207°. It is sparingly soluble in cold water, ether and benzene, fairly soluble in chloroform and readily soluble in alcohol, acetone and glacial acetic acid.

Anal. Calcd. for $C_{10}H_6O_3$: C, 68.96; H, 3.44. Found C, 68.8, 68.7; H, 3.9, 3.8.

Coumaral-phenylhydrazone.—The hydrazone is prepared in glacial acetic acid medium; yellow, microcrystalline substance, moderately soluble in alcohol, readily soluble in acetone and glacial acetic acid; m. p. 205–207°.

Anal. Calcd. for $C_{16}H_{12}O_2N_2$: N, 10.6. Found: N, 10.67, 10.8.

Coumaroin.—Coumaroin is prepared in the usual manner like benzoin and crystallized from water; microcrystalline, reddish-yellow substance, moderately soluble in water and alcohol. It reduces Fehling's solution and softens at 178–180°.

Anal. Calcd. for $C_{20}H_{12}O_6$: C, 68.96; H, 3.44. Found: C, 69.1, 68.8; H, 3.7, 3.9.

Dicoumaral-acetone.—Two grams of 6-aldehyde-coumarin is dissolved in 2 g. of caustic soda in 10 cc. of water and warmed with 5 cc. of acetone on the water-bath at 70–80° for two to three hours with a reflux condenser. The solution is then cooled and filtered and the filtrate acidified with dilute acetic acid. The yellow precipitate thus obtained is thoroughly washed with water and crystallized from absolute alcohol, giving yellow, needle-shaped crystals, insoluble in water and moderately soluble in alcohol and acetone; m. p. 159°.

Anal. Calcd. for $C_{23}H_{16}O_5$: C, 74.6; H, 3.78. Found: C, 74.2, 74.3; H, 4.1, 4.

Coumaral-acetophenone.—The method of preparation is the same as with acetone; colorless micro crystals from absolute alcohol, insoluble in water and fairly soluble in alcohol; m. p. above 250°.

Anal. Calcd. for $C_{18}H_{12}O_3$: C, 78.26; H, 4.34. Found: C, 77.9, 77.7; H, 4.6, 4.7.

Dyes Derived from 6-Aldehydo-coumarin. Azo-methine Dyes

Coumaral-*p*-toluidine.—The preparation of coumaral-toluidine is typical: 2 g. of 6-aldehydo-coumarin (dissolved in boiling alcohol) and 2 g. of *p*-toluidine (dissolved in glacial acetic acid) are boiled on the water-bath with a reflux condenser for four to five hours. The alcohol is then evaporated on the water-bath, when needle-shaped crystals of the compound separate. These are filtered off, washed with water acidified with hydrochloric acid and finally crystallized from a mixture of absolute alcohol and glacial acetic acid (6:1); yellow, needle-shaped crystals, insoluble in water, sparingly soluble in alcohol, readily soluble in glacial acetic acid; m. p. 145–147".

Anal. Calcd. for $C_{17}H_{13}O_2N$: N, 5.3. Found: N, 5.45, 5.3.

Other azo-methine dyes prepared are listed in Table 1.

Triphenylmethane Dyes

Tetramethyldiaminodiphenylcoumarylmethane.—Two grams of 6-aldehydo-coumarin and 10 cc. of dimethylaniline are heated on the boiling water-bath for thirty hours with an air condenser with frequent additions of concentrated hydrochloric acid (10 cc. in all). The solution is then made alkaline with caustic soda, distilled in steam, filtered and acidified with hydrochloric acid. The green solution is filtered and ammonia is added to the filtrate, when a greenish-white precipitate is obtained. The precipitate is filtered off, washed with water, and finally crystallized from acetone; yield, 90% of

the theoretical; colorless, needle-shaped crystals, insoluble in water, sparingly soluble in alcohol, moderately soluble in acetone, soluble in hot caustic alkalies and also in acids; m. p. 220°.

Anal. Calcd. for $C_{26}H_{26}O_2N_2$: N, 7. Found: N, 7.2, 7.1.

Tetramethyldiaminodiphenylcoumarylcarbinol (**Coumaral** Green).—The leuco-base is oxidized with lead dioxide in the usual manner. The hydrochloride is a deep bluish-green substance, producing a bluish-green shade on silk, wool and tannined cotton.

Pyronine Dyes

Tetraresorcinol-coumarein (III).—The preparation of this compound is typical. A mixture of 1 mole (2 g.) of dried 6-aldehydo-coumarin, 4 moles (5 g.) of dried resorcinol and 2 cc. of concentrated sulfuric acid (sp. gr. 1.84) is heated on an oil-bath for four to five hours at 120–130° with an air condenser. Copious evolution of sulfur dioxide takes place, as detected by its pungent odor and the development of a blue color on starch-iodate paper. The product is washed with water, dissolved in caustic soda solution and the original compound is precipitated with dilute hydrochloric acid. It is then dissolved in alcohol and the alcoholic solution is poured into water till a turbidity is produced. The solution is then filtered and the filtrate allowed to stand overnight with more water. The precipitate thus obtained is dried at 110° in an air oven. Pyronine dyes prepared, together with their derivatives, are listed in Table II.

TABLE IIA

PYRONINE DYES FROM COUMARIN

Prepared by condensing one mole of coumarin with four moles of combining compound in the presence of sulfuric acid (sp. gr. 1.84) at 120–130°

[a] Micro-crystals from boiling alcohol.

[b] Purified by dissolving in acetic acid and precipitating with ammonia, finally recrystallizing from alcohol.

[c] Acetate used; softens at 140°, m. p. 155°.

Summary

1. 6-Aldehydo-coumarin or *p*-coumaric aldehyde, melting at 189°, has been prepared by the application of Reimer and Tiemann's reaction on coumarin; it gives a hydrazone, an oxime and a semicarbazone, responds to Claisen's reaction and undergoes benzoin condensation in the usual manner.

2. Interesting azo-methine dyes have been obtained by the condensation of 6-aldehydo-coumarin with (1) mono-amines such as *p*-toluidine, β-naphthylamine, *p*-nitraniline and amino-azobenzene; (2) diamines such as benzidine, *o*-, *m*- and *p*-phenylenediamines; (3) dyes such as rosaniline, safranine and chrysoidine which contain free NH_2 groups.

3. Beautiful triphenylmethane dyes have been obtained by condensing the aldehyde with dimethylaniline and o-cresotinic acid.

4. Pyronine dyes have been obtained by condensing the aldehyde with diethyl-m-aminophenol and also with such hydroxy compounds as resorcinol, hydroquinone and gallic acid in the presence of sulfuric acid. The C=O group in the lactone ring as well as the aldehyde group reacts in these condensations except in the case of diethyl-m-aminophenol.

EFFECTS OF LIGHT UPON NITRATE ASSIMILATION IN WHEAT[1]

BY W. E. TOTTINGHAM AND HENRY LOWSMA

RECEIVED FEBRUARY 2, 1928 PUBLISHED SEPTEMBER 5, 1928

In a previous article[1a] on temperature effects in the metabolism of wheat the senior writer stressed the need of determining the adequacy of spectral balance when the illumination is wholly from an artificial source. The present paper deals with the assimilation of nitrate by young wheat plants, as affected by differences in spectral distribution and total intensity of light. As grown in our climatic chambers under water cells, the Marquis variety of spring wheat, which we have employed solely, requires between 1200 and 2000 foot candles of illumination at about 18° in a twelve-hour day, from Mazda C electric lamps. This estimate is based upon the maximum yield of dry matter. It is not clear, however, that this is the most significant index of optimal illumination, as will appear in a test to be presented presently. In this case more nitrate was assimilated, but at the expense of tissue production, when the Mazda lamps were supplemented by the visible and long ultraviolet rays from a carbon arc.

[1a] W. E. Tottingham, *Plant Physiol.*, **1**, 307 (1926).

While it is well known that short ultraviolet light is generally injurious to plants, little is known concerning specific effects of blue-violet and long ultraviolet rays. Plant physiologists have long known that the tropic effects of light are due primarily to the shorter wave lengths of the visible spectrum, but these is little, if any, published work showing the metabolic response of the organism to this particular factor.

Experimental Part

Our preliminary experience dealt with selective effects of greenhouse glass upon irradiation of maize (Zea *mais*) by sunlight. Seedlings of the Golden Glow variety from ordinary field stock were reared in sand in a greenhouse without permitting direct access of the sun's rays. Uniform selection as to appearance and size was then made for transference to water cultures of one plant to each jar of about 0.9 liter (1.0 quart) capacity. The nutrient solution was one designed to supply a high proportion of nitrate, containing 0.2% of sodium nitrate in 0.3% of total salts. A modification of this formula contained 0.2 as much nitrate. At intervals of three to four days the residual solutions were replaced by fresh portions. On sufficiently clear days a chosen section of the cultures was placed outside the greenhouse for direct exposure to solar radiation during about one and five-tenths hours at midday, taking care that the temperature change was gradual and similar for all cultures. Each section included eight plants. A second test was made in cooler weather, when the difference in irradiation was possible only on warmer days. The temperature was 6.0 to 12.0° warmer in the house than out of doors during periods of exposure in both tests, and the vapor pressure deficit of the atmosphere was 80 to 70% greater in the former location in the second test. In so short a period of exposure 'temperature would hardly be a critical factor in metabolism and, furthermore, maize appears to be relatively stable in composition with varying environment.[2] Moreover, general experience has shown a conservation of carbohydrates at lower temperatures, with decreased percentage of nitrogen. It might be expected that increased transpiration would favor the absorption of nitrate in the cultures continuously housed, but the work of Muenscher[3] indicates that these functions are independent of each other. There are thus small grounds for anticipating increase of nitrate assimilation in the exposed plants.

At the expiration of each culture period the fresh tissues were extracted with water and analyzed by methods which are specified elsewhere.[4]

The residual nutrient solutions were restored to their original volumes for the determination of nitrate, Strowd's modification of DeVarda's method[6] being employed here for both extracts and nutrient solutions. In view of the large variability in physiological behavior of maize, it was deemed inexpedient to deal with smaller units than the total mixed tissue and solution of each section of cultures. Hence, one can hardly express variability of the results. It should be noted that the radiation in the second test was only 40% of that in the first and the average daily maximum temperature out of doors was 13.9° lower in the former case. The results with maize are assembled in Table I.

[a] Calories for two and three days' exposure after last change of nutrient solution, 221 and 194, respectively.

[b] Excretion from the plant.

[c] Total sugars after hydrolysis.

Other tests were made with spring wheat (*Triticum sativum*) of the Marquis variety, using the same form of nutrient solution as before. A preliminary trial shows the range of variability which may be expected in results of this character. The seed used was a pure line selection provided by Dr. J. G. Dickson of the Department of Plant Pathology in this institution. Seedlings four days old were irradiated for sixteen hours per day by tungsten incandescent lamps at an intensity of 200 foot-candles, with the use of a blower to reduce heat effects. The temperature at the surface of the culture jars ranged from 17 to 18°. After twenty-one days' exposure, the entire plant was dried at 70° for analysis. These results are given in Table II. In all of the tests on wheat it has been impracticable to report variability, because of the limited repetition of culture treatment. With water cultures generally, forty plants were supported in a 3.5-liter jar and with soil cultures reared to maturity, ten or twelve plants per pot of 3.5 kg. of soil. Even with duplicate culture treatment the yield was insufficient for more than single analyses of immature plants.

In test 2 upon wheat, a 500-watt Mazda lamp was supplemented by a carbon arc for increasing the proportions of shorter visible wave lengths and the long ultraviolet. The latter was a Thomsen inclosed lamp of 7.5 amp. capacity, operating on 110 volts A.C. Its globe was replaced by a conical tin reflector similar to those used with the tungsten lamps. Measurements with a Sharp-Millar photometer employing a selective screen for the red rays showed the intensity of illumination from the arc to be about 0.25 that from the filament lamp. Comparative measurements at various wave lengths were made by means of a spectrophotometer and the results are quoted hereafter.

This test covered a period of ten days with seedlings which had attained an age of one week. By daily use of the arc lamp for one to one and one-half hours the intensity of red rays was increased about 2.0%, corresponding to about 150% increase in the long ultraviolet. The interposing of common window glass between lamps and plants eliminated effectiveness of rays shorter than about 3000 Å. At the termination of irradiation the tissues of the plant tops only were well ground and extracted with water in the fresh state, determining nitrate (as hereafter) by the colorimetric method of Burrell and Phillips.[6] The data of this series are in Table III, with graphic presentation in Fig. 1.

TABLE III

INFLUENCE UPON THE METABOLISM OF WHEAT OF INCREASING THE SHORTER WAVE LENGTHS OF LIGHT ABOVE 3000 Å. ILLUMINATION OF 200 FOOT CANDLES. INCREASE OF ULTRAVIOLET BY THE CARBON ARC, 200%

The radiation curves in our figures were derived from the following sources: spectral energy distribution of the 1000-watt gas filled tungsten lamp, from data supplied through correspondence by Dr. W. E. Forsythe of the Nela Research Laboratories, whose data were derived from color temperatures; the graphs of Coblentz, Dorcas and Hughes[7] for the

emission spectrum of the carbon arc, as determined by a spectrometer and thermopile. Our own measurements of relative intensity of visible radiations from the tungsten lamp and carbon arc between 4060 and 6720 Å. were made by means of a Konig-Martens spectrophotometer. This instrument was made available through the kindness of Professor J. R. Roebuck of the Department of Physics, this institution. As a base of comparison we have employed our measurements of light intensity from the two sources by means of a Sharp-Millar photometer, with a screen of potassium dichromate, assuming that the observed difference was valid for wave length 6000 Å.

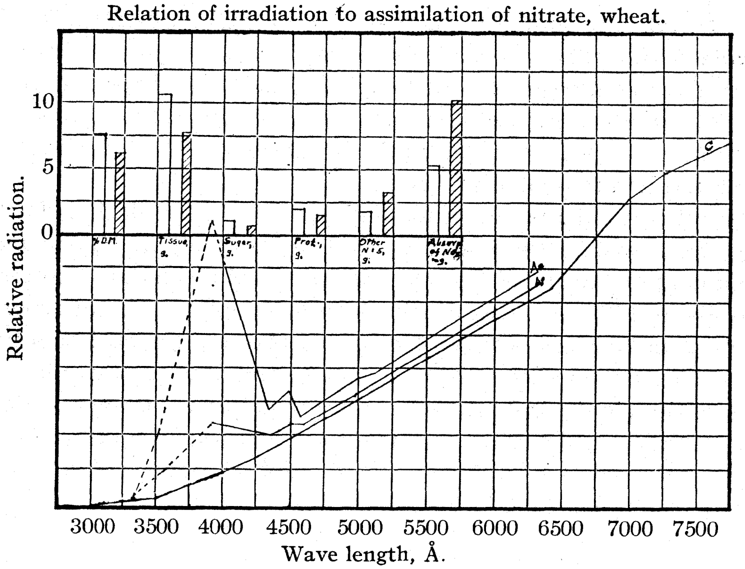

Fig. 1.—Cobstructed from the data of Table III. Line C shows the spectral distribution of radiation from the Mazda lamps. The radiation supplied by the additional use of the carbon arc is shown by line Ae. Curve Af shows the effective radiation based upon relative times of operation of the two types of lamps. In the altitudinal graphs clear areas represent responses to Mazda lamps, hatched areas those to the combined lamps.

The comparison in the long ultraviolet region is determined from Table 2 and Fig. 2 of Coblentz and associates. It is apparent from our Fig. 1 that the arc added about 3% to the intensity of visible radiations from the filament lamp and from 0 to about 300% in the long ultraviolet, with a maximum at about 3900 Å.

A further test was made of the effects of long ultraviolet radiation. In this case rays shorter than 3000 Å. were eliminated as before, while in a parallel group of cultures rays shorter than 4000 Å. were withheld by a special glass.[8] It was necessary, of coarse, to compensate for inequalities in light transmission by the different glasses, as given in the publication cited and by our own measurements with a Sharp-Millar photometer. The distances between the light filters and plants were adjusted accordingly. Water cultures reared in the greenhouse for seventeen days were irradiated for sixteen days. The intensity of 200 foot candles from the tungsten lamp was increased about 4.0% in the red rays by the arc and about 400% in the long ultraviolet. Without the use of special means to dispose of heat it was not possible to irradiate at higher intensities, but the temperature was here maintained at 16.0 to 17.0°. The leaves receiving the more restricted radiation were wider than the others but turned yellow toward the close of exposure. Table IV shows the data obtained from analysis of the tops only.

Relation of irradiation to assimilation of nitrate, wheat.

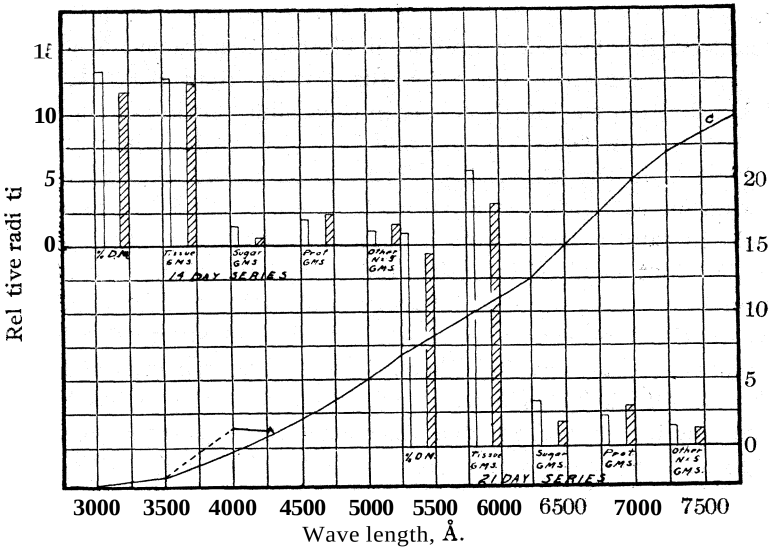

Fig. 2.—Constructed from the data of Table VI. Curve C shows the spectral distribution of radiation from the Mazda lamp. Curve A shows part of the additional radiation when the arc lamp was used. The latter increased the red rays about 0.5%, the long ultraviolet 50%. In the altitudinal graphs clear areas represent responses to the Mazda lamp, hatched areas those to the combined lamps.

It should be noted that for such tests as this, in which only a part of the plants is considered and the nutrient solution is renewed, one is not justified in expecting the plant analysis to conform to variations in the nutrient solution. In other words, the data do not permit the striking of balances between absorption from the solution and accumulation in

the plant. A more complete check on this issue will be desirable in future work.

In a succeeding test the variability in illumination was made still greater, glass G34Y eliminating wave lengths shorter than 6000 Å. (orange), Noviol A limiting the effects chiefly to the visible portion of the spectrum, or to rays greater than 4000 Å., and Noviol O withholding rays shorter than 3700 Å. in the ultraviolet. The further use of Celo glass extended the radiation well into the ultraviolet, to about 2800 Å. Seedlings five days old in sand cultures were irradiated for nineteen days by lamps at about 300 foot candles' intensity and nine days further by sunlight in addition to a total estimated intensity of about 1200 foot candles. The plants deprived of yellow to violet light developed broader leaves but were more flaccid than the others. They were also etiolated and susceptible to attack by mildew. Under Celo glass the plants were erect, with narrow leaves, while in the other cases they appeared to be normal. The temperature here ranged from 17.0 to 20.0° and the tissues were analyzed from the fresh state. Data of this series appear in Table V.

TABLE V

INFLUENCE OF SPECTRAL PORTIONS UPON THE METABOLISM OF WHEAT AT AN AVERAGE INTENSITY OF ABOUT 300 FOOT CANDLES, TUNGSTEN AND ARC LAMPS SUPPLEMENTED BY SUNLIGHT

Quality of light, Å.	Yield of dry matter, g.	Yield of dry matter, %	Glucose, %	Sucrose, %	Total sugar, g.	Protein N, %	Protein g.	Other organic N, %	Nitrate N. %
Above 2800	8.2	13.5	2.2	3.9	0.50	2.4	1.23	2.2	0.2
Above 3700	11.4	11.9	2.7	2.6	.60	2.4	1.70	1.7	.3
Above 4000	11.1	11.8	1.9	3.6	.61	2.4	1.64	2.0	.3
Above 6000	9.5	12.1	3.0	4.4	.70	2.1	1.33	1.6	.8

It appeared that the planes of illumination thus far employed were probably deficient for full photosynthetic activity by the wheat plant, and that it would therefore be desirable to test the effect of spectral balance at much higher planes of light intensity. The adequacy of illumination was tested by the yields of dry matter in the climatic chambers already described,"' with the modification of covering the water cell by a sheet-iron dome adapted to forced ventilation and installing reflectored lamps therein. Differences in light intensity were secured by changing the elevation of culture jars on the rotating table. The cultures were irradiated for sixteen hours daily and the temperature was maintained at about 15.0°. With the further control of relative humidity at a uniform value of about 70.0%, the only markedly variable environmental factor was light intensity. Three tests with water cultures in periods of irradiation from 9.0 to 17.0 days showed, both by yields and sugar content, that 600 foot candles was much inferior to 1200 foot candles from this source of illumination. Other cultures on soil were continued for twenty-one and thirty-one days, at 13.0 to 14.0°, and with the light intensity ranging from about 2000 to 7000 foot candles in one case, and 2250 to 8000 foot candles in the other. In this case arc lamps were used at a constant distance through glass with an increase of about 0.4 to 0.1% in the red rays and about 40 to 50% in the long ultraviolet. The shorter test gave slight indication of deficiency of the lower plane of illumination but the longer one showed no difference either in yields of dry matter or percentage of nitrogen therein. These results indicate that the optimal range of this form of radiation for wheat, at the temperature here effective, lies between 1200 and 2000 foot candles and probably nearer to the latter value, as measured by yield of tissue.

On the basis of the preceding results a final test was made of the effect of supplementary radiation in the shorter wave lengths at total intensities ranging from about 1200 to 5000 foot candles as the plants increased in height. Sand cultures reared for twenty-one days in the greenhouse were subjected to controlled illumination in the chambers at about 18.0' for periods of fourteen and nineteen days. The increase of radiation due to the arc was about 0.5 to 0.8% in the red rays and 50 to 80% in the ultraviolet. In this case the tissues were dried at 98° before analysis. The data are given in Table VI, supplemented by Fig. 2.

TABLE VI

Discussion

The data with maize show reduction of efficiency in the assimilation of nitrate and synthesis of soluble protein, and partly also of basic forms of nitrogen, by passage of sunlight through greenhouse glass. In the first test, at least, the sugar content did not vary sufficiently to account for the above difference. It seems probable that the results were due to deficiency of the shorter wave lengths of light under glass, for, as is well known, these are highly absorbed. Some authorities, such as Hovestadt,[9] give as the transparency of ordinary crown glass 10.0 cm. thick 90 to 95% for red to yellow, 70 to 80% for blue to violet and 60% or less for long ultraviolet. Stone[10] made tests on the diminution of chemical activity of light in passing through greenhouse glass. We understand that he followed the degree of oxidation in exposed solutions of ferric oxalate. The decrease was 14% in July and 43% in December.

From the test of variability with wheat it would seem that one could attach significance to variations of 10.0% and more in the composition of the plants and of twice this extent in the absorption of nitrate.

From the results of the second test with wheat it is apparent that the increase in proportion of long ultraviolet and visible blue-violet above that in the spectrum of the Mazda C lamp markedly increased the absorption of nitrate, and to a less extent enhanced the synthesis of amino forms of nitrogen. This activity is reflected in decreased content of nitrate and sugars in the plants receiving the more complete radiation. It will be noted that the differences in the absorption of nitrate are not accounted for by differences in the composition of plant tissue. This apparent discrepancy can well be explained by the fact that we have no data on nitrate absorption from the previous portions of nutrient solution, and the added fact that the root tissue was not analyzed. Computations based on the data of Coblentz, Dorcas and Hughes[7] and our own tests of spectral distribution indicate that the energy of wave lengths 3500 to 4500 Å., as related to those from 4500 to 7500 Å., or from the region of long ultraviolet to short blue waves to that from short blue to short infra-red, had a ratio of about 1:6 with our combined lamps as compared with 1:3 in sunlight. Thus a considerable increase in the proportion of shorter wave lengths of light produced a significant increase in protein synthesis.

From the third test (Table IV) it appears that the long ultraviolet rays as here effective were conducive to increased absorption of nitrate without promoting its assimilation. Final conclusions on this matter must await further trials. In the succeeding test the rays from 3700 to 4000 Å., or just below the range of the visible spectrum, were not found to be effective in this manner from the data on tissue. On the other hand, light extending into the middle ultraviolet considerably reduced the yields of tissue and of protein therein without sensibly affecting the composition.

---

[9] Hovestadt, "Jena Glass and its Scientific and Industrial Applications," transl. by J. D. and A. Everett, London, **1902**, pp. 47, **50.**

[10] Stone, Mass. Agric. Expt. Station, Bull. 144, **1913.**

This effect should probably be ascribed to the well-known injurious action of shorter ultraviolet rays upon living matter. Absence of rays shorter than orange led to reduced yields of tissue and protein. The relative accumulation of nitrate and sugars in this case indicates inefficiency in protein synthesis.

While the foregoing tests might be criticized as inconclusive, due to the relatively low planes of total light intensity, this cannot apply to the final trials. The illumination here exceeded the intensity already reported as producing a maximum yield of plant tissue. Although the effect of the arc upon total intensity was here very small (about 0.5% increase in the red rays, and 50% in the ultraviolet), a considerable increase of protein at the expense of sugars is evident. Again, this process was accompanied by a decline in the production of tissue. It was deemed impracticable to follow the absorption of nitrate from sand cultures. Attention is called to the increased percentage of water in plant tissue subjected to increase of the shorter wave lengths of light, excepting the effect of shorter ultraviolet.

Summary

1. Data are presented from the growth of maize in water cultures during late summer. These indicate that the absorption of nitrate and synthesis of protein are promoted by light rays which are absorbed by greenhouse glass under the conditions here effective.

2. Data are presented from the growth of wheat in sand and water cultures which were irradiated by electric lamps for periods of ten to twenty-one days. With total intensities of 200 to 1200 foot candles and upward the long ultraviolet region was increased about 50 to 400% by use of carbon arcs. The concomitant increase in red-orange rays was about 0.5 to 4.0%, with unmeasured increases in the shorter wave lengths of the visible spectrum.

3. In the early growth phases of wheat, relatively limited increases in the proportion of shorter visible light rays greatly enhance the absorption of nitrate and significantly increase the synthesis of protein. These effects are accompanied by small increments of the percentage of water in the tissue and declines in the yields of sugars and total dry matter. Long ultraviolet rays seem to be effective in the absorption of nitrate, but the present results do not establish any further role.

4. The proportion of blue-violet rays in our artificial light was considerably smaller than in sunlight. Further study is desirable with sunlight or a similarly balanced spectrum,

THE EFFECT OF STRUCTURE OF ORGANIC HALIDES ON THEIR RATE OF REACTION WITH INORGANIC HALIDES. II. THE EFFECT OF THE METHYLTHIO GROUP. A NEW VESICANT[1]

BY W. R. KIRNER

RECEIVED FEBRUARY 27, 1928 PUBLISHED SEPTEMBER 5, 1928

A study of the effect of a sulfur atom on the reactivity of an ω-chlorine atom which is in the same molecule and separated by one, two or three methylene groups should be of interest in connection with the "acid theory" for the mechanism of skin vesication of mustard gas proposed by Lynch, Smith and Marshall[2] and contradicted by later work of Peters and Walker.[3]

To make the conditions for this investigation as simple as possible it was proposed to synthesize a series of sulfur-halogen compounds each of which contained but one chlorine atom; this avoided complications such as the reciprocal induced effect of one chlorine atom on another which might occur if more than one chlorine atom is present in the molecule. The series selected was the w-chloroalkyl methyl sulfides, CH_3SCH_2Cl, $CH_3SCH_2CH_2Cl$ and $CH_3SCH_2CH_2CH_2Cl$. In these compounds the sulfur atom is attached on one side to the simplest alkyl radical and the chlorine atom is separated from the sulfur atom by one, two and three carbon atoms, respectively. The synthesis of the first member, unfortunately, was not successful; the reactivity of the second and third members was measured using the procedure which has been previously described.[4]

The following table contains the data obtained from the reaction velocity measurements.

TABLE I

REACTION VELOCITY DATA

Compound	K_{50}	K_{60}	A	Relative reactivity at 50°, *n*-butyl chloride taken as unity
n-C_4H_9Cl	0.0415	0.1189	4920	1.00
$CH_3SCH_2CH_2Cl$	.0629	.1666	4540	1.52
$CH_3SCH_2CH_2CH_2Cl$	.1044	.2373	3830	2.52

The above results illustrate still another case in which the γ-halogen compound is more reactive than the *β*, the ratio being 1.66:1.00 at 50° and 1.42:1.00 at 60°.[5] Although the first member of the series is missing it seems safe to predict that the a-compound would be more reactive than

the β- and γ-compounds inasmuch as in all of the various homologous series which have been measured by this method the a-halogen compounds of a **given** series possess, without exception, a very much greater reactivity than any other member. **Also,** chlorodimethyl ether, CH_3OCH_2Cl, the oxygen analog of the missing sulfur compound, was found to possess a very reactive chlorine atom.[6] This is corroborated by the work of Kilpi[7] and Palomaa,[8] who measured the velocity of hydrolysis of various groups, such as Cl, COOR, OCOR, $CONH_2$ and CN when influenced by the presence of an alkyloxy group such as CH_3O, separated from each other by one, two or three methylene groups. In every case they found the order of reactivity to be a > γ > β. Therefore, the evidence points to the existence in the series of ω-halogen alkyl methyl sulfides of a definite, though weak, alternation in reactivity of the chlorine atom through a saturated carbon chain as the chlorine atom is moved further and further from the activating methylthio group.

The relative order of reactivity of the first two members of the series confirms that of Peters and Walker[3] who found that the α,α′-dichlorodimethyl sulfide was hydrolyzed more rapidly than the β,β′-dichlorodiethyl sulfide. The relative reactivity of the β- and y-chloro-alkyl methyl sulfides toward potassium iodide has recently been confirmed, quantitatively, by Bennett and Berry in a study of the β- and y-chloro-alkyl phenyl sulfides; they found that the y-compound reacts about **3.5** times as fast as the β. The order was just reversed, however, when their reactivity was measured by hydrolysis in a 50% aqueous alcoholic solution according to the procedure of Olivier.[10] Although Bennett and Berry state that this method is "likely to be free from the defects of subsidiary reactions," Olivier has shown that the hydrolysis of benzyl chloride under the conditions of the experiment yields benzyl ethyl ether as well as benzyl alcohol, that is, both constituents of the solvent react with the halogen. The results obtained by Olivier on the reactivity of benzyl chloride and various substitution products do not agree with those of Franzen,[11] who carried out his measurements using sodium ethylate and thus worked in an alkaline solution.

The order of reactivity of the ω-chloro-alkyl methyl sulfides toward potassium iodide in absolute acetone solution is undoubtedly α > γ > β; this is not in agreement with the order given by Bennett and Hock[12] for

the rate of hydrolysis of the ω,ω'-dichlorodialkyl sulfides which they list as: $\alpha,\alpha' > \beta,\beta' > \gamma,\gamma' < \delta,\delta'$. *But, the order in which the α,α' and β,β' appear was taken from the paper of Peters and Walker, while the position of the β,β' was determined relative to the γ,γ' by comparative hydrolysis in an alcoholic alkaline solution. The δ,δ' compound was not isolated and its reactivity was estimated from the reactivity of the corresponding dihydroxy compound.*

It should be pointed out that the hydrolysis of these dihalogen compounds has been quite well established as a two stage reaction,[13] a fact which may vitiate any conclusions which are drawn, since the reactivity of the two chlorine atoms will be different because the activating group in the first stage is quite different from that in the second. Still more important is the fact that Bennett and Hock measured the hydrolysis of the β,β'- and γ,γ'-dichlorodialkyl sulfides in a nearly $N/5$ alcoholic solution of sodium hydroxide. Although they assume the reaction to be one of simple replacement, it has been shown[14] that treatment of mustard gas with sodium ethylate yields vinyl sulfide as the main product. Even the slow hydrolysis of mustard gas by alkali in 50% alcohol in the cold does not yield thiodiglycol, but a substance which seems to be a polymer of vinyl sulfide. It is evident, therefore, that this reaction is not a simple replacement of the chlorine atom by the hydroxyl group but involves the elimination of hydrogen chloride from the 8-chlorine and the rather reactive a-hydrogen atom. These observations were confirmed by Bales and Nickelson.[15]

The hydrolysis of the α,α'- and γ,γ'-compounds appears to proceed normally since, in the former, the halogens are attached to the same carbon atoms holding the active a-hydrogens and, in the latter, the halogens are removed a sufficient distance from the active a-hydrogens so that there is no tendency for the elimination of hydrogen chloride in either case. Bloch and Höhn[16] were able to substitute the two halogens in the α,α'-compound by methoxy groups using a methyl alcohol solution of potassium hydroxide or ammonium hydroxide; some dihydroxy compound was also formed which then decomposed into formaldehyde, thioformaldehyde and water. Bennett and Hock[12b] prepared the diphenoxy compound from the y,γ'-dihalide and, although they do not report their yield, neither do they mention any of the difficulties which are expressed by Helfrich and Reid in the corresponding reaction on the β,β'-compound.

Therefore, the order of reactivity which is given by Bennett and Hock

is not derived from a study of the rate at which a given, clearly defined reaction proceeds, but instead is obtained from several reactions which differ in mechanism.

Vesicant Action

A drop of β-chloro-ethylmethyl sulfide from a 4mm. glass rod was applied to the skin on the left forearm and a similar drop of γ-chloropropylmethyl sulfide was applied to the right forearm. The liquid disappeared in the course of a few minutes. In the case of the β-chloroethyl compound a well defined blister, 1 cm. × 0.8 cm. and about 3 mm. high, had developed after about twenty hours and was surrounded by a reddened area about 2 cm. × 1.3 cm. The blister was punctured aseptically and pressed dry, but filled again. A brownish scar was still plainly evident ten months after the substance had been applied. Judging from war reports (for example, The American University Experiment Station Monograph on Dichlorodiethyl Sulfide) concerning the vesicant action of mustard gas, the above substance seems to act as rapidly and in precisely the same manner as does mustard gas. In fact, the description and photographs given by Warthin and Weller[17] concerning the action of mustard gas on a patient's forearm coincide exactly with the observations made by the author in an experiment performed on himself. The γ-chloropropylmethyl sulfide was found to possess no vesicant properties whatsoever.

It is quite apparent that *only when the halogen is in the β-position with respect to the sulfur atom will the resulting compound possess vesicant properties.* A search of the literature has revealed no case where an α-, γ- or δ-halogenalkyl sulfide is reported and confirmed as a vesicant compound. There seems to be no obvious relationship between the reactivity of the chlorine atom (at least in replacement reactions) and vesicant action.

Experimental

A. Preparation of an Aqueous Solution of Potassium Methyl Mercaptide

Methyl mercaptan was prepared according to the directions of Klason (or Claesson)[18] who methylated sodium hydrosulfide with methyl sodium sulfate. The mercaptan was absorbed in a 50% solution of potassium hydroxide and the resulting solution was treated with a saturated solution of lead acetate until a filtered test portion yielded a brilliant yellow precipitate of lead methyl mercaptide uncontaminated with any black lead sulfide; this insured an aqueous solution of potassium methyl mercaptide free from potassium sulfide or hydrosulfide.

B. Preparation of an Anhydrous Ethereal Suspension of Sodium Methyl Mercaptide

An anhydrous ethereal solution of methyl mercaptan was prepared and converted into an anhydrous ethereal suspension of the sodium salt according to Klason.[19] The

---

[18] Klason, *Ber.*, 20, 3408 (1887).

[19] Klason, *J. prakt. Chem.*, 15, 196 (1877).

absence of water was imperative in the reaction with chloromethyl acetate since it is hydrolyzed readily, particularly in alkaline solution. Higher yields were obtained using the anhydrous suspension of the sodium mercaptide rather than the aqueous alkaline solution in the reactions with the chlorohydrins.

For the preparation of the anhydrous ethereal suspension of sodium methyl mercaptide the aqueous solution of the potassium salt was treated with 1:1 hydrochloric acid and the liberated methyl mercaptan was dried by passing it through a tower containing anhydrous potassium carbonate and then condensed by passing through a coil maintained at −20° and collected in anhydrous ether. The anhydrous ethereal solution thus obtained was placed in a large bottle; metallic sodium, in large pieces, was added and the bottle stoppered and protected from moisture by a calcium chloride tube; it was then placed in an ice-bath and allowed to stand overnight. The sodium did not react with the dissolved mercaptan, only a small amount of grayish sediment being present which was shown to be flakes of metallic sodium. When a little absolute methyl or ethyl alcohol was added to the ethereal solution the reaction started immediately with rapid evolution of hydrogen even at 0° and with the formation of a large amount of a beautiful white flaky precipitate.

The ether used as the solvent had been dried over calcium chloride, then over sodium and finally distilled from phosphorus pentoxide so that it was free from water and alcohol. Apparently a small amount of alcohol is necessary to catalyze the reaction between the sodium and the mercaptan. The mercaptan may be too weak an acid to react with the sodium directly though it reacts with either sodium methylate or ethylate. The following equations represent the probable mechanism of the reaction

$$CH_3SH + Na = \text{No reaction} \quad (1)$$
$$2CH_3CH_2OH + 2Na = 2\,CH_3CH_2ONa + H_2 \quad (2)$$
$$CH_3SH + CH_3CH_2ONa = CH_3SNa + CH_3CH_2OH \quad (3)$$

The alcohol regenerated in Reaction 3 then reacts with more sodium and the cycle repeats until no more mercaptan remains. The non-reactivity of the alcohol-free ethereal solution of mercaptan was not due to the amount of surface exposed by the sodium because sodium wire was also used, which presented a much greater surface than the sticks of sodium originally used. There was no reaction in this case either until a small amount of alcohol was added.

On treating the total ethereal solution with absolute ethyl alcohol (12.5 cc. of alcohol per liter of the ethereal solution), cooling in an ice-bath and allowing the reaction to proceed overnight, it was found that the reaction took place readily and that next morning the bottle was over half full of a white fluffy precipitate of sodium methyl mercaptide. More sodium was added until the reaction was complete; any unreacted sodium was removed and the mercaptide allowed to stand under the ether until ready for use.

C. Preparation of Methylthio Methyl Acetate, $CH_3SCH_2OCOCH_3$

The reactions which were expected to result in the formation of the first member of the series follow.

$$\text{Anhydrous } CH_3SNa + ClCH_2OCOCH_3 = CH_3SCH_2OCOCH_3 + NaCl \quad (1)$$
$$CH_3SCH_2OCOCH_3 + H_2O = CH_3SCH_2OH + CH_3COOH \quad (2)$$
$$CH_3SCH_2OH + SOCl_2 = CH_3SCH_2Cl + HCl + SO_2 \quad (3)$$

Reaction 1 proceeded smoothly and the new compound, methylthio methyl acetate was obtained. Hydrolysis, however, did not yield the expected products.

Chloromethyl acetate was made, using the directions of L. Henry,[20] by chlorination

---

[20] Henry, Ber., 6, 740 (1873).

of methyl acetate in the sunlight at 0–5°. A given weight of chloromethyl acetate was added dropwise to about a 10% excess of the ethereal suspension of sodum mercaptide in a flask fitted with a reflux condenser. It was found advisable to use an excess of the mercaptide because the final purification by fractional distillation was greatly simplified. An approximately determined weight of the mercaptide was obtained by shaking the ethereal suspension and pipetting off a definite volume, filtering and weighing the solid. From this weight the volume of suspension to be used in an experiment was determined.

The addition of each drop of chloromethyl acetate caused the ether to boil; the addition was regulated so that the ether slowly refluxed. When the addition was complete the mixture was refluxed three hours and allowed to stand overnight. Next morning the sodium chloride and unchanged mercaptide were filtered off and washed with ether, the filtrate transferred to a flask and the ether distilled off from a water-bath. The residue was placed in a Claissen fractionating flask and fractionated in vacuum. After three complete fractionations a product boiling at 53–55' at 11 mm. was obtained; this fraction was used for analysis. The boiling point at 20 mm. was 60–62°; yield, 38%. The yield could undoubtedly be improved, for the reaction was ——ed out with sodium mercaptide residues which contained about 10% of metallic sodium. The substance was analyzed by weighing it into a thin walled glass bulb which was sealed and heated to redness in a Parr sulfur bomb with 3 g. of sodium peroxide; the sulfur was determined as barium sulfate in the usual manner.

Anal. Subs., 0.1097: $BaSO_4$, 0.2155. Calcd. for $C_4H_8O_2S$: S, 26.7. Found: 27.0.

D. Attempt to Prepare Hydroxydimethyl Sulfide. Hydrolysis of Methylthio Methyl Acetate

The acetate described above was hydrolyzed using a 2.5% solution of hydrogen chloride in absolute methanol. The reaction mixture separated into two layers one of which was insoluble in ether and contained no sulfur and the other was soluble in ether. The latter, after two fractionations, boiled at 70–71° at 48 mm., and contained sulfur but gave a negative Beilstein test. Two analyses gave, respectively, 52.65 and 52.16% S. Calcd. for C_2H_6OS, 41.05. Obviously, some substance other than that desired was produced in the hydrolysis. In view of the instability of the dihydroxydimethyl sulfide prepared by Bloch and Höhn,[16] it is questionable whether the hydroxymethyl methyl sulfide is capable of existence. It probably decomposes readily into methyl mercaptan and formaldehyde.

E. Preparation of β-Hydroxyethyl Methyl Sulfide, $CH_3SCH_2CH_2OH$

The sodium methyl mercaptide was filtered from the ether in which it was suspended, dried on filter paper and its weight determined; 88 g. (1.26 moles) was used. This was placed in a one liter flask fitted with a stirrer and reflux condenser. Three hundred and fifty cc. of dry ether (the same ether from which the mercaptide had been filtered) was added and 101 g. (1.26 moles) of ethylene chlorohydrin was added dropwise. No reaction took place at first, so the flask was warmed in a water-bath until the ether started refluxing and on continued addition of the chlorohydrin enough heat was liberated by the reaction to keep the ether gently boiling. After all of the chlorohydrin was added the mixture was refluxed for three and one-half hours and allowed to stand overnight.

The precipitate of sodium chloride and unreacted mercaptide was filtered off and the ether distilled through a Glinsky column. The residue was transferred to a 300cc. Claissen fractionating flask and twice fractionated in vacuum; 90 g. of a product boiling from 62–70' at 16 mm. was obtained (the main portion boiled at 68–70°), which corresponds to a **78%** yield. The product was a water white liquid of rather unpleasant odor, quite soluble in water and extremely soluble in alcohol and ether. Its boiling point at **30** mm. was **80.5–81°**; $d^{20^\circ}_{20^\circ} = 1.0640$; $n^{30^\circ}_{D} = 1.4867$.

Anal. Subs., **0.0725, 0.0743:** $BaSO_4$, **0.1829, 0.1870.** Calcd, for C_3H_8OS: S, **34.79.** Found: **34.66, 34.58.**

Using an aqueous alkaline solution of potassium methyl mercaptide in the reaction with ethylene chlorohydrin, similar to the method employed by Demuth and Meyer,[21] for the preparation of β-hydroxyethyl ethyl sulfide, the yield was but **33%.**

F. Preparation of γ-Hydroxypropyl Methyl Sulfide, $CH_3SCH_2CH_2CH_2OH$

The procedure used was exactly the same as described above for the lower homolog. One hundred and five grams **(1.5** moles) of dry sodium methyl mercaptide in suspension in **360** cc. of ether and **141.8** g. **(1.5** moles) of trimethylene chlorohydrin were used. Two fractionations yielded **120** g. of a product boiling from 90–97° at **17** tnm., the bulk of the material distilling from **93–94"**; yield, **76%.** The product was a water white liquid of unpleasant odor. It was fairly soluble in water and very soluble in alcohol and ether; boiling point at 30 mm., 105–105.5°; $d^{20^\circ}_{20^\circ} = 1.0314$; $n^{30^\circ}_{D} = 1.4832$.

Anal. Subs., **0.0888:** $BaSO_4$, **0.1973.** Calcd. for $C_4H_{10}OS$: **30.2.** Pound: **30.53.**

Using an aqueous alkaline solution of the potassium salt gave a yield of **54.5%.**

G. Preparation of β-Chloro-ethyl Methyl Sulfide, $CH_3SCH_2CH_2Cl$

This substance was prepared by treatment of the corresponding hydroxy compound with thionyl chloride, using chloroform as the solvent according to the procedure of Steinkopf, Herold and Stöhr.[21b] The entire reaction was carried out in the same flask from which the product was finally distilled. This precaution was taken because of the similarity in structure of this substance to mustard gas and to β-chloro-ethyl ethyl sulfide (which Meyer[22] states is poisonous, but less so than mustard gas).

Fifty grams **(0.54** mole) of β-hydroxyethyl methyl sulfide was dissolved in **100** g. of dry chloroform and placed in a 300-cc. Claissen fractionating flask which was fitted with a thermometer in place for distillation, with a dropping funnel, and with its side arm protected by a calcium chloride tube; **83.3** g. **(0.7** mole) of thionyl chloride dissolved in **200** g. of dry chloroform was placed in the dropping funnel and added dropwise. Each drop produced an evolution of sulfur dioxide and hydrogen chloride and the mixture warmed up and so was cooled at intervals by immersion in ice water. Vigorous shaking was maintained.

After a small amount of thionyl chloride had been added, each additional drop produced a local turbidity which finally resulted in the separation of **a** layer on the surface of the chloroform. About one hour was required for the addition of the thionyl chloride. The mixture was allowed to stand at room temperature for one and one-half hours and then the chloroform was distilled off from a boiling water-bath. During this process the upper oily layer disappeared and the solution became homogeneous. The residue was systematically fractionated in vacuum. After two fractionations a product boiling at 55–56° at **30** mm. was obtained. The yield in a number of experiments varied between **70** and 80%.

The product was a water white liquid with an odor resembling that of mustard gas. The boiling point at **20** mm. was **44'**; $d^{20^\circ}_{20^\circ} = 1.1245$; $n^{30^\circ}_{D} = 1.4902$.

---

[21] (a) Demuth and Meyer, *Ann.*, **240,310 (1887).** (b) See also Steinkopf, Herold and Stohr, *Ber.*, **53B,** 1010 **(1920).**

[22] Meyer, *Ber.*, 20, 1729 (1887).

Anal. Subs., 0.1653, 0.1974: $BaSO_4$, 0.3526, 0.4221. Calcd. for C_3H_7SCl: 28.99. Found: 29.30, 29.37.

An unsuccessful attempt was made to prepare the Grignard reagent of this substance, using the ordinary technique and also Baeyer's activated magnesium. This inactivity is analogous to that experienced by Reid and Helfrich[14] in attempting to prepare the Grignard reagent from mustard gas, and to Hamonet's attempts to obtain the magnesium compound of the corresponding oxygen ethers of the type $ROCH_2CH_2Cl$.[23]

H. Preparation of γ-Chloropropyl Methyl Sulfide, $CH_3SCH_2CH_2CH_2Cl$

This substance was made by exactly the same procedure as described above. In this case the addition of the thionyl chloride produced practically no heat and no layers formed during the reaction. After two fractional vacuum distillations a fraction boiling at 62–65' at 21 mm. was obtained. The yields varied between 70 and 75%. The substance was a water white liquid with an odor resembling that of the β compound. The boiling point of the product used for analysis was 71 2" at 29 mm.; $d_{20°}^{20°} = 1.0863$; $n_D^{30°} = 1.4833$.

Anal. Subs., 0.2094: $BaSO_4$, 0.3930. Calcd. for C_4H_9SCl: 25.73. Found: 25.79.

[23] Wurtz, "Dictionnaire de Chimie," 2, 751. Compare Bennett and Hock, *J. Chem. Soc.*, 129, 472 (1927).

A were identical with that previously described.' It was necessary to modify slightly the procedure used in making the titration and to employ the method of extraction which was described in the paper just referred to. When the potassium iodate was added to the mixture being titrated, a yellow color developed which persisted long after the theoretically required amount had been added; this yellow color completely covered the end-point. It was shown to be due to the action of the potassium iodate on the organic sulfur chloride or iodide. Preliminary experiments proved that when the organic sulfur compound was extracted with chloroform before addition of the potassium iodate, sharp end-points were observed and consistent results obtained. Only negligible amounts of iodine were liberated during the reaction proper and on addition of the aqueous acid, so that no correction was necessary:

The author is exceedingly grateful to Professor J. B. Conant who suggested this problem and offered much valuable advice during the course of the work.

Summary

1. The method previously developed for determining the effect of structure of organic halides on their rate of reaction with inorganic halides has been extended to include the influence of the methylthio group. This group causes a definite, though weak, alternation in the reactivity of an w-chlorine atom through at least three carbon atoms in a saturated chain.

2. In an attempt to correlate the structure of w-halogen alkyl sulfides with vesicant action it was found that only when the halogen atom was in the β-position with respect to the sulfur atom did the resulting compound possess vesicant properties. This appears to be true of β,β′-dihalogen alkyl sulfides also. No apparent relationship exists between vesicant action and the chemical reactivity (at least in replacement reactions) of the halogen atom, a fact which is not in agreement with the acid theory of skin vesication.

3. A new vesicant, β-chloro-ethyl methyl sulfide, has been prepared, which judging from rather crude tests seems to produce the same general effects as mustard gas and at approximately the same rate.

4. The following substances have been prepared and their properties described for the first time: methylthio methyl acetate; β-hydroxyethyl methyl sulfide; β-chloro-ethyl methyl sulfide; γ-hydroxypropyl methyl sulfide; y-chloropropyl methyl sulfide.

THE CRYSTAL STRUCTURE OF UREA AND THE MOLECULAR SYMMETRY OF THIOUREA

BY STERLING B. HENDRICKS

RECEIVED APRIL 27, 1928 PUBLISHED SEPTEMBER 5, 1928

The following study of the crystal structure of urea has been undertaken because it is one of the few simple organic compounds having high crystallographic symmetry. Thiourea is of interest since as a simple derivative of urea it offers an opportunity for comparing the molecular symmetry of the two substances,

Urea

Urea, $CO(NH_2)_2$, crystallizes in the tetragonal scalenohedral division of the tetragonal system[1] with the axial ratio, $a:c = 1:0.8333$. H. Mark and K. Weissenberg[2] have previously made a partial determination of the crystal structure of urea. Their results can be summarized as follows. The dimensions of the unit of structure are $d_{001} = 4.70$ Å., $d_{100} = 5.63$ Å., the space group is 4d–3 with oxygen and carbon at (c)[3] and nitrogen at (e) with $u_N = 0.13$.

Crystals showing development of (111) and (110) were grown from alcohol–water solutions of urea. A Laue photograph made with the incident x-ray beam normal to (110) shows a twofold axis and two planes of symmetry. This observation requires the structure to be isomorphous with one of the point groups 4d, 4e, 4*D* or 4Di. Since point group 4d is in agreement with the previously assigned crystallographic symmetry, the assumption is made that the structure is isomorphous with it.

Laue photographs were made with the incident x-ray beam normal to and making small angles with the normals to (110) and (100). Spectrum photographs were made on which (110) and (001) reflected in the equatorial region of the plate. These faces were initially parallel to the x-ray beam and were oscillated through a 20° angle. In the case of (110) the *c* axis was in the axis of revolution while for (001) the normal to (110) was in the axis. The smallest unit of structure compatible with the data obtained from these photographs (see Tables I–III) has $d_{001} = 4.77$ Å. and $d_{100} = 5.73$ Å. (calculated from the crystallographic axial ratio and the measured value of d_{001}). The density calculated on the basis of such a unit structure containing two $CO(NH_2)_2$ is 1.26 in agreement with the experimentally determined value 1.335.[4]

[a] Oscillation through 30° with the normal to $(1\bar{1}0)$ in the axis of oscillation, (110) was initially parallel to the x-ray beam, Mo K radiation.

[b] It is to be remembered that the times of exposure are not the same for all of the spectra listed.

Reflections were present in the first order from planes (*hkl*) having h, k and *l* odd (Table III). The underlying lattice is therefore the simple tetragonal one necessitating the consideration of only the space groups from 4d–1, to 4d–8. The observed presence of reflection from (001) on spectrum photographs and from (113) and (115) in the first order on Laue photographs cannot be explained by space groups 4d–2, or 4d–4.[5] The presence of reflections from $(03\bar{4})$, $(10\bar{2})$, $(01\bar{5})$ in the first order on Laue photographs eliminates space groups 4d–6, 4d–7 and 4d–8. The observed absence of reflection in the odd orders from (100) (Table II) cannot be accounted for by space groups 4d–1, or 4d–5. In the case of either 4d–1 or 4d–5 if a $CO(NH_2)_2$ group is assumed to be present it would be necessary for two (CO) groups of two different urea molecules to be distributed in

[a] Tungsten general radiation, 54,000 V peak.

[b] The structure factor calculations given in this paper are for $u_N = 0.13$; $v_N = 0\ 20$; $v_C = 0\ 32$; $v_O = 0\ 57$. The relative reflecting powers of N, O and C are assumed to be the same.

[c] The incident x-ray beam made an angle of about 8° with the normal to (110).

[d] A second photograph. The incident x-ray beam made an angle of about 2° with the normal to (010)

a linear distance of 4.77 Å., an unlikely distribution. Space group 4d–3 is in agreement with the x-ray data.

If it is assumed that there are two $CO(NH_2)_2$ groups present in the unit of structure, then the C and O atoms of such a group must be at:[3] (c) $0\frac{1}{2}v$; $\frac{1}{2}0\bar{v}$, and the N atoms at *(e)* $u, \frac{1}{2} - u, v$; $\frac{1}{2} - u, \bar{u}, \bar{v}$; $\bar{u}, u + \frac{1}{2}, v$; $u + \frac{1}{2}, u, \bar{v}$. To determine the structure completely it is necessary to evaluate four parameters, three of which are in the c direction.

Without assumptions concerning the relative reflecting powers, the comparisons (see Table II) (420) > (310), and (320) > (410) restrict the value of u_N to 0.10 to 0.14. If one assumes that C, O and N have approximately the same relative reflecting power (within 25%), the comparison (510) > (320) restricts the value of u_N to 0.12 to 0.14; the value of u_N is therefore taken as 0.13 ± 0.01.

If one assumes that the C–O distance is between 1.0—1.7 Å., that the C–N distance is between 1.0–1.5 Å and that C, O and N have approximately the same relative reflecting powers (within 25%), the comparisons, using the value of u_N given above, (002) > (001), $(13\bar{3})$ > $(\bar{1}\bar{1}3)$ and $(\bar{3}0\bar{4})$ > $(\bar{5}\bar{3}0)$ restrict the values of v_N, v_C and v_O to the regions shown in Fig. 1. The intensity differences in these cases are quite large. A further limitation of parameter values can be made by the utilization of planes having less pronounced intensity differences. The restrictions necessitated by the comparisons $(12\bar{2})$ > $(\bar{3}\bar{2}0)$, $(\bar{4}1\bar{1})$ > (412), (510) > $(51\bar{2})$, $(0\bar{1}\bar{5})$ > $(1\bar{1}\bar{5})$ are shown in Fig. 1. The probable parameter values determined in this manner are v_N = 0.20 ± 0.02; v_C = 0.32 ± 0.02; v_O = 0.57 ± 0.03. It must be emphasized that these narrower limits depend upon comparisons between planes the reflections from which do not differ greatly in intensity.

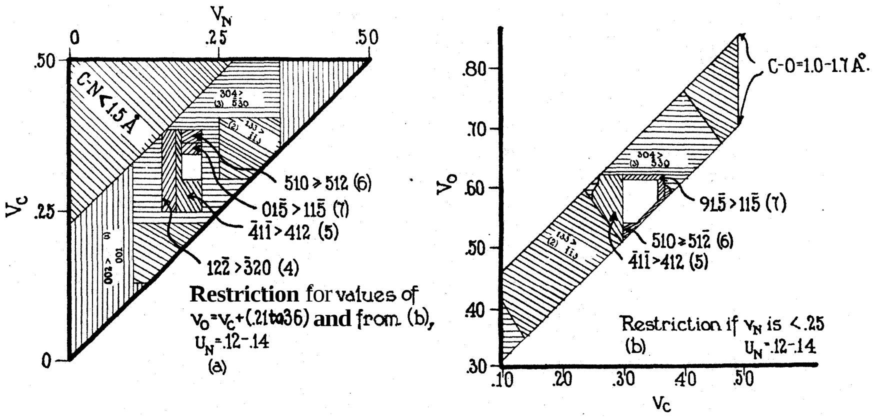

Fig. 1.—Intensity comparisons leading to a restriction of the values of the parameters for urea.

Structure factors, $S = A^2 + B^2$, calculated for reflections from the various planes, are listed in Tables I–III. In these calculations it was assumed that the relative reflecting powers of C, O and N are equal and that the values of the parameters are, u_N = 0.13, v_N = 0.20, v_C = 0.32 and v_O = 0.57. The structure factors calculated for $(14\bar{4})$ and $(10\bar{2})$ change rapidly with small changes in the parameter values. The observed intensities and the calculated structure factors, Tables I–III, are concomitant.

Thiourea

Thiourea, $CS(NH_2)_2$, crystallizes in the rhombic bipyramidal division of the rhombic system with the axial ratio $a:b:c = 0.7163:1:1.1155$.[6] Crystals, tabular parallel to $(100)_{\text{crys.}}$ and $(010)_{\text{crys.}}$, were obtained from alcohol and alcohol–water solutions of thiourea.

Spectrum photographs, with 20° oscillation, were made with the crystallographic axes in the axis of rotation. In these photographs the various pinacoids were initially parallel to the x-ray beam. Partial reproductions (Mo $K\alpha_1$ reflections) of some of these photographs are given in Fig. 4. The smallest unit of structure compatible with these data and with the spectrum and Laue data listed in Tables IV and V has $d_{(001)\text{crys.}} = 8.57$ Å.

---

[6] Ref. 1, p. 555.

(Table IV), $d_{(010)\text{crys.}} = 7.68$ Å. and $d_{(100)\text{crys}} = 5.50$ Å. The values of $d_{(010)\text{crys.}}$ and $d_{(100)\text{crys.}}$ were calculated from the crystallographic axial ratio and the measured value of $d_{(001)\text{crys.}}$. The density calculated on the basis of such a unit containing $4CS(NH_2)_2$ is 1.371 in agreement with the experimentally determined value 1.406.[6]

The presence of reflections in the first order from $(120)_{\text{crys.}}$ and $(021)_{\text{crys.}}$ requires the lattice to be the simple orthorhombic one. The observed presence of reflections in the first order from $(120)_{\text{crys.}}$, $(021)_{\text{crys.}}$, $(101)_{\text{crys.}}$ and $(110)_{\text{crys.}}$ can be accounted for only by space groups $2Di-1$, $2Di-5$, $2Di-13$, and $2Di-16$. The characteristic absences of reflections required by the general positions of these space groups are:[7] $2Di-1$, none; $2Di-5$, $(h0l)$ in odd orders when l is odd; $2Di-13$, $(hk0)$ in odd orders when $(h + k)$ is odd; $2Di-16$, $(h0l)$ in odd orders when $(h + 1)$ is odd; $(hk0)$ in odd orders when k is odd. Reflections were absent on the spectrum photographs from the following planes having one index zero which were in position to reflect (crystallographic axes): (012), (014), (016), (034), (102), (203), (104), (205), (106), (201), (401), (302), (410), (210), (220), (001), (003), (010), (030), (100), (300), (160), (025), (023), (520), (220). The only one of the above space groups explaining these absences of reflections is $2Di-16$. This space group, in the general case, does not account for absence of reflections from (410), (210), (160), (025), (023), (220). The relationships between the crystallographic indices and the space group indices are: $h_{\text{sp. g.}} = l_{\text{crys.}}$; $k_{\text{sp. g.}} = k_{\text{crys.}}$; $l_{\text{sp. g.}} = h_{\text{crys.}}$.

Inspection of the Laue data listed in Table V shows that first order reflections are present from only two planes having $(h + k + 1)$ odd, namely, $(160)_{\text{sp. g.}}$ and $(12\bar{4})_{\text{sp. g.}}$. The listed planes from which reflections were not obtained represent all planes having interplanar spacings between 0.935 Å and 1.547 Å which were in position to reflect in the first order between $\lambda = 0.24$–0.48 Å. All of these planes have $(h + k + l)$ odd with $h_{\text{sp. g.}}$ either equal to one or two. Inspections of the spectrum data (Fig. 4) shows that first order reflections are present from a number of planes having $(h + k + 1)$ odd, in particular (space group axes) (160), (320), (120), (021) and (041). With the exception of $(220)_{\text{crys.}}$ all of the previously listed planes, the absence of reflections from which are not accounted for by the general space group criteria, have $(h + k + 1)$ odd.

In order to have a $CS(NH_2)_2$ group in the unit of structure the C and S atoms of such a molecule must be at $2Di - 16$,[8] (c) $0uv$; $\frac{1}{2}, \frac{1}{2} - u, \bar{v}$; $0, u + \frac{1}{2}, \frac{1}{2} - v$; $\frac{1}{2}, \bar{u}, v + \frac{1}{2}$, with the nitrogen atoms in the general positions (d) $x\,y\,z$; $x + \frac{1}{2}, \frac{1}{2} - y, \bar{z}$; $\bar{x}, y + \frac{1}{2}, \frac{1}{2} - z$; $\frac{1}{2} - x, \bar{y}, z + \frac{1}{2}$; $\frac{1}{2} - x, \frac{1}{2} - y, \bar{z}$; $\bar{x}yz$; $x + \frac{1}{2}, \bar{y}, z + \frac{1}{2}$; $x, y + \frac{1}{2}, \frac{1}{2} - z$, or in two crystallographi-

---

[7] R. W. G. Wyckoff, *Z. Krist.*, **61**, 425 (1925).

[8] Ref. 3, p. 64.

cally non-equivalent sets at (c). The observation that the 6th order reflection from $(100)_{\text{sp. g.}}$ is stronger than the 4th order can be explained only if the nitrogen atoms are at (d).

Examination of the special types of reflections required by the above arrangement shows that in the case of (c) if the value of u is $\frac{1}{4}$ or $\frac{3}{4}$ then reflections will be absent in the odd orders from planes having (h + k + l) odd. It must be remembered that the sulfur atom is much heavier than the carbon, nitrogen or hydrogen atom and thus at a particular wave length probably has a relative increasingly greater effective scattering power for x-rays, with decreasing interplanar spacings. Thus if the sulfur atom is at (c) with the value of u_S equal, or approximately equal, to $\frac{1}{4}$ or $\frac{3}{4}$, then reflections from planes having (h + k + l) odd would be due to the carbon and nitrogen atoms alone. One would thus expect the relative intensity of the reflections from such planes to decrease rapidly with decreasing interplanar spacings. Such an explanation would be in accord with the experimental observation.

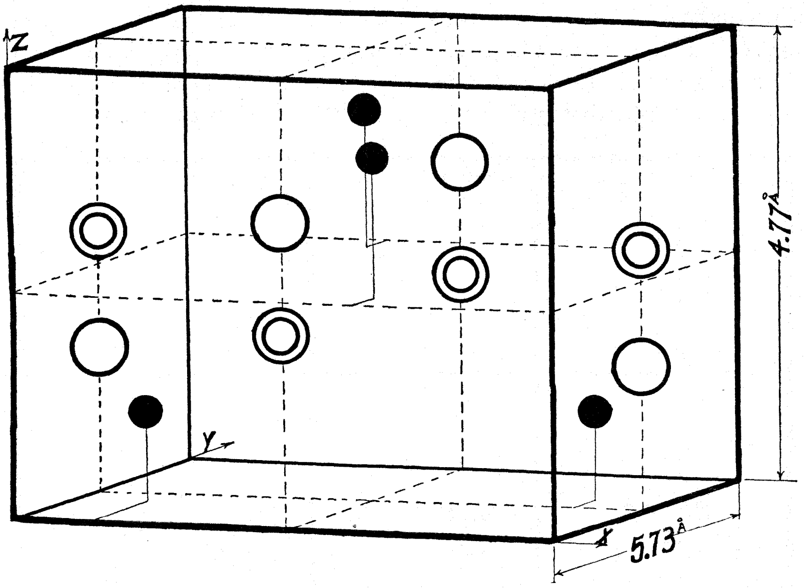

Fig. 2.—A representation of the unit of structure containing two $CO(NH_2)_2$. The nitrogen atoms are represented by the small black circles, the oxygen atoms by the ringed circles and the carbon atoms by the large circles.

The intensity observations, $(600)_{\text{sp. g.}} > (400)_{\text{sp. g.}}$, and $(800)_{\text{sp. g.}} \geqslant (400)_{\text{sp. g.}}$, can be explained only if x_N = 0.10—0.16. The intensity distribution for these planes shows that x_N is probably equal to 0.14 ± 0.02. The observed low intensity of reflection of (040), $(060) >> (040)$ cannot be explained if y, = 0.22—0.28, under the assumption that $u_S = \frac{1}{4}$ or

In fact the data could best be explained by a value of y_N not differing greatly from 0.15 or 0.35. The presence of seven parameters prevents a more complete analysis of the structure at the present time.

Discussion

A representation of the unit of structure containing two $CO(NH_2)_2$ is shown as Fig. 2. Within the probable limits of the parameter values the interatomic distances within a particular molecule are: C–O, 1.05 to 1.42 Å; $C–NH_2$, 1.07 to 1.30 Å. Even though the limits are broad these distances are much less than the C–C distance in the diamond. They are in agreement with the values found for $C–N(CH_2–NH_3)$ and $C–C(CH_2–CH_2)$ distances in the mono-alkyl ammonium halide series which are being studied in this Laboratory.[9] The value as a rule is between 1.20 to 1.30 Å. with no particular distinction between carbon and nitrogen.

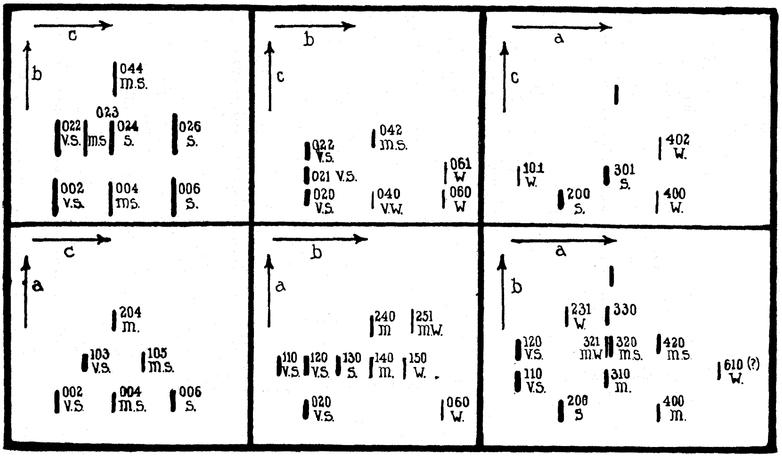

Fig. 3.—A partial reproduction of spectrum photographic data (Mo Kα_1 lines only) from thiourea. 20° oscillation. Crystallographic indices.

The $CO(NH_2)_2$ molecule has a twofold axis and two planes of symmetry (point group 2e). The angle between the axis of a (CO) group and a line connecting (NH_2) with the carbon atom of a $CO(NH_2)_2$ group is 52–73.5". The resulting configuration of a $CO(NH_2)_2$ molecule is shown as Figure 4a.

The results of crystal structure investigations of inorganic compounds have led many authors to a concept of space filling with spherical or approximately spherical atoms in crystals of inorganic compounds. The expression of ionic radii on such a basis has been of great assistance in investigations of the structures of complex inorganic substances. An examination of the very limited results obtained with molecular compounds,

---

[9] S. B. Hendricks, Z. *Krist.* (in press).

the crystal structure of which have been completely determined, indicates that the only structural similarity is the approximate constancy of certain interatomic distances. The closest distances between atoms of separate molecules are usually much greater than the interatomic distances within the molecules, and greater than the values calculated from the inorganic "ionic radii." Such a result is of course not an unexpected one.

In the case of urea the closest possible distance of approach between two atoms not of the same molecule is ($O-NH_2$) about 3.0 Å., with a probable value of approximately **3.15** Å. In the previously determined structure of carbon dioxide[10] the C–O distance within a CO_2 molecule is about 1.05 Å., while the closest distance of approach O–O is about **3.23** Å. In the structure of hexamethylenetetramine[11] the closest approach between two atoms not of the same molecule is (C–C) about **3.72** Å. with a corresponding distance (C–N) of about **1.33** Å. within the molecule. In the determined structure of benzene hexahydrobromide and chloride[12] the closest distances of approach between halogen atoms are Br–Br about 3.40 Å. and 3.748. with the smaller distance probably that within the $C_6H_6Br_6$ molecule.

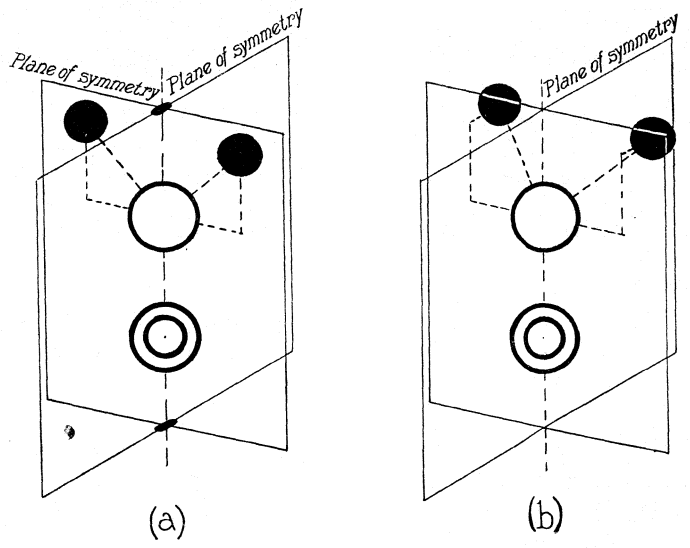

Fig. 4.—Possible configurations of the (a) urea and ((a) and (b)) of the thiourea molecule. The nitrogen atoms are represented by the small black circles, the oxygen atoms by the ringed circles and the carbon atoms by the large circles.

---

[10] **W. H. Keesom and J. De Smedt,** *Verslag. Akad. Wetenschappen. Amsterdam,* **33,** *888* **(1924). The results of the above authors were checked by L. Thomassen and S. B. Hendricks (unpublished work), $a_0 = 5.60$, $u_0 = 0.11$.**

[11] **R. G. Dickinson and A. L. Raymond,** THIS JOURNAL, **45, 22 (1923).**

[12] **R. G. Dickinson and C. Bilicke,** *ibid.,* **50, 764 (1928).**

The presence of the hydrogen atoms undetermined in positions vitiates the above analysis except in the discussion of carbon dioxide. Only in the case of the hexahydrohalides of benzene are the distances of closest approach near the values suggested by the inorganic "atomic radii."

The analysis of the structure of thiourea is not complete enough to allow close comparison with that of urea. The geometrical relationships between the molecules cannot be similar for the two compounds. The minimum molecular symmetry of thiourea is that of the point group 2c, which has a plane of symmetry. It is possible, as is shown in Fig. 4a, that all of the atoms of a thiourea molecule might be coplanar.

It has been suggested that thiourea has the formula  $H-S-C{\Large\langle}^{NH}_{NH_2}$ rather than  $S=C{\Large\langle}^{NH_2}_{NH_2}$. The existence of salts of the general formula  $R-S-C{\Large\langle}^{NH}_{NH_2}$ ·HI, the behavior of thiourea on oxidation in acid solutions and other chemical properties are said to be evidence in favor of the first formula. The observed crystallographic equivalence of the nitrogen atoms shows that in the solid state the symmetrical formula is correct.

Summary

The crystal structure of urea $CO(NH_2)_2$ has been determined by the use of Laue and spectrum photographs. The unit of structure containing two $CO(NH_2)_2$ has d_{100} = 5.73 Å. and d_{001} = 4.77 Å. The space group is $4d-3$ (V_d^3) with O and C at (c) $0\frac{1}{2}v$, $\frac{1}{2}0\bar{v}$; and N at (e) $u, \frac{1}{2}-u, v$; $\frac{1}{2}-u$, 4, $\bar{v}$; $\bar{u}, u+\frac{1}{2}, v$; $u+\frac{1}{2}, u, \bar{v}$. The probable parameter values are $u_N = 0.13 \pm 0.01$, $v_N = 0.20 \pm 0.02$, $v_C = 0.32 \pm 0.02$ and $v_O = 0.57 \pm 0.03$.

Laue and spectrum photographs were made from crystals of thiourea. The unit of structure containing four $CS(NH_2)_2$ has a_0 = 5.50 Å., b_0 = 7.68 Å. and c_0 = 8.57 Å. The space group is 2Di—16 (V_h^{16}) with S and C at (c) $0uv$; $\frac{1}{2}, \frac{1}{2}-u, \bar{v}$; $0, u+\frac{1}{2}, \frac{1}{2}-v$; $\frac{1}{2}$, a, $v+\frac{1}{2}$ and with N in the general positions. The molecular symmetry is that of the point group $2c$ (C_S) which has a plane of symmetry.

NITRO-AMINOGUANIDINE

BY ROSS PHILLIPS AND JOHN F. WILLIAMS

RECEIVED MAY 11, 1928 PUBLISHED SEPTEMBER 5, 1928

Nitroguanidine, $HN{=}C(NH_2)NHNO_2$, was first prepared by Jousselin[1] by dissolving guanidine nitrate in concentrated sulfuric acid, when the compound separated upon dilution with water. More recently several articles[2] have appeared concerning this compound. It is used principally as an explosive. Thiele[2a] prepared nitrosoguanidine as well as aminoguanidine, $HN{=}C(NH_2)NHNH_2$, by reduction of nitroguanidine. Hofmann and Stollé[3] and also Pellizzari and co-workers[4] prepared diaminoguanidine hydrochloride, $HN{=}C(NHNH_2)_2{\cdot}HCl$, by the action of cyanogen chloride on hydrazine in ethereal or aqueous solutions. Pellizzari and Gaiter[5] also prepared triaminoguanidine by treating guanidine or its mono- or diamino derivative with the calculated amount of hydrazine. This work was verified and a good yield of triaminoguanidine obtained by heating an alcoholic solution of guanidine nitrate and hydrazine at 100° for five hours.

Apparently nitro-aminoguanidine, $HN{=}C(NHNO_2)NHNH_2$, has never been prepared, as no reference to it was found in the literature. In 1920, while working on guanidine compounds, it was found that an interesting substance formed when nitroguanidine was heated with a solution of hydrazine. This substance is the subject of the present investigation.

Preparation of Nitro-aminoguanidine

The nitroguanidine used in this experiment was prepared by dissolving guanidine nitrate in concd. sulfuric acid, and pouring this solution into ice water. The crystals obtained were twice recrystallized from water.[2c,e]

Hydrazine sulfate, 32.53 g., was placed in a 2000-cc. Erlenmeyer flask with 200 cc. of distilled water and 500 cc. of *N* ammonia water. When the hydrazine sulfate had dissolved, 26 g. of nitroguanidine was added. The flask was then heated to 50–60°, during which time the nitroguanidine went into solution, nitrous oxide gas began to evolve and the reaction liquor turned to an orange-red color. In about one hour at the above temperature, gas ceased to form and the liquor was rapidly evaporated to about one-third its volume. On cooling, a white crystalline powder separated which was filtered off, washed with cold water and dried in the air; yield, 13.1 g. This was purified by dissolving in boiling water containing decolorizing carbon, and filtering. Upon chill-

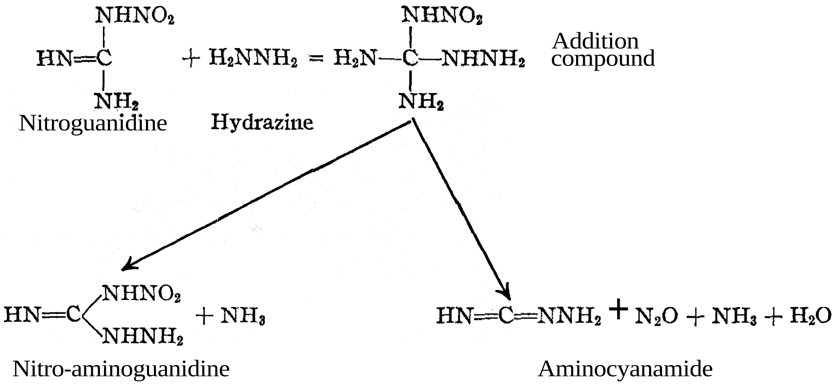
ing the filtrate a pure crystalline powder formed. Changes in the above procedure were tried but no better yield was obtained.

Repeated yields of approximately 50% were obtained, which would seem to indicate the following reaction.



No indication of aminocyanamide (which is perhaps decomposed in the reaction liquor) was obtained. Nitro-aminoguanidine and ammonia were formed in the quantities indicated above and nitrous oxide came off freely.

Analysis of Nitro-aminoguanidine

The analysis of nitro-aminoguanidine presented **a** difficulty not easily met. The standard processes for the determination of nitrogen, such as the modified Kjeldahl, nitrometer and alkaline fusion methods, failed to yield the nitrogen expected. The following procedure proved successful.

One five-hundredth mole, 0.2383 g., was dissolved in 2 cc. of 1:1 sodium hydroxide solution and washed into a nitrometer with 3 cc. of water. Two grams of cupric sulfate dissolved in 4 cc. hot water was next introduced. Gas immediately formed and slowly subsided. The nitrometer bulb was now cautiously and later vigorously heated with steam for two hours. On cooling the gas measured 70.2 cc. at 0°. There was then carefully introduced 10 cc. of concd. sulfuric acid, and after gently mixing there still remained an insoluble copper precipitate. The nitrometer bulb was again heated with steam for one hour and cooled. The gas now measured 96.7 cc. at 22° and at 741 mm. and was then analyzed. The liquid remaining in the nitrometer measured 18 cc. and was reserved for a separate analysis. By passing aliquot portions of the gas into Hempel gas pipets containing, respectively, 1:1 sodium hydroxide, cuprous chloride and alkaline pyrogallol solutions, a shrinkage with the first indicated that 9% of the gas was carbon dioxide, while no shrinkage in the remaining solutions showed the absence of carbon monoxide and oxygen. A small portion mixed with air failed to give a brown coloration showing the absence of nitric oxide. The gas consisted of a mixture of nitrogen and nitrous oxide, the latter as shown by the splinter-glow test, and its solubility in alcohol indicated approximately one volume of nitrous oxide to three volumes of nitrogen. This residual mixture of 88.0 cc. of gas was calculated as nitrogen by substitution in the Dumas formula

$$V_0 = \frac{V(B - W)}{760} \times \frac{273}{273\ t}$$

$$88.0\text{ cc.} \times \frac{732}{760} \times \frac{273}{295} \times 0.00125 = 0.09787 \text{ grams of nitrogen}$$

This represented about 70% of the calculated quantity of nitrogen.

The liquid remaining in the nitrometer was analyzed by the Gunning modification of the Kjeldahl method[6] and 0.0421 g. of nitrogen obtained in the form of ammonia: nitrogen as gas, 0.09787 g.; nitrogen as NH_3, 0.04210 g.; nitrogen found, 0.13997 g.; calcd., 0.14008.

Properties of Nitro-aminoguanidine

Nitro-aminoguanidine is a white, crystalline powder belonging to the monoclinic system; soluble in water to the extent of 0.34% at 20° and 3.0% at 70°; insoluble in most organic solvents. It dissolves readily in caustic alkali solutions with the formation of a yellow color, does not evolve ammonia when this solution is boiled but loses its identity after standing for several hours in the caustic alkaline solution. It melts accompanied by explosion at about 190°. It reduces solutions of permanganate and dichromate, Nessler's reagent and ammoniacal silver nitrate in the cold. With the latter reagent gas is evolved and metallic silver is precipitated, along with an explosive silver compound.

Similarly, it reduces Fehling's solution with the formation of an explosive copper compound. With nickel solutions interesting and characteristic reactions occur. If to a solution of nitro-aminoguanidine containing caustic alkali a trace or more of a nickel salt is added, an intense deep blue color develops and lasts for fifteen to twenty minutes. This test can be made to detect as little as 0.0002 mg. of nickel. Cobalt and a number of other metals failed to give this test. In the absence of caustic alkali, however, and in the presence of ammonia, nitro-aminoguanidine will yield, with solutions of nickel, a fawn colored nickel precipitate which will be described later. Like nitroguanidine it may be ground in a mortar without detonation, but differs from the former when heated near a flame on an iron spatula. Each separate particle of nitro-aminoguanidine explodes as it becomes ignited by the flame, leaving a yellow, insoluble residue. It condenses with aldehydes and ketones, as will be described.

Tests for Nitro-aminoguanidine

Although the above-described nickel test is characteristic, other tests for the compound may be mentioned. Davis and others[2]" give qualitative tests for nitroguanidine. The first is based upon the purple color which develops when a few drops of sodium hydroxide solution is added to a solution of nitroguanidine containing a little ferrous sulfate. The second test depends upon the reduction of copper or silver acetates by the re-

---

[6] "Methods of Analysis," A. O. A. C., 1925, p. 9.

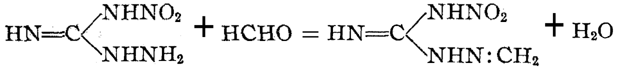
duced nitroguanidine, that is, the aminoguanidine formed when nitroguanidine is treated with zinc dust in acetic acid solution.

We found that nitro-aminoguanidine gives both these tests. In fact, in the second test, it reacts more energetically than does nitroguanidine. A simple qualitative test for nitro-aminoguanidine was found to be as follows. When 2 mg. or more is dissolved in warm, concd. sulfuric acid, gas is evolved and a light green solution develops and lasts. When a few drops of a 5% ferrous sulfate solution is added, the color changes to a cherry red. Nitroguanidine, nitro-urea and hydrazine do not give this test.

Reactions of Nitro-aminoguanidine

A. Reactions with Aldehydes and Ketones

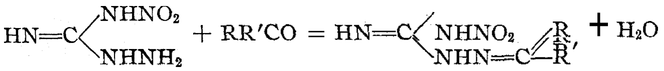
When aldehydes or ketones were added to a saturated solution of nitro-aminoguanidine, crystalline precipitates formed. For example, the formaldehyde reaction took place as follows. To about 10 cc. of a warm saturated solution of nitro-aminoguanidine there was added 4 to 5 drops of 37% formaldehyde solution. Upon standing and cooling, long needles of the condensation product formed, the reaction taking place, perhaps, in the following manner



$$HN{=}C\begin{matrix}\diagup NHNO_2\\ \diagdown NHNH_2\end{matrix} + HCHO = HN{=}C\begin{matrix}\diagup NHNO_2\\ \diagdown NHN{:}CH_2\end{matrix} + H_2O$$

Similar hydrazones were obtained with acetaldehyde, citral, benzaldehyde and vanillin. The aromatic aldehyde hydrazones were nearly insoluble in water while the aliphatic hydrazones were somewhat soluble in water.

Ketones yielded in a similar manner their corresponding products and white, needle-like crystals were obtained with acetone, methylethyl ketone, diethyl ketone and pyruvic acid, $CH_3COCOOH$. The general reaction with ketones is expected to take place as follows



$$HN{=}C\begin{matrix}\diagup NHNO_2\\ \diagdown NHNH_2\end{matrix} + RR'CO = HN{=}C\begin{matrix}\diagup NHNO_2\\ \diagdown NHN{=}C\begin{matrix}\diagup R\\ \diagdown R'\end{matrix}\end{matrix} + H_2O$$

These condensation products with aldehydes and ketones were observed, when dried, to detonate when ignited. This was not the case when similar compounds of diaminoguanidine (the benzaldehyde compound was prepared and examined) were ignited. This property of detonation was considered evidence that the nitro group is retained in the former case. Also, the property of nitro-aminoguanidine of forming condensation products with aldehydes and ketones was considered evidence of the presence of a hydrazine group. Indication of the reduction of the nitro group in the benzaldehyde hydrazone was obtained. This compound was suspended in water slightly acidified with hydrochloric acid and zinc dust was added. After standing for two hours at room temperature, the solution was filtered and on evaporation the filtrate gave abundant crystals of a hydrochloride which did not detonate. Nitro-aminoguanidine did not yield insoluble, crystalline hydrazones with glucose, fructose, galactose or arabinose,

B. Reactions with Metals

The composition of the explosive compounds of silver and copper with nitro-aminoguanidine has not been determined. They differ from the nickel compound in that they are formed during the decomposition of nitro-aminoguanidine, while the nickel compound is in the nature of an addition product.

Preparation of Nickel Nitro-aminoguanidine

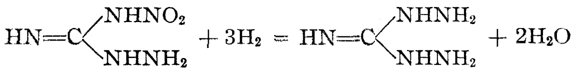
Five cc. of nickel sulfate solution, containing 0.093 g. of metallic nickel, was placed in a 250cc. beaker and diluted with 100 cc. of hot water. Five cc. of N ammonia water was added, followed immediately by a solution of 0.5 g. of nitro-aminoguanidine dissolved in 50 cc. of hot water. The precipitate formed was boiled gently for fifteen to twenty minutes, filtered through a weighed crucible, washed with hot water and dried at 110°. The weight became constant in three hours, giving 0.4955 grams of the compound. The filtrate was evaporated and a delicate test made for the presence of nickel but none was found. Since the solution of nickel sulfate used contained a known amount of nickel (electrolytically determined) and all of it was shown to have reacted, the precipitate contained 18.75% Ni; calcd. for $NiO[HN{=}C(NHNO_2)NHNH_2]_2$, 18.76%. The filtrate, after the removal of the nickel compound, was found to have 0.225 g. of ammonium sulfate together with the excess of nitro-aminoguanidine.

The precipitate is insoluble in hot or cold water and organic solvents. It dissolves in caustic alkali solutions with the formation of an intense deep blue color. It is decomposed by sulfuric acid with the formation of a toxic gas. It explodes with a flash when placed in a flame but may be heated in a test-tube to 220° without detonation. It explodes mildly when struck with a hammer.

It would seem that nitro-aminoguanidine may serve as a reagent for nickel determination, having the advantage over dimethylglyoxime of being water soluble.

Reduction of Nitro-aminoguanidine

If the new compound has the structure assigned, then it should yield diaminoguanidine on reduction, as follows



$$HN{=}C\begin{cases}NHNO_2\\NHNH_2\end{cases} + 3H_2 = HN{=}C\begin{cases}NHNH_2\\NHNH_2\end{cases} + 2H_2O$$

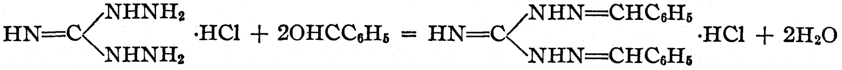
This was actually found to be the case.

The experiment was made in the following manner: 1.19 g. of nitro-aminoguanidine was mixed with 7 g. of zinc dust and cracked ice in a 200cc. cylinder. There was then slowly introduced with stirring 50 cc. of 10% acetic acid solution. The temperature was kept below 10° by repeated additions of ice. After stirring for one hour, the solution was allowed to reach room temperature and then filtered. The zinc was removed from the filtrate by hydrogen sulfide, and after the removal of the zinc sulfide the solution was evaporated on the steam-bath with the aid of a current of air. When the excess of acetic acid was evaporated, the residue was dissolved in a little water and the calculated amount of hydrochloric acid, 20 cc. of $N/2$, added. After again evaporating to dryness, a slight excess of hydrochloric acid was added to insure complete removal of acetic acid. The dried residue was next extracted with hot alcohol, filtered and upon cooling in the ice box crystals were obtained; weight 0.75 g., 60% yield. They were again recrystallized from alcohol, dried and examined; melted with decomposition at 176°. Hofmann reported 174°; Pellizzari, 185°.

Anal. Calcd. for HCl: 29.0. Found: 28.90.

The nitrate was prepared from the hydrochloride by double decomposition with silver nitrate (in excess of nitric acid) and recrystallized from alcohol. The slightly impure crystals melted from 140–144°. Pellizzari reported 143°. These salts of diaminoguanidine agreed with those reported by Hofmann and Pellizzari by forming yellow radiating needles with picric acid, reduced ammoniacal silver nitrate in the cold and also solutions of gold, platinic and cupric salts, and with benzaldehyde they formed crystalline condensation products in the cold.

The benzaldehyde compound with diaminoguanidine, dibenzylidenediaminoguanidine, was prepared as follows. To a solution of diaminoguanidine hydrochloride there was added an excess of benzaldehyde and, after stirring, a white precipitate formed. The reaction took place in the following manner



$$HN{=}C\begin{cases}NHNH_2\\NHNH_2\end{cases}\cdot HCl + 2OHCC_6H_5 = HN{=}C\begin{cases}NHN{=}CHC_6H_5\\NHN{=}CHC_6H_5\end{cases}\cdot HCl + 2H_2O$$

The excess benzaldehyde was removed with ether, the crystals were washed with water, dissolved in sodium carbonate solution and extracted with ether. After the ether was evaporated the residue was recrystallized from alcohol and yellow crystals of dibenzylidenediaminoguanidine were obtained, m. p. 178° (corr.); reported by Hofmann 176°; by Pellizzari, 180°. The base was insoluble in water but soluble in alcohol. The hydrochloride of dibenzylidenediaminoguanidine was prepared from the base and when recrystallized from alcohol yielded fine, cotton-like, nearly white crystals, m. p. 230°; reported by Hofmann, 232°; by Pellizzari, 230°. This sums up the evidence showing the reduction of nitro-aminoguanidine to diaminoguanidine.

It is likely that the new compound, nitro-aminoguanidine, in addition to being useful in analytical chemistry with reference to nickel, aldehydes and ketones, may also find use in the chemistry of explosives.

The assistance of Professor E. Raymond Riegel is gratefully acknowledged.

Summary

1. The preparation of nitro-aminoguanidine is described as well as its analysis, properties and reactions.

2. Its structure is indicated by its method of preparation, its power to form hydrazones, its yielding the characteristic purple color with alkaline ferrous sulfate, its reduction to diaminoguanidine and, finally, its analysis for nitrogen.

3. Crystalline compounds with aldehydes and ketones were prepared.

4. The compound nickel nitro-aminoguanidine is described, which may lead to a new qualitative and quantitative test for nickel.

5. A special procedure for nitrogen determination is given.

THE PREPARATION OF SOME PYRROLIDINE DERIVATIVES[1,2]

BY F. B. LAFORGE

RECEIVED MAY 18, 1928 PUBLISHED SEPTEMBER 5, 1928

It is rather surprising that among the many synthetic and natural organic compounds which have been tested as contact insecticides, so few have been found to possess outstanding toxic action.

In the present state of our knowledge it would seem that of the natural products, the pyrethrins, rotenon (from derris) and nicotine are in a class by themselves. Whatever insecticidal action may be possessed by any other compound, either natural or synthetic, is in every case of a distinctly lower order, and it is not possible to arrange a list of compounds of progressively higher toxicity up to that of the order of the three mentioned. However, further study may yield results which will invalidate this generalization.

Owing to the work of Staudinger and Ruzicka[3] the chemical nature of the pyrethrins is well understood. They are both complicated esters containing a number of unsaturated bonds and asymmetric carbon atoms. As far as is known; even the slightest change in the complicated chemical structure of either lowers its specific action to a marked degree and generally destroys it altogether.

From what is known of tubotoxin, it seems probable that the same will hold true for that compound.

The investigations reported in this paper were undertaken to determine, if possible, whether the toxicity of nicotine is specific for the whole molecule or whether this effect is owing to some special grouping of its component parts.

From the formula for nicotine, which is β-pyridyl-α-N-methylpyrrolidine, it might be reasonable to assume that either the pyridine or the pyrrolidine group were responsible for its insecticidal property. Accordingly, a number of new substituted pyrrolidines were prepared and tested, besides a number of known ones, but none were found to possess toxicity approaching that of nicotine.

Substitution of the methyl or phenyl group in the a-position of the pyrrolidine molecule leads to comparatively inert compounds which do not show increased toxicity if they are in addition methylated on the

---

[1] A study of the insecticidal action of these compounds is being made in cooperation with Dr. C. H. Richardson, Deciduous Fruit Insect Investigations, Bureau of Entomology.

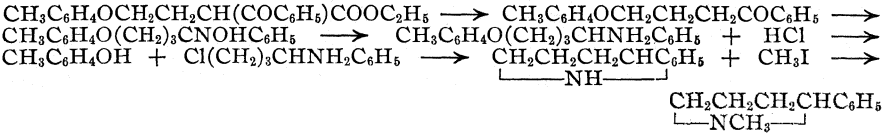
[2] Presented at the Insecticide Symposium, St. Louis meeting of the American Chemical Society, April, 1928.

[3] Staudinger and Ruzicka, *Helv. Chim. Ada*, 7, 177–259, 377458 (1924).

nitrogen. For instance, a-methyl, α,α-dimethyl[4] and a-phenylpyrrolidine, and their N-methyl derivatives were only slightly toxic.

The preparation of a-phenyl-N-methylpyrrolidine presented unusual difficulties. The action of methylamine on 1-phenyl-1,4-dibromobutane, $C_6H_5CHBr(CH_2)_2CH_2Br$, resulted in an unsaturated compound instead of the expected phenylmethylpyrrolidine. Although it was possible to prepare a-phenylpyrroline, attempts to reduce it were unsuccessful, nor was it possible to close the side chain of 1-phenyl-1-N-methylaminobutane by the method of Löffler.[5]

The compound was finally prepared from *β-p*-cresoxy-ethylbenzoylacetic ester by the following steps.



$$\begin{aligned}&CH_3C_6H_4OCH_2CH_2CH(COC_6H_5)COOC_2H_5 \longrightarrow CH_3C_6H_4OCH_2CH_2CH_2COC_6H_5 \longrightarrow\\ &CH_3C_6H_4O(CH_2)_3CNOHC_6H_5 \longrightarrow CH_3C_6H_4O(CH_2)_3CHNH_2C_6H_5 + HCl \longrightarrow\\ &CH_3C_6H_4OH + Cl(CH_2)_3CHNH_2C_6H_5 \longrightarrow \underbrace{CH_2CH_2CH_2CHC_6H_5}_{NH} + CH_3I \longrightarrow\\ &\underbrace{CH_2CH_2CH_2CHC_6H_5}_{NCH_3}\end{aligned}$$

α-Methylpyrrolidine.—This derivative has been prepared and studied by Penner and Tafel,[6] but it may be more conveniently obtained by the general method of Gabriel.[7]

β-p-Cresoxy-ethylacetoacetic Ester.—Fifty grams of acetoacetic ester (twice the theoretical quantity) was added to a solution of 4.5 g. of sodium in 75 cc. of alcohol, followed by 41 g. of *β-p*-cresoxy-ethyl bromide.[8] The solution was allowed to stand several hours and then was boiled for five hours under reflux. The alcohol was evaporated, the residue suspended in water and the insoluble oil extracted with ether. The ether solution, which was dried with calcium chloride, yielded about 70 g. of oil on evaporation.

The oil was distilled in a vacuum of 16 mm. The fraction boiling up to 130° con-

---

[4] The reduction of acetonylacetonedioxime prepared by the method of Paal (*Ber.*, 18, 59 (1885))under the same conditions as those used by Tafel in the case of the corresponding hydrazone (*Ber.*, 22, 1860 (1889)), results in a mixture of dimethylpyrrolidine and 2,5-diaminopentane. The last compound shows no tendency to form the ring structure and can only be transformed into dimethylpyrrolidine by dry distillation of the hydrochloride. Since two dimethylpyrrolidines should exist according to theory, it would appear that the one represented by the space formula  $CH_3\underset{NH_2}{\overset{H}{C}}CH_2CH_2\underset{NH_2}{\overset{H}{C}}CH_3$ might easily lose ammonia to form dimethylpyrrolidine, whereas if the position of one amino group were reversed, this reaction might not take place except under drastic conditions and would then result in an isomeric compound. A whole series of isomeric substituted pyrrolidines is possible with increase in the number of methyl groups, up to six optical pairs of tetramethylpyrrolidines, analogous to the hexitols in the sugar group.

sisted mostly of acetoacetic ester. About 10 g. of a fraction boiling at 130-196° was obtained. The fraction boiling at 196–206° consisted of *β-p*-cresoxy-ethylacetoacetic ester. It was refractionated and yielded 25 g. of a product boiling at 202-204" (uncorr.).

Anal. Subs, 0.1874: CO_2, 0 4634; H_2O, 0.1212. Calcd. for $C_{15}H_{20}O_4$: C, 68.77; H, 7.43. Pound: 67.43, 7.19.

γ-*p*-Cresoxypropylmethyl Ketone, $CH_3C_6H_4O(CH_2)_3COCH_3$.—Twelve grams of *β-p*-cresoxy-ethylacetoacetic ester was heated on the steam-bath with 2 g. of sodium hydroxide in 75 cc. of alcohol. Sodium bicarbonate separated out during the heating. The solution was diluted with water, acidified with acetic acid and the alcohol evaporated off. The separated oil was taken up in ether and the ether residue was distilled at 16 mm., yielding 6 g. of a fraction boiling at 163–180°. Several similar fractions were combined and the fraction boiling at 175–175° was collected. This material crystallized on standing and was freed from adhering oil by pressing between filter paper. It was easily soluble in all organic solvents and was analyzed without further purification.

Anal. Subs., 0.1560: CO_2, 0.4314; H_2O, 0.1163. Calcd. for $C_{12}H_{16}O_2$: C, 75.00; H, 8.33. Found: C, 75.42; H, 8.28.

The seniicarbazone of the ketone prepared in the usual manner crystallized from alcohol in needles melting at 158°.

γ-*p*-Cresoxybutyric Acid.—The combined alkaline solutions from the saponification of 100 g. of *β-p*-cresoxy-ethylacetoacetic ester yielded 10 g. of γ-*p*-cresoxybutyric acid on acidification. It was recrystallized from 40% alcohol and melted at 84–85°.

Anal. Subs., 0.1630: CO_2, 0.4087; H_2O, 0.1035. Calcd. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.21. Found: C, 68.37; H, 7.05.

γ-*p*-Cresoxypropylmethyl Ketoxime.—The oxime was obtained in good yield by warming 8 g. of the ketone dissolved in 75 cc. of an alcoholic solution of hydroxylamine prepared from 3 g. of the hydrochloride. After evaporation of the solvent, the residue crystallized to a solid cake. It was dissolved in ether, the solution was washed with water and dried with potassium carbonate and the solvent removed. The oxime may be recrystallized from petroleum ether or dilute alcohol and when pure melts at 54°.

Anal. Subs., 0.1647: CO_2, 0.4214; H_2O, 0.1214. Calcd. for $C_{12}H_{17}NO_2$: C, 69.57; H, 8.21. Found: C, 69.78; H, 8.18.

1-*p*-Cresoxy-4-amino-*n*-pentane, $CH_3C_6H_4O(CH_2)_3CHNH_2CH_3$.—Twenty-three grams of the oxime was dissolved in 300 cc. of 95% alcohol and reduced with 1000 g. of 2 5% sodium amalgam added in four portions of 250 g. each, followed by 25 cc. of glacial acetic acid over a period of four hours. The separated sodium acetate was filtered off and the solution diluted with 800 cc. of water and placed in a freezing mixture. About 14 g. of unchanged oxime was recovered by this treatment and was reduced again with sodium amalgam. The combined filtrates were concentrated to 150 cc. and extracted with ether. The ethereal solution yielded a small quantity of oxime. The aqueous solution was treated with sodium hydroxide, the separated oil taken up in ether and the ethereal solution dried with solid potassium hydroxide. About 10 g. of pure amine was obtained, boiling at 280–283° (uncorr.) at 760 mm.

Anal. Subs., 0.1570: CO_2, 0.4265; H_2O, 0.1355. Calcd. for $C_{12}H_{19}NO$: C, 74.61; H, 9.84. Found: C, 74.09; H, 9.59.

The amine combines with carbon dioxide from the air, forming a solid crystalline carbonate. The hydrochloride is also crystalline but somewhat hygroscopic.

α-Methylpyrrolidine.—Twenty grams of the hydrochloride was sealed in a glass tube with 70 cc. of aqueous hydrochloric acid, saturated at 0° and heated for fifteen hours at 100°. The contents of the tube presented two layers, the lighter one being *p*-cresol which was removed by extraction with ether from the aqueous solution of the hydrochloride of 1-chloro-4-aminopentane. On evaporation the compound was left as a thick sirup.

The product was dissolved in a small quantity of water and the solution made strongly alkaline. On the addition of solid potassium hydroxide, the methylpyrrolidine separated as an oily layer, which was separated and further dehydrated with potassium hydroxide. The product distilled between 94 and 97°, which agrees fairly well with the figure given by Fenner and Tafel.[6] The yield was 8 g.

Anal. Subs., 0.1300: CO_2, 0.3340; H_2O, 0.1555. Calcd. for $C_5H_{11}N$: C, 70.58; H, 12.94. Found: C, 70.07; H, 13.29.

1-Phenyl-1-bromobutane and **1-Phenyl-1-methylaminobutane.**—Twenty grams of phenylpropylcarbinol prepared by the method of Klages[9] was saturated with hydrobromic acid gas at 0°. In a few minutes the liquid became turbid and after standing overnight had separated into two layers The oily layer was taken up in ether, and the excess hydrobromic acid was removed by washing with water. The ethereal solution was dried with calcium chloride and yielded 32 g. of residue. It was not analyzed. The bromo compound was dissolved in 50 cc. of methyl alcohol and poured into 160 cc. of a 25% methyl alcoholic solution of methylamine. After standing overnight, the solution was evaporated, leaving a mixture of oil and crystalline methylamine hydrobromide. It was dissolved in dilute hydrochloric acid and the solution was extracted with ether. The aqueous solution was made alkaline, and the separated oil was extracted with ether and dried with potassium carbonate. On evaporation it yielded 20 g. of oily residue, which boiled at 117–118° at 33 mm. (220' at 765 mm.).

Anal. Subs., 0.1378: CO_2, 0.4097; H_2O, 0.1258. Calcd. for $C_{11}H_{17}N$: C, 80.98; H, 10.43. Found: C, 81.22; H, 10.14.

The amine is insoluble in water, and it is probably owing to this property that efforts to close the side chain to the pyrrolidine ring by brominating on the nitrogen and eliminating the hydrobromic acid in accordance with the method of Loffler were unsuccessful.

A second attempt was made to prepare a-phenyl-N-methylpyrrolidine through the following steps

$$C_6H_5CHOHCH_2CH{=}CH_2 + 2HBr \longrightarrow C_6H_5CHBr(CH_2)_2CH_2Br + NH_2CH_3 \longrightarrow C_6H_5\underline{CH(CH_2)_2CH_2N}CH_3$$

It resulted, however, in an isomeric, open-chain unsaturated compound.

1-Phenyl-1,4-dibromobutane.—Twenty grams of allylphenylcarbinol[10] was saturated in direct sunlight in a quartz flask with hydrobromic acid gas. In two hours the reaction was complete and no more gas was absorbed. The product was taken up in ether, washed with ice water and the solution dried with calcium chloride. The residue weighed 36.5 g., which is close to the theoretical yield. The product could not be distilled. Thirty-two grams of the crude product was added in small portions to 200 cc. of a 25% methyl alcoholic solution of methylamine.

After standing overnight, the solvent and excess amine were removed by evaporation and the residue was dissolved in dilute hydrochloric acid and extracted with ether. The aqueous solution yielded an oily product, which was taken up in ether, and the solution was dried with solid potassium hydroxide. The ether residue consisted of 17 g. of oil, which when twice distilled at 770 mm. yielded 10 g. of product, boiling at 209–216°.

---

[9] Klages, *Ber.*, 37, 2312 (1904).

[10] Klemenko, J. *Russ. Phys.-Chem. Soc.*, 43,212 (1911).

The analysis agrees for $C_{11}H_{15}N$, but its reactions indicate that it is unsaturated, and its properties do not agree with those of α-phenyl-N-methylpyrrolidine, which was finally prepared by another procedure.

Anal. Subs., 0.1202: CO_2, 0.3595; H_2O, 0.0980. Calcd. for $C_{11}H_{15}N$: C, 81.99; H, 9.31. Found: C, 81.56; H, 9.05.

The compound should be represented by one of the three formulas $C_6H_5CH{=}CH\text{-}CH_2CH_2NHCH_3$, $C_6H_5CHNCH_3CH_2CH{=}CH_2$ or $C_6H_5CH{=}CHCH(NHCH_3)CH_3$.

Benzoyltrimethylene.—This compound was prepared from benzoylacetic ester[11] and ethylene bromide according to the method of Perkin[12] slightly modified. The method consists in heating the ester in alcoholic solution under pressure with half the theoretical quantities of ethylene bromide and sodium ethylate. The only change made was to repeat this treatment with one-half the original quantities of bromide and sodium ethylate, which resulted in a better yield. Benzoyltrimethylene bromide was prepared according to the Perkin directions.[12]

α-Phenyl-N-methylpyrroline.—Seventeen grams of benzoyltrimethylene bromide was added to about 75 cc. of 25% methyl alcoholic methylamine. After evaporation of the solvent, the oily residue was extracted with dilute hydrochloric acid. The insoluble portion was extracted with ether and the solution dried and evaporated, yielding about 8 g. of product, boiling at 136–139° at 34 mm. and at 239–246° at 760 mm. It contained no nitrogen. The analysis and boiling point indicate that it was regenerated benzoyltrimethylene.

Anal. Subs., 0.1735: CO_2, 0.5201; H_2O, 0.1105. Calcd. for $C_{10}H_{10}O$: C, 82.19; H, 6.85. Found: C, 81.84; H, 7.09.

Perkin[12] refers to the action of silver nitrate and sodium ethylate on benzoyltrimethylene bromide and states that the resulting compound is probably 3-benzoyl-*n*-propyl alcohol. He did not analyze his product, but we have found that any base will regenerate the benzoyltrimethylene from the bromide. The acid solution referred to above was treated with sodium hydroxide, the separated oil was taken up in ether and the solution was dried with potassium carbonate and evaporated. The residue boiled at 134–139° at 34 mm. The analysis agreed for phenylmethylpyrroline.

Anal. Subs., 0.1427: CO_2, 0.4327; H_2O, 0.1021. Calcd. for $C_{11}H_{13}N$: C, 83.01; H, 8.17. Found: C, 82.69; H, 7.96.

The compound could not be made to absorb hydrogen in the presence of a platinum catalyst nor were any other attempts to reduce it successful.

β-*p*-Cresoxyethylbenzoylacetic Ester, $CH_3C_6H_4OCH_2CH_2CH(COC_6H_5)COOC_2H_5$.—One hundred and seven grams of benzoylacetic ester and 60 g. of *p*-cresoxy-ethylene bromide (one-half of the equivalent quantity) were dissolved in an absolute alcoholic solution of sodium ethylate prepared from 150 cc. of absolute alcohol and 6.4 g. of sodium. After boiling for six hours under reflux, the solvent was removed, water added and the reaction products were dissolved in ether. The ethereal solution was washed with water and dried with calcium chloride, yielding 145 g. of oily product on evaporation. It was subjected to fractional distillation in vacuum. The fraction boiling below 260° (8 mm.) was discarded. About 40 g. of product distilling at 240–250" consisted of impure *p*-cresoxyethylenebenzoylacetic ester. There was some decomposition during distillation and the compound could not be prepared absolutely pure. It was again distilled for analysis.

Anal. Subs., 0.1575: CO_2, 0.4353; H_2O, 0.0823. Calcd. for $C_{20}H_{22}O_4$: C, 73.62; H, 6.75. Found: C, 74.73; H, 5.80.

[11] Claisen, Ann., 291, 70 (1896).

[12] Perkin, J. *Chem. Soc.*, 47,836 (1885).

γ-*p*-Cresoxypropylphenyl Ketone, $CH_3C_6H_4O(CH_2)_3OCC_6H_5$.—The ketone cleavage of the ester was carried out by heating with slightly more than the calculated quantity of alcoholic potassium hydroxide for four hours on the steam-bath. The product remaining after evaporation of the solvent was an oil, which was dissolved in ether, and the solution was dried and evaporated. The product was fractionated at 8 mm. The major portion boiled at 250–260° with slight decomposition. The distillate crystallized at once and, after removal of adhering oil by pressing between filter paper, it was recrystallized from about 5 parts of 95% alcohol. It crystallizes in large prisms which melt at 63°. The yield was from 40 to 50% of the weight of the ester employed.

In subsequent operations the ester was not distilled, the fractions boiling below ZOO° at 32 mm. being removed and the crude ester saponified. The ketone may also be obtained from the crude ester by saponification and distilling off the products boiling under 200" and allowing the undistilled material to crystallize. Analysis of the pure ketone gave the following results.

Anal. Subs., 0.2021: CO_2, 0.5965; H_2O, 0.1269. Calcd. for $C_{17}H_{18}O_2$: C, 80.31; H, 7.08. Pound: C, 80.49; H, 6.97.

γ-*p*-Cresoxypropylphenyl Ketoxime.—Five grams of ketone was dissolved in an alcoholic solution of hydroxylamine prepared from 1.5 g. of hydroxylamine hydrochloride and 0.5 *g.* of sodium. After the solution was heated for one hour on the steam-bath, the solvent was removed, leaving a sirupy product which crystallized to a solid cake. It crystallized from petroleum ether in long prisms, melting at 75°. The yield was quantitative.

Anal. Subs., 0.1617: CO_2, 0.4462; H_2O, 0.1012. Calcd. for $C_{17}H_{19}NO_2$: C, 75.47; H, 7.06. Found: C, 75.27; H, 6.88.

1-*p*-Cresoxy-4-amino-4-phenylbutane Hydrochloride, $CH_3C_6H_4O(CH_2)_3CH(NH_2\text{-}HCl)C_6H_5$.—Twenty-five grams of oxime was dissolved in 500 cc. of 95% alcohol and reduced with 1800 g. of 2.5% sodium amalgam which was added in portions of about 250 g. each, followed by the addition of 25 cc. of glacial acetic acid over a period of three hours. The temperature was kept below 40" during the reaction.

The sodium acetate was filtered off and washed with alcohol, and the alcoholic solutions were concentrated on the steam-bath to 150 cc. An oily substance, probably the acetate of the amine, separated out and was extracted with ether.

On being shaken with 75 cc. of 15% hydrochloric acid, the ether solution became filled with a mass of white crystals of the hydrochloride of the base. The aqueous solution was made alkaline with sodium hydroxide and extracted with ether. The ether was evaporated, leaving an oil which also crystallized when treated with dilute hydrochloric acid. The combined yield was 20 g. of the hydrochloride. It was crystallized from hot water, from which it separated in long needles. The nitrate is also difficultly soluble in water and crystallizes in plates.

Anal. Subs., 0 1616: CO_2, 0.4145; H_2O, 0.1100. Subs., 0.1215: AgCl, 0.0595. Calcd. for $C_{17}H_{22}NOCl$: C, 70.22, H, 7.57; Cl, 11.87. Found: C, 69.95; H, 7.56; Cl, 11.68.

1-Phenyl-1-amino-4-chlorobutane Hydrochloride.—Twenty-two grams of p-cresoxy-aminophenylbutane hydrochloride was heated in a sealed tube with 150 cc. of aqueous hydrochloric acid saturated at 0" for twenty hours. The separated cresol was removed with ether and the aqueous solution concentrated on the steam-bath. The compound crystallized on evaporation. A part was recrystallized for analysis from about 5 parts of hot water. It melted with decomposition at 200–205°. The yield was 13 g.

Anal. Subs., 0.1340: AgCl, 0.1749. Calcd. for $C_{10}H_{15}NCl_2$: Cl, 31.65. Found: 31.06.

α-Phenylpyrrolidine.—Twelve grams of phenylaminochlorobutane hydrochloride was dissolved in water and a strong solution of potassium hydroxide added. The oil which separated reacted suddenly with evolution of heat to form a-phenylpyrrolidine. The product was extracted with ether and the solution dried with solid potassium hydroxide. The ether residue boiled at 236–238° (uncorr.) at 757 mm. The yield was 8 g.

Anal. Subs., 0.1400: CO$_2$, 0.4155; H, 0.1154. Calcd. for $C_{10}H_{13}N$: C, 81.63; H, 8.84. Found: C, 80.94; H, 9.15.

α-Phenyl-N-methylpyrrolidine.—Four grams of α-phenylpyrrolidine was dissolved in 25 cc. of methyl alcohol containing 4 g. of methyl iodide. After twelve hours the solvent was evaporated and the residue treated with strong potassium hydroxide solution. Most of the oil was soluble in ether but a part remained undissolved. The ethereal solution was dried with solid potassium hydroxide and the ether evaporated, leaving 2.6 g. of base, which distilled at 760 mm. at 225–227° (uncorr.). The yield of pure product was 2.2 g.

Anal. Subs., 0.1460: CO$_2$, 0.4374, H_2O, 0.1161. Subs., 0.1560: N, 11.2 cc. at 29° and 762 mm. Calcd. for $C_{11}H_{15}N$: C, 81.99; H, 9.31; N, 8.69. Found: C, 81.71; H, 8.83; N, 8.23.

Summary

A number of pyrrolidine derivatives have been prepared with reference to their chemical relation to nicotine and tested as contact insecticides.

Methods are described for the preparation of a-methyl- and α-phenylpyrrolidine and a-phenylpyrroline and their N-methyl derivatives. The various intermediary compounds and the results of several unsuccessful attempts to prepare substituted pyrrolidines are described in the experimental part.

WASHINGTON, D. C.

[CONTRIBUTION FROM THE INSECTICIDE DIVISION, BUREAU OF CHEMISTRY AND SOILS]

THE PREPARATION AND PROPERTIES OF SOME NEW DERIVATIVES OF PYRIDINE[1,2]

BY F. B. LAFORGE

RECEIVED MAY 18, 1928 PUBLISHED SEPTEMBER 5, 1928

In a previous article it was pointed out that whereas nicotine, which is β-pyridyl-α-N-methylpyrrolidine, stands out as one of the few known organic compounds possessing insecticidal properties of a very high order, none of the several other substituted pyrrolidines which have been tested approach it in toxicity.

It is natural to inquire whether or not the pyrrolidine group is essential to the specific toxic effect of nicotine on insects and whether or not some

---

[1] A study of the insecticidal action of these compounds is being made in cooperation with Dr. C. H. Richardson, Deciduous Fruit Insect Investigations, Bureau of Entomology.

[2] Presented at the Insecticide Symposium, St. Louis meeting of the American Chemical Society, April, 1928.

other groups attached to the pyridine radical would result in compounds of the same order of toxicity.

Accordingly, a number of new synthetic pyridine derivatives were prepared and tested on insects. All these derivatives were of a very low order of toxicity. On the other hand, three known compounds derived from nicotine itself, metanicotine,  nicotyrine,  and dihydrometanicotine,  were of high toxicity, the first compound being almost equal to nicotine itself in this respect. The other two, although less toxic than metanicotine, still exhibited this property to a degree which far exceeded that of any purely synthetic pyridine derivative which we have prepared and tested. These synthetic compounds are all open chain pyridylamino derivatives which were obtained by reduction of the oximes or hydrazones of pyridyl ketones.

Since considerable quantities of these ketones were required for the investigations, it was necessary to develop satisfactory methods for their preparation. A number of pyridyl ketones have been described by Engler,[3] who prepared them by distillation of pyridinecarboxylic acid calcium salts with the calcium salts of the fatty acids, and by Pinner[4] by the condensation of pyridinecarboxylic acid esters with the esters of fatty acids in the presence of sodium ethylate and cleavage of the resulting pyridoylacetic esters. The method of Engler gives low yields of very impure products. Pinner does not state his yields, but numerous attempts to prepare pyridyl ketones by the method described by him were unsuccessful. Even when every precaution was taken in carrying out the reaction, the yields were at the best exceedingly small and usually nothing but nicotinic acid could be recovered from the reaction product.

The method by which methyl and propyl pyridyl ketones were finally prepared leaves something to be desired, but it was adequate for the preparation of several hundred grams of these compounds.

Nicotinic acid hydrochloride or the free acid prepared from the cheaper nitrate was the starting material, It was esterified and the ester transformed into the acid amide which was converted into the cyanide. These operations are described by R. Camps, but as the directions given by that author are somewhat inadequate, some slight changes in the methods were introduced.

According to Blaise,[5] aromatic cyanides react with the Grignard reagent,

---

[3] Engler, Ber., 22, 597 (1889), 24, 2541 (1891).

[4] **Pinnw,** *Ber.*, **34,4234** (1901).

[5] **Blaise,** *Compt.* **rend., 333,** 1217 (1900).

producing fairly good yields of the aromatic alkyl ketones. This method was used for the preparation of pyridyl ketones.

β-Pyridylethylamine,  was prepared by reduction of the β-pyridyl methyl ketoxime and from this the corresponding N-ethyl derivative was obtained. The resulting compound differs from nicotine in that it has an open four carbon chain instead of the closed pyrrolidine ring, and it is not methylated on the nitrogen atom. It may be represented by the formula .

β-Pyridylpropyl ketone was prepared from β-pyridine cyanide and *n*-propyl iodide by the Grignard reaction. As the oxime of the ketone could not be obtained in crystalline form, the hydrazone was prepared and reduced to the β-pyridylbutyl amine represented by the formula .

The hydrazone of this ketone as described by Engler was prepared from the crude ketone, and was made for the purpose of isolating the ketone itself in pure condition.

It was found that a crystalline hydrazone could be obtained easily from the crude ketone prepared by the Grignard reaction, but it differed in its chemical and physical properties from the one described by Engler. Its melting point (130°) differed from that recorded by Engler (182°), and it could not be changed even by repeated recrystallization.

Engler prepared the pure ketone from his hydrazone by decomposition with concentrated hydrochloric acid.

When the same treatment was applied to the hydrazone prepared by us, it resulted in a quantitative yield of a crystalline base, which is in all probability 1-pyridyl-2-ethylindol , analogous to the methylindol from acetone hydrazone.

The amine resulting from the reduction of the hydrazone was methylated on the nitrogen to β-pyridylbutyl-N-methylamine, , which differs from nicotine in that an open chain of the same number of carbon atoms is substituted for the N-methylpyrrolidine ring.

Ethyl Nicotinate.—The following method, which is a slight modification of the one described by R. Camps,[6] was found most convenient for the preparation of ethyl nicotinate. Eighty grams of nicotinic acid hydrochloride or 70 g. of the free acid was dissolved in a mixture of 150 g. of absolute alcohol and 150 g. of concentrated sulfuric acid, and the solution was heated for about four hours in a flask on the steam-bath. The

---

[6] R. Camps, *Arch. Pharm.*, 240,366 (1902).

solution was cooled and divided roughly into three portions, which were poured onto cracked ice. Ammonia was then added in a quantity sufficient to render the solution strongly alkaline. Generally some ester separated as an oily layer but most of it remained dissolved. The solution was extracted four times with ether, the last two or three ether extracts being used to extract the other portions.

The ethereal solutions were washed with water and dried with potassium carbonate, after which the solvent was removed. The yield of pure ester boiling between 222 and 224° was always from 71 to 75 g. If pure material is used to start with, it is not necessary to distil the ester if it is to be used for the preparation of the amide.

Nicotinic Acid **Amide.**—Since the directions for the preparation of this derivative are rather inadequate, it seems desirable to add a few details to those given by Camps.

One hundred grams of nicotinic ester was covered with about 1.5 volumes of concentrated aqueous ammonia saturated at 0°. The flask was kept loosely closed for about eighteen hours, after which time the lower layer generally dissolved on shaking. The solution was again saturated with ammonia gas and allowed to stand for several hours. The process was again repeated, after which, as a rule, crystals of the amide began to appear in the solution. At this stage the contents of the flask was evaporated to dryness in a dish on the steam-bath. The crystalline cake was ground and further dried at 120°. The yield was nearly quantitative.

β-Pyridine Cyanide.—In the preparation of the cyanide from the amide, a few details should be added to those given by Camps.[6]

Eighteen grams of powdered amide and 25 g. of phosphorus pentoxide were placed in a distilling flask of about 150 cc. capacity and mixed by shaking. The mixture was subjected to distillation in a vacuum of about 30 mm. The heating must be done by means of an oil-bath, the temperature of which is rapidly raised to about 300°. The oil-bath was then removed and the heating continued with a free flame as long as a distillate was obtained. The cyanide crystallized on cooling to a snow-white solid which was redistilled at ordinary pressure. All but a trace boiled at 201° at 760 mm. The yield was consistently from 19.5 to 20.5 g. This cyanide was used for the preparation of pyridyl ketones.

β-Pyridylmethyl Ketone.—Twenty grams of β-pyridyl cyanide dissolved in about 100 ce. of dry ether was slowly added with vigorous stirring to the solution of Grignard reagent prepared from 40 g. of methyl iodide and 7 g. of magnesium in about 150 ce. of ether. A voluminous yellow precipitate of the addition compound was produced. At this stage most of the ether is distilled off and replaced by an equal quantity of dry benzene. After boiling for about an hour, the contents of the flask was decomposed by the addition of water followed by about 100 g. of 40% sulfuric acid. The red aqueous solution was made alkaline with sodium hydroxide and subjected to steam distillation until about 2 liters of distillate was collected. The distillate was acidified with hydrochloric acid and concentrated to 60 ce. on the steam-bath. The solution was treated with sodium hydroxide and the separated oil extracted with ether. The dried ethereal solution yielded about 14 g. of oily residue, which was distilled at ordinary pressure. The yield of pure product varied from 11 to 12 g. The boiling point, 217–220°, agreed with that found by Engler.

β-Pyridylmethyl Ketoxime.—Fifteen grams of the ketone was dissolved in 75 cc. of a solution of hydroxylamine prepared from 9 g. of the hydrochloride. After standing for about twelve hours the solution was heated on the steam-bath for a short time and then evaporated to a sirup.

The residue crystallized on cooling to a solid cake, which was washed with benzene and then recrystallized from the same solvent. The yield of pure product was 15 g. It melted at 113°. Engler gives 112° as the melting point of the compound.

β-Pyridylethylamine, —Five grams of the oxime was dissolved in 75 cc. of 95% alcohol and 40 g of zinc dust and 40 g of glacial acetic acid were added alternately in small portions over a period of several hours. After about twenty-four hours the undissolved zinc and zinc acetate were filtered off and washed with alcohol. The alcoholic solution was evaporated to a small volume and after the addition of water the evaporation was repeated several times to remove as much as possible of the acetic acid. Strong potassium hydroxide solution was added to the concentrated solution and the separated oil extracted with ether. The dried ethereal solution yielded on evaporation about 4.5 g. of residue, practically all of which distilled between 219 and 221° at 765 mm.

Anal. Subs., 0.2370, 0.1632 CO_2, 0.5951, 0 4087: H_2O, 0.1738, 0.1165. Subs., 0 1350: N, 27.4 cc. at 23° and 772 mm. Calcd. for $C_7H_{10}N_2$: C, 68.84; H, 8.19; N, 22.95. Found: C, 68.48, 68.29; H, 8.14, 7.93, N, 23.13.

The picrate formed in aqueous solution melted at 186–187°.

β-Pyridylethyl-N-ethylamine, —Four grams of the primary amine, was added to 5 g. of ethyl iodide in 10 cc. of absolute alcohol and the solution was allowed to stand for forty-eight hours at room temperature.

The alcohol was expelled on the steam-bath, the residue was dissolved in 25 cc. of water and made strongly alkaline with potassium hydroxide. The separated oil was only partly soluble in ether. The ether residue was dissolved in about 15 cc. of 10% hydrochloric acid, and the solution was cooled and treated with a solution of 4 g. of sodium nitrite in 10 cc. of water.

The nitroso compound separated as an oil on addition of sodium hydroxide solution. It was extracted with ether and the ether residue was heated for one-half hour on the steam-bath with 7 ec. of concentrated hydrochloric acid. The secondary amine was separated by the addition of concentrated potassium hydroxide solution and extraction with ether. The dried ethereal solution gave 3 g. of crude product on evaporation. It was twice distilled at 773 mm. and yielded 2 g. of product boiling between 223 and 226". In another experiment 16 g. of the primary amine gave 8 *g.* of the ethyl derivative.

Anal. Subs., 0.2114: N, 35.0 cc. at 19° and 767 mm. Calcd. for $C_9H_{14}N$: N, 18.67. Found: 19.11.

β-Pyridylpropyl Ketone.—Twenty grams of β-pyridine cyanide in 100 cc. of dry ether was slowly added to the Grignard reagent prepared from 7.7 g. of magnesium and 55 g. of n-propyl iodide. The reaction product was boiled for two hours and then cooled with ice and decomposed with water and finally with saturated ammonium chloride solution. Nearly all of the yellow precipitate formed in the reaction dissolved. The ethereal solution was separated and dried, yielding about 28 g. of crude product. The fraction which distilled between *235* and 260° contained the ketone.

It was redistilled and the fraction of 240–248° was analyzed for nitrogen, but the figures obtained on several preparations ranged from 10.9 to 11.3% instead of the theoretical 9.4% for $C_9H_{11}NO$. Closer figures could not be obtained on analysis of the steam distilled product. Therefore the crude product was converted into the phenyl hydrazone.

β-Pyridylpropyl Ketone Phenylhydrazone.—This derivative has been described by Engler, who prepared it from the impure ketone which he obtained by distillation of the mixture of nicotinic and propionic acid calcium salts. The author employed the hydrazone for the purpose of isolating the pure ketone, which is stated to be easily obtainable by cleavage of the hydrazone with hydrochloric acid.

Thirty grams of the crude ketone fraction boiling between 235 and 260° was heated for two hours on the steam-bath with 25 g. of phenylhydrazine. Crystallization took place on cooling. The crude product was extracted with 50% alcohol and then recrystallized by dissolving in the necessary quantity of hot 95% alcohol and adding an equal volume of hot water. The recrystallized substance melted at 129–130°. The yield was 24 g. For analysis it was twice recrystallized from acetic ester without altering its melting point. Engler gives 182° as the melting point of the hydrazone.

Anal. Subs., 0.1248: CO_2, 0.3450; H_2O, 0.0835. Calcd. for $C_{15}H_{17}N_3$: C, 75 31; H, 7.11. Found: C, 75.40; H, 7.43.

Semicarbazone of β-Pyridylpropyl Ketone.—The semicarbazone was obtained by heating the crude ketone in alcoholic solution with the calculated quantity of semicarbazide. The resulting product recrystallized from water melted at 169–170°.

Anal. Subs., 0.1845: N, 44.2 cc. at 21° and 768 mm. Calcd. for $C_{10}H_{14}N_4O$: N, 27.19. Found: 27.43.

1-β-Pyridyl-2-ethylindol,  —When the hydrazone is brought into contact with strong hydrochloric acid, it instantly changes to a bright yellow, crystalline product difficultly soluble in water.

The resulting compound was dissolved in hot water, and on addition of alkali the free base was obtained as a pure white, crystalline solid melting sharply at 158'.

Anal. Subs., 0.1821: CO_2, 0.5383; H_2O, 0.1000. Subs., 0.2058: N, 22.9 cc. at 24° and 764 mm. Found: C, 80.80; H, 6.10; N, 12.48.

These figures agree for a compound of the formula $C_{15}H_{14}N_2$, differing from that of the hydrazone, $C_{15}H_{17}N_3$, by —NH_3. It seems altogether probable that the substance is an indol derivative of the formula given above, for which the theory requires C, 81.08; H. 6.30; N, 12.61.

1-β-Pyridylbutylamine,  —Twenty-three grams of the hydrazone was dissolved in 300 cc. of 95% alcohol and 200 g. of zinc dust and 200 g. of glacial acetic acid were added alternately in small quantities over a period of several hours. After standing for about eighteen hours, the solution was filtered and the undissolved material was washed with alcohol. The filtrate was concentrated on the steam-bath to a small volume and the evaporation was repeated to remove most of the acid. The solution was finally concentrated to a sirup, which was dissolved in 150 cc. of water, cooled and treated with saturated sodium hydroxide solution until the precipitate of zinc hydroxide which at first formed had almost completely dissolved.

At the same time the amine, together with the aniline formed in the process, separated as an oily layer, which was extracted with ether. The dried ethereal solution yielded 16 g. of the mixture.

The aniline was separated by suspending the oil in 60 cc. of water and adding dilute hydrochloric acid until the aqueous solution was acid to litmus paper. The undissolved aniline was extracted with ether and the pyridyl amine was recovered from the acid solution by addition of sodium hydroxide and extraction with ether. The yield of crude product was 13 g., 9.4 g. of which boiled between 247 and 251°.

Anal, Subs., 0.1678: CO_2, 0.4438; H_2O, 0.1372. Subs., 0.1532: N, 24.0 cc., at 23° and 778 mm. Calcd. for $C_9H_{14}N_2$: C, 72.00; H, 9.33; N, 18.67. Found: C, 72.13; H, 9.09; N, 18.15.

1-β-Pyridylbutyl-N-methylamine,  $C_5H_4N\cdot CH(C_3H_7)NHCH_3$.—Thirteen grams of the primary amine was dissolved in 40 cc. of water, the solution was cooled with ice and 12 g. of dimethyl sulfate was added in small portions with constant shaking. After several hours a solution of potassium hydroxide was added and the reaction product was extracted with ether. The dried ethereal solution was evaporated and the resulting oil, which weighed 11 g., was distilled. The yield of the product boiling between 240 and 250° was 6.5 g. It was redistilled at 760 mm. and the fraction boiling between 244 and 247" was taken for analysis.

Anal. Subs., 0.1422: CO_2, 0.3810; H, 0.1213. Subs., 0.1735: N, 26.4 cc. at 26° and 765 mm. Calcd. for $C_{10}H_{16}N_2$: C, 73.17; H, 9.75; N, 17.07. Found: C, 73.08; H, 9.48; N, 16.91.

Metanicotine.—This derivative was prepared according to the method of Pinner.[7] It boiled between 275 and 278" at 760 mm. As a check on its purity, its optical activity was determined: 1.1368 g. of substance in 10.275 g. of water rotated in a 1dm. tube −0.062°, indicating that the quantity of nicotine in the preparation could not be greater than 3%.

Dihydrometanicotine.—Löffler[8] has prepared this compound by reduction of metanicotine with hydriodic acid. It may be obtained more easily by direct reduction with hydrogen in the presence of reduced platinum oxide catalyst by the method of Adams.[9]

Fourteen grams of metanicotine in 100 cc. of alcohol and 14.4 cc. of concentrated hydrochloric acid absorbed the required quantity of hydrogen in about one hour. The alcohol was evaporated and the base set free with potassium hydroxide and extracted with ether. The ether residue weighed 14 g., 12 g. of which distilled within 1.5" of the boiling point (258–259°) recorded by Löffler.

Summary

A new method is described for the preparation of pyridyl alkyl ketones by the use of the Grignard reaction. Methyl- and propylpyridylamines were obtained by reduction of the corresponding oximes or hydrazones. Although these compounds are chemically very similar to nicotine, they were, nevertheless, of low toxicity to insects, as were also their N-alkyl substitution products.

Metanicotine, nicotyrin and dihydrometanicotine were of a high order of toxicity, the first mentioned being only slightly below that of nicotine.

THE PREPARATION OF ALPHA-, BETA- AND GAMMA-BENZYLPYRIDINES[1,2]

BY F. B. LAFORGE

RECEIVED MAY 18, 1928 PUBLISHED SEPTEMBER 5, 1928

In a recent paper by Tattersfield and Gimingham[3] the announcement was made that benzylpyridines possess unusual insecticidal properties. The material used by these authors was a mixture of the *a*- and γ-benzylpyridines prepared by the method of Tschitschibabin.[4]

Since this method is extremely simple, and gives satisfactory yields, it would probably be capable of development into a commercial process should it be established that the benzylpyridines were of value as insecticides.

In order to provide material for insecticidal studies considerable quantities of this benzylpyridine mixture have been prepared. α-Benzylpyridine was separated by the picrate method, but a more convenient process than that described by Tschitschibabin was found for obtaining the γ-derivative. This consisted in the oxidation of the benzylpyridine mixture to the corresponding ketones, the separation of the y-ketone by recrystallization of the picrate and reduction of the ketone back to the benzyl compound.

β-Benzylpyridine was prepared from β-pyridylphenyl ketone by reducing its oxime to the corresponding amine, from which the carbinol was obtained and reduced with hydriodic acid. By these methods, which are described below in detail, the three benzylpyridines were prepared in pure condition.

a- and y-Benzylpyridine

The method of Tschitschibabin has been simplified by omitting the first treatment with sodium hydroxide and ether extraction, the hot reaction mixture being poured directly into water, which dissoves the hydrochlorides of the bases, leaving the tarry materials. The nearly colorless, aqueous solution is poured off and treated with sodium hydroxide solution. The bases are collected in ether and after evaporation of the solvent are distilled. The fraction boiling at 270–310° consists almost entirely of benzylpyridines. The portion boiling at 310–370° is probably a very indefinite mixture containing dibenzylpyridines.

---

[1] A study of the insecticidal action of these compounds is being made in cooperation with Dr. C. H. Richardson, Deciduous Fruit Insect Investigations, Bureau of Entomology.

[2] Presented at the Insecticide Symposium, St. Louis meeting of the American Chemical Society, April, 1928.

[3] Tattersfield and Gimingham, *Annals of Applied Biology*, *14*, 217 (1927).

[4] Tschitschibabin, *J. Russ. Phys.-Chem. Soc.*, 33, 249 (1901); 47, 1297 (1915); *Chem. Zentr.*, [2] 72, 127 (1901); [2] 87, 146 (1916).

The proportions employed were usually 72 g. of pyridine, 98 g. of benzyl chloride and 1 g. of copper-bronze powder. The yield of the benzylpyridine fraction is about 60 *g.* About 15 g. of the higher fraction and from 15 to 20 g. of pyridine are recovered. Analysis of the first fraction gave the following results.

Anal. Subs., 0.0989: CO_2, 0.3074; H_2O, 0.0576. Calcd. for $C_{12}H_{11}N$: C, 85.21; H, 6.51. Found: C, 84.77; H, 6.47.

The a-derivative may be prepared from the mixture of benzylpyridines in a pure state by fractional crystallization of the picrates.

The picrate mixture obtained from alcoholic solution consists of prisms and needles which do not differ much in solubility in any solvent. A rough separation may be made by quickly treating the mixture with a quantity of boiling water insufficient for complete solution. The undissolved portion consists mostly of the prisms of the a-compound. It is dissolved in warm acetone, from which large prisms of the a-compound crystallize on cooling. The solvent is poured off before the needles of the β-compound begin to be deposited. These prisms are finally recrystallized from alcohol and melt sharply at 139–140° (uncorr.).

The free base obtained from the picrate boiled at 275–276° (corr.), which boiling point is in agreement with the figures reported by Tschitschibabin.

The picrate of y-benzylpyridine could not be separated from the mixture in a pure state by crystallization from benzene, as reported by that author. The pure base was, however, obtained by an indirect method.

The original mixture of the two benzylpyridines was oxidized to the ketones with potassium permanganate.[5] From the mixture of the two ketones the picrate of the y-form is very easily separated from the picrate of the a-compound by crystallization from alcohol. It melts as reported by Tschitschibabin at 160°.

The free ketone was obtained from the picrate in the form of a white, crystalline solid. It was dissolved in ether and after removal of the solvent boiled at 315° (corr.). After recrystallization from petroleum ether it melted at 72°.

Reduction of the γ-Benzyl Ketone by the Method of Clemmensen.[6]—Eleven grams of the pure ketone was dissolved in about 200 cc. of 10% hydrochloric acid and heated with 50 g. of amalgamated zinc for ten hours on the steam-bath. The colorless solution was decanted and neutralized with sodium hydroxide solution. The precipitate which formed consisted of the zinc double salt of γ-benzylpyridine, together with some zinc hydroxide. It was filtered off and extracted repeatedly with 70% acetone, which dissolved the zinc double salt. The acetone was evaporated on the steam-bath, leaving the crystalline zinc compound, which is nearly insoluble in water. It is easily obtained

---

[5] Tschitschibabin, J. *Russ. Phys.-Chem. Soc.*, **33**, 300 (1901); *Chem. Zentr.*, *73*, 206 (1902).

[6] Clemmensen, Ber., 46, 1837 (1913); 47, 61 (1918).

pure by recrystallization from benzene. The yield of the pure compound was 11 g. It melts sharply at 161° (uncorr.).

Anal. Subs., 0.1403, 0.1790: CO_2, 0.3162, 0.3999; H_2O, 0.0652, 0.0812. Calcd. for $C_{24}H_{22}N_2{\cdot}ZnCl_2$: C, 61.01; H, 4.66. Found: C, 61.46, 60.94; H, 5.15, 5.04.

The zinc double salt was boiled for ten minutes with a 50% potassium carbonate solution, and the resulting colorless oil was extracted with ether. The ether residue boiled at 287° (corr.) at 760 mm., which is the figure given by Tschitschibabin for γ-benzylpyridine. The yield was 6.5 g.

β-Benzoylpyridine.—β-Benzoylpyridine has been prepared by Bernthsen and Mettegang[7] and Jeiteles[8] from β-benzoylpyridinecarboxylic acid obtained by the condensation of quinolinic acid anhydride and benzene in the presence of aluminum chloride. It may be more conveniently prepared from β-pyridine cyanide and bromobenzene by the Grignard method.

Twenty grams of β-pyridine cyanide[9] in about 200 cc. of dry ether was slowly added with constant stirring to the Grignard reagent prepared from 38 g. of bromobenzene and 5.8 g. of magnesium in about 400 cc. of ether. A yellow precipitate separated which was decomposed by the slow addition of water. Saturated ammonium chloride solution was then added and the flask shaken until practically all of the solid had dissolved. The ethereal solution was dried and the solvent evaporated, leaving a red oil.

The quantity varied somewhat, but was usually about 35 grams. It contains the ketone, together with considerable quantities of impurities. If treated with fairly strong hydrochloric acid solution, it completely resinifies, but it may be separated into a basic and non-basic portion by suspending it in 150 to 200 cc. of water and carefully adding 10% hydrochloric acid with constant stirring until no more of the oil dissolves. It is best to pour off the solution after about 50 cc. of acid has been employed and to treat the undissolved oil with more dilute acid. The non-basic oil usually amounts to about 9 g. The acid solution yields about 25 g. of oil on addition of sodium hydroxide. This oil is still impure, but the major portion distils between 270 and 320°. The distillate, which weighed about 17 g., was dissolved in 300 cc. of hot alcohol and a hot alcoholic solution of picric acid was added, The picrate of the ketone crystallized even from the hot solution in balls of needles, which melt at 161° (uncorr.). The melting point was not changed by recrystallization. The yield was 24 g. The picrate was decomposed by suspending in 250 cc. of hot water and adding 30 cc. of concentrated ammonia. The ketone separated as a light yellow oil, which was taken up in ether and the ethereal solution washed with water and dried. The ether residue boiled between 318 and 319" (corr.).

Anal. Subs., 0.2108: CO_2, 0.6114; H_2O, 0.0993. Calcd. for $C_{12}H_9NO$: C, 78.70; H, 4.92. Found: C, 79.11; H, 5.24.

The oxime was prepared by dissolving 8 g. of the ketone in 60 cc. of an alcoholic solution of hydroxylamine prepared from 6 g. of the hydrochloride and 2 g. of sodium and filtering from the sodium chloride. After heating for several hours on the steam-bath the solution was concentrated to one-half of its volume and 2 volumes of water was added. The oxime crystallized in good yield and melted between 140 and 155". It was recrystallized from benzene and melted at 161°.[8]

Anal. Subs., 0.1510: CO_2, 0.4066; H_2O, 0.0738. Calcd. for $C_{12}H_{10}N_2O$: C, 72.81; H, 5.05. Found: C, 73.44; H, 5.40.

---

[7] Bernthsen and Mettegang, *Ber.*, 20, 1209 (1887).

[8] Jeiteles, *Monatsh.*, 17, 515 (1896).

[9] R. Camps, *Arch. Pharm.*, 240,366 (1902).

β-Pyridylphenylmethylamine.—Sixteen and one-half grams of pure oxime were dissolved in 200 cc. of 95% alcohol, the solution was treated with 150 g. of zinc dust and 150 g. of glacial acetic acid was added alternately in small quantities over a period of about two hours. After the solution had stood overnight, the residue of zinc acetate and unaltered zinc was filtered off and washed with alcohol. The alcoholic solution was concentrated on the steam-bath with addition of water from time to time to expel the alcohol and most of the excess acid. The concentrated solution was treated with an excess of strong sodium hydroxide solution, and the separated oil was extracted with ether. The ether residue was distilled and yielded 14 g. of pure product, boiling at 329–331° (corr.), at 760 mm.

Anal. Subs., 0.1934: CO_2, 0.5565; H_2O, 0.1168. Calcd. for $C_{12}H_{12}N_2$: C, 78.26; H, 6.52. Found: C, 78.54; H, 6.71.

β-Pyridylphenylcarbinol.—The amine was transformed into the corresponding alcohol by dissolving it in about the calculated quantity of dilute hydrochloric acid and adding an aqueous solution of sodium nitrite, which caused a vigorous evolution of nitrogen. After standing for a few hours the solution was made alkaline with sodium hydroxide solution and the separated oil extracted with ether. The ether residue was a thick sirup which could not be made to crystallize. The yield was 9 g. from 11 g. of amine.

β-Benzylpyridine.—β-Benzylpyridine has been prepared by Tschitschibabin[10] by direct reduction of the corresponding ketones, but the fact is not mentioned in the reference books, and this compound was prepared by the method described before the original article was noted.

The crude sirupy carbinol was reduced by heating in a sealed tube for three and one-half hours with 30 g. of fuming hydriodic acid. The contents of the tube presented two layers. The heavy, black liquid, consisting of the periodide of benzylpyridine, insoluble in water, was separated, washed with water and decomposed by warming with concentrated sodium hydroxide solution. The separated dark oil was taken up in ether and the solution was shaken with sodium bisulfite to remove dissolved iodine. The ether residue was light brown and yielded on distillation 4.5 g. of the pure compound, boiling at 287–288° (corr.) at 760 mm. After standing for several days it crystallized to a solid cake. The analysis agrees for benzylpyridine. The picrate recrystallized from alcohol melts at 119° (uncorr.).

Anal. Subs., 0.1818: CO_2, 0.5661; H_2O, 0.1091. Calcd. for $C_{12}H_{11}N$: C, 85.21; H, 6.51. Found: C, 84.93; H, 6.67.

Summary

The method of Tschitschibabin for the preparation of α- and γ-benzylpyridine has been modified and a more convenient process found for the separation of the γ-derivative.

A new method is described for the preparation of β-benzylpyridine.

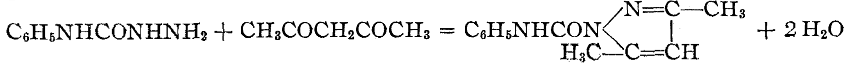
DIKETONES. I. THE REACTION BETWEEN 4-PHENYLSEMICARBAZIDE AND ACETYLACETONE

ALVIN S. WHEELER AND R. D. NORTON[1]

RECEIVED MAY 28, 1928 PUBLISHED SEPTEMBER 5, 1928

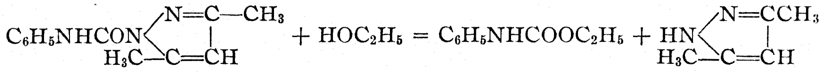
Two earlier attempts[2] were made in this Laboratory to solve the problem presented in the reaction between 4-phenylsemicarbazide and acetylacetone. Posner[3] worked out the reaction between semicarbazide and acetylacetone, obtaining 3,5-dimethylpyrazole-1-carbonamide. In our reaction two compounds are produced: one with a low melting point and very soluble in organic solvents; the other of high melting point and insoluble in organic solvents. The amount of either can be greatly increased by small changes in conditions. The low melting compound seemed to be a pyrazole on account of its pleasant odor but it could not be purified. At 60–70° it melted to an opaque liquid and above 200° to a clear liquid. Nitrogen determinations were too high. In the present study a purification method was found and a correct nitrogen analysis obtained by increasing the length of the combustion tube 100%. The reaction is carried out in alcoholic solution with very little water present. Purification was effected by extraction with petroleum ether, since both hot alcohol and hot water decompose the product. The investigation of the high melting compound (m. p. 255–257°) is reserved for future study.

The low melting compound (m. p. 69°) was proved to be a new substance, 1-phenylcarbamyl-3,5-dimethylpyrazole, according to the following equation



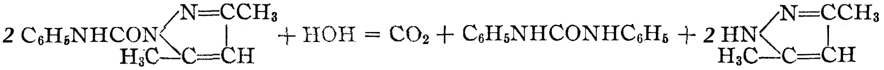
$$C_6H_5NHCONHNH_2 + CH_3COCH_2COCH_3 = C_6H_5NHCON\begin{array}{l}N{=}C{-}CH_3\\ \quad\quad |\\ H_3C{-}C{=}CH\end{array} + 2\,H_2O$$

We were able to split off the long side chain, C_6H_5NHCO, with boiling alcohol, obtaining phenylurethan and 3,5-dimethylpyrazole



$$C_6H_5NHCON\begin{array}{l}N{=}C{-}CH_3\\ \quad\quad |\\ H_3C{-}C{=}CH\end{array} + HOC_2H_5 = C_6H_5NHCOOC_2H_5 + HN\begin{array}{l}N{=}CCH_3\\ \quad\quad |\\ H_3C{-}C{=}CH\end{array}$$

Boiling water reacts with two molecules, giving carbanilide, carbon dioxide and dimethylpyrazole



$$2\,C_6H_5NHCON\begin{array}{l}N{=}CCH_3\\ \quad\quad |\\ H_3C{-}C{=}CH\end{array} + HOH = CO_2 + C_6H_5NHCONHC_6H_5 + 2\,HN\begin{array}{l}N{=}CCH_3\\ \quad\quad |\\ H_3C{-}C{=}CH\end{array}$$

Bromine reacts with the phenylcarbamyl derivative in methyl alcoholic solution, substituting the hydrogen atom in Position 4. Boiling water

splits this product, giving 3,5-dimethyl-4-bromopyrazole, described by Morgan and Ackerman.[4]

Experimental Part

1-Phenylcarbamyl-3,5-dimethylpyrazole, $C_{12}H_{13}ON_3$.—Nine and five-tenths g. of 4-phenylsemicarbazide hydrochloride was dissolved in the least possible amount of water and mixed with 45 cc. of alcohol. Another solution was made of 4 6 cc. of acetylacetone, 30 cc. of alcohol and 5 g. of sodium acetate dissolved in the least possible amount of water. The second solution was slowly added with stirring to the first. A white precipitate of microscopic crystals formed at once as a rule. After standing for thirty minutes this was filtered off. Water was added to the filtrate and a second precipitate was filtered and added to the original product. The yield was about 9 g. On heating it melted to an opaque liquid at 60–70° and to a clear liquid above 200°. Petroleum ether extracted only the low melting compound. Upon its evaporation with an air jet long, white needles separated. These melted to a clear liquid at 69°. The product possesses the pleasant odor of dimethylpyrazole. As much as 8.5 g. of the pure product has been obtained with the above quantities. The amount of water used greatly affects the yield. The product is insoluble in water but soluble in the usual organic solvents

Anal. Calcd. for $C_{12}H_{13}ON_3$: N, 19.53. Found: 19.49, 19.86.

In order to get good analyses it was necessary to use a combustion tube 155 mm. in length.

Proof of Structure

Reaction with Boiling Alcohol.—One g. of the product was dissolved in *25* cc. of absolute alcohol and boiled under a reflux for an hour. The alcohol was evaporated off on the steam-bath and a viscous liquid remained which crystallized on cooling. This solid was treated with hot water, an oily substance remaining insoluble. This was filtered off and it crystallized on standing. The filtrate was concentrated over steam to a very small volume. On cooling flake-like crystals separated. They melted at 106–107° and had a very pleasant odor. This compound was 3,5-dimethylpyrazole, described by Rosengarten.[5] Its picrate and double silver salt were prepared in order to more fully identify it. The picrate formed fine, yellow needles melting at 166–167°. The double silver nitrate salt was formed by treating the compound with silver nitrate in water solution. The voluminous precipitate was recrystallized from hot water, forming long, white needles melting at 162°. Rosengarten gives 152°.

Anal. Calcd. for $(C_5H_8N_2)_2 \cdot AgNO_3$: Ag, 29.79. Found: 29.36, 29.45.

The oily substance which crystallized on cooling was recrystallized from petroleum ether. The ether was warmed slightly and decanted from an oily substance which settled out on the bottom of the beaker. If the solution is heated too much and agitated, the impurity also goes into solution. Long, white needles were obtained on cooling the ether, melting at 51–52', which is the melting point of phenylurethan. The latter was more fully identified by boiling with aniline, forming carbanilide, melting at 238°.

Reaction with Boiling Water.—The phenylcarbamyl derivative was boiled with water under a reflux for an hour. The condenser was connected with a tube containing lime water. Carbon dioxide was evolved, as evidenced by the formation of calcium carbonate. A second product condensed in considerable quantity in the condenser. This proved to be carbanilide, melting at 238°.

---

[4] Morgan and Ackerman, J. *Chem. Soc.*, **123,** 1316 **(1923).**

[5] Rosengarten, *Ann.,* 279, 237 (1894).

Anal. Calcd. for $C_{13}H_{12}ON_2$: N, 13.20. Found: 13.15.

The carbanilide was converted into acetanilide (m. p. 116°) by heating with acetic anhydride.

The aqueous solution in the flask was concentrated to small volume and dimethylpyrazole crystallized out.

Reaction with Ammoniacal Silver Nitrate.—The phenylcarbamyl derivative was boiled with an ammoniacal alcoholic silver nitrate solution under a reflux for an hour. A grayish powder separated. This was analyzed for silver.

Anal. Calcd. for $C_5H_7N_2Ag$: Ag, 53.19. Found: 52.94.

In this product an atom of silver has replaced the side chain attached to nitrogen. The silver was removed with hydrochloric acid and dimethylpyrazole obtained.

1-Phenylcarbamyl-3,5-dimethyl-4-bromopyrazole, $C_{12}H_{12}ON_3Br$.—One g. of the phenylcarbamyl derivative was dissolved in 25 cc. of absolute methyl alcohol and 0.75 g. of bromine, dissolved in a little methyl alcohol, was added dropwise with stirring. White, plate-like crystals formed. These were filtered off and washed with methyl alcohol They melted at 100-101°.

Anal. Calcd. for $C_{12}H_{12}ON_3Br$: Br, 27.21. Found: 26.83.

The bromo derivative was hydrolyzed with boiling water. The product containing the bromine melted at 123° and proved to be 3,5-dimethyl-4-bromopyrazole, described by Morgan and Ackerman,[4] who gave 118° as the melting point. However, we brominated dimethylpyrazole according to their directions and obtained the melting point 123°.

Summary

1. 1-Phenylcarbamyl-3,5-dimethylpyrazole is formed by the action of 4-phenylsemicarbazide on acetylacetone, together with a substance of high melting point.
2. It yields with boiling alcohol phenylurethan and 3,5-dimethylpyrazole.
3. It yields with boiling water carbanilide, carbon dioxide and 3,5-dimethylpyrazole.
4. With bromine in alcoholic solution it gives a monobromo derivative with bromine in position 4.

THE CONDENSATION OF RHODANIC ACIDS WITH 5-NITRO-ISATIN. RHODANAL-$\Delta^{5,3'}$-5'-NITRO-OXINDOLES[1]

BY HOWARD A. JONES[2] AND RAYMOND M. HANN[3]

RECEIVED MAY 28, 1928 PUBLISHED SEPTEMBER 5, 1928

The susceptibility to reaction of various heterocyclic rings containing as an integral portion of their structure the CO-CH_2-S linkage has resulted in considerable study of these compounds. Among the more interesting of such heterocycles may be mentioned the rhodanic acids, the anhydrides of substituted dithiocarbamoglycolic acids. The methylene hydrogen of these 2-thio-4-thiazolidones reacts readily in the presence of a condensing agent with ketonic and quinoid oxygen. Advantage has been taken of this fact to prepare derivatives with aldehydes,[4] alloxan,[5] isatin[6] and phenanthraquinone.[7]

Hill and Henze[8] have condensed isatin and isatin-a-chloride with hydantoin and substituted hydantoins to obtain the corresponding oxindoles and pseudo indoxyls. Gränacher and Mahal[9] have demonstrated conclusively that isatin and rhodanic acid condense with elimination of the ketonic oxygen in the 3-position with formation of rhodanal oxindole. The generality of the reaction has been further examined in this Laboratory by the preparation of a series of substituted rhodanal-$\Delta^{5,3'}$-oxindoles.[10]

In continuing a study of the effect of constitutional variation upon absorption of light, we have had occasion to prepare certain rhodanal-$\Delta^{5,3'}$-5'-nitro-oxindoles, and the present paper reports the preparation and properties of these new derivatives. The condensation of rhodanic acids with 5-nitroisatin proceeds normally in an acetic acid medium in the presence of sodium acetate, the indigoid derivatives being separated by addition of water. The reaction is as follows

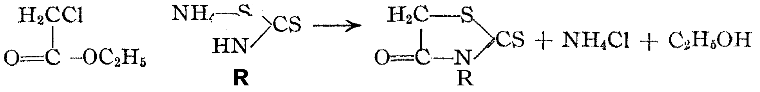
Experimental

Preparation of rhodanic acids. The rhodanic acids used in this investigation were prepared by the Miolati–von Braun synthesis. The general steps in this synthesis are (1) the preparation of the substituted ammonium dithiocarbamate from the primary amines and (2) the interaction of these intermediate products with esters of a-halogen fatty acids, resulting in loss of alcohol and ammonium halide and subsequent ring closure to yield rhodanic acids. The reactions are

$$RNH_2 + CS_2\ 4\ NH_4OH = HNRCSSNH_4 + H_2O \qquad (1)$$



(2)

The synthesis for phenyl, o- and *p*-anisyl, *ψ*-cumyl and *β*-naphthyl homologs was carried out along the general procedures of Andreasch and Zipser,[11] Antulich,[12] Kaluza[13] and Wagner[14] with the substitution of bromo-acetic ester in place of the corresponding chloro compound. The yield was increased by this procedure, due to a more complete reaction in ring closure.

Preparation of 5-Nitro-isatin.—The substituted isatin was prepared by nitration of isatin according to the directions of Calvery, Noller and Adams.[15] The yield was excellent and the substance was used without further purification.

Preparation of **Aryl Rhodanal-$\Delta^{5,3'}$-5′-nitro-oxindoles.**—Two grams of 5-nitro-isatin was dissolved in 25 cc. of glacial acetic acid and to this solution a molecular quantity of rhodanic acid and 5 g. of fused sodium acetate were added. The solution was then refluxed under a condenser for about three hours, unless bumping due to separation of reaction product became too violent to allow such treatment. In the latter case, the solution was cooled, the solid filtered off and the filtrate again refluxed until the time of total heating was three hours. After cooling, the solution was treated with water to precipitate the condensation product and dissolve any separated sodium acetate. The combined solid products of reaction were recrystallized or reprecipitated from glacial acetic acid.

The rhodanal-$\Delta^{5,3'}$-5′-nitro-oxindoles are red, crystalline derivatives, somewhat soluble in acetic acid and insoluble in water. They dissolve in sulfuric acid with the production of brilliant red colors. The melting points of the derivatives were obtained by Mr. J. F. Clevenger[16] in the micro melting point apparatus recently designed and described by him.

CHLOROFORM SOLUBLE METAL PYRIDINE CYANATES

BY TENNEY L. DAVIS AND ALBERT V. LOGAN

RECEIVED JUNE 5, 1928 PUBLISHED SEPTEMBER 5, 1928

Many compounds of pyridine with inorganic salts have been prepared and described.[1] The first mention that any of these substances is soluble in chloroform appears to be in the paper of Spacu,[2] in which the author described a delicate qualitative test in which cupric pyridine thiocyanate was precipitated from a water solution of cupric thiocyanate by the addition of pyridine. Chloroform dissolved the substance more readily than water and yielded an emerald green solution which served for the detection of one part of copper in 300,000–800,000, one of pyridine in 2000 and one of thiocyanate in 50,000. Spacu, on the basis of copper and nitrogen determinations, assigned to his substance the composition, $Cu(NCS)_2 \cdot 2C_5H_5N$. E. A. Werner[3] later developed a similar test for cyanate. The

azure blue chloroform solution on evaporation yielded a bluish-lilac colored substance to which, on the basis of a copper determination, he assigned the composition, $Cu(NCO)_2 \cdot 2C_5H_5N$.

Since cupric pyridine sulfate, nitrate, chloride, etc., are insoluble in chloroform, it seems probable that the solubility of the cyanate and thiocyanate in that solvent is due to the organic nature of their acid constituents. We have found that the cupric, cobaltous and nickelous salts of the aliphatic nitramines and the cupric derivatives of biuret and various related substances combine with pyridine to form complex salts which are soluble in chloroform. Before studying these substances further, it has seemed best to gain a fuller knowledge of the metal pyridine cyanates.

We have found that copper, nickel, cobalt, cadmium, zinc and silver all form pyridine cyanates which are soluble in chloroform, and have established the composition of the complex salts by analysis for the metal and for pyridine. Cupric, nickelous, cobaltous and cadmium cyanates each form two pyridine compounds, one with more and one with less pyridine, one stable only in an atmosphere saturated with pyridine and one fairly stable in open vessels in the laboratory. Zinc dipyridine cyanate and silver monopyridine cyanate deliquesce in an atmosphere saturated with pyridine, evidently forming compounds with more of that material. These metal pyridine cyanates are insoluble in petroleum ether and carbon tetrachloride, insoluble or slightly soluble in ether, benzene and toluene, and varying from very slightly to very readily soluble in methyl and ethyl alcohol and acetone.

Cobaltous hexapyridine cyanate forms rose-colored crystals which lose pyridine rapidly in the open to leave a bright blue mass of the dipyridine compound. In chloroform solution the hexapyridine compound apparently dissociates to form the dipyridine compound and free pyridine, for the solution possesses an intense blue color. On strong cooling the solution becomes violet or lilac or pink-colored according to the degree of cold, and the same color changes are produced at room temperature by the addition of pyridine—which evidently retards the dissociation. When the pink or almost colorless solution is heated to boiling, it takes on an intense blue color even if a large excess of pyridine is present. By the careful addition of pyridine to a chloroform solution of cobaltous hexapyridine cyanate we have obtained a liquid which shows a striking change of color between the temperature of tap water, room temperature and the temperature of the body. Similar color changes occur in water solution and to a less striking degree in various organic solvents. Solutions in methyl or ethyl alcohol, acetone or xylene are purple, lavender, light blue or pale dirty brown, respectively, at low temperatures or when an excess of pyridine is present.[4]

---

[4] Schonn, *Z.* anal. *Chem.*, **9,** 209 (1870), used sodium thiocyanate as a qualitative test for cobalt. If the amount of cobalt is very small, the blue color appears only on warming.

Cobaltous hexapyridine cyanate and cupric hexapyridine cyanate[5] raise the boiling point of chloroform more than would be expected if they were completely dissociated in the solution into pyridine and the metal dipyridine cyanate. The solutions do not appear to contain ions, for they have no action on a piece of metallic zinc.

Preparation of the Compounds.—One-tenth of a mole of potassium cyanate and an equivalent amount of the metal salt were dissolved separately in water and the solutions were mixed. Pyridine was added until no further change occurred and then a little more so that a slight excess was present. The precipitated metal pyridine cyanate was extracted with 100–200 cc. of chloroform. The solution was filtered through paper previously wet with chloroform and allowed to evaporate spontaneously. The deposited crystals were freed from superficial pyridine by means of filter paper and were kept in a desiccator which contained pyridine and sticks of caustic potash in separate vessels. This procedure yielded the pyridine saturated compounds. The compounds containing less pyridine were obtained by leaving the saturated compounds uncovered in watch glasses for periods varying from two days to a week. After the samples had assumed the appearance of homogeneity they were bottled for analysis.

Determination of **Pyridine.**—For the determination of pyridine the samples were decomposed by boiling with caustic soda and the pyridine was distilled off and titrated. Since the pyridine was accompanied by ammonia from the hydrolysis of the cyanic acid, it was necessary to use a procedure which would take account of ammonia, and that of A. C. Houghton[6] for the determination of pyridine in ammonia liquors was finally adopted. The accuracy of the method was tested by blank determinations on weighed samples of purified pyridine, b.p. 114–115°. The pyridine was dissolved in 100 cc. of water, a few drops of ammonia added, the whole neutralized with sulfuric acid and then made alkaline with 5 cc. of normal sodium hydroxide solution and steam distilled from a 1000-cc. round-bottomed flask. The vapors passed through a 500-cc. Erlenmeyer flask containing sodium hypobromite solution (from 2.5 cc. of bromine and 100 cc. of 10% sodium hydroxide solution) which destroyed the ammonia, thence through a Kjeldahl bulb into the condenser and finally into a known amount of $N/10$ sulfuric acid solution. Best results were secured by collecting 100–125 cc. of distillate during thirty to forty minutes. Methyl red, Congo red, cochineal, methyl red-methylene blue mixture and methyl orange were all tried as indicators; none gave a very sharp end-point but methyl orange proved to be the best. After the method had been worked out, blank determinations were made as follows.

---

[5] The only ones which we have tried.

[6] Houghton, J. Ind. Eng. *Chem.*, 1, 698 (1909).

TABLE I

BLANK DETERMINATIONS

Pyridine taken, g.	Pyridine found By titration of aliquot					Average	Error, %
0.4493	0.4475	0.4450	0.4440			0.4455	−0.85
.5206	.5240	.5180	.5280	0.5230		.5232	+.50
.5546	.5610	.5640	.5540	.5450	0.5550	.5577	+.22

.6073	.6200	.6210				.6205	+2.17
.4855	.4890	.4870	.4900	.4840	.4790	.4858	+.06
						Average error, %	0.798

The results show that the method is accurate to about 1%. The metal pyridine cyanates were analyzed by treating a sample of about 1 g. with water and 5 cc. of normal sodium hydroxide solution, and proceeding as described above.

Description of the Compounds.—Cupric hexapyridine cyanate[7] crystallizes from chloroform in azure blue prisms which retain their color and form as long as they remain in an atmosphere of pyridine. Exposed to the air for a short time the crystals change to a pale blue or bluish-lilac colored powder of cupric dipyridine cyanate, described by Werner.[3] After exposure to the air for several months, or after heating at 100° for a few hours, the latter substance changes to a pale green powder of cupric cyanate.

Nickelous hexapyridine cyanate[8] crystallizes from chloroform in blue prisms of a lighter color than those of the cupric compound. It loses pyridine to form a pale blue powder of nickelous tetrapyridine cyanate and finally an apple green powder of nickelous cyanate.

When pyridine is added to the bright blue solution which results from the interaction of potassium cyanate and cobaltous chloride, a blue precipitate forms at once and changes to one of a pink color when an excess of pyridine is added. This dissolves in chloroform and the solution, which contains free pyridine, deposits rose-colored hexagonal prisms of cobaltous hexapyridine cyanate. That substance in the open loses pyridine rapidly to yield bright blue cobaltous dipyridine cyanate, which on long exposure or heating yields lilac-colored cobaltous cyanate, which in a moist atmosphere changes in part to carbonate and oxide.

Cadmium hexapyridine cyanate[9] is considerably less soluble in chloro-

---

[7] Pfeiffer and Pimmer (Ref. 1) found cupric pyridine nitrates which contained two, three, four and six molecules of pyridine.

[8] Grossmann (Ref. 1) obtained a nickelous tetrapyridine thiocyanate and Varet (*ibid.*) nickelous di- and tetrapyridine bromides.

[9] Grossmann (Ref. 1) and Varet (*ibid.*) have obtained hexa- and dipyridine compounds of cadmium thiocyanate and of the halides, as well as some compounds containing one and four molecules of pyridine.

form than the corresponding copper and nickel compounds. It crystallizes in small white crystals which lose pyridine to farm a white powder of cadmium cyanate.

Zinc dipyridine cyanate[10] was more difficult to prepare than the other compounds, for it was not easily extracted by chloroform from water solution and an excess of pyridine interfered with its crystallization. It crystallizes from chloroform in granular white crystals which do not lose

[a] In order that it may be evident that the analyses really fix with certainty the amount of pyridine in the complexes, the calculated values for the substances containing one more and one less molecule of pyridine than the found substances are included in the table. The figures reported for pyridine are in each case the average results from the titration of four or five aliquots.

[b] Analyzed after exposure for a week to the open air.

---

[10] Grossmann (Ref. 1) and Varet (*ibid.*) obtained zinc thiocyanates, cyanides and halides with two, three and four molecules of pyridine.

their form on exposure to the air and which retain their pyridine rather strongly, for analysis showed no appreciable loss of pyridine after a week's exposure. In an atmosphere saturated with pyridine it deliquesces to form a sirupy liquid, a phenomenon which suggests that a compound containing more than two molecules of pyridine is formed.

Silver monopyridine cyanate[11] crystallizes from chloroform in very thin, silky, white needles which deliquesce in an atmosphere of pyridine and are but little affected by light. On exposure to the air it loses pyridine to form silver cyanate which is markedly more sensitive to the action of light.

Effect on Boiling Point of Chloroform.—An attempt was made to determine the extent to which cobaltous hexapyridine cyanate dissociates in chloroform solution by observation of its effect in raising the boiling point of that solvent. Preliminary experiments showed that pyridine alone in chloroform solution, even as much as 9 g. in 80 g. of solvent, behaved as a non-volatile solute and had the normal effect in raising the boiling point. The results of a typical experiment, in which 64.2 g. of chloroform was used, are tabulated below.

TABLE III

RESULTS OF EXPERIMENT

$Co(NCO)_2 \cdot 6C_5H_5N$, g.	Observed ΔT, °C.	Expected ΔT if no dissociation	Apparent number of molecules
0.1740	0.11	0.016	6.87
.2255	.14	.021	6.67
.2085	.11	.019	5.79
.6080	.36	.056	6.43

When pyridine was added to the solution which remained at the end of the experiment, it acted normally in its effect in raising the boiling point still farther.

Sixty-eight one-hundredths g. of cupric hexapyridine cyanate raised the boiling point of 76.6 g. of chloroform 0.34°, or 6.54 times as much as the amount (0.052°) which would be expected if no dissociation had occurred. The abnormal results deserve further study.

Summary

Cupric hexapyridine and dipyridine cyanate, nickelous hexapyridine and tetrapyridine cyanate, cobaltous hexapyridine and dipyridine cyanate, cadmium hexapyridine and dipyridine cyanate, zinc dipyridine cyanate and silver monopyridine cyanate have been prepared and characterized by analysis for pyridine and for the metal.

Cobaltous hexapyridine cyanate and cupric hexapyridine cyanate raise the boiling point of chloroform about six and one-half times as much as would be expected if they were undissociated molecules.

---

[11] Grossmann (Ref. 1) prepared silver monopyridine thiocyanate.

Cobaltous hexapyridine cyanate yields a blue solution in chloroform which turns lilac-colored or pink if the temperature is lowered or if pyridine is added. By adjusting the amount of excess pyridine in such a solution, a liquid may be secured which changes color with very moderate changes of temperature.

STUDY OF THE POSSIBLE ISOMERISM OF CERTAIN ANALOGS OF RESOLVABLE DIPHENYL COMPOUNDS[1]

BY J. F. HYDE AND ROGER ADAMS

RECEIVED JUNE 18, 1928 PUBLISHED SEPTEMBER 5, 1928

A configuration in which the two aromatic nuclei are coaxial and not in the same plane apparently accounts for all of the known facts concerning the optical activity in certain diphenyl compounds. It is generally accepted that the asymmetry arises from the influence which the groups located in the ortho position to the connecting bond have in preventing free rotation of the two nuclei. The exact nature of the interference to free rotation remains still to be determined.

Mills[2] considers it to be entirely mechanical in nature. The groups are unable to get by each other due to their size and proximity in space. Meisenheimer[3] has offered additional evidence to favor mechanical interference and has pointed out that spacings of the groups from the nucleus as well as between the two rings must be considered.

Turner and Le Fèvre[4] consider the problem from the point of view of residual affinity on each ring and the influence of the electrical nature of the ortho substituted groups.

It seems reasonably certain that the isomerism is not due to the specific effect of any particular group on the nuclei.[5]

Diphenyl derivatives of the general types Ia, Ib, Ic, in which the ortho

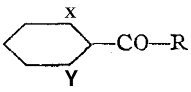
[5] Christie and Kenner, *J. Chem. Soc.*, 121, 614 (1922); *ibid.*, 123, 779 (1923); Christie, James and Kenner, *ibid.*, 123, 1948 (1923); Christie, Holderness and Kenner, *ibid.*, 129, 671 (1926); Bell and Kenyon, *Chemistry Industry*, 45, 864 (1926); Turner and Le Fèvre, *ibid.*, 46, 218 (1927).

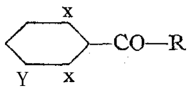
substituting groups may be the same and in which the individual rings are asymmetric should be capable of resolution. The free rotation is prevented in these cases by groups in the ortho positions which are identical, The asymmetry is introduced by the same or different groups in another part of the molecule. If the restricted rotation is due simply to mechanical interference, these substances should be resolvable. If, on the other hand, the influence is entirely electrical, the two rings might assume a coplanar position resulting in a compound that is non-resolvable. While the resolution of such a compound might not make the cause of steric hindrance clearer, it would certainly establish the present mechanical theory more firmly.

This investigation had as one of its objects the preparation and resolution of an individual compound falling in one of the types mentioned. Although this part of the work is not completed, the publication of Mascarelli[6] setting forth in detail the views just given, though without any experimental evidence, has made it advisable to publish the completed results on closely related compounds.

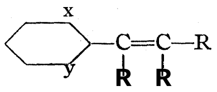
If the prevention of free rotation is entirely a matter of the space occupied by interfering groups and does not require a direct association of two aromatic rings, then it should be possible to resolve still other types of compounds which could become asymmetric due to steric hindrance. Such types are represented by the general formulas IIa, IIb, IIIa, IIIb, where R stands for groups of the proper size.



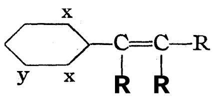
IIa



IIb



IIIa



IIIb

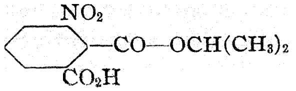
In such compounds as IIa, IIb, IIIa and IIIb, any effect due to the direct joining of two rings to each other is eliminated. The carbon–carbon double bond and possibly the carbon–oxygen double bond adjacent to the ring should have more or less of a directive influence on the valencies of that carbon as is the case with a rigid ring structure. The molecules would undoubtedly be less rigid, but if the free rotation around the bond joining the unsaturated linkage to the substituted ring is prevented, any position of the olefin or carbonyl group and the unsubstituted ring in space should give an asymmetric molecule. The possibility of this occurring in the case of the carbonyl compounds as in types IIa and IIb seems much less probable than in the olefins IIIa and IIIb. If the carbonyl group itself will not interfere with free rotation, it is possible that the R groups in the molecules, if large enough, might cause interference.

Although the syntheses of representatives of types I, II and III are

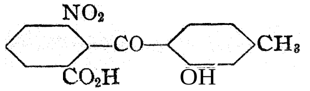
---

[6] Mascarelli, *Atti. accad. Lincei,* [6] **6,** 60 **(1927).**

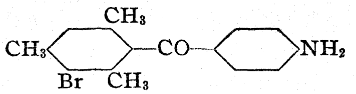
under way, in this paper merely compounds falling into group II will be described and discussed. The following four compounds were prepared



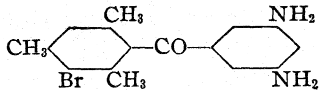
IV



V



VI



VII

The one numbered IV was made directly by the action of isopropyl alcohol on 3-nitrophthalic anhydride, the one numbered V by the condensation of nitrophthalic anhydride with m-cresol, and those numbered VI and VII by the condensation of nitro- and dinitro-benzoyl chloride with bromomesitylene followed by subsequent reduction. The resolution of IV and V was attempted with brucine and of VI and VII with camphorsulfonic acid.

In carrying out the fractional crystallization of the salts there was no definite separation, nor did the relative size of the fractions give any indication of salts of different solubilities. In order to prove the possibility of the existence of optical isomerism, it was considered essential to isolate a sample of the material which should show at least momentary rotatory power and be entirely free from optically active reagent. In no case were optically active compounds obtained by decomposition of the salts.

It was shown that the carbonyl group in such ketones as VI was very unreactive, as indicated by failure of all attempts to reduce it or to cause it to react with the Grignard reagent. The carbonyl group is, therefore, protected from influences outside of the molecule and it must be that the volume of the carbonyl group is not sufficient to interfere (on rotation) with the ortho groups of the substituted ring. Moreover, the o-hydroxy substituted phenyl group apparently has no effect.

Certain anomalies appeared in the rotation of the salts. The brucine salt of 2-(2-hydroxy-4-methylbenzoyl)-3-nitrobenzoic acid, V, has an α_D $+18.3°$, while under the same conditions brucine has an α_D $-119°$. Kuhn and Albrecht[7] noticed a similar phenomenon in the case of the quinine salt of 4,4′-dinitrodiphenic acid, which had an α_D $+110°$, whereas in the same solvent quinine had an α_D $-117°$. No active acids, however, were isolated. They also observed that the quinine salts of *m*-nitrobenzoic acid and of phthalic acid have, under the same conditions, a rotation similar to that of quinine. A possible explanation for such abnormal rotations in the salts would be the assumption that a complete transformation to one form of two possible diastereoisomers had occurred

---

[7] Kuhn and Albrecht, *Ann.*, 455, 272 (1926).

upon the addition of the optically active reagent. Haworth[8] in reviewing the work of Kuhn on diphenyl compounds, has accepted this observation of abnormal rotation as conclusive evidence of the existence of labile optical isomers in diphenyl compounds with only one ortho substituting group in each ring. He suggests that this behavior serves to distinguish these compounds from those diphenyl derivatives with three ortho substituting groups of proper size and character which make possible the isolation of the two diastereoisomeric salts and the two enantiomorphic diphenyl compounds. These conclusions of Haworth cannot be considered of more than passing interest as they are based on far too few facts. He has made no mention of the extensive work of Hilditch,[9] who has studied a large variety of salts of various alkaloids and has observed just such anomalous effects as have appeared in this investigation and in the investigation of Kuhn and Albrecht. Hilditch has shown that if there are conjugated systems in proximity to the optically active part of the molecule, the rotatory power is markedly influenced. He has also observed that the nature of the groups, particularly in the ortho position to the one combined to the active reagent, may induce anomalous rotations. These latter types are quite similar in character to the diphenyl compounds studied by Kuhn and to the substances described in this research, though the anomalies could hardly be attributed to the same cause as that assigned by Haworth to 4,4′-dinitrodiphenic acid and its salt.

The camphorsulfonic acid salts of amino and diamino-benzoylbromomesitylene led to negative results as far as optically active amines were concerned. The salts, however, showed a curious behavior. In certain solvents the substances changed in rotation upon standing. At first this was assumed to be a gradual change of one salt to the diastereoisomer. However, it is significant that this was observed only in chloroform. The camphorsulfonate of aminobenzoylbromomesitylene had an α_D +13.8° at first and an α_D +7.6° after several hours' standing. Upon evaporation of the solution after determining the second rotation, the solid salt was obtained. If this was redissolved in chloroform, however, the original rotation was again observed, and only after standing did it diminish. Apparently other salts of camphorsulfonic acid show this same phenomenon. The aniline salt was studied and showed an even greater variation in rotation on standing in chloroform solution. It appears to be due to a change in the character of the molecule either by tautomerism or by combination with a solvent.[10] Whatever the change may be, it does not appear to be a permanent one and is not characteristic of the base used.

The synthesis of compounds of the type I has been attempted by diazo-

tizing methyl anthranilate and other analogous amines and coupling with bromomesitylene in order to produce diphenyl derivatives. Amino bromomesitylene has also been diazotized, and attempts to couple it with various benzene derivatives in order to produce the proper diphenyl compound have all resulted as yet in failure. Now, however, it seems possible to get a diphenyl compound of the type desired through dimesityl.

Experimental Part

Benzoylbromomesitylene.—A mixture of 0.33 mole of bromomesitylene and 0.3 mole of benzoyl chloride was dropped very slowly into a reaction flask containing 0.47 mole of aluminum chloride and 260 g. of carbon disulfide. This took about an hour and the stirring was continued for about two hours longer. Finally, part of the carbon disulfide was distilled off, using a water-bath. The reaction mixture was then decomposed by pouring into ice water containing some hydrochloric acid. The product distilled as a light yellow, viscous oil at 173–175° at 1 to 2 mm., which was practically colorless on redistillation, The yield was 91 g. (92%). This viscous liquid on stirring and allowing to stand for several hours solidified to a white, granular, crystalline mass with a melting point of 48–49°. No attempt was made to recrystallize the compound.

Anal. (Parr Bomb). Subs., 0.2101: 7.05 cc. of 0.1005 N $AgNO_3$. Calcd. for $C_{16}H_{15}OBr$: 26.40. Found: 26.76.

An attempt was made to condense benzoylbromomesitylene with ethyl bromoacetate in the presence of zinc. After several trials it was found that no reaction had taken place and merely the original product was obtained. Phenylmagnesium bromide also would not react with this compound.

An attempt to oxidize the benzoylbromomesitylene to the benzoylbromodimethylbenzoic acid resulted in the formation of a neutral, viscous liquid. The reaction was accompanied by the evolution of carbon dioxide.

A Clemmensen reduction to the corresponding hydrocarbon gave negative results.

***p*-Nitrobenzoylbromomesitylene.**—This was prepared in exactly the same way as that described for benzoylbromomesitylene except that the bromomesitylene had to be heated in order to make the acid chloride dissolve in it and it was necessary to continue the heating during the reaction (about four hours) to prevent crystallization. Upon decomposing, some chloroform was added so that the solvent was a mixture of carbon disulfide and chloroform. The resulting ketone, after removing the carbon disulfide and chloroform, was crystallized by dissolving in acetone, filtering and adding twice the volume of ethyl alcohol to the hot solution. After recrystallizing once more from the same combination of solvents, the product consisted of light yellow plates, melting at 154–155°. The yield was 29.5 g. (85%).

Anal. (Parr Bomb). Subs., 0.2269: 6.44 cc. of 0.1005 *N* $AgNO_3$. Calcd. for $C_{16}H_{14}O_3NBr$: 22.98. Found: 22.86.

3,5-Dinitrobenzoylbromomesitylene.—This was prepared in an analogous way to the mononitro. Very poor results were obtained unless the reaction mixture was warmed somewhat and stirred for at least four or five hours. The product was not distilled but merely crystallized from acetone. It formed light yellow plates melting at 160–161.5°. The yield was 9.5 g. (24%).

Anal. Subs., 0.2366: 11.74 cc. of 0.0502 N $AgNO_3$. Calcd. for $C_{16}H_{13}O_5N_2Br$: 20.35. Found: 20.09.

***p*-Aminobenzoylbromomesitylene.**—A suspension of 21 g. of nitrobenzoylbromomesitylene in 50 cc. of alcohol was reduced with 0.1 g. of platinum-oxide platinum black[11] and hydrogen. When the theoretical amount of hydrogen was absorbed, the catalyst was filtered and the solvent evaporated. The product was purified by dissolving in carbon disulfide and by adding gradually an equal amount of benzene. It crystallized in fine, white needles; melting point, 138°.

Anal. Subs., 0.1735: 10.66 cc. of 0.0502 *N* $AgNO_3$. Calcd. for $C_{16}H_{16}ONBr$: 25.15. Found: 24.67.

p-Aminobenzoylbromomesitylene Hydrochloride.—This was prepared by dissolving the free base in ethyl acetate and treating with hydrogen chloride. The hydrochloride crystallized out rather slowly in white, needle-like crystals and was recrystallized from the same solvent.

Anal. Subs., 0.1291: 3.66 cc. of 0.1005 N $AgNO_3$. Calcd. for $C_{16}H_{17}ONBrCl$: 10.01. Found: 10.12.

If, instead of using ethyl alcohol as a solvent, ethyl acetate was used, and 0.05 g. of catalyst for 14.4 g. of nitro compound, the reduction did not go readily to completion and a light red azo compound was found contaminating the amine. The former was removed by ethyl alcohol, in which it was insoluble. It melted at 203–205°.

Anal. Subs., 0.1295: 8.06 cc. of 0.0502 *N* $AgNO_3$. Calcd. for $C_{16}H_{14}ONBr$: 25.31. Found: 25.02.

3,5-Diaminobenzoylbromomesitylene.—This was reduced in a manner similar to the mono-amino compound and formed yellowish-brown crystals from alcohol, melting at 168–169°, which turned dark brown upon standing for a short time.

Anal. Subs., 0.1301: 7.92 cc. of 0.0502 *N* $AgNO_3$. Calcd. for $C_{16}H_{17}ON_2Br$: 24.02. Found: 24.44.

p-Aminobenzoylbromomesitylene d-Camphorsulfonate.—The d-camphorsulfonic acid used melted from 190–191" and gave α_D $+21.08°$ in water. The salt was readily produced by dissolving 5 g. of the amino ketone in 30 cc. of ethyl acetate and adding this hot solution to a solution of 3.48 g. of d-camphorsulfonic acid in 30 cc. of ethyl acetate. After standing for half an hour, 7 g. of the possible 8.5 g. of salt crystallized in white, flat plates, melting at 175–200° with decomposition. The rotations were determined in a Schmidt-Haensch saccharimeter, using a 2-decimeter tube. The weighed sample was in each case dissolved in 20 cc. of the desired solvent at 20°. This salt gave a value α_D $+13.7°$ (15 minutes) in chloroform, which, on standing for several hours, gradually became smaller and smaller until a constant value of +7.1° (38 to 40 hours) resulted. The fraction from the mother liquors gave essentially the same initial rotation and only a slightly higher final rotation. A rather large sample of this salt was fractionally crystallized. After three times the rotation was determined. The specific rotations on three fractions were, respectively, +12.7°, +12.8° and +11.4°, using acetone as a solvent. Two of these fractions in chloroform gave rotations of approximately +14° which, on standing, dropped to approximately +7°. Upon removing the chloroform from a solution which had given the low rotation, a product was obtained which, on redissolving in chloroform, gave a rotation of over 14°, which again gradually fell off upon standing.

Anal. Subs., 0.1938: 7.01 cc. of 0.0502. *N* $AgNO_3$. Calcd. for $C_{16}H_{16}ONBr$-$C_{10}H_{16}SO_4$: 14.54. Found: 14.53.

3,5-Diaminobenzoylbromomesitylene d-Camphorsulfonate.—This was prepared from equimolecular quantities of the acid and the amine in acetone solution. The

---

[11] Adams, Shriner and Voorhees, "Organic Syntheses," John Wiley and Sons, Inc., New York, **8**, 92–99 (1928).

precipitated salt was in the form of fine, white needles, melting at 216–218°. It was fractionated five times and the rotations of the individual fractions were taken in methyl alcohol, using a 2-decimeter tube and making the solution up to 20 cc. at 20°. The rotation was +21.2° for the first fraction, +20.2° for the second, +16.4" for the third, +15.0" for the fourth and +18.2° for the fifth. Upon standing these solutions became colored and fluorescent and further readings were impossible. It was noticed, however, that the readings gradually fell off irregularly, somewhat as in the case of the monoamino compound. In this case decomposition of some sort obviously was taking place.

Anal. Subs., 0.1943: **4.75** cc. of 0.0502 N $AgNO_3$. Calcd. for $C_{16}H_{17}ON_2Br_2\cdot 2C_{10}H_{16}SO_4$: 10.03. Found: 9.82.

The carefully fractionated salts of the mono- and diaminobenzoylbromomesitylenes were decomposed with ammonia by adding concentrated ammonia water to a methyl alcoholic solution of the salt. Further dilution with water precipitated the free organic base. The free bases obtained from these salts with acid melted exactly as they had before forming the salt and showed no detectable rotation.

Brucine Salt of **2-Carboisopropoxy-3-nitrobenzoic** Acid.—The free acid prepared by the method of Nicolet and Sacks[12] was converted to the brucine salt by mixing its ethyl acetate solution with a similar solution of brucine. The brucine used melted at 174–176°, and had an α_D −119.0". The salt formed bright yellow needles melting indefinitely from 90–95° with decomposition. After five careful fractional crystallizations from acetone, the rotations of the fractions were taken in chloroform. A 2-decimeter tube was used and the solutions were made up to 20 cc. at 20°. The α_D of the five fractions were, respectively, −19.0°, −19.4°, −19.9°, −18.8" and −21.3". No changes in rotations were observed on standing. Upon treating the chloroform solution of the crystallized salt with dry ammonia and then dissolving the precipitated ammonium salt in water and acidifying, the isopropylnitrophthalic acid was recovered and showed no signs of rotation.

Anal. Subs., 0.2217: CO_2, 0.5056; H_2O, 0.1264. Calcd. for $C_{34}H_{37}N_3O_{10}$: H, 5.71; C, 63.06. Found: H, 6.37; C, 62.20.

Brucine 2(2-Hydroxy-4-methylbenzoyl)3-nitrobenzoic Acid.—The acid was obtained by the method of Eder and Widmer[13] and the salt was formed in hot ethyl acetate. It forms yellow, needle-like crystals melting from 160–165° with decomposition. Upon fractionating four times from benzene, the rotations of the various fractions were determined. The α_D values were +18.3 for the salt initially, +18.39 for the first fraction and +16.3 for the fourth fraction. A 2-decimeter tube was used as in other cases. The samples were made up to 20 cc. at 20°, using acetone as a solvent. No rotation was observed in the free acid obtained by the precipitation of the ammonium salt and then acidification of the water solution.

Anal. Subs., 0.1169: CO_2, 0.2842; H_2O, 0.0546. Calcd. for $C_{38}H_{37}N_3O_{10}$: C, 65.60; H, 5.32. Found: C, 66.30; H, 5.26.

Aniline-*d*-camphorsulfonate.—The salt was prepared in the usual way and in chloroform gave the following rotations, using a 2-decimeter tube: 0.2079 *g.* subs. in 20 cc. of chloroform at 20° gave α_D +33.3° (ten minutes), +26.8° (five hours), +16.6° (seven hours), +6.6° (forty-eight hours).

Summary

1. *p*-Aminobenzoylbromomesitylene, 3,5-diaminobenzoylbromomesitylene, 2-carbo-isopropoxy-3-nitrobenzoic acid and 2-(2-hydroxy-4-methyl-

ADDITION REACTIONS OF UNSATURATED ALPHA-KETONIC ACIDS. II

BY MARIE REIMER AND MARION HOWARD

RECEIVED JUNE 21, 1928 PUBLISHED SEPTEMBER 6, 1928

It has been previously shown[1] that the action of sunlight on the methyl ester of benzalpyruvic acid brings about addition of two molecules at the ethylenic linkage, cyclobutane derivatives being formed. The fact that p-methoxybenzalpyruvic acid and its methyl ester did not form such addition products, being entirely unaffected by sunlight, led to a comparative study of the addition reactions of the two ketonic acids and their esters with bromine[2] in which it was found that the ease with which both compounds combined with bromine was the same.

This study of unsaturated a-ketonic acids has now been continued with benzalpyruvic acid in which a substituting methoxyl group is in the *ortho* instead of the *para* position to the side chain. It has been found that the o-methoxybenzalpyruvic acid and its methyl ester also combine readily with bromine but that in almost all other respects the properties of the compound have been changed to a marked degree by this shift in the position of the methoxyl group. The color is deepened, that of o-methoxybenzalpyruvic acid being a brilliant orange, that of the *p*-methoxy acid a bright yellow.[3] The solubilities of the o-methoxy acid, its sodium salt and its methyl ester in the appropriate solvents are greater than those of the corresponding *p*-methoxy compounds; the acid and its esters do not combine with solvent of crystallization, a conspicuous characteristic of benzalpyruvic acid and its p-methoxy derivatives; the dibromo addition products are less stable than those of the other unsaturated a-ketonic acids studied, hydrogen bromide being lost with great ease. The most striking difference between the two methoxy derivatives is that *o*-methoxybenzalpyruvic acid and its methyl ester are sensitive to light; the aqueous solution of the acid is hydrolyzed rapidly in the sunlight; the acid, exposed in the dry condition, slowly loses its brilliant color; the methyl ester exposed to bright sunlight liquefies within a few minutes due to admixture with a light product.

[3] Hodgson and Handley, *J. Chem. Soc.,* **1928, p. 162.**

Benzalpyruvic acid and its *p*- and a-methoxy derivatives react with concentrated sulfuric acid to give brilliantly colored solutions as is ordinarily the case with α,β-unsaturated ketones. That the ketone group in these ketonic acids is essential for this color reaction is proved by the fact that loss of this group by oxidation with hydrogen peroxide to give derivatives of cinnamic acid is accompanied by loss in the ability to form these brilliantly colored compounds. Most striking is the unexpected effect of the bromine atom in the methoxy compounds, the *ortho* and *para* compounds in this case giving similar results. If bromine is in the side chain, a distinct series of color changes, yellow to red-violet, takes place on addition of concentrated sulfuric acid; if there is also bromine in the ring another quite different series of color changes to blue or green ensues. The difference is so marked that it is possible by this reaction to determine, with very small quantities of material, whether bromine is present in the side chain, also in the ring or absent, as well as to detect the presence of the ketone group. This behavior is described more fully in the experimental part.

Experimental Part

Preparation of o–Methoxybenzalpyruvic Acid

Seventeen and six-tenths grams (**0.2** mole) of pyruvic acid was added to **160** cc. of 10% sodium hydroxide solution (**0.4** mole), the solution cooled to 0°, **27.2** g. (**0.2** mole) of o-methoxybenzaldehyde added and the mixture shaken vigorously. At the end of an hour the emulsion which was at first formed had entirely disappeared and the brownish colored solution was clear. There was no separation of a sodium salt as in the preparation of benzal- and *p*-methoxybenzalpyruvic acids. When this reaction mixture was allowed to stand overnight, a procedure necessary with *p*-methoxybenzalpyruvic acid to insure good yields, the o-methoxy compound was found to have been almost completely hydrolyzed to o-methoxybenzaldehyde and pyruvic acid. Addition of chilled concentrated hydrochloric acid to the cooled, strongly alkaline solution immediately after one hour of shaking precipitated the bright yellow sodium salt of o-methoxybenzalpyruvic acid in about **80%** yield. The hydrochloric acid was added with vigorous stirring until the first traces of an orange-colored substance appeared. The yellow, granular sodium salt was filtered, freed from mother liquor by suction, dissolved in cold water and the solution acidified. The *o*-methoxybenzalpyruvic acid precipitated as a granular solid of a brilliant orange color. A less pure product was obtained in small quantity from the mother liquor.

The acid separates from boiling water in long, fine needles; from benzene in compact needles of a brilliant red-orange. As boiling with water or exposure of the aqueous solution to the light brings about hydrolysis of the acid, crystallization from benzene is to be recommended. The acid is readily soluble in the usual organic solvents. It melts at **131°**.

Anal. Subs., **0.2035:** CO_2, **0.4804;** H_2O, **0.0904.** Calcd. for $C_{11}H_{10}O_4$: **C, 64.07;** H, 4.85. Found: C, 64.37; H, 4.97.

On exposure of the dry, finely powdered acid to bright sunlight, the brilliant color soon fades noticeably. The colorless, light product protects most of the acid from the light so that this reaction proceeds with extreme slowness.

The Methyl Ester of the acid was obtained in pure condition with great difficulty owing to its extreme solubility in almost all solvents and to its unusual ease of hydrolysis. The ester was repeatedly prepared by the reaction of methyl alcohol and hydrogen chloride, by the use of dimethyl sulfate and of diazomethane from carefully purified acid. In all cases it separated as a heavy oil from which, after long standing, a few crystals separated. The oily product, very soluble in the usual solvents, was purified by dissolving it in a large volume of ligroin, cooling the solution slowly, finally in a freezing mixture. The ester separated in long, bright yellow needles melting at 48°.

Anal. Subs., 0.1167: CO_2, 0.2782; H_2O, 0.0581. Calcd. for $C_{12}H_{12}O_4$: C, 65.43; H, 5.57. Found: C, 65.01; H, 5.49.

After standing for several weeks in the dark, but exposed to the moisture of the air, a sample was found to have been largely hydrolyzed to the bright, orange-colored acid. When the ester was exposed to the bright sunlight it liquefied within a few minutes due to admixture with light products. There was no hydrolysis. The two crystalline products of this light reaction will be reported on in a later paper.

The Ethyl Ester prepared by the action of ethyl alcohol saturated with hydrogen chloride is a bright yellow oil boiling at 223° (15 mm.).

Anal. Subs., 0.1630: CO_2, 0.3971; H_2O, 0.0926. Calcd. for $C_{13}H_{14}O_4$: C, 66.64; H, 6.03. Found: C, 66.44; H, 6.35.

Reactions with Bromine

o-Methoxybenzalpyruvic Acid Dibromide, $o\text{-}CH_3OC_6H_4CHBrCHBrCOCOOH$.—The addition of bromine to the acid was carried out in the usual way in cooled chloroform solution. The bromine was decolorized rapidly. When the product was poured out and the chloroform evaporated in a current of moist air, there was a copious evolution of hydrogen bromide; in a current of dry air there was no evidence of loss of hydrogen bromide. The oily residue gradually solidified. After washing the product with cold ligroin, a straw-colored solid remained, which melted with vigorous decomposition at about 90°. As analyses of the product, crystallized from chloroform or benzene, gave results much too high in carbon and hydrogen for the dibromide, the crude product, washed rapidly with cold ligroin, was analyzed.

Anal. Subs., 0.1589: CO_2, 0.2147; H_2O, 0.0530. Calcd. for $C_{11}H_{10}O_4Br_2$: C, 36.06; H, 2.73. Found: C, 36.84; H, 3.70.

The substance is evidently the impure dibromide. Repeated analyses of different products gave no better results. It would seem to be impossible to prepare the dibromide without loss of some hydrogen bromide.

β-Bromo-o-methoxybenzalpyruvic Acid, $o\text{-}CH_3OC_6H_4CH{=}CBrCOCOOH$ (173°).—This acid is readily obtained by warming the dibromide just described in benzene solution, boiling it with water, or heating it on a water-bath until there is no further evolution of hydrogen bromide. It crystallizes from chloroform, chloroform mixed with ligroin, or methyl alcohol in stiff, colorless needles melting at 173°.

Anal. Subs., 0.1859: CO_2, 0.3153; H_2O, 0.0581. Calcd. for $C_{11}H_9O_4Br$: C, 46.31; H, 3.15. Found: C, 46.27; H, 3.51.

By oxidation of this acid in alkaline solution with hydrogen peroxide, bromomethoxycinnamic acid (171°) was obtained in quantitative yield. Since the bromine atom lost from the dibromide is undoubtedly the one in the position ***beta*** to the ketonic group and *gamma* to the carboxyl, the oxidation product of the compound thus formed must have the bromine atom in the *alpha* position to the carboxyl group.

$$CH_3OC_6H_4CHBrCHBrCOCOOH \longrightarrow CH_3OC_6H_4CH{=}CBrCOCOOH \longrightarrow CH_3OC_6H_4CH{=}CBrCOOH$$

The acid (171°) is therefore α-bromo-*o*-methoxycinnamic acid.[4] It is described in the latest edition of Beilstein[5] as "*a* or β bromo" *o*-methoxycinnamic acid.

The Methyl Ester of β-bromo-*o*-methoxybenzalpyruvic acid can be prepared in quantitative yield by the reaction of an ethereal solution of diazomethane on the purified acid. It separates from methyl alcohol in firm clumps of colorless needles melting at 88–89°.

Anal. Subs., 0 1540: CO_2, 0.2708; H_2O, 0.0542. Calcd. for $C_{12}H_{11}O_4Br$: C, 48.16; H, 3.69. Found: C, 47.95; H, 4.00.

When the acid was treated with methyl alcohol saturated with hydrogen chloride, almost the entire amount was recovered unchanged, a behavior like that of other unsaturated a-ketonic acids. Only a minute quantity of a substance crystallizing in fine, yellow needles, melting at 86°, possibly an isomeric ester, was isolated.

By the action of bromine on the methyl ester of o-methoxybenzalpyruvic acid, neither the methyl ester of the dibromide nor of the unsaturated bromo acid was obtained. The product, crystallized from diluted methyl alcohol, was a mixture of the unsaturated bromo acid (173") and of an unsaturated bromo acid (210°) with bromine in the ring, to be described later. The reaction had evidently consisted in addition of bromine, loss of hydrogen bromide, bromination in the ring and hydrolysis of the ester.

Reaction with Excess of Bromine

5-Bromo-o-methoxybenzalpynrvic Acid Dibromide, (2)-CH_3O-(5)-BrC_6H_3CHBr-$CHBrCOCOOH$.—*o*-Methoxybenzalpyruvic acid was dissolved in chilled chloroform, one gram molecular proportion of bromine added slowly, then a second gram molecular proportion of bromine added and the mixture was allowed to stand in the ice chest from three to four days. The product, after evaporation of the chloroform in a current of dry air, was a straw-colored solid melting with vigorous decomposition at 95–100°. It is soluble in the usual organic solvents except ligroin. That the substance contained bromine in the ring was proved by its oxidation with a hot solution of potassium permanganate to 5-bromo-2-methoxybenzoic acid. Analyses of the substance washed with cold ligroin gave results consistently high in carbon and hydrogen and low in bromine for a tribromo compound, showing loss of hydrogen bromide during the manipulation. When the crude product of bromination was stirred for a few minutes with cold methyl alcohol it was changed to a colorless solid which proved to be the methyl ester of the tribromo acid. The substance separates from hot methyl alcohol in clear, firm crystals melting at 103–106°. Analyses of the substance as in the case of the acid gave results about 1% high in carbon and hydrogen for a tribromo ester, showing loss of hydrogen bromide. The same product was obtained in no purer form by the action of diazomethane on the tribromo acid.

p-Bromo-5-bromo-2-methoxybenzalpyruvic Acid, (2)-CH_3O-(5)-$BrC_6H_3CH{=}CBr$-$COCOOH$, (colorless, 210°).—This acid was prepared in practically quantitative yield by boiling the tribromo acid just described in 40% acetic acid, from which it separated in fine, colorless needles melting with vigorous decomposition at 210°.

Anal. Subs., 5.928 mg.; CO_2, 7.97 mg.; H_2O, 1.31 mg. Calcd. for $C_{11}H_8O_4Br_2$: C, 36.26; H, 2.19. Found: C, 36.67; H, 2.47.

On oxidation with cold potassium permanganate 5-bromo-2-methoxybenzoic acid was obtained. Treatment with hydrogen peroxide in alkaline solution gave α-bromo-2-methoxycinnamic acid (221°).[4]

The Methyl Ester prepared by the action of diazomethane on an ethereal solution

---

[4] Reimer and Howard, THIS JOURNAL, 50, 196 (1928).

[5] Vol. X, p. 293.

of the acid is a colorless solid separating from a small volume of boiling ether in firm clumps melting at 131°.

Anal. Subs., 4.431 mg.; CO_2, 6.23 mg.; H_2O, 1.05 mg. Calcd. for $C_{12}H_{10}O_4Br_2$: C, 38.09; H, 2.65. Found: C, 38.35; H, 2.65.

When the methyl ester of 5-bromo-2-methoxybenzalpyruvicacid dibromide (103–106") was hydrolyzed an acid, isomeric with that just described, and its ester were obtained.

β-Bromo-5-bromo-2-methoxybenzalpyruvic Acid (Yellow, 210°).—The methyl ester of the tribromo acid was covered with a 2% solution of potassium in methyl alcohol and the mixture stirred. The liquid became bright lemon yellow and, as the original colorless ester went into solution, a yellow solid separated. After five minutes the mixture was filtered. A considerable portion of the yellow solid formed was soluble in water. From this solution and from the filtrates hydrochloric acid precipitated an acid which crystallized from benzene in fine needles of a deep yellow color.

Anal. Subs., 6.28 mg.; CO_2, 8.25 mg.; H_2O, 1.45 mg. Calcd. for $C_{11}H_8O_4Br_2$: C, 36.26; H, 2.19. Found: C, 35.78; H, 2.58.

On heating in a melting point tube, the yellow color fades out completely between 145 and 150° and the colorless product melts at 210°. A mixture of the yellow acid and the colorless (210°) acid melted at 210°. The yellow acid is evidently the geometrical isomer of the colorless (210°) acid with a transition temperature of about 150". On repeated crystallization from benzene and on exposure to the light the same transformation takes place.

The yellow solid formed by the action of potassium methylate on the methyl ester of the tribromo acid (103–106") which was not soluble in water was crystallized from methyl alcohol. It separates in fine, pale yellow needles melting at 143°.

Anal. Subs., 0.1238; CO_2, 0.1729; H_2O, 0.0327. Calcd. for $C_{12}H_{10}O_4Br_2$: C, 38.09; H, 2.65. Pound: C, 38.08; H, 2.91.

The analysis and the fact that the compound gives the yellow acid just described on hydrolysis with alcoholic potassium hydroxide prove it to be the methyl ester of this acid. It can be prepared in quantity by shaking the methyl ester of the tribromo acid (103–106°) with methyl alcohol and a slight excess of potassium acetate in the cold for a few minutes.

Reaction with Bromine in Methyl Alcoholic Solution

This reaction was carried out as previously described.[2] There was no addition of methyl hypobromite under varying conditions of concentration, temperature and speed of addition of bromine. When bromine vapor was passed through the diluted alcoholic solution of the acid as fast as it was decolorized, the product was an oil which gradually solidified. It was proved to be a mixture of the dibromide of o-methoxybenzalpyruvic acid and the unsaturated bromo acid (173°) formed from it by loss of hydrogen bromide. By careful manipulation of the mixture a quantitative yield of the unsaturated bromo acid was obtained.

Reaction of Benzalpyruvic Acid and its Methoxy Derivatives with Concentrated Sulfuric Acid

Two to three drops of pure, concentrated sulfuric acid were placed on a glazed porcelain plate, approximately one milligram of the substance to be tested was added and stirred into the acid. Under this treatment, cinnamic acid, its *p*- and o-methoxy derivatives and their bromine substitution products gave no color or a pale to bright yellow, fading out to colorless in a short time. The colors with the ketonic acids are shown in the following table.

TABLE I

COLORS WITH KETONIC ACIDS

Substance	Color	Color with concentrated sulfuric acid
$C_6H_5CH{=}CHCOCOOH$	Pale yellow	Deep yellow → brown
$C_6H_5CHBrCHBrCOCOOH$	Colorless	Yellow → red-brown → dark brown
$C_6H_5CH{=}CBrCOCOOH$	Colorless	Yellow → red-brown → dark brown
$C_6H_5CH{=}CBrCOCOOCH_3$	Colorless	Yellow → red-brown → dark brown
p-$CH_3OC_6H_4CH{=}CHCOCOOH$	Deep yellow	Orange
p-$CH_3OC_6H_4CHBrCHBrCOCOOH$	Cream color	Orange → brown → red-violet
p-$CH_3OC_6H_4CHBrCHBrCOCOOCH_3$	Colorless	Orange → brown → red-violet
p-$CH_3OC_6H_4CH{=}CBrCOCOOH$	Colorless	Orange → brown → red-violet
p-$CH_3OC_6H_4CH{=}CBrCOCOOCH_3$	Colorless	Orange → brown → red-violet
p-$CH_3OBrC_6H_3CH{=}CBrCOCOOH$	Pale yellow	Orange → brilliant green → blue
p-$CH_3OBrC_6H_3CH{=}CBrCOCOOCH_3$	Pale yellow	Orange → brilliant green → blue
o-$CH_3OC_6H_4CH{=}CHCOCOOH$	Orange	Deep cherry-red
o-$CH_3OC_6H_4CHBrCHBrCOCOOH$	Straw color	Yellow → red-violet
o-$CH_3OC_6H_4CH{=}CBrCOCOOH$	Colorless	Red-brown → red-violet
o-$CH_3OC_6H_4CH{=}CBrCOCOOCH_3$	Colorless	Red-brown → red-violet
o-$CH_3OBrC_6H_3CHBrCHBrCOCOOH$	Colorless	Green → deep blue
o-$CH_3OBrC_6H_3CHBrCHBrCOCOOCH_3$	Colorless	Green → deep blue
o-$CH_3OBrC_6H_3CH{=}CBrCOCOOH$	Colorless	Green → greenish-blue
o-$CH_3OBrC_6H_3CH{=}CBrCOCOOCH_3$	Colorless	Green → greenish-blue
o-$CH_3OBrC_6H_3CH{=}CBrCOCOOH$	Deep yellow	Brown → olive-green
o-$CH_3OBrC_6H_3CH{=}CBrCOCOOCH_3$	Yellow	Olive-green

These color changes are rapid and sharp. The last color given in the table for each substance persists for an hour or more, then gradually changes to brown. If bromine is in the side chain, this brown color persists for several days; if in the ring, all color fades out in two to three hours.

It is noteworthy that these changes of color with sulfuric acid: yellow in the case of benzalpyruvic acid, orange and red with *p*- and o-methoxybenzalpyruvic acids, respectively, reddish-violet with a methoxyl group together with bromine in the side chain, and blue and green with bromine also in the ring are the same and in the same order as the color changes brought about by increased numbers of systems of conjugated double linkages in unsaturated hydrocarbons when treated with concentrated sulfuric acid.[6] The accumulation of substituting groups in our compounds has, in the reaction with sulfuric acid, the same effect as an increase in the condition of unsaturation and of conjugation in these hydrocarbons.

After these experiments had been completed, a paper by Pfeiffer and Wizinger[7] appeared in which the color reactions of sulfuric acid with a, a-dianisylethylenes are described. It is striking that these substances give violet colors with sulfuric acid only when there is halogen in the side chain, as is the case with our compounds.

Summary

For the purpose of comparison with other unsaturated a-ketonic acids, o-methoxybenzalpyruvic acid and its reactions with bromine have been studied.

The color reactions of sulfuric acid with benzalpyruvic acid, *p*-methoxybenzalpyruvic acid and o-methoxybenzalpyruvic acid are described.

THE ACTION OF SODIUM BENZYL CYANIDE WITH CINNAMIC ESTER. II[1]

BY S. AVERY

RECEIVED JUNE 22, 1928 PUBLISHED SEPTEMBER 5, 1928

Introduction

In 1897, Walther and Schickler[2] brought together equal moles of sodium ethylate, benzyl cyanide and cinnamic ester in the presence of ether. From the products of the reaction they isolated a substance melting at 162–163°. This they believed to be cinnamplbenzyl cyanide, but as the analysis indicated the presence of one molecule more of water than this compound would call for, they regarded it as a hydrated derivative.

Three years later Erlenmeyer[3] isolated as a product resulting from the reaction of dry sodium ethylate, cinnamic ethyl ester and benzyl cyanide

a substance melting at 99–100° having the composition $C_{29}H_{19}O_2N$. He suggested the following as structural possibilities.

I $C_6H_5CHCH_2COOC_2H_5$ / C_6H_5CHCN

II $C_6H_5CH_2CHCOOC_2H_5$ / C_6H_5CHCN

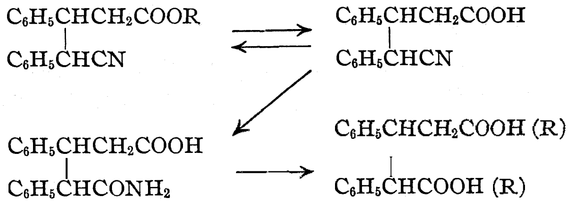
Erlenmeyer found, further, that this substance on saponification gave the "cinnamylbenzyl cyanide" (m. p. 162–163°) of Walther and Schickler. Hence the latter could not have the structure previously ascribed to it, and Erlenmeyer suggested that it was probably the imide of diphenylglutaric acid.

In 1908 Avery and McDole[4] showed that the substance melting at 162–163° was in reality β,γ-diphenyl-γ-cyanobutyric acid. This made it evident that Erlenmeyer's formula I was correct, and eliminated II as a possibility.

The preceding is a partial summary of the published researches relating to the compounds derived from the action of benzyl cyanide (1 molecule) with cinnamic ester (1 molecule). It is the hope of the author that the present paper will supply the most important gaps in our knowledge of these compounds and of their saponification products. The following compounds of this series have been studied



Of the compounds just outlined, β,γ-diphenyl-γ-monamide glutaric acid and β,γ-diphenyl-γ-cyanobutyric methyl ester have not been previously reported. α,β-Diphenylglutaric ethyl ester is of interest as it has been prepared by Borsche[6] through the action of phenyl acetic ester on cinnamic ester thus leading to the synthesis of the α,β-diphenylglutaric acid without the use of benzyl cyanide. Further, this glutaric acid, according to the researches of Kishner,[6] and Meerwein and Dott[7] is one of two stereoisomers, which are best distinguished through a comparison of the methyl with the ethyl esters.

Turning now to the possibility of the condensation of one molecule of benzyl cyanide with two molecules of cinnamic ester, we find that Erlen-

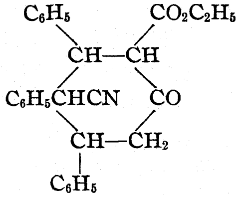
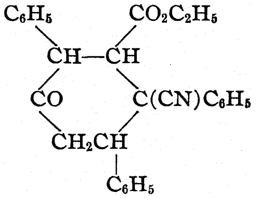
meyer,[8] at the temperature of the steam-bath, obtained a body melting at 206–207°, having the empirical formula $C_{28}H_{25}O_3N$, representing the direct union of benzyl cyanide with two molecules of cinnamic ester minus one molecule of the corresponding alcohol. For the structure of the substance, he suggests the following possibilities

I

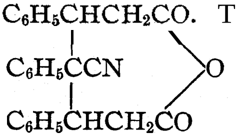


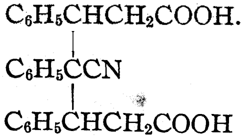
II



Formula I shows condensation as effected in the @-position in relation to the two carboxyl groups. Formula II shows condensation as effected in the a-position toward one and in the @-position toward the other carboxyl group. Both formulas show secondary ring formation. The experimental part of this paper shows that the substance under consideration may also **be** prepared by the action of sodium **β,γ-diphenyl-γ-cyanobutyric** ester on cinnamic ester. It is hardly probable that benzyl cyanide in condensing with first one and then with a second molecule of cinnamic ester should form first a *β*- and then an a-condensation product. Finally, the work of Dieckmann, referred to later, shows that ring formation in the case of dibasic esters takes place with elimination of alcohol in the a-position in relation to the unchanged ester group. For these reasons we may regard Formula II as excluded. This confirms Formula I excepting only the typographical error of one excess H atom.

Using methods similar to those employed by Erlenmeyer, Avery and McDole isolated a substance melting at 231–232° (uncorr.) for which they suggested "only tentatively" the formula $C_6H_5CHCH_2CO$. The experimental part of this communication shows this to have been incorrect, and that the substance was really 2-keto-4,5,6-triphenyl-5-cyanohexahydrobenzoic methyl ester. They gave, however, to the acid obtained by hydrolyzing this product the correct formula, namely, $C_6H_5CHCH_2COOH$.



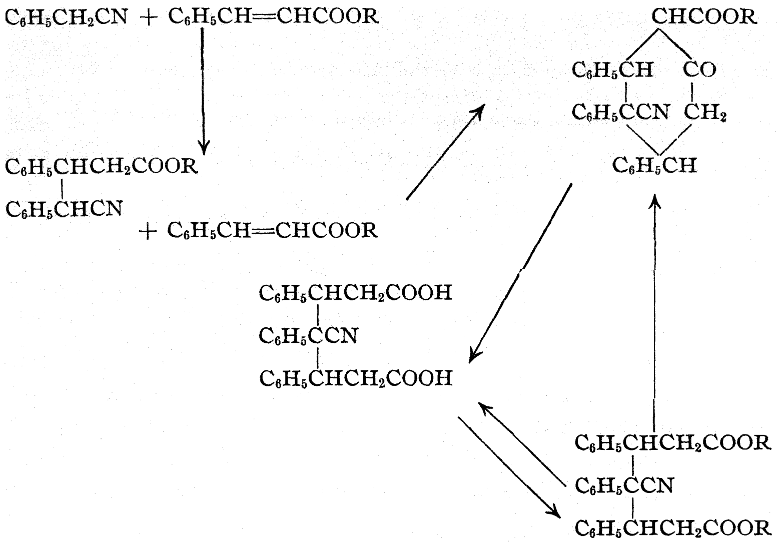


$$\begin{array}{l} C_6H_5CHCH_2COOH \\ \quad | \\ C_6H_5CCN \\ \quad | \\ C_6H_5CHCH_2COOH \end{array}$$

The course of the reactions when one molecule of benzyl cyanide reacts with two of cinnamic ester is as follows.

---

[8] E. Erlenmeyer, Jr., *Ber.*, **33**, 2009–2010 (1900).



The reactions just outlined may be explained by assuming that the β,γ-diphenyl-γ-cyanobutyric ester first formed reacts further with cinnamic ester to form an ester of the pimelic series, but that in the presence of the condensing agent it immediately gives off alcohol, forming an ester of the hexahydrobenzoic series. This latter reaction is to be expected in the light of Dieckmann's[9] investigations on ring formation with dibasic esters. As in the case of less complex 2-keto-hydrobenzoic esters, this ester hydrolyzes to an acid of the pimelic series from which the pimelic esters may be obtained.

Experimental Part

β,γ-Diphenyl-γ-cyanobutyric Methyl Ester.—Five g. of sodium dissolved with heating in a small excess of methyl alcohol was added to 25.5 g. of benzyl cyanide and the mixture was cooled to approximately 20°; 35.7 g. of melted methyl cinnamate was then added, the mixture well shaken and placed in a bath at 0° for approximately five hours, then allowed to stand at 20 to 25° for several days. A crystalline mass gradually formed. This was macerated with a strong aqueous solution of ammonium chloride, filtered and washed. The yield including the substance recovered from filtrates after twice crystallizing amounted to 41–42 g. or 67% of the theoretical. The crystals are long, transparent needles, soluble in benzene, chloroform, acetic ether and hot alcohol, difficultly soluble in petroleum ether. A sample recrystallized to constant melting point melted sharply at 106.5" (corr.).

Anal. Calcd. for $C_{18}H_{17}O_2N$: C, 77.4; H, 6.1; N, 5. Found: C, 77.7; H, 6.1; N, 5.

This compound is also formed when benzyl cyanide is condensed with ethyl cinnamate using sodium methylate as a condensing agent; also when β,γ-diphenyl-γ-cyanobutyric acid is treated with methyl alcohol and hydrogen chloride gas. The latter

---

[9] Dieckmann, *Ber.*, 27, 103 (1894); *Ann.*, 317, 100 (1901).

reaction shows it as the methyl ester of an acid, the structure of which was previously determined by Avery and McDole. The procedure just described is similar to that followed by Erlenmeyer in working with the corresponding ethyl compounds.

β,γ-Diphenyl-γ-cyanobutyric Ethyl Ester.—The synthesis of this coinpound corresponds exactly to that of the methyl ester, except that ethyl derivatives are used throughout. A *50%* yield was obtained; melting point, *101*.5° (corr.); crystalline form and solubility similar to the methyl ester.

Anal. Calcd. for $C_{19}H_{19}O_2N$: C, *77.8;* H, *6.5;* *N*, *4.8.* Found: *C*, *77.9;* H, *6.6;* *N*, 4.8.

The sharp melting point (slightly higher than found by previous investigators) and the closely checking analysis indicate a high degree of purity in the preparation. On saponification it gives the corresponding acid, thus clearly indicating its composition.

β,γ-Diphenyl-γ-cyanobutyric Acid.--Some difficulty is encountered in preparing this compound in a pure condition. Contamination with the ester resulting from incomplete saponification, and contamination with the corresponding monamide acid due to the saponification proceeding too far, are equally to be avoided.

Five g. of the pure ester (methyl or ethyl) was dissolved in *50* cc. of *95%* ethyl alcohol, *1*.5 g. of potassium hydroxide in solution added, and the solution digested on the steam-bath. Water was added from time to time until the total volume equaled about *80* cc. Heating was continued for about fifteen minutes after a drop no longer became turbid with water. Then strong acetic acid was added in excess. On cooling and diluting little by little a granular precipitate formed. Care is to be taken not to cool and dilute so rapidly as to form a milky emulsion. Ultimately a large excess of water is added. The yield is about 90% of the theoretical.

The ester may also be saponified by dissolving in strong acetic acid and boiling, while gradually diluting with hydrochloric acid; melting point, 163.5–165° (corr.) according to rate of temperature increase. It partially decomposes on melting. Benzene was found to be the best solvent for separating the acid in a pure condition from the more soluble esters and from the less soluble monamide glutaric acid.

β,γ-Diphenyl-γ-monamide Glutaric Acid.—A compound melting from 200–205° had been noted in previous investigations but no definite suggestions were made in regard to its composition or structure. It is readily formed when @,?-diphenyl-y-cyanobutyric acid or a corresponding ester is boiled with strong alcoholic potash, evaporated with the addition of small amounts of water and finally brought to a temperature of *100"*. On dissolving the salt-like mass and acidifying, a milky or resinous substance forms which becomes crystalline on standing. Recrystallized from alcohol or, better, from acetic acid it forms glistening, transparent flakes. It melts at 200–205° with the evolution of ammonia. It is nearly insoluble in ligroin, difficultly soluble in benzene or chloroform and readily in hot alcohol or acetic acid.

Anal. Calcd. for $C_{17}H_{17}O_3N$: C, *72.0;* H, *6.05;* *N*, 4.9. Found: C, *71.8;* H, *6.05;* N, 4.9. Titration: *6.85* cc. of *N*/10 NaOH neutralized *0.1928* g. Calcd.: *6.8* cc.

α,β-Diphenylglutaric Acid and Esters.—The acid may be prepared by hydrolyzing β,γ-diphenyl-γ-monamide glutaric acid, β,γ-diphenyl-γ-cyanobutyric acid, or its esters, with concentrated hydrochloric acid solution under pressure. Three hours' heating at *150"* gave satisfactory results. When the temperature of the melting point apparatus is increased at the rate of about 1° per minute, the reading is 225–228° (corr.); melting point of ethyl ester, **93.3**" (corr.); methyl ester, *143.0"* (corr.). The methyl ester made by the method of Borsche melted at the same temperature as the methyl ester made from the pure acid by the action of methyl alcohol and hydrochloric acid, and not 7° lower as found by Meerwein and Dott,[10] and cited by them as an evidence of the presence of an admixture of a stereoisomer. It appears, therefore, that only the "fumaroid" form, to follow Kishner's designation, is found in the synthesis of α,β-diphenylglutaric acid by the method of Avery and McDole or by the method of Borsche.

2-Keto-4,5,6-triphenyl-5-cyanohexahydrobenzoic Ethyl Ester.—The following is a modification of Erlenmeyer's method: **3** g. of sodium as sodium ethylate, nearly free from ethyl alcohol, was mixed with **7.5** g. of benzyl cyanide and **22.5** g. of ethyl cinnamate was added. To the mixture **75** cc. of toluene was added and the whole boiled with a return flow condenser for three hours. After cooling, glacial acetic acid was added in a quantity sufficient to neutralize the sodium, then ligroin in excess and the solids were filtered under pressure. The cake formed was digested with **95%** alcohol, cooled and filtered, washed with alcohol and finally with water; yield, 15.5 g., which on recrystallizing from **95%** alcohol gave **13** g. of nearly pure white crystals.

Almost equally good results can be obtained by heating the mixture of cyanide, sodium ethylate and ester over a hot-plate to **101°**, stirring constantly. On cooling, a resinous product is formed which on acidifying with acetic acid and digesting with 95% alcohol gives a light yellow, crystalline residue. This is filtered off and washed first with alcohol, then with water and recrystallized from alcohol.

The ester is purified as follows. After dissolving in a small quantity of chloroform, butyl or amyl alcohol is added. The solution is then concentrated to crystallization on the steam-bath; melting point, **208–209°** (corr.).

This substance can also be prepared by heating at 100° equal moles of β,γ-diphenyl-β-cyanobutyric ethyl ester, ethyl cinnamate and sodium ethylate. A yield of approximately 50% of the theoretical has been obtained. Finally, the same substance is obtained when β,γ,δ-triphenyl-γ-cyanopimelic ester is treated with sodium ethylate. These reactions leave no doubt in regard to the structure of the compound.

2-Keto-4,5,6-triphenyl-5-cyanohexahydrobenzoic Methyl Ester.—This substance was prepared by Bessie F. Whitney using the methods described under the ethyl ester. It crystallizes in beautiful beveled plates; melting point, 242–244° (corr.); more difficultly soluble in alcohol, benzene, chloroform, etc., than the ethyl ester.

Anal. Calcd. for $C_{27}H_{23}O_3N$: C, **79;** H, **5.7;** N, 3.4. Found: C, 79; H, **5.8;** **N, 3.3.**

The ester was also prepared as follows: **0.39** g. of potassium in 5 cc. of absolute methyl alcohol was mixed with **2.79** g. of β,γ-diphenyl-γ-cyanobutyric methyl ester and **1.62** g. of methyl cinnamate. The mixture was stirred with a thermometer and then heated in an oil-bath until the thermometer read above **100'**. One cc. of acetic acid and **25** cc. of chloroform were added and the resinous mass was brought into solution by heating and stirring. The nearly clear, straw-colored solution was concentrated to **15** cc., **15** cc. of butyl alcohol was added and the solution again concentrated to about **15** cc., when crystals began to form. After cooling these were washed first with butyl alcohol and then with water. The white, glistening crystals weighed **2.5** g., 59% of the theoretical yield. Recrystallized once, the substance melted at 242–244° (corr.).

Finally, the ester under consideration was prepared as follows: **0.88** g. of β,γ,δ-triphenyl-γ-cyanopimelic methyl ester was dissolved in ether and a drop of absolute methyl alcohol added; **0.08** g. of potassium was added and when nearly dissolved **2** cc. of absolute methyl alcohol also, and the solution was warmed and acidified with acetic acid. Water was added and the mixture warmed to drive off the ether, crystals gradually forming. It was then cooled, filtered and washed. The crystalline mass

---

[10] Meerwein and Dott, **J. prakt. Chem., 97, 269 (1918).**

was recrystallized and found to melt at 242–244° (corr.) The crystalline form was identical with that of the substance prepared by other methods.

β,γ,δ-Triphenyl-γ-cyanopimelic Acid.—This compound is to be expected as the result of saponifying an ester of 2-keto-4,5,6-triphenyl-5-cyanohexahydrobenzoic acid. Ten g. of the ethyl ester was placed in a flask, 50 cc. of 95% alcohol added and 5 cc. of a 50% solution of potassium hydroxide. The mixture was heated on the steam-bath for about ten minutes, then transferred to an evaporator, 25 cc. of water added and evaporated nearly to dryness. The residue was again treated with strong, alcoholic potassium hydroxide, again evaporated nearly to dryness, diluted and filtered. The filtrate was acidified strongly with hydrochloric acid, yielding a wax-like solid and a milky liquid, the former gradually passing into a crystalline mass and the latter into loose crystals. The snowy white, well washed and dried substance weighed 9.8 g. It is most easily purified by dissolving in ether, evaporating to a small volume, adding benzene and condensing to crystallization. It crystallizes from dilute alcohol as prisms, apparently containing alcohol of crystallization, which it loses on the steam-bath, becoming amorphous; melting point, 218–219° (corr.).

Anal. Calcd. for $C_{26}H_{23}O_4N$: C, 75.5; H, 5.6; N, 3.4. Found: C, 75.6; H, 5.6; N, 3.4.

It was found by the combustion analysis, by titration and in respect to the melting point and solubilities, to be identical with the substance isolated by Avery and McDole.

β,γ,δ-Triphenyl-γ-cyanopimelic Methyl Ester.—Ten g. of the corresponding acid was placed in a flask with 50 cc. of absolute methyl alcohol and hydrogen chloride was passed in to saturation. The acid dissolved and a granular precipitate gradually formed. On refluxing and cooling, an almost solid mass of white crystals formed. The mother liquor was filtered off, the crystals were washed with cold methyl alcohol, and then recrystallized from hot methyl alcohol; yield, about 90% of the theoretical; melting point, 108.2° (corr.). It crystallized from methyl alcohol in needles or spikes depending on the rate of cooling.

Anal. Calcd. for $C_{28}H_{27}O_4N$: C, 76.2; H, 6.2. Found: C, 76.2; H, 6.3.

On saponifying the ester, the corresponding pimelic acid is formed. On treating the ester with methyl alcohol the corresponding hexahydrobenzoic methyl ester is formed.

β,γ,δ-Triphenyl-γ-cyanopimelic Ethyl Ester.—This substance was made exactly as the methyl ester except that ethyl alcohol was used; melting point, 102.5° (corr.). Solubilities and crystalline form were similar to those of the methyl ester. On saponification, the corresponding pimelic acid is regenerated.

Anal. Calcd. for $C_{30}H_{31}O_4N$: C, 76.9; H, 6.7; N, 3. Found: C, 77.0; H, 6.9; N, 3.

Composition of the Compound Tentatively Designated as an "Anhydride" of a Dibasic Acid by Avery and McDole[11]

This substance was first prepared by the action of sodium methylate on a mixture of ethyl cinnamate and benzyl cyanide. (At that time the migration of ester radicals had been studied only slightly.) A body was obtained melting not very sharply at 231–232° (236–237°, corr.). The analytical data corresponded fairly well to the theoretical composition of such a body, namely, $C_{26}H_{21}O_3N$. It corresponds equally well to $C_{27}H_{23}O_3N$, which it really is.

---

[11] Avery and McDole, THIS JOURNAL, 30, 599 (1908).

When the work of Avery and McDole was repeated recently, using, however, methyl instead of ethyl cinnamate, the same results were obtained except that the product melted at 242–244' (corr.). When, however, ethyl ester and alcohol were used, the product melted at 208–209° (con.). The "supposed anhydride" is therefore 2-keto-4,5,6-triphenyl-5-cyanohexahydrobenzoic methyl ester, synthesized from the ethyl ester through the migration of methyl group from the sodium methylate used in the reaction and probably containing small amounts of the ethyl ester, as shown by the lower melting point.

Summary

The compounds resulting from the union of one molecule of sodium benzyl cyanide with one of the cinnamic ester, and also the compounds resulting from the union of one molecule of sodium benzyl cyanide with two molecules of cinnamic ester, have been prepared and studied.

The reaction of benzyl cyanide with cinnamic ester in the cold with moisture carefully excluded has been found to be exactly analogous to Michael's reaction in the classic example of sodium malonic ester. Complete hydrolysis leads to compounds of the glutaric series.

At higher temperatures the first condensation product of benzyl cyanide with cinnamic ester unites with a second molecule of cinnamic ester and forms derivatives leading by hydrolysis to the pimelic series. The reactions in passing from the ketohexahydrobenzoic ester to the pimelic esters are reversible.

In so far as appears to be possible, all compounds of both series have been hydrolyzed in successive stages. Methyl and ethyl esters have been made not only by direct synthesis but also by esterifying the free acids.

Through the preparation of a number of new compounds both series are now fairly complete. These explain more fully than heretofore the nature of the reactions involved. Errors in the literature of the subject have been corrected.

THE RELATIVE REACTIVITIES OF NORMAL BUTYL BROMIDE AND BROMOBENZENE TOWARD MAGNESIUM IN ETHER

BY HENRY GILMAN AND E. A. ZOELLNER

RECEIVED JUNE 22, 1928 PUBLISHED SEPTEMBER 5, 1928

Several explanations have been proposed for the orienting influences of various elements and groups in substitution reactions of benzene and other aromatic types. The Fliirscheim hypothesis has been criticized because of the implicit assumption that some bonds are strong and others weak. The following extract is from a recent text.[1] "Silver nitrate will remove bromine from methyl bromide much more readily than from bromobenzene, which appears to support Flürscheim's ideas, since it suggests that the strength of the bonds joining bromine to carbon is different in the two organic molecules. But in the formation of the Grignard reagent it is found that magnesium acts with ***equal***[2] ease upon methyl bromide and bromobenzene; so that no difference in reactivity is noticeable."

Several studies in this Laboratory indicated that alkyl halides, in general, react more readily than the corresponding aryl halides with magnesium in ether to form the respective Grignard reagents. The results of the present studies support this view. First, in some semi-quantitative investigations on the effect of negative catalysts[3] on the formation of organomagnesium halides, it has been shown that n-butyl bromide reacts with magnesium in ether distinctly more readily than does bromobenzene to form the respective Grignard reagents.[4] Second, the yields of n-butylmagnesium bromide and phenylmagnesium bromide as quantitatively determined, under corresponding conditions, at several time intervals showed that larger amounts of the alkylmagnesium bromide were formed in a given time.

It should be remembered here that the reaction between an RX com-

---

[1] "Recent Advances in Organic Chemistry" by Alfred W. Stewart, fifth edition, Vol. I, p. 338, 1927, published by Longmans, Green and Co., Ltd. The particular criticism in this and in other texts may possibly have its origin in Holleman's "Die direkte Einführung von Substituenten in den Benzolkern," p. 212–213, published by Veit and Co., Leipzig, in 1910. One of the statements made there is the following: "However, one observes that in ethereal solution the halogen in the benzene ring is just as easily replaced by magnesium as that in alkyl halides." No measurements of this were made (private communication from Dr. Holleman), but the observation is understandable in view of the comparative readiness with which bromobenzene reacts with magnesium in ether.

[3] Studies by R. J. VanderWal.

[4] The color test described by Gilman and Schulze was used in these experiments, THIS JOURNAL, 47,2002 (1925), and Bull. *soc. chim.*, 41,1279 (1927).

pound and magnesium to form a Grignard reagent is accompanied by other reactions, such as the Würtz-Fittig reaction which is probably preceded by the formation of free radicals and disproportionation.[5] Furthermore, the positive color test[4] for the Grignard reagent, despite its high sensitivity, must wait on the formation of an amount of the RMgX compound in excess of that required to react with any incidental moisture and impurities in the ether such as peroxides. Attention should be directed, in connection with these studies, to a recent paper by Rudd and Turner[6] on the competitive interaction of alkyl and aryl halides with magnesium. These authors allowed a mixture of two different halides (one mole of each) to compete for one atom of magnesium, and the product was analyzed for halogen after complete dissolution of the metal. Obviously their results do not represent the exact quantities of Grignard reagent formed, and there is the possibility that one RMgX compound may have affected the rate of formation of the other.' Both of these points were mentioned by them. The pairs of halides they allowed to compete for magnesium had *different* halogens.

Experimental Part

The quantitative experiments were made under the general conditions and in the special apparatus used by Gilman and co-authors in earlier studies on the quantitative estimation[s] of the Grignard reagent and on the yields[g] of some RMgX compounds.

The halides were very carefully dried and then distilled prior to use. Commercial magnesium was used and the particles (after crushing in a mortar and sieving) were essentially uniform. In each run **0.05** mole of halide, **0.054** atom of magnesium and 30 cc. of dry ether were used.

The magnesium was first covered with **6.5** cc. of ether and then, after having added a crystal of iodine, **30** drops (or its equivalent) of the halide was added and the mixture was heated for ten minutes without stirring in a bath kept at 45°. This insured the start of reaction prior to the addition of the main quantity of halide. The remainder of the halide and ether was then added rapidly with stirring (the time of addition here was ten seconds) and from this point was taken the time given in Table I.

At the end of a given time interval (forty-five or ninety seconds) the reaction flask

---

[5] **A** preliminary account of this study was made at the St. Louis Meeting of the American Chemical Society, April 17, **1928,** by Gilman, Fothergill, Kirby and Heck. The final results will be published shortly.

[6] Rudd and Turner, *J. Chem. Soc.,* **133,686 (1928).**

[7] An indication of this is found in some competitive studies of halides, such as n-butyl bromide and bromobenzene, toward magnesium. The yields of derivatives of these two Grignard reagents (formed at the same time with an insufficient amount of magnesium) differ frotn the acid titration values.

[8] Gilman, Wilkinson, Fishel and Meyers, THIS JOURNAL, **45, 150 (1923)**; Gilman and Meyers, *Rec. trav. chim.,* **45, 314 (1926).**

[9] Gilman and Meyers, THIS JOURNAL, **45, 159 (1923);** Gilman and McCracken, *ibid.,* **45, 2462 (1923);** ***Rec. trav. chim.,*** **46, 463 (1927);** Gilman and Zoellner, THIS JOURNAI,,50,425 (1928).

was chilled in a bath of ice and water. Experiments showed that the reaction was virtually stopped by such chilling, for the yield of RMgX at the beginning of the chilling period was only about **2.5%** less than that determined at the end of one-half hour of chilling. Three aliquots were removed for analysis at the beginning of the chilling period. After removing the aliquots the mixture was allowed to react at room temperature for forty-five minutes and then two aliquots were removed for analysis.

The analyses of these final two aliquots have no essential bearing on the relative reactivities of the halides since the reaction was complete at that time.[9] However, they did serve, first, as an additional check on the technique and, second, to call attention to marked differences in the respective total quantities of Grignard reagents at the end of each experiment. For when runs were made with both halides, under the general conditions followed in the ninety seconds experiments but *without* removal of the three aliquots, the yield of phenylmagnesium bromide (92.7%) and that of n-butylmagnesium bromide (79.7%) checked those in the reactivity runs when interruptions were made for the removal of aliquots. Under the conditions usually employed for the preparation of the Grignard reagent (slow addition, etc.)[9] the yield of phenylmagnesium bromide is 96.2% and that of n-butylmagnesium bromide, 94%.[10] This marked drop in the yield of n-butylmagnesium as a consequence of rapid addition is of particular significance. It emphasizes a reactivity of n-butyl bromide that is distinctly greater than that shown by the respective quantities of Grignard reagent actually determined (see Table I) inasmuch as the drop in yield (from 94 to 79.7%) very probably resulted, in large part,[11] from n-butylmagnesium bromide being used up in side reactions.[5]

Table I includes the averages of several runs where aliquots were removed at two different time intervals. The aliquots from a given experiment agreed within the experimental error for such work, namely, about one per cent.[8,9] The average values for analyses made of duplicate runs of a given halide after ninety seconds of reaction agreed within 2.7%; and

TABLE I

RESULTS OF ANALYSES

Halide	Moles	Time of reaction, secs.	Yield of corresponding RMgX, %
Bromobenzene	**0.05**	**45**	**36.9**
n-Butyl bromide	**.05**	**45**	**53.7**
Bromobenzene	**.05**	**90**	**51.7**
n-Butyl bromide	**.05**	**90**	**65.4**

---

[10] Other studies in progress on the effect of rapid addition of halide on the yield of Grignard reagent show no apparent correlation as yet with the type of RX compound used.

[11] In so far as the immediate purpose of this paper is concerned it does not matter how much of this drop is due to Grignard reagent that has disappeared as a result of side reactions. The significant thing is that the n-butyl bromide has reacted more rapidly than the bromobenzene toward magnesium.

those after forty-five seconds of reaction agreed within 6.5%. Quite probably these average errors can be significantly reduced with a more refined technique such as, for example, the use of a definite quantity of iodine instead of the somewhat arbitrary "crystal of iodine." The rates of some other halides are being measured under more exact conditions.

The authors wish to acknowledge help in some of these experiments from J. B. Dickey.

Summary

n-Butyl bromide reacts more rapidly than bromobenzene with magnesium in ether. This result is of direct value in connection with some theories proposed to account for orientation in the benzene nucleus.

OXIDATION IN THE BENZENE SERIES BY GASEOUS OXYGEN. IV. MECHANISM OF THE SLOW OXIDATION OF SATURATED HYDROCARBONS

BY H. N. STEPHENS

RECEIVED JUNE 25, 1928 PUBLISHED SEPTEMBER 5, 1928

Previous papers by the writer[1] have shown that alkyl benzenes are oxidized slowly by gaseous oxygen at a temperature of about 100°. Methylbenzenes yielded mono-aldehydes and the corresponding acids, while hydrocarbons containing two or more carbon atoms in the side chain were attacked only at the a-carbon atom, yielding ketones. When alkyl substituents replaced all of the hydrogen on the a-carbon atom, no oxidation took place under the conditions employed; therefore we must conclude that the linkages between this particular carbon atom and its hydrogen are the points of weakness which are attacked by oxygen.

In studying some of these oxidations it was found that the water formed by the reactions exerted a retarding effect and later, when excess water was used with the hydrocarbons, complete inhibition of oxidation resulted. Important exceptions to this behavior were noted in hydrocarbons which have only one hydrogen atom attached to the a-carbon atom, in which cases no inhibitory action was noted.

In seeking an explanation of the inhibitory action of water, it did not seem to us sufficient merely to classify it under the vague and unsatisfactory term "anticatalysis." Neither did it seem possible to account for the phenomenon on the basis of a protective action in which the water molecules might be assumed to attach themselves loosely to the hydrocarbon molecules, preventing ready access of oxygen to the vulnerable

---

[1] Stephens, THIS JOURNAL, 48, 1824, 2920 (1926).

point. The exceptions to the inhibitory action, which have just been noted, seem to preclude this possibility, as there is no apparent reason why cumene or cymene should not be protected as well as other hydrocarbons.

As has been suggested in previous papers, the simplest and most reasonable explanation seems to lie in the assumption of a reversible stage in the oxidation which involves the elimination of water. In the oxidation of the *iso*propyl group, however, in which only one hydrogen is attached to the α-carbon atom, it has been assumed that the elements of methyl alcohol, instead of the elements of water, tend to be eliminated.

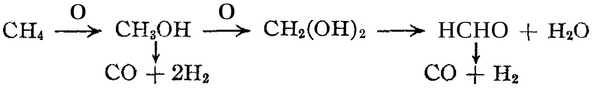
In order to justify such an assumption it was necessary, of course, to obtain additional information about the mechanism of oxidation, the most important problem being to determine the nature of the earlier stages. During the past few years there seems to have been a growing tendency to assume that the oxidation of saturated hydrocarbons passes through all the possible intermediate stages, starting with the alcohol. This view owes its origin chiefly to the work of Bone and his collaborators, which has given rise to the well-known "hydroxylation" theory.

As far as the writer is aware, only one case is on record in which an alcohol has actually been identified as a product of oxidation of a saturated hydrocarbon and in this case the oxidizing agent was ozone.[2] However, this lack of experimental evidence has not been considered a serious drawback to the "hydroxylation" theory, as Bone and Stockings[3] have shown that ethyl alcohol is much more readily oxidized than ethane. Thus it is considered that the alcohol, assumed to be the primary oxidation product, is oxidized further, as rapidly as it is formed.

Another important line of evidence in favor of intermediate formation of alcohols[4] lies in the fact that when methane is exploded with an insufficient supply of oxygen, an increase in the initial pressure of the gases causes a decrease in the proportion of water formed. The interpretation of this fact by Bone and Townsend involves the assumption that at higher pressures the tendency of methane to decompose

$$CH_4 \text{ (1 vol.)} \longrightarrow C + 2H_2 \text{ (2 vols.)}$$

would be repressed; that is, the loosening of the carbon to hydrogen valences which it is necessary to assume in their "hydroxylation" scheme, would be less pronounced. Therefore, in the series of reactions postulated by Bone's theory



$$\begin{array}{ccccccc} CH_4 & \xrightarrow{O} & CH_3OH & \xrightarrow{O} & CH_2(OH)_2 & \longrightarrow & HCHO + H_2O \\ & & \downarrow & & & & \downarrow \\ & & CO + 2H_2 & & & & CO + H_2 \end{array}$$

---

[2] Bone and Drugman, *Proc.* Chem. *Soc.,* 20, 127 (1904).

[3] Bone and Stockings, *ibid.,* 20, 106 (1904).

[4] Townsend, *Proc.* Roy. *Soc., London,* **116A,** 652 (1927).

although it is assumed that normally (that is, at ordinary pressures) there is a tendency toward a "non-stop" oxidation of CH_4 to $CH_2(OH)_2$; under the influence of higher pressures greater difficulty is experienced in introducing the second atom of oxygen and there is more tendency for the oxidation to stop at the alcohol stage. Then, as methyl alcohol has been shown to decompose into CO and H_2, the total amount of water formed would be decreased. In passing, it might be pointed out that it is not clear why the introduction of the second oxygen atom should be disfavored rather than the first, as this is not in accord with the fact that ethyl alcohol is oxidized more readily than ethane.

As the assumptions made by the writes to account for the inhibitory action of water do not definitely provide a place for the alcohol stage, it seemed desirable to find out, if possible, whether or not the alcohol stage was an intermediate one in the production of aldehydes and ketones. With this end in view a study of the oxidation of several a-phenyl carbinols was made[5] and it was found, with one exception (that of *iso*propylphenyl carbinol), that a small amount of ketone was formed at 100". However, in this study and in some later experirnents, other evidence was found which argues very strongly against the alcohol stage being an intermediate one in the oxidation of hydrocarbons. Assembling material both from papers already published and from the present paper we may present the following arguments.

1. The main products obtained from alcohols at 100° were high boiling liquids, which were presumably ethers. Also benzoic acid was formed in the oxidation of all secondary alcohols. None of these products was detected in the oxidation of hydrocarbons.

2. Oxidations of xylene and ethylbenzene were carried out in the presence of acetic anhydride in an attempt to get an ester of the intermediate alcohol but in neither case was any ester detected. To eliminate the possibility of the ester being oxidized, xylyl acetate was treated with oxygen under the usual conditions but no toluic aldehyde was formed. The only effect of acetic anhydride was to increase the rate of oxidation, due to the removal of water.

3. Water inhibits the oxidation of all of the alcohols studied. In the hydrocarbons containing normal alkyl groups, the oxidation of which is completely inhibited by water, we must, therefore, assume that the oxidation of hydrocarbon to alcohol is inhibited. In the oxidation of cumene, however, water does not inhibit the reaction, although the oxidation of the corresponding alcohol, dimethylphenyl carbinol, is completely inhibited. In this case, then, it would be expected that the alcohol, if it is an intermediate product, would accumulate and that no acetophenone would be formed. As it has been shown that cumene is oxidized

---

[5] Stephens, THIS JOURNAL, **50**, 186 (1928).

directly to acetophenone in the presence of water, with no formation of dimethylphenyl carbinol, the assumption that the alcohol is an intermediate stage seems unjustifiable.

4. Finally, it has been shown that, using equimolecular amounts of ethylbenzene and phenylmethyl carbinol, a much greater yield of acetophenone is obtained in a given time from the hydrocarbon than from the alcohol. In this particular case, then, the non-existence of alcohol in the final products from the hydrocarbon cannot be explained on the basis of the more rapid oxidation of the alcohol. On the contrary, the alcohol would be expected to accumulate, if it were an intermediate oxidation product.

In the face of the above arguments, it seems impossible to grant that the alcohol stage is an intermediate one in the oxidation of alkyl benzenes to aldehydes or ketones and if this is true for alkyl benzenes, there seems no reason why it should not be true for paraffin hydrocarbons. The retarding action of water on the oxidation of ethane at 415 and 440° has been noted by Bone and Andrews[6] and thus one point of similarity is definitely established. The writer takes the view that the benzene nucleus merely exerts a directive influence without affecting, in any fundamental way, the mechanism of oxidation. Granting this, any theory of the mechanism of oxidation ought to be able to explain oxidations in both classes of hydrocarbons. As Bone's theory assumes the existence of the alcohol stage, which, apparently, is not justifiable and also provides no explanation for the inhibitory action of water, the following scheme is submitted in the belief that it is capable of explaining satisfactorily all of the known facts

$$\text{Hydrocarbon} + O_2 \rightleftharpoons \text{Complex} \rightleftharpoons H_2O + \underset{\substack{\downarrow \\ \text{Aldehyde or ketone}}}{\text{unsaturated residue}}$$

In the oxidation of the alkyl benzenes, it is believed, although not definitely proved, that the reaction takes place chiefly, if not exclusively, in the vapor phase; therefore, the first stage may be considered as a homogeneous gas reaction in which one molecule of hydrocarbon associates with one molecule of oxygen. To call the bimolecular aggregate thus formed a molecular compound might possibly be misleading, as it is considered as being extremely unstable and, consequently, short-lived. On account of the slowness of these oxidations it must be assumed that the majority of these temporary associations are followed by dissociation into the original molecules; that is, the first stage is strictly reversible. It might be mentioned, in passing, that it seems much more reasonable to consider molecular oxygen as the oxidizing agent rather than atomic, as assumed by Bone and his co-workers. At explosion temperatures, the presence of atomic oxygen will be granted, but as the "hydroxylation"

---

[6] Bone and Andrews, *J. Chem. Soc.*, **89**, 659 (1906)

theory is applied to slow oxidations as well as to rapid combustions, the existence of appreciable concentrations of oxygen atoms at 100° would have to be assumed, which is apparently contrary to fact.

The Inhibitory Action of Water

Although the majority of the bimolecular aggregates just dealt with are assumed to dissociate again, a small proportion might be expected to decompose, as shown in the second stage of oxidation, with elimination of the elements of water and formation of an "unsaturated residue." Now, if this reaction is reversible, the extremely interesting phenomenon of the inhibitory action of water can be explained in a very simple way. On the other hand, it seems impossible, on the basis of the hydroxylation theory, to devise any simple explanation of this behavior. It will be seen readily that, if this stage is reversed, no permanent oxidation product can be formed.

The final stage of this series of reactions involves a rearrangement, or orientation, of the "unsaturated residue" into the stable form of an aldehyde or ketone and this reaction could hardly be thought of as other than an irreversible one. On this account, the oxidation as a whole would be irreversible and the action of water on an aldehyde or ketone could not be expected to yield the corresponding hydrocarbon and oxygen.

It might be mentioned that the purpose of introducing the "unsaturated residue" is twofold; first, to account for the irreversibility of the reaction as a whole and, second, to take cognizance of the fact that it must take a finite time, however short, for an unsaturated fragment from the decomposition of a molecule or aggregate to orientate itself into a stable configuration. Then, if this residue has a definite life period, the presence of a sufficient concentration of water vapor could cause the second stage of the oxidation to be reversed.

In the oxidation of the isopropyl group in cumene, or cymene, the series of reactions shown above would be the same except for the elimination of the elements of methyl alcohol instead of water. In this case, it would be expected that oxidation would accompany, or immediately follow, this elimination and actually the product that is obtained is not methyl alcohol but formic acid. As was anticipated, the presence of methyl alcohol in excess did not inhibit the oxidation of cumene and other work is at present under way to attempt to throw more light on this reaction.

To return once more to the oxidation of methane under high pressure and with a small proportion of oxygen present,[4] it seems quite possible, in accord with the above theory, to grant the correctness of the assumption that some methyl alcohol was formed. Under ordinary conditions (ordinary pressures arid with a sufficient supply of oxygen) it seems reasonable to assume that the simplest possible type of reaction will take place, that is, a bimolecular one. However, if the concentration of methane were very high, with respect to that of oxygen, there seems every possibility of two molecules of methane associating with one molecule of oxygen. That is, according to the widely accepted view of Trautz and Schleuter,[7] there would be ample opportunity for a second methane molecule to encounter a bimolecular oxygen–methane aggregate, while the two molecules were still under their mutual sphere of influence. Now, the decomposition of this trimolecular aggregate would be most simply represented by the equation

$$CH_4 \cdot O_2 \cdot CH_4 \longrightarrow 2CH_3OH$$

Thus, under these special conditions, the formation of an alcohol from a hydrocarbon seems quite possible. It must be pointed out, however, that the alcohol thus formed is a by-product and not an intermediate in the oxidation of the hydrocarbon.

Finally, we might turn to the only case on record in which an alcohol has been detected as an oxidation product of a saturated hydrocarbon, that of the production of ethyl alcohol from ethane by means of ozone.[3] If we assume the same type of reaction as in the case of oxygen, we should expect the bimolecular aggregate thus formed to decompose, giving ethyl alcohol and oxygen.

$$C_2H_6 \cdot O_3 \longrightarrow C_2H_5OH + O_2$$

Ozone, then, cannot be compared too strictly with oxygen, as the former can give an alcohol through bimolecular impacts, while the latter cannot. One other possibility might be mentioned in this connection. In the work of Bone and Drugman a large excess of ethane was employed and it is conceivable that some trimolecular impacts might occur under these conditions. If this does take place, the resulting aggregates might decompose according to the scheme

$$C_2H_6\,O_3 \cdot C_2H_6 \longrightarrow C_2H_5OH + CH_3CHO + H_2O$$

also yielding ethyl alcohol.

To sum up very briefly, the normal primary reaction between a saturated hydrocarbon and oxygen is assumed to depend on bimolecular impacts. Under exceptional conditions, as has just been indicated, trimolecular collisions may take place to some extent. Only in this latter event can any alcohol be formed and the alcohol would thus be considered as a by-product rather than an intermediate oxidation product.

Experimental Part

A. Oxidation in the Presence of Acetic Anhydride

Xylene.—Twenty g. of xylene and 20 g. of acetic anhydride oxidized at 102–104° for twenty-one days yielded 7.85 g. of crude toluic aldehyde, b. p. 78–81° (10 mm.); previously reported, 1.9 g. of aldehyde from 90 g. of xylene in 30 days at 100°.

---

[7] Trautz and Schleuter, *Z. anorg Chem* , 136, 1 (1924).

Ethylbenzene.—Twenty-five g. of ethylbenzene and 25 g. of acetic anhydride oxidized for eleven days at 102–104° yielded 9.0 g. of crude acetophenone; previously reported, 9.5 g. of acetophenone from 50 g. of ethylbenzene in twenty-four days at 110–115°.

Xylyl Acetate.—Twelve g. of xylyl acetate, b. p. 103–106° (10 mm.), oxidized for eleven days at 102–104°, yielded no tolnic aldehyde.

B. Parallel Oxidation of Ethylbenzene and Phenylmethyl Carbinol

Twenty-five g. of phenylrnethyl carbinol, oxidized for eleven days at 122–124° yielded 0.85 g. of acetophenone, isolated as semicarbazone.

Twenty-one g. of ethylbenzene, oxidized as above for eleven days, yielded **6.3** g. of crude acetophenone, b. p. 77–83° (8mm.).

Summary

A new mechanism of the oxidation of saturated hydrocarbons by gaseous oxygen is proposed, which accounts for the inhibitory action of water in oxidations studied by the writer.

It is shown that the oxidation of a hydrocarbon to aldehyde or ketone does not go through the alcohol stage.

THE INTERRELATION OF HYDROGEN-ION ACTIVITY AND CONCENTRATION OF SALT IN THE ACTIVATION OF PANCREATIC AMYLASE[1]

BY H. C. SHERMAN, M. L. CALDWELL AND M. ADAMS

RECEIVED JUNE 28, 1928 PUBLISHED SEPTEMBER 5, 1928

It has long been known that the presence of electrolyte is essential to the activity of pancreatic amylase, but quantitative data obtained under sufficiently controlled conditions have not been available to afford satisfactory explanations of this influence or to permit strictly quantitative comparisons of different electrolytes.

In view of this fact and of the theoretical and practical importance of the subject, series of investigations to obtain quantitative and comparable data concerning the influence of various electrolytes upon the activity of pancreatic amylase have been carried out in which the influence of the other factors involved has been recognized and eliminated as completely as possible. In this way it was hoped that the magnitude of the influence, if any, exerted by each salt might be quantitatively established, that other interrelated factors might be recognized, that more light might be thrown upon the way in which such influences are exerted and that

---

[1] We are greatlv indebted to the Carnegie Institution of Washington for grants in aid of this investigation.

thus more knowledge of the nature and mode of action of the enzyme itself might be obtained.

The study should also be of value in establishing and making it possible to maintain the most favorable conditions for future measurements of enzymic activity.

The results of one series of experiments in which several typical "buffer" salts were studied have already been published.[2] These results led to the conclusion that the influence upon the activity of pancreatic amylase which had hitherto been attributed to such salts as the phosphates, citrates and borates of sodium is mainly if not entirely due to the influence which they exert upon the hydrogen-ion activities of the systems. This explanation would, however, not apply to all electrolytes and the study has, therefore, been extended to include several representative neutral salts.

In the many previous investigations on the influence of neutral salts on the activity of pancreatic amylase, it has generally been assumed that the optimal hydrogen-ion activity for the enzyme as determined in the presence of one concentration of a salt is also the optimal hydrogen-ion activity for that enzyme in the presence of any other concentration of the salt under consideration. Moreover, when there has been any attempt to compare the influence of different salts on the activity of pancreatic amylase there has been no attempt to determine the optimal concentration for each of the salts studied.

Recent investigations[3] have indicated a need for investigating these assumptions as it has been shown that the factors which influence enzymic activity are much more dependent upon one another than has heretofore been generally recognized.

Experimental

The experimental work may be divided into three parts. (1) A study of each salt was made first to determine the influence of changes in its concentration on the optimal hydrogen-ion activity for the hydrolysis of starch by pancreatic amylase. (2) The optimal concentration of each salt was then ascertained by comparing the hydrolysis of starch by pancreatic amylase in the presence of different concentrations of the salt, the enzymic activity being measured at the optimal hydrogen-ion activity in each case. (3) It was then possible to make direct comparisons of the hydrolysis of starch by pancreatic amylase in the presence of each of these salts with the starch in each case adjusted to the hydrogen-ion activity and to the concentration of salt which is most favorable for pancreatic

---

[2] Sherman, Caldwell and Dale, THIS JOURNAL, 49, 2596 (1927).

[3] (a) Hahn and co-workers, *Z. Biol.*, 71, 286, 302 (1920); (b) 73, 10 (1921); (c) 74, 217 (1922); (d) 76, 227 (1922); (e) Myrback, *Z. physiol. Chem.*, 149, 1 (1926); (f) Sherman, Caldwell and Adams, THIS JOURNAL, 49, 2000 (1927).

amylase activity. The results of the first phase of this work will be reported briefly in this paper while the other phases will be treated more fully later.

This first series of experiments, therefore, was undertaken to determine the interrelation of hydrogen-ion activity and concentration of salt in the activation of pancreatic amylase. This was accomplished by making parallel measurements of the enzymic activity in the presence of systematically graded hydrogen-ion activities for each concentration of each salt studied.

The salts studied were sodium, potassium and lithium chlorides, and the bromide, fluoride, nitrate, chlorate, sulfocyanate and sulfate of sodium. These were carefully purified by recrystallization.

Because of the difficulties involved in obtaining sodium iodide free from traces of iodine, this salt was omitted from the present series. In our opinion it is impossible at present to separate the influence upon enzymic activity which may be attributable to the iodide ion from that of the traces of free iodine also present in solutions of sodium iodide.

Three preparations of pancreatic amylase were used for these investigations: a commercial pancreatin of high amylase activity obtained by the courtesy of Parke, Davis and Company in 1922, and two purified preparations, one prepared according to the method of Sherman and Schlesinger,[4] the other according to the same method except that the addition of maltose before dialysis was omitted and the final alcohol solution was dialyzed for twelve to fourteen hours instead of forty hours. The activities of these preparations expressed on the Sherman and Kendall[5] scale were 280, 940 and 1130, respectively.

The method of measuring the amylase activity was by the gravimetric determination of the reducing sugar produced from the starch by the enzyme, as shown by the reduction of Fehling's solution and the formation of cuprous oxide. The details of this method have been described in previous publications from this Laboratory.[6] The concentration of each enzyme preparation was kept constant throughout the series of experiments, the solutions being made up immediately before use in ice-cold water containing **0.0005** M disodium phosphate.

Selection of a Suitable Buffer.—In order to make a quantitative study of the influence of these neutral salts it was desirable to have present some buffer salt which would not itself influence the enzymic activity but by means of which it would be possible to control accurately the hydrogen-ion activities of the substrates. Mixtures of the phosphates of sodium had been found, as shown above,[2] to answer these requirements. This finding, that phosphate has no influence upon the activity of pancreatic amylase in half-hour hydrolyses of 2% starch at 40°, has been confirmed and extended.

---

[4] Sherman and Schlesinger, THIS JOURNAL, **33, 1196 (1911); 34, 1104 (1912).**

[5] Sherman, Kendall and Clark, ibid., **32,1093 (1910).**

[6] Sherman and Walker, ibid., 41, 1866 **(1919);** Adams, *Dissertation,* Columbia University, 1927.

In the absence of any neutral salt but in the presence of a total phosphate concentration of 0.01 M, the enzyme solutions in the concentrations in which they were used throughout this investigation produced no measurable hydrolysis of starch. An unfavorable hydrogen-ion activity^{3} of the system was not a factor here as the measurements of enzymic activity were made in the presence of systematically graded differences in hydrogen-ion activities from *PH 5.7* to **PH** 7.7.

When the concentration of the commercial pancreatin was doubled, there was evidence of slight enzymic activity. This was greatest in solutions corresponding in hydrogen-ion activity to **PH** *5.3* but was very slight at best and was evidently due to the small amount of electrolyte impurities present in the commercial pancreatin, because, under similar conditions, the purified enzyme preparations produced no measurable hydrolysis of starch. These results justified the use of 0.01 M phosphate buffer mixtures throughout this investigation.

The total phosphate concentration was held constant in all the starch solutions but the relative amounts of primary and secondary phosphates were varied in order to obtain the desired hydrogen-ion activities. The hydrogen-ion activities were measured electrometrically for each starch solution used.

Results **with** Individual Salts.—The results with sodium chloride are shown graphically in Fig. 1. It is seen from these results that the optimal hydrogen-ion activity for pancreatic amylase activity in the presence of sodium chloride **is** different for each concentration of sodium chloride as this is increased from 0.0005 to 0.01 *M*. Above 0.01 M, the optimal *PH* is the same (PH 7.1 – 7.2) with increasing concentrations of sodium chloride.

[a] Mixtures of acid and alkaline sodium phosphates corresponding to a total concentration of 0.01 M phosphate were present in all cases.

As shown in Table I, the results obtained with the other salts studied were similar, but the concentration of the salt at which the optimal hydrogen-ion activity for the enzymic activity ceases to be appreciably influenced depends upon the salt.

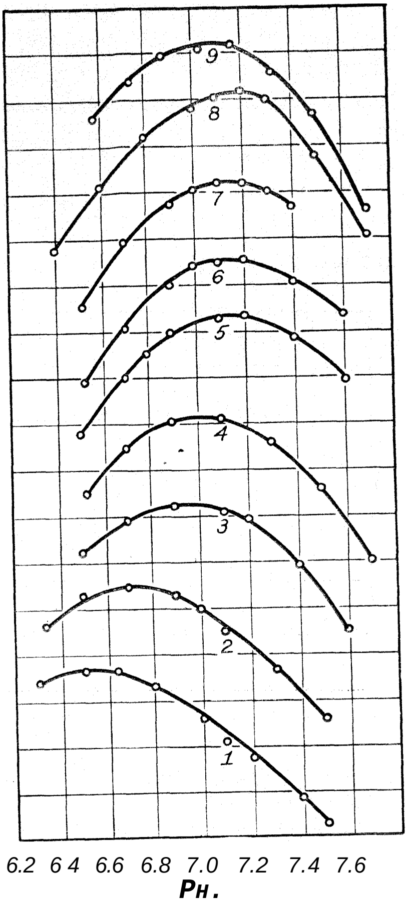
Thus this concentration was found to be 0.01 *M* for sodium chloride, potassium chloride or sodium bromide; 0.05 *M* for sodium nitrate or sodium chlorate; 0.10 *M* for sodium sulfocyanate and 0.20 *M* for sodium fluoride. In each case as the concentration of the salt is decreased below these concentrations, the enzyme is most active in increasingly more acid solutions.

A comparison of the results given in Table I also shows that the optimal hydrogen-ion activity for pancreatic amylase is somewhat different in the presence of these different salts, even when enough of each salt is present to eliminate the influence of changes in its concentration.

Sodium sulfate was found to be without influence upon the activity of pancreatic amylase even when the hydrogen-ion activities of the solutions were varied at graded intervals from PH 5.7 to PH 7.7 and the concentrations of the salt from 0.01 to 0.10 M.

Because of the insolubility of lithium phosphate it was not possible to study lithium chloride in the same way in which the other salts were investigated and the results with this salt will be given in a later paper.

Conditions for the Enzymic Activity in the Presence of More than One Salt.—Experiments similar to those just described were also carried out with mixtures of two salts. In previous investigations[7] dealing with the influence



Pancreatin (power 280). 1—0.0005 M NaCl; 2—0.001 M NaCl; 3—0.0025 *M* NaCl; 4—0.005 *M* NaCl; 5—0.01 *M* NaCl; 6—0.02 *M* NaCl; 7—0.03 *M* NaCl; 8—0.05 M NaCl; 9—0.10 *M* NaCl.

Fig. 1.—Influence of the concentration of sodium chloride upon the activity of pancreatic amylase at different hydrogen-ion activities. All the points on any one curve are comparable but the curves are not placed to indicate relative activity of the enzyme in the presence of different concentrations of salt. This is true of the curves in all subsequent figures.

[7] Michaelis and Pechstein, *Biochem. Z.*, 59, 77 (1914); Hahn and Harpuder, *Z. Biol*, 71, 286, 302 (1920).

of more than one salt upon the activity of pancreatic amylase no attempt has been made first to establish quantitatively the optimal conditions for the activity of pancreatic amylase in the presence of mixtures of these salts. In the present experiments the activity of the enzyme was measured in the presence of 0.02 M sodium chloride with additions of 0.01 to 0.20 M sodium nitrate or 0.01 to 0.10 *M* sodium sulfate.

Pig. 2 shows the results obtained with mixtures of sodium chloride and sodium nitrate. The results with mixtures of sodium chloride and sodium sulfate were similar. The optimal hydrogen-ion activity for the enzyme in the presence of mixtures of 0.02 *M* sodium chloride and sodium sulfate was PH 7.1–7.2 when the sodium sulfate was present in total concentrations of 0.01 to 0.05 M, and *PH* 6.9 when the concentration of sulfate present was increased to 0.10 *M*. It was found that as the concentration of sodium nitrate or sodium sulfate was increased the enzymic activity was favored by solutions of greater hydrogen-ion activity, that is, by more acid solutions.

Fig. 2.—Influence of the concentration of sodium nitrate upon the activity of pancreatic amylase at different hydrogen-ion activities in the presence of 0.02 M sodium chloride.

Summary

The optimal hydrogen-ion activity for pancreatic amylase in the presence of different concentrations of sodium or potassium chlorides or of sodium bromide, fluoride, nitrate, chlorate, sulfocyanate or sulfate has been quantitatively investigated.

The optimal hydrogen-ion activity for pancreatic amylase is dependent both upon the kind and concentration of salt present.

In the presence of each of the salts investigated here, the optimal hydrogen-ion activity for pancreatic amylase decreases with increasing concentration of the salt up to a certain salt concentration, beyond which it ceases to he appreciably influenced.

The concentration of salt at which the optimal hydrogen-ion activity for the enzymic activity ceases to be appreciably influenced depends on the salt.

In the presence of more than one of these salts the optimal hydrogen-ion activity depends upon the concentration of the salts present.

Sodium sulfate and sodium phosphate were found to be without influence on the activity of pancreatic amylase.

THE INFLUENCE OF CONCENTRATION OF NEUTRAL SALT ON THE ACTIVATION OF PANCREATIC AMYLASE[1]

BY H. C. SHERMAN, M. L. CALDWELL AND M. ADAMS

RECEIVED JUNE 28, 1928 PUBLISHED SEPTEMBER 5, 1928

In a previous paper[2] the optimal hydrogen-ion activity for pancreatic amylase in the presence of different concentrations of each of a series of neutral salts has been reported. These having been established, it was possible to continue the investigation and to determine the optimal concentration of each salt for the activity of the enzyme. The results of this phase of the work will be reported briefly in this paper.

Experimental

A series of parallel hydrolyses of starch by pancreatic amylase was carried out in the presence of different concentrations of each salt with the hydrogen-ion activity in each case adjusted to that previously found to be optimal[2] for the enzyme in the presence of the concentration of salt being studied. The conditions for making up solutions and measuring enzymic activity as there described[2] were maintained throughout. Fig. 1 shows the results obtained from a direct comparison of the activity of pancreatic amylase in the presence of from 0.005 to 0.10 M sodium chloride. The enzyme was found to exert its optimal activity in the presence of from 0.02 to 0.05 M sodium chloride.

With potassium chloride the concentrations investigated were 0.01,

---

[1] We are greatly indebted to the Carnegie Institution of Washington for grants in aid of this investigation

[2] Sherman, Caldwell and Adams, THIS JOURNAL, 50, 2529 (1928).

0.02, 0.03 and 0.05 *M*, and 0.03 to 0.05 *M* potassium chloride solutions were found to permit optimal enzymic activity. From a direct comparison of the activity of pancreatic amylase in the presence of 0.01, 0.03, 0.05, 0.10 and 0.20 *M* sodium bromide it was found that 0.03 to 0.20 *M* was the most favorable concentration.

Measurements of the activity of pancreatic amylase in the presence of 0.03, 0.05, 0.10, 0.15 and 0.20 *M* sodium nitrate showed that 0.10 to 0.20 *M* was the most favorable concentration of sodium nitrate.

The results obtained in the presence of 0.05, 0.10, 0.15 and 0.20 *M* sodium chlorate solutions were similar to those obtained with sodium nitrate.

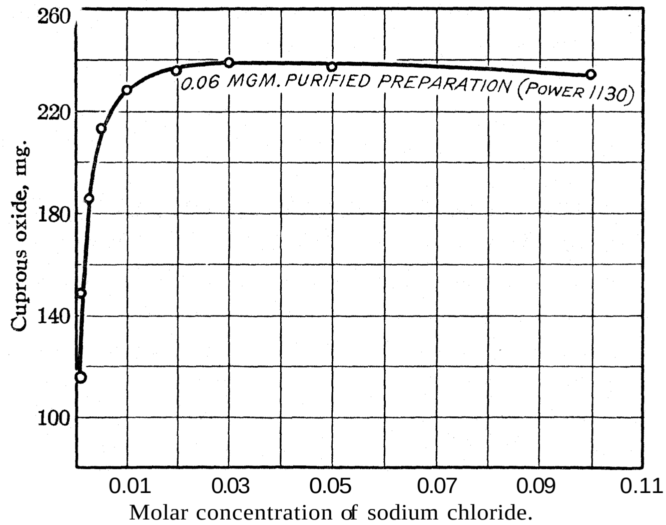

Fig. 1—Influence of concentration of sodium chloride on the activity of pancreatic amylase.

Comparisons of the activity of pancreatic amylase in the presence of 0.10, 0.15, 0.175 and 0.20 *M* sodium sulfocyanate or in the presence of 0.10, 0.15, 0.175, 0.20, 0.25 and 0.30 *M* sodium fluoride showed that a concentration of from 0.15 to 0.20 *M* sodium sulfocyanate or 0.20 to 0.30 *M* sodium fluoride was sufficient for the maximum activation which these salts are capable of producing.

An examination of the data summarized in Table I shows that the concentration of salt necessary for maximum activation of pancreatic amylase depends upon the individual salt present.

There is an increase in the enzymic activity as the concentration of salt is increased up to a maximum activity of the enzyme in the presence of each salt. Within the limits of concentration investigated here, further increases in the concentration of salt had practically no influence on the

TABLE I

THE OPTIMAL CONCENTRATIONS OF CERTAIN SALTS WITH THE CORRESPONDING OPTIMAL HYDROGEN-ION ACTIVITIES FOR THE ACTIVITY OF PANCREATIC AMYLASE[a]

Salt	Optimal concn., *M*	Optimal P_H
Sodium chloride	0.02–0.05[b]	7.1–7.2
Potassium chloride	03– .05	7.1–7.2
Sodium bromide	.03– .20	7.1
Sodium nitrate	.10– .20	7.1
Sodium chlorate	.10– .20	6.9–7.1
Sodium sulfocyanate	.15– .20	6.7–6.8
Sodium fluoride	20– .30	6.7–6.8

[a] Mixtures of acid and alkaline sodium phosphates corresponding to a total concentration of 0.01 M phosphate were present in all cases.

[b] The practically constant activity obtained within the limits of concentration considered here would indicate that there is enough of the salt present fully to activate the enzyme in each case.

activity of the enzyme or on the hydrogen-ion activity which is optimal for the enzyme in its presence. In the presence of insufficient salt to produce maximum activation, as the concentration of salt is decreased, the enzyme exerts its optimal activity in increasingly more acid solutions. Pancreatic amylase exerts its optimal activity in more acid solutions in the presence of those salts which require higher concentrations for complete activation. All of these results emphasize again the need of carefully standardizing and controlling the conditions for measuring enzymic activity.

Summary

The concentration of sodium or potassium chloride or of sodium bromide, nitrate, chlorate, sulfocyanate or fluoride most favorable (in each case) to the activation of pancreatic amylase has been quantitatively established.

The optimal concentration (in terms of molarity) is found to be different for different neutral salts.

The activity of pancreatic amylase is favored by more acid solutions in the presence of those salts of which higher concentrations are required for its complete activation.

A QUANTITATIVE COMPARISON OF THE INFLUENCE OF NEUTRAL SALTS ON THE ACTIVITY OF PANCREATIC AMYLASE[1]

BY H. C. SHERMAN, M. L. CALDWELL AND M. ADAMS

RECEIVED JUNE 28, 1928 PUBLISHED SEPTEMBER 5, 1928

In previous papers[2] the optimal hydrogen-ion activities and concentrations of salts for pancreatic amylase in the presence of different salts have been reported. With these conditions established it was possible to continue the investigation and obtain direct comparisons of the influence of these salts (each under its own optimal conditions) on the activity of the enzyme. The salts studied were the chlorides of sodium, potassium and lithium and the bromide, nitrate, chlorate, sulfocyanate, fluoride, sulfate and phosphate of sodium. Mixtures of sodium chloride with either sodium nitrate or sulfate were also studied.

Experimental

The results for the individual salts are summarized in Table I, and are given in terms of the effect of sodium chloride, taken as 100, because this salt was found to have the most favorable influence upon the enzyme.

TABLE I

COMPARISON OF THE ACTIVITY OF PANCREATIC AMYLASE IN THE PRESENCE OF VARIOUS NEUTRAL SALTS EACH AT ITS OPTIMAL HYDROGEN-ION ACTIVITY AND CONCENTRATION[a]

	Activity, compared to that obtained in the presence of 0.03 M NaCl

[2] Sherman, Caldwell and Adams, THIS JOURNAL, 50, 2529, 2535 (1928)

salts.[2] Sodium hydroxide, 0.01 *M*, was used instead of mixtures of sodium phosphate to adjust the solutions to different hydrogen-ion activities. It was not possible to measure experimentally the hydrogen-ion activities of these unbuffered, nearly neutral, solutions or to plan to reproduce any one of them exactly for use in comparisons. However, by planning parallel and overlapping determinations of enzymic activity, it was possible to eliminate the influence of hydrogen-ion activity and to obtain relative values for the optimal activity of the enzyme in the presence of different concentrations of lithium chloride, which were comparable with each other and with the optimal activity of the enzyme in the presence of sodium chloride. Thus 0.005, 0.02, 0.03 and 0.05 M lithium chloride solutions were studied and it was found that the optimal activity of the enzyme in the presence of 0.02 or 0.05 *M* lithium chloride was 80 to 90% of the optimal activity of the enzyme in the presence of sodium chloride. This was found to be true whether the hydrogen-ion activities of the sodium chloride solutions were adjusted with mixtures of sodium phosphates or with sodium hydroxide. This would indicate that the lower activity of the enzyme in the presence of lithium chloride was not due to the absence of phosphate in the case of lithium chloride.

From the results summarized in Table I, it would seem that, of the ions considered here, the anions are by far the most important in their influence upon this enzyme. Pancreatic amylase may be activated to the same extent by potassium or sodium chlorides but the concentration of potassium chloride necessary fully to activate pancreatic amylase is slightly greater than the concentration of sodium chloride needed. Lithium chloride activates pancreatic amylase but even when optimal concentrations are used the activity obtained is not equal to that obtained in the presence of either sodium or potassium chlorides. The cations, therefore, seem to have some slight influence.

Of the anions studied, chloride is the most efficient ion and the salts considered here may be placed in the following order in their influence on the hydrolysis of starch by pancreatic amylase: sodium and potassium chlorides, lithium chloride, sodium bromide, sodium nitrate, sodium chlorate and sodium sulfocyanate, sodium fluoride. The results obtained with the purified and the commercial enzyme preparations have been found to be similar throughout these experiments.

A Study of the Possible Interrelation of the Influence of Different Neutral Salts.—The next series of experiments was planned to study the influence on the activity of pancreatic amylase of the presence of more than one of these salts. The activity of the enzyme was measured in the presence of 0.02 *M* sodium chloride with additions of 0.01 to 0.20 *M* sodium nitrate or 0.01 to 0.10 M sodium sulfate. Direct comparisons of the activity of the enzyme in the presence of each combination of salts were made with the activity of the enzyme in the presence of 0.02 M sodium chloride alone. In these series of experiments 0.02 *M* sodium chloride solutions were used instead of 0.03 M as in the previous experiments in order to reduce the sodium chloride concentration to the minimum capable of producing complete activation of the enzyme. Each solution was adjusted to the hydrogen-ion activity previously found[2] to be most favorable under the conditions maintained in this investigation. The results are summarized in Table II and are given in terms of the effect of sodium chloride taken as 100.

TABLE II

INFLUENCE OF THE CONCENTRATION OF SODIUM SULFATE OR SODIUM NITRATE ON THE ACTIVITY OF PANCREATIC AMYLASE IN THE PRESENCE OF SODIUM CHLORIDE[a]

Concentration of sodium nitrate, *M*	Activity compared to that obtained in the presence of NaCl Purified preparation, power 1130	Pancreatin, power 280
0.01	91	92
.10	66	68
.20	55	54
Concentration of sodium sulfate, *M*		
0.01	100	100
.05	93	94
.10	90	92

[a] Mixtures of acid and alkaline sodium phosphates corresponding to a total concentration of 0.01 M phosphate were present in all cases.

From the data given in Table II it is seen that as the concentration of sodium nitrate or sulfate is increased the activity of pancreatic amylase decreases. The addition of sodium nitrate has a much more noticeable effect in decreasing the activity of the enzyme than additions of sodium sulfate. The activity of pancreatic amylase in the presence of 0.02 *M* sodium chloride is reduced by the addition of sodium nitrate even when the concentration of sodium nitrate present is much lower than the concentration of sodium chloride.

Possible Explanations of the Influence of Neutral Salts upon Enzymic Activity.—The results of these investigations show that there is some decided specific influence of these salts on the activity of pancreatic amylase but how this influence is exerted is not yet known.

Several previous investigators[3] have reported indications of a relation between the concentration of enzyme and the concentration of sodium chloride necessary to activate it. For this reason a series of experiments was carried out to see whether decreasing the concentration of enzyme to one-half that previously used would change the results obtained. A series of starch solutions containing graded concentrations of sodium

---

[3] Starkenstein, *Biochem.* Z., 24, 210 (1910); 47, 300 (1912); Norris, *ibid.*, 7, 622 (1913).

chloride from 0.005 to 0.05 *M*, each adjusted to the optimal hydrogen-ion activity previously determined, were hydrolyzed in parallel using for every 100 cc. of 2% starch 0.03 instead of 0.06 mg. of the purified preparation which had a power of 1130. The optimal activity of the enzyme was found to occur in the presence of 0.02 to 0.05 *M* sodium chloride, iust as had been observed in the presence of the more concentrated enzyme solutions.

Other investigators[4,5] state that the concentration of starch influences the amount of salt that is essential. Experiments with 4% instead of 2% starch were therefore also carried out.

The optimal hydrogen-ion activity for the activity of pancreatic amylase in the presence of 4% starch solutions containing 0.01 to 0.05 M sodium chloride was first determined and was found to be PH 6.8 to 7.2, which is similar to the optimal PH 7.1 to 7.2 observed[2] for the enzyme in the presence of 2% starch. The concentration of sodium chloride permitting the optimal activity of pancreatic amylase was found to be 0.02 to 0.05 M, which is the same as that found for the enzyme in the presence of 2% starch.

These results do riot necessarily indicate that there is no relation between concentration of starch, enzyme and salt, because there is already present in 2% starch solutions a large excess of starch and further increase in the concentration of starch would not necessarily call for further increase in the concentration of sodium chloride. It is evident, however, that for the conditions regularly used in determining amylase activity in this Laboratory, solutions of 0.02 to 0.05 *M* sodium chloride and hydrogen-ion activities corresponding to PH 7.0 to 7.2 will permit optimal enzymic activity when the substrate is 2 to 4% starch and when the concentration of enzyme is such that the activity is within the limits usually maintained here, the formation of 100 to 240 mg. of maltose in thirty minutes at 40°.

There are several possible explanations of the influence of neutral salts on the activity of pancreatic amylase but the experimental evidence substantiating most of these expianations is not conclusive.

It is possible that the influence of neutral salts on the activity of pancreatic amylase may be due to some influence on the colloidal state of the enzyme. Sherman, Thomas and Caldwell[6] found that the isoelectric point of malt amylase coincides with the optimal hydrogen-ion activity for the enzymic activity of malt amylase. This would indicate that malt amylase is most active in a state in which it is least soluble and most readily salted out.

If the optimal hydrogen-ion activity and the isoelectric point also coin-

[6] Sherman, Thomas and Caldwell, THIS JOURNAL, 46, 1711 (1924).

cide for pancreatic amylase, as has been indicated,[7] it would be expected that those neutral salts which are most effective in precipitating it would have the most favorable influence on its activity. When the anions which have been considered in this investigation are arranged in the order of their favorable effect upon the hydrolysis of starch by pancreatic amylase, the following order results: chloride, bromide, nitrate, chlorate and sulfocyanate, fluoride. Except for sulfate, which was found to exert no influence on the activity of pancreatic amylase, this is the same order that has been observed in the influence of neutral salts on the precipitation of proteins and other neutral substances and the reverse of that obtained by Pfeiffer and Wurgler[8] on the influence of these anions on the solubility of amino acids. This salting out factor which depends upon the specific properties of the ions is generally observed in more concentrated solutions of salt than we are considering in this investigation. In the lower concentrations of salt with which we are concerned here, the influence exerted by different ions as determined by freezing point and solubility measurements depends upon the valence type of the salt. This does not seem to hold here as the activity of pancreatic amylase is very different in the presence of salts of the same valence type and appears to be uninfluenced by the divalent sulfate ion. Moreover, the cations do not seem to fall into the order expected if their influence is one of salting out the enzyme. The order of their favorable influence upon enzymic activity is sodium and potassium, lithium, instead of lithium, sodium, potassium.

This makes it seem probable that we are dealing with some specific reaction between the enzyme, and the salt or substrate, or both, rather than merely with an influence of salt on the total ionic strength and activity of the solution.

Summary

The influence of sodium, potassium and lithium chlorides and of the bromide, fluoride, nitrate, chlorate, sulfocyanate and sulfate of sodium upon the activity of pancreatic amylase has been quantitatively investigated and compared.

The influence of neutral salts on the activity of pancreatic amylase was found to be the same for the purified preparations of the enzyme and for commercial pancreatin and seems therefore, to he a property of the enzyme itself rather than of any impurities that may be present.

The salts which are less favorable to the activity of pancreatic amylase are required in higher concentration and in turn exert their most favorable influence in solutions of higher hydrogen-ion activities than do those salts which are more efficient activators.

The activity of pancreatic amylase in the presence of two anions which

---

[7] Sherman, Caldwell and Adams, THIS JOURNAL, 48,2947 (1926).

[8] Pfeiffer and Wurgler, *Z. Physiol*, 97, 128 (1916).

exert a specific influence on its activity, such as the nitrate and chloride ions, is intermediate between the activity of the enzyme in the presence of each taken separately. The activity of the enzyme in the presence of such a mixture of salts is dependent on the relative concentrations of the ions. Anions which alone do not influence the activity of the enzyme seem to have comparatively small influence on the activity of the enzyme in the presence of anions which exert a decidedly specific influence.

Reducing the concentration of enzyme by one-half or using 4% instead of 2% starch does not appreciably influence the concentration of sodium chloride necessary for complete activation of the enzyme or the optimal hydrogen-ion activity.

The presence of neutral salt is essential to the activity of pancreatic amylase. The influence exerted by different salts appears to be very specific.

The anion is far more influential than the cation, although the latter seems to have some slight influence on the activity of the enzyme.

Of the ions studied, chloride is the most efficient ion and the salts may be placed in the following order in their influence on the hydrolysis of starch by pancreatic amylase: sodium and potassium chlorides, lithium chloride, sodium bromide, sodium nitrate, sodium chlorate and sodium sulfocyanate, sodium fluoride. Sodium sulfate and phosphate were found to be without influence on the activity of pancreatic amylase.

A consideration of the influence of the different anions on the activity of pancreatic amylase indicates that these have specific effects on the enzyme or substrate.

THE MECHANISM OF CARBOHYDRATE OXIDATION. X. (a) THE ACTION OF POTASSIUM HYDROXIDE ON MANNOSE. (b) A COMPARISON WITH THAT OF GLUCOSE AND FRUCTOSE

BY WILLIAM LLOYD EVANS AND DAVID CHARLES O'DONNELL[1]

RECEIVED JUNE 29, 1928 PUBLISHED SEPTEMBER 5, 1928

It has been shown[2] that glucose, fructose, mannose and galactose may be oxidized with alkaline potassium permanganate solutions into carbon dioxide, oxalic acid and small amounts of acetic acid. At lower alkali normalities and at a temperature of 25°, it was observed that the oxalic acid–carbon dioxide ratios obtained from both glucose and galactose were not of the same value. However, as the normality of the alkali was in-

---

[1] Read at the Detroit Meeting of the American Chemical Society, September 6, 1927.

[2] (a) Evans and co-workers, THIS JOURNAL, 47, 3085 (1925); (b) Evans and Buehler, *ibid*, 47, 3008 (1925)

creased in both cases, there seemed to be a tendency for the amounts of oxalic acid and carbon dioxide derived from these two carbohydrates to become more nearly the same. As the temperature of these oxidations was increased, this tendency toward identical yields became so marked that at 75° it was found that the amounts of these reaction products were practically the same. In the case of glucose, mannose and fructose at 50°, and at the lower alkali normalities, there were observable differences in the oxalic acid-carbon dioxide ratios, but these differences tended to disappear in the region of higher alkali normalities. At 75°, the yields of reaction products from glucose, fructose and galactose were practically the same. It has been suggested that alkaline solutions of the carbohydrates contain equilibrated systems which are easily influenced by a change in these experimental factors—a condition which ought to give rise to the differences observed in the amounts of the reaction products obtained in these oxidations.

By reason of this suggestion, it has become of much interest to study the behavior of these carbohydrates toward aqueous solutions of potassium hydroxide of various concentrations and at different temperatures for the purpose of observing whether the same general tendencies observed in the presence of oxidizing agents would also be observed in their absence. The general methods employed in this phase of the problem have been given in much detail in previous papers from this Laboratory. Because the earlier results on glucose and galactose and the more recent ones on fructose[3] have been reported, the two principal purposes in this study were these: *(a)* to learn if the behavior of mannose toward changes in alkali concentration and temperature were the same as those to be expected on the basis of the above suggestion; *(b)* to make a comparative summary of the results obtained by us and other workers[4] in this Laboratory to see if, by reason of the structural relations, certain predicted similarities in the behavior of the mannose–glucose–fructose group of hexose sugars could be detected.

Experimental Part

Chemicals.—The same precautions were taken with reference to the degree of purity of all reagents and chemicals used throughout this work as were observed in the previously reported experiments in this series of carbohydrate studies.'

Treatment of Mannose with Potassium Hydroxide.—The procedure adopted in the treatment of mannose with aqueous solutions of potassium hydroxide of appropriate normality was exactly the same as that used by Evans and Hass[5] in their work on glyceric aldehyde.

The amount of hexose sugar used in each experiment was 2.25 g. This was dissolved in 25 cc. of potassium hydroxide solution of the desired normality.

---

[3] Evans and Hutchman, THIS JOURNAL, 50, 1496 (1928).

[4] Evans, Edgar and Hoff, *ibid.*, 48, 2665 (1926).

[5] Evans and Hass, ibid., 48,2703 (1926).

Determination of Formic, Acetic and Lactic Acids.—Formic, acetic and lactic acids were identified and determined by methods previously described. By reason of some later work on fructose, we redetermined the amount of lactic acid obtained from glucose and potassium hydroxide solutions.

Determination of Pyruvic Aldehyde Osazone.—Owing to the fact that mannose differs from the sugars previously studied in this series, in that it forms an insoluble phenylhydrazone, the method for determining the amounts of pyruvic aldehyde osazone had to be modified as follows. The general procedure used in the case of fructose by Evans and Hutchman[3] was followed in every detail in our experiments with both mannose and glucose. It was found necessary to separate the pyruvic aldehyde osazone from the insoluble mannose phenylhydrazone by treating the mixture with acetone, a reagent in which the pyruvic aldehyde osazone was found to be completely soluble. The acetone solution was evaporated to dryness, the residue being washed with 30% alcohol, dried in a vacuum oven at 65° and then weighed. The osazone thus obtained was identified by its melting point (144–146°) and by the color test with sulfuric acid, a reagent which causes it to give an olive green color, which changed into a slate blue and finally to a violet.

Qualitative Reactions.—The reaction mixtures were qualitatively examined at appropriate places during the progress of a given experiment for hydroxy acids, acetol and pyruvic acid.[4]

Our quantitative data have been expressed in the form of graphs.

Theoretical Part

Mannose and Potassium Hydroxide.—The views[2a,4] which have been used in the interpretation of the results obtained from the alkaline oxidation of certain carbohydrates and also those resulting from the behavior of aqueous solutions of potassium hydroxide toward these same sugars are summarized at this point. (a) The classical experiments of Lobry de Bruyn and Alberda van Ekenstein[6] show that mannose, as well as either glucose or fructose, gives rise to an equilibrated system which may be represented by the following

$$d\text{-Mannose} \rightleftarrows d\text{-Glucose} \rightleftarrows d\text{-Fructose} \rightleftarrows d\text{-Pseudo-fructose} \rightleftarrows d\text{-}\alpha\text{-Glucose} \rightleftarrows d\text{-}\beta\text{-Glucose}$$

The equilibria arising from the use of each of these three sugars taken individually are not quantitatively identical.[6,7] (b) Through an elaboration of the views of Wohl and Neuberg,[8] and Fischer,[9] Nef[10] concluded from the results of oxidation experiments that mannose would yield a system of enediols in alkaline solutions which he represented by the following reaction.

$$CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\underset{H}{\overset{OH}{C}}-\overset{OH}{C}=CHOH \rightleftarrows CH_2OH-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-\overset{OH}{C}=\overset{OH}{C}-CH_2OH \rightleftarrows$$

d-Mannose-1,2-enediol *d*-Mannose-2,3-enediol

$$CH_2OH-\underset{OH}{\overset{H}{C}}-\overset{OH}{C}=\overset{OH}{C}-\underset{H}{\overset{OH}{C}}-CH_2OH$$

d-Mannose-3,4-enediol

It is clear that glucose and fructose should also yield the same enediols as does mannose. When these enediols are ruptured at their respective double bonds, the resulting systems will still be qualitatively identical. The fission products of such an action will give rise to an extension of the above system through the formation of other enediols containing a smaller number of carbon atoms. In the presence of appropriate oxidizing agents, these bivalent carbon atom intermediates will be oxidized to their respective acids. Therefore, it follows that the alkaline oxidation of mannose, glucose and fructose should yield products which are *qualitatively* the same but not necessarily *quantitatively* so. This point of view is supported by the literature in this field of investigation. (*c*) In offering an explanation for the quantitative differences observed in the oxidation of these well-known carbohydrates in alkaline potassium permanganate solutions, the suggestion was made that these reactions are best understood when it is assumed that a more general equilibrium, consisting of reactions (a) and (b), is present in the alkaline solutions of these sugars. Changes in the experimental factors, such as concentration of alkali and temperature, should give rise to changes in an equilibrium of this kind which, in the presence of oxidizing agents, would become evident through a variation in the *amounts* of the reaction products formed. Furthermore, it was pointed out that should these alkaline solutions give rise to irreversible equilibria, then it is probable that the speed of the slowest reaction in the series of changes taking place must be the factor that is influenced by the two experimental conditions, temperature and alkali concentration.

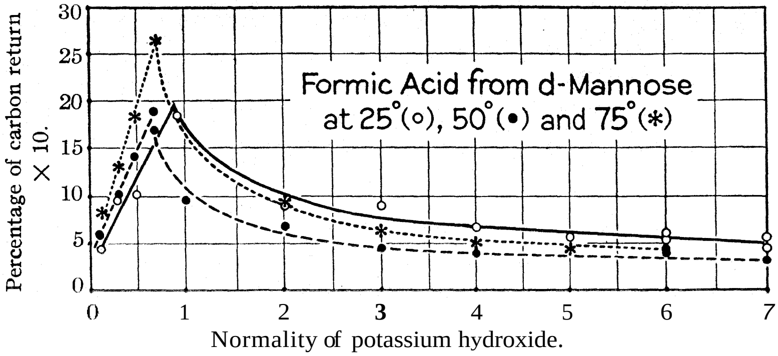
Mannose-1,2-enediol. Formic Acid.—When mannose-1,2-enediol is ruptured at the double bond, the active forms of formaldehyde and arabinose are produced. Formic acid should be found in alkaline solutions in which such an action takes place. Our results are shown in Fig. 1. It is obvious that the amounts of formic acid are a function of the alkali normality and the temperature employed. This behavior of mannose is in complete accord with that of glucose and fructose when these carbohydrates are studied under exactly the same experimental conditions. Upson[11]

---

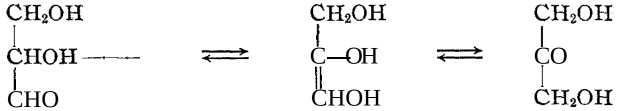
[11] (a) Power and Upson, THIS JOURNAL, 48, 195 (1926); (b) Jensen and Upson, *ibid.*, 47, 3019 (1925).

and his collaborators found that formic acid is a product of the oxidation of glucose in the presence of calcium hydxoxide and also when Soldiani's reagent is used. These investigators also isolated the arabonic derivatives in each case. Gustus and Lewis[12] have shown that 2,3,4,6-tetramethyl-d-glucose yields formic acid when it is oxidized with alkaline hydrogen peroxide solutions. There are many similar cases in the literature.[13]

Mannose-3,4-enediol. (a) Pyruvic Aldehyde.—(I) When one molecule of the 3,4-enediol common to mannose, glucose and fructose is ruptured at its double bond, two molecules of the active form of glyceric adehyde are produced. In the absence of oxidizing agents, the glyceric aldehyde so formed will then give rise to the equilibrated system represented by the following reaction.



Pig. 1.



$$\begin{matrix} CH_2OH \\ | \\ CHOH \\ | \\ CHO \end{matrix} \rightleftharpoons \begin{matrix} CH_2OH \\ | \\ C{-}OH \\ \| \\ CHOH \end{matrix} \rightleftharpoons \begin{matrix} CH_2OH \\ | \\ CO \\ | \\ CH_2OH \end{matrix}$$

Glyceric aldehyde Triose enediol Dihydroxy-acetone

It has been shown previously that pyruvic aldehyde is formed when glyceric aldehyde and dihydroxy-acetone are treated with aqueous solutions of potassium hydroxide. The amounts of the aldehyde thus formed are a function of the alkali concentration, the temperature and the speed with which it is converted into lactic acid. If glyceric aldehyde is present as a fission product in alkaline solutions of mannose and glucose, then it follows that these two carbohydrates should also give rise to pyruvic aldehyde whose amounts would be dependent upon the same factors as those

---

[12] Gustus with Lewis, THIS JOURNAL, **49,** 1512 (1927).

[13] (a) Cross, Bevan and Smith, J. *Chem. Soc.,* **73, 463** (1898); (b) Meisenheimer, *Ber., 41, 1009* (1908); (c) McLeod, *Am. Chem. J.,* **37,** 20 (1907); (d) Anderson, *ibid.,* **42,** 401 (1909); (e) Spoehr, *ibid.,* **43,** 227 (1910); (f) Glattfeld, *ibid.,* **50,** 163 (1913).

observed when the aldehyde is obtained from either glyceric aldehyde or dihydroxy-acetone. This was found to be the case. Our results are shown in Figs. 2 and 3. (II) According to the demands of the theory, alkaline solutions of all the hexose sugars should show exactly the same qualitative behavior as that of the trioses in this respect because the active form of glyceric aldehyde is a fission product of the 3,4-enediol, a tautomer which is common to all of this series of carbohydrates. In addition to the pyruvic aldehyde data which we have obtained from mannose and glucose in these experiments, we have assembled for the purposes of comparative study all similar data obtained in this Laboratory that have a

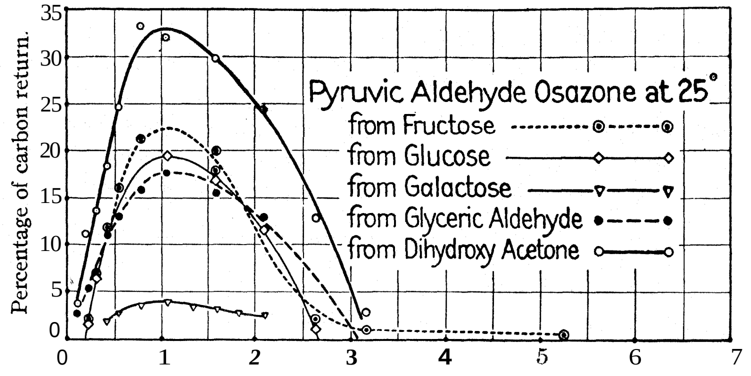


Fig. 2.

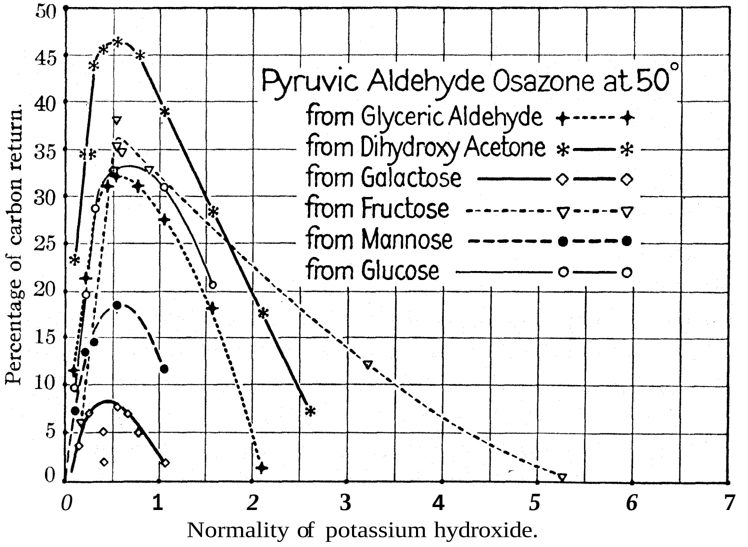

Fig. 3.

bearing on this point in carbohydrate chemistry, It has been shown previously that alkaline solutions of fructose and galactose, during a period of forty-eight hours as well as glucose for ninety-six hours, give rise to the formation of pyruvic aldehyde. (111) Owing to the fact that glucose. mannose and fructose do not form identical equilibria at the temperatures used, it was to have been expected that the yields of pyruvic aldehyde osazone from this series of sugars should not be the same. It does not follow from this fact, however, that there may not be experimental conditions under which this might not be true. At the only temperature beyond 50°, namely, 75°, at which work on this point has been carried out, it has been found that tarry materials seriously interfere with the demands of precise work. From the data in Figs. 2 and 3, it is seen that the maximum yields of pyruvic aldehyde osazone derived from the glucose, fructose and mannose at 25° (except mannose) and 50°, occur at approximately 1.0 *N* and 0.50 N alkali, respectively. This is also true for galactose. It is a very significant fact that both glyceric aldehyde and dihydroxy-acetone also yield their maximum return of pyruvic aldehyde osazone at these two temperatures and at practically the same alkali normality as do these hexose sugars—an observation which seems to us to be most convincing evidence for the theoretical views expressed above to the effect that the hexose carbohydrates in alkaline solutions of appropriate

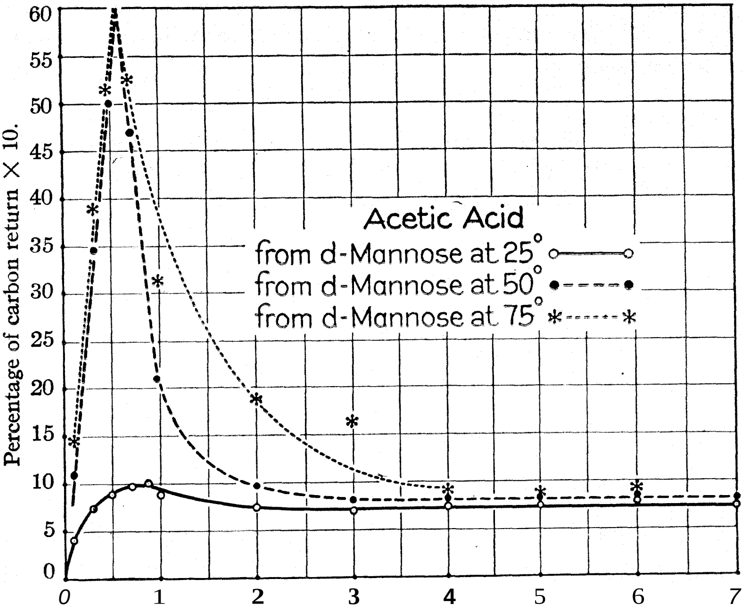

Fig. 4.'

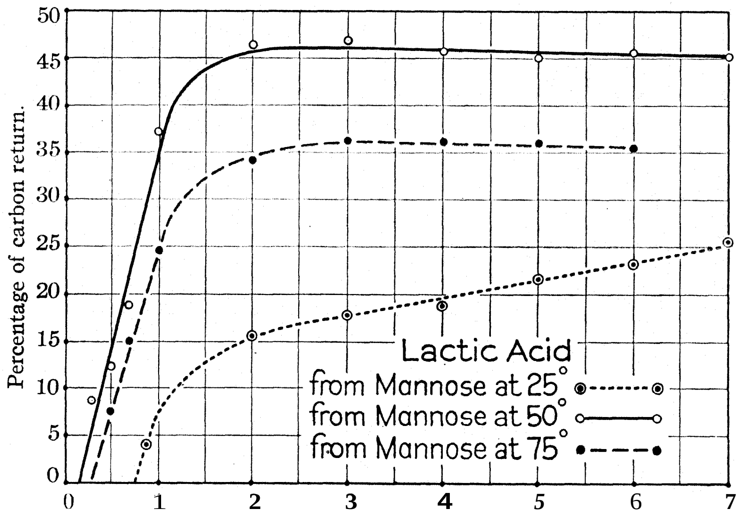
normality will give rise to glyceric aldehyde as an intermediate compound in the formation of pyruvic aldehyde, which, in turn, is converted into lactic acid. Although we had no other hexose sugars at our disposal, it may be safely predicted that the other carbohydrates of this series will also show the same behavior. (Dr. D. C. O'Donnell and Karl B. Nordstroni of this Laboratory are at present studying the pentose sugars from this point of view.)

(b) Acetic Acid.—In previous papers it was pointed out that the acetic acid and a portion of the formic acid obtained from the carbohydrates thus far studied must arise from the action of the potassium hydroxide on the dissociation products of pyruvic aldehyde shown in the following reaction

$$CH_3COCHO \longrightarrow CH_3CHO + CO$$

The results obtained with mannose (Fig. 4) are of the same general character as those obtained previously with glucose and fructose.



Normality of potassium hydroxide.

Fig. 5.

(c) Lactic Acid.—In the action of aqueous solutions of potassium hydroxide on mannose, as well as its action on fructose and glucose, it has been observed that a maximum point of production was found for both acetic and formic acids. As previously pointed out,[4] this must be due to the fact that pyruvic aldehyde at that alkali normality and temperature is rearranging to lactic acid with the same speed that it is dissociating after the manner of the above equation. When the speed of rearrangement of the aldehyde to lactic acid becomes greater with the increased alkali normality, the yields of acetic and formic acids should decrease accordingly and that of the lactic acid should increase. Our results on lactic acid from mannose and glucose are shown in Figs. 5 and 6, respectively. They are essentially of the same general character as those obtained

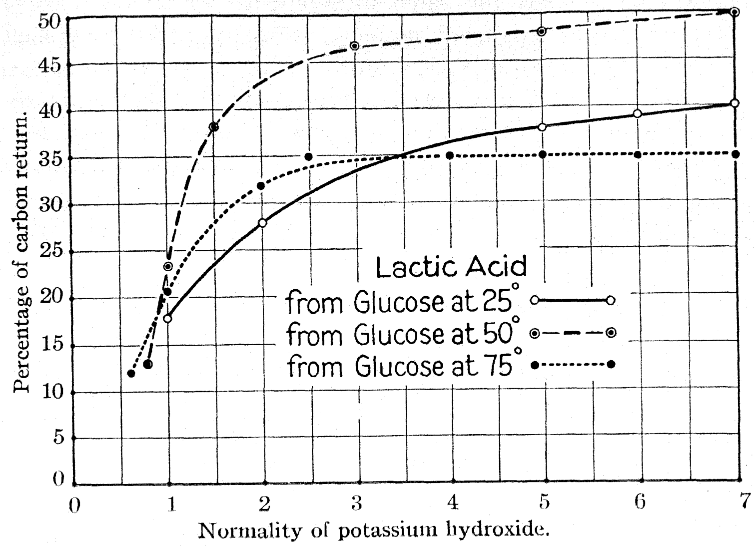


Fig. 6.

previously with fructose. In all three cases the amounts of lactic acid obtained at 75° are less than those obtained at 50°, a fact which is probably due to the pronounced tar formation at the higher temperature. In

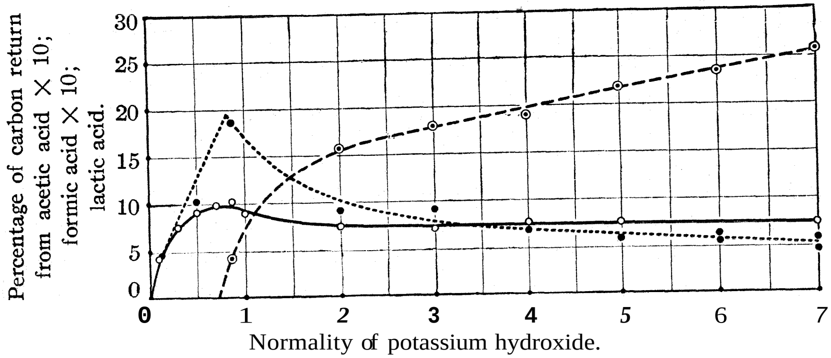

Fig. 7.—Production relation of acetic acid, ○; formic acid, ●; and lactic acid, ⊙ from mannose at 25°.

this connection it should be noted that we did not examine these tars for the presence of saccharinic acids.

In the pyruvic aldehyde osazone curves (Figs. 2 and 3), the maximum yield in each case is regarded as the point at which the velocity of rearrangement of pyruvic aldehyde to lactic acid is just equal to that of the osazone formation at that temperature and alkali concentration. According to the explanation given above for the sources of pyruvic aldehyde, acetic, formic and lactic acids, the same interdependence should exist in the yields of these compounds from mannose as was observed previously with fructose.[3] This is shown in Figs. 7 and 8. For the purposes of this comparative study we have assembled in Figs. 9 and 10 our lactic acid and pyruvic aldehyde osazone results from glucose and also those for acetic and formic acids obtained by Evans, Edgar and Hoff from the same carbohydrate. It is thus seen that this same interdependence is found in this sugar also. The fact that this same interdependence which is common to mannose, glucose and fructose is also present in the trioses, seems to us most convincing evidence for the point of view expressed above with reference to the important role played by pyruvic aldehyde when these three carbohydrates are acted upon with aqueous solutions of potassium hydroxide. It may be safely predicted that all the hexose sugars will show this important interdependence in the yields of pyruvic aldehyde, lactic, acetic and formic acids.

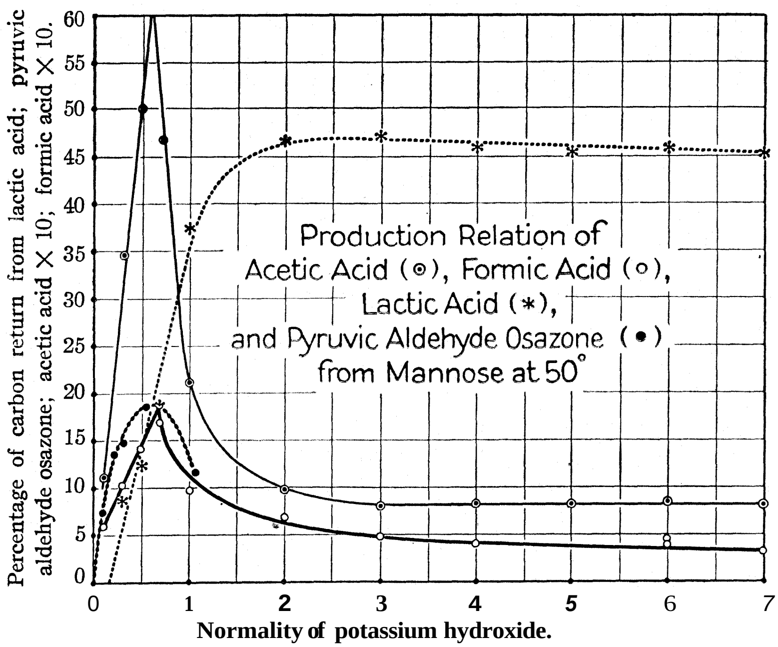

Fig. 8.

Influence of Alkali Concentration and Temperature on Mannose, Glucose and Fructose.—It has been shown that the temperature and the alkali concentration exercise a marked effect on the products obtained in the oxidation of these carbohydrates with potassium permanganate. The quantitative differences observed at the lower alkali normalities and at the lower temperatures have been attributed to the fact that these three sugars taken individually do not give rise to identical equilibria. However, in the alkaline oxidation of fructose and glucose with potassium permanganate at 75°, it was found that the amounts of oxalic acid and carbon dioxide obtained from these two carbohydrates were practically the same. This must have been due to the fact that both experimental factors, the alkali concentration and the temperature (or some temperature between that and 50°) influenced the general equilibrium in each case to

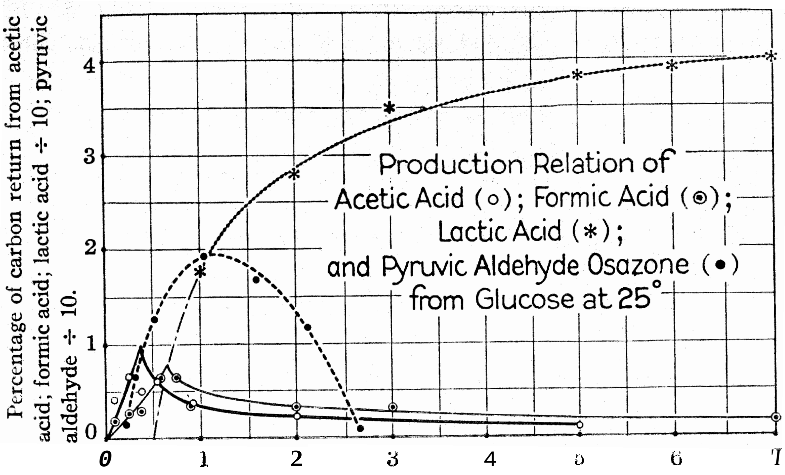

Fig. 9.

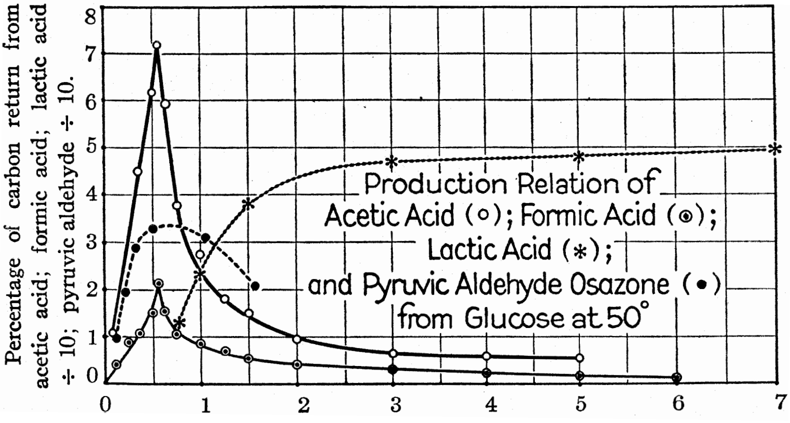

Pig. 10.

such an extent that the resulting solutions had become practically identical both qualitatively and quantitatively. If this is so, then the amounts of lactic acid obtained by the action of alkalies, in the absence of potassium permanganate, on mannose, glucose and fructose should also be the same in each case. In Fig. 11 we have shown that within the limits of experimental error this is true. In this connection it is of much interest to note that Nef[14] obtained closely agreeing results when he oxidized mannose, glucose and fructose with copper hydroxide in the presence of sodium hydroxide, a fact which undoubtedly depended on the close relationship existing between the equilibria in the alkaline solution of each of these carbohydrates. In a recent study of the methods for determining the copper number of glucose, Amick[15] came to the important conclusion that the amount of oxidation is dependent on the alkalinity of the solution.

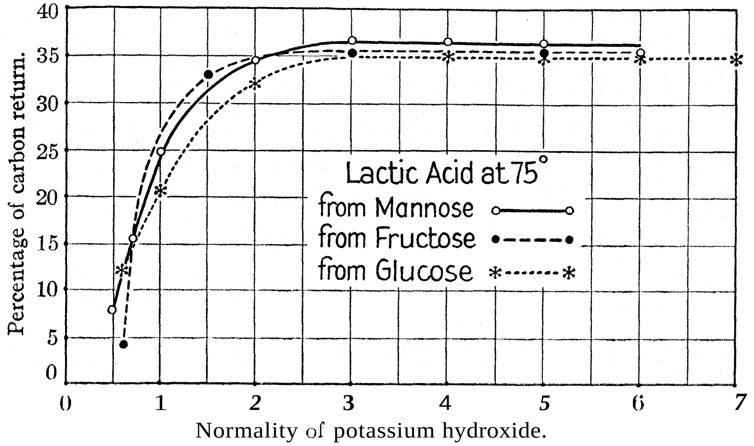

Fig. 11.

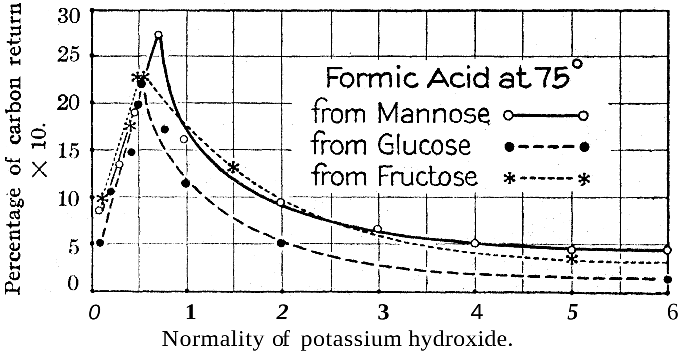

Fig. 12.

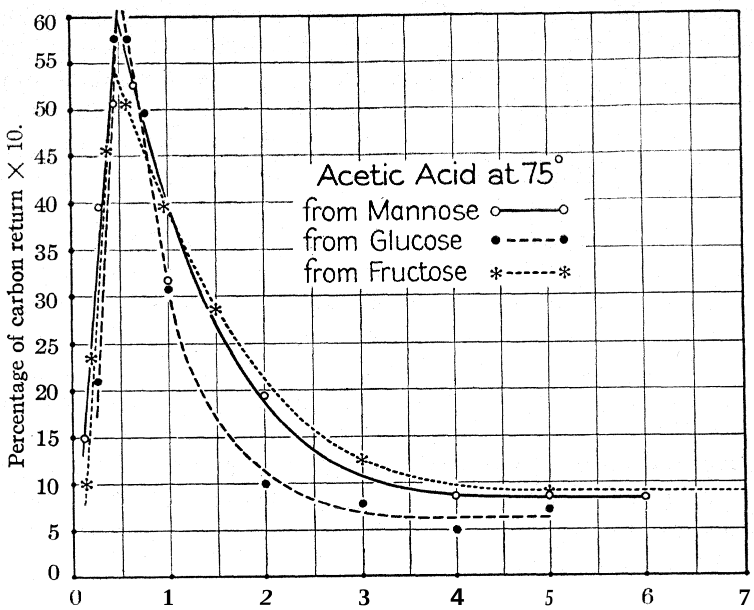
[14] Nef, *Ann.*, 357, 271, 277, 282 (1907).

[15] Amick, *J. Phys Chem* , **31**, 1476 (1927).

Finally, the yields of formic and acetic acids obtained from these three sugars at 75° are shown in Figs. 12 and 13 to be practically the same. Since the amounts of these two acids are relatively small, it has been necessary to multiply our results by 10 in order to show this point. This has magnified the experimental errors of our quantitative methods, which already in themselves have inherent errors. However, the comparison of the data for these two acids at 75° seems to be in complete harmony with the views set forth above with reference to the general condition of the equilibrium existing in alkaline solutions of these three well-known carbohydrates. On the basis of one of the statements above, it may be safely assumed that the relationship of the yields of acetic and formic acids obtained from the other hexose sugars will be approximately the same as that shown here for the mannose–glucose–fructose group.[16]



Normality of potassium hydroxide.

Fig. 13.

Summary

1. The action of aqueous solutions of potassium hydroxide of various concentrations on mannose was studied at 25, 50 and 75° in order to ascertain whether this hexose, like fructose and glucose, reacts in accordance with the suggestion that the alkaline solutions of these well-known carbohydrates contain an equilibrated system which can be disturbed by changes in the experimental conditions, temperature and alkali normality.

[16] Ref. 4, p 2672-2673.

2. The reaction mixtures were examined quantitatively for pyruvic aldelyde, lactic, acetic and formic acids. Changes in temperature and alkali concentration produced changes in the yields of these compounds which were of the same general character as those obtained under exactly the same conditions from fructose and glucose.

3. The interdependence of the reactions producing pyruvic aldehyde, lactic, acetic and formic acids in alkaline solutions of glyceric aldehyde and dihydroxy-acetone is also found to exist between the reactions producing these same products when they are obtained from alkaline solutions of mannose, glucose and fructose under the same experimental conditions. This fact is regarded as evidence for the assumption that the formation of glyceric aldehyde, a fission product of 3,4-hexose enediols, is an intermediate step in the production of these compounds from the hexose sugars. It is predicted that this interdependence will be found to exist in the products of the interaction of aqueous solutions of potassium hydroxide and of all those hexose sugars which are not available for laboratory experimentation at the present time,

4. At the lower temperatures and the lower alkali normalities, the amounts of reaction products obtained from mannose, glucose and fructose are not the same. This is understood on the ground that the equilibria formed in each individual case with the hexose and the alkali are not quantitatively identical.

5. At 75° the amounts of lactic, acetic and formic acids obtained from mannose, glucose and fructose are practically the same in each case. These facts seem to support the view that the equilibrated systems in the alkaline solutions of these hexose sugars are identical at this temperature.

NEW BROMINE SUBSTITUTION PRODUCTS OF VANILLIN AND SOME OF THEIR DERIVATIVES[1]

BY L. CHAS. RAIFORD AND W. C. STOESSER

RECEIVED JUNE 30, 1928 PUBLISHED SEPTEMBER 5, 1928

One purpose of this work was to complete the list of possible bromine substitution products of vanillin and to use these compounds in studying the effect of the ortho substituents of an aldehyde in its reaction with an amino compound. Kauffmann and Franck[2] were unable to convert 2-aminoresorcinoldimethyl ether into either a thiocarbanilide or a benzyli-

---

[1] Condensed from a portion of the thesis submitted by W. C. Stoesser to the faculty of the Graduate College of the State University of Iowa in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Kauffmann and Franck, Brr , 40,3999 (1907)

dene derivative. Sachs and Appenzeller[3] failed to prepare both the oxime and the hydrazone from tetramethyl-2,4-diaminobenzaldehyde. In apparent opposition to this Blanksma[4] condensed 2,4,6-trinitrobenzaldehyde with aniline, but reported no yield, while Lowy and collaborators[5] obtained good yields of benzal derivatives from 2,4-dinitro- and 2,4,6-trinitrobenzaldehydes with various aromatic amines, though they studied no aldehyde containing a substituent other than the nitro radical.[6] These differences suggested further study of the question.

In previous reports[7] from this Laboratory one dibromo and two new monobromo compounds of vanillin were described. Each of these products was characterized by the preparation of several derivatives, especially those obtainable by reaction with amino compounds, but it was recognized that their activities as aldehydes should be studied further. In our previous work retardation due to the presence of ortho substituents was noted in a few cases only, though the work included no instance in which both ortho positions were substituted. It seemed necessary to test that point further because the work on record included too few radicals. Tabular summaries of the present work (see experimental part) will show that when only one ortho position is substituted the hindrance is not noticeable in the cases studied, and that when both are involved the retardation is less pronounced than might have been expected.

A second purpose in this study was to test further the extent to which substituents in the benzene nucleus may determine the positions taken by new groups. When Pschorr and Sumuleanu[8] nitrated acetylvanillin they obtained a 2-nitro derivative; later Raiford and Stoesser[7] found that bromination of the same starting material gives a 6-bromo compound exclusively, which shows that the acetoxy radical directs to the meta position, but to a different one in the instances cited, which suggests that the directive influence of this radical may depend on the specific character of the entering substituent. But in an unsymmetrical structure[9] like vanillin, it is not to be expected that positions 2 and 6 will be equally favored in substitution even by the same entering group. In fact, in a repetition of Pschorr and Sumuleanu's nitration, using a larger amount

[9] The directive influence of the acetoxy radical in symmetrical structures is being studied by Mr. McCormack in this Laboratory.

of starting material, it was found that if the total mass of acetylnitro product is hydrolyzed before an attempt is made to purify it, two compounds may be isolated: 80% of the 2-nitro derivative, m. p. 136°, described by the authors named, and about 5% of another mononitro product, m. p. 212°, which should be the 6-derivative.[10]

A third purpose in this study was to test further the observations of Brady and Dunn[11] that "no evidence of the existence of a second isomeride has been obtained in the case of any of the hydroxybenzaldoximes," but that "certain negative substituents in the benzene ring seem to favor the existence of two isomeric oximes." In the work described below one oxime, probably the *anti* form, was readily obtained from every bromine derivative of vanillin. Attempts to obtain the isomeride by Goldschmidt's[12] method caused the loss of the methyl radical and the formation of the oxime of the corresponding bromoprotocatechuic aldehyde.[13] Treatment of the available forms with gaseous hydrogen chloride for the purpose of transmutation[14] failed also.

Experimental Part

Derivatives of 6-Bromovanillin

Acetate[15] of the Oxime of 6-Bromovanillin.—Ten g. of the oxime[7a] was mixed with 20 cc. of acetic anhydride, allowed to remain for one hour with occasional stirring and the solid filtered off; yield, 98%. Repeated crystallization from benzene gave nearly colorless needles, m. p. 149–151°.[16]

Anal. Subs., 0.2248: 7.79 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_{10}H_{10}O_4NBr$: Br, 27.78. Found: 27.72.

The Oxime of Acetyl-6-bromovanillin.—A mixture of 5 g. of the acetyl derivative, 1.58 g. of hydroxylamine hydrochloride, an equal weight of sodium acetate and 15 cc. of alcohol was refluxed for half an hour. Addition of water precipitated a yield of 89%. Crystallization from alcohol gave colorless needles; m. p. 150–152°. A mixture of this and its isomer, just described, melted between 122 and 130°.

Anal. Subs., 0.2163: 7.43 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{10}H_{10}O_4NBr$: Br, 27.78. Found: 27.48.

Acetate of the Oxime of Acetyl-6-bromovanillin.—Four g. of the acetyl derivative just described and 8 cc. of acetic anhydride were heated to the boiling point and allowed

---

[10] The other one demanded by theory melts at 176° [Bentley, *Am. Chem. J.*, *24*, 173 (1900)] and was proved by Vogel [*Monatsh.*, *20*, 383 (1899)] to have the nitro radical in position 5.

[13] *Anal.* Subs., 0.2111: 9.15 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_7H_6O_3NBr$: Br, 34.48. Found: 34.68.

[14] Luxmore, *J. Chem. Soc.*, *69*, 181 (1896).

[15] The acetyl group has here replaced the hydrogen of the oxime radical.

[16] In about six months this had dropped to 140–141°, which accords with the observations of Janny [*Ber.*, *15*, 2782 (1882)], Gabriel [*Ber.*, 16, 520 (1883)] and Holleman, [*Rec. trav. chim.*, 13, 429 (1894)].

to cool and crystallize. Removal of the solid and treatment of the filtrate with water gave additional product; total yield, **87%.** Recrystallization from alcohol gave colorless diamond-shaped plates; m. p. 153–154". This product was also obtained by warming a mixture of the acetate of the oxime, acetic anhydride and one drop of sulfuric acid until all was dissolved and allowing it to crystallize.

Anal. Subs., **0.2399: 7.25** cc. of **0.1** *N* $AgNO_3$. Calcd. for $C_{12}H_{12}O_5NBr$: Br, 24.24. Found: **24.18.**

3-Methoxy-4-acetoxy-6-bromobenzonitrile.—This was obtained in nearly quantitative yield by boiling **5** g. of the acetate of the oxime with 10 cc. of acetic anhydride for an hour and then adding water. Repeated crystallization from alcohol gave nearly colorless masses that appeared like cotton; m. p. 148–149°.

Anal. Subs ,0 2044: AgBr,0 1422. Calcd for $C_{10}H_8O_3NBr$: Br, 29.63. Found: 29.60.

6-Bromovanillic Acid.—Ten g. of the above-described nitrite and 100 cc. of 6 *N* potassium hydroxide solution were refluxed for three and one-half hours and then acidified with hydrochloric acid; yield, 98%. Repeated crystallization from dilute alcohol gave irregular masses that, after drying at 110°, melted at **190–191°.**

Anal. Subs , 0.2101: AgBr, **0.1595.** Calcd. for $C_8H_7O_4Br$: Br, **32.39.** Found: 32.31.

Dibromo and Tribromovanillin Derivatives

Nitration of **Acetylvanillin.**—One hundred g. of acetylvanillin was rapidly added to **400** g. of fuming nitric acid which was kept between 2 and 6°, and the clear red solution was poured into 1.5 liters of ice and water. **The** product separated as a green oil which solidified after a brief period. When this was hydrolyzed by boiling with potassium hydroxide solution, and the clear but very d&-colored liquid was poured into excess of concentrated hydrochloric acid, a mixture of two nitro compounds was precipitated. Extraction of the dry material with cold alcohol removed 2-nitrovanillin; m. p. 136°. Crystallization of the residue from acetic acid gave vellow plates of the isomeric 6-nitro derivative; m. p. 212°. The latter was analyzed.

Anal. Subs., 0.4834: **31.8** cc. of N_2 at 21° and **730** mm. Calcd. for $C_8H_7O_5N$: **N, 7.11.** Found: **7.3.**

Acetyl-2-nitro-5-bromovanillin—Ten g. of acetyl-5-bromovanillin[17] was added to **40** g. of fuming nitric acid, the mixture held between **25** and 30° and stirred until clear, and the solution then poured into ice and water. The oil which separated at first solidified after a short time; yield, 80%. It was repeatedly crystallized by treatment of its hot benzene solution with ligroin (b. p. 60–70°) and was obtained in nearly colorless granules that became yellow on exposure to light; m. p. **128".**

Anal. Subs, **0.4090, 0.2446: 17.5** cc. of N_2 at 25° and **729** mm.; AgBr, **0.1439.** Calcd. lor $C_{10}H_8O_6NBr$: N, **4.40;** Br, **25.16.** Found: N, **4.7,** Br, **25.04.**

2-Nitro-5-bromovanillin.—This was obtained by hydrolysis of the above-described acetyl derivative and also by bromination of 2-nitrovanillin. Sixty g. of the nitro compound and 1 g. of iodine were added to a solution of **16.5** cc. of bromine in **200** cc. of acetic acid, the mixture warmed until all was dissolved and allowed to stand overnight. When the solution was poured into water the bromine derivative was precipi-

---

[17] This was obtained in 90% yield by slowly adding acetyl chloride to a cold 40% solution of 5-bromovanillin in pyridine, allowing the mixture to stand overnight and then pouring it into an excess of dilute sulfuric acid.

tated in 95% yield. Crystallization from benzene gave nearly colorless prisms, m. p. 150–151°.

Anal. Subs., 0.2326: 8.39 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_8H_6O_5NBr$: Br, 28.99. Found: 28.86.

2-Amino-5-bromovanillin.—Ferrous hydroxide was prepared by treatment of a solution of 300 g. of ferrous sulfate in 1 liter of water with 400 cc. of concentrated ammonia water, and to this hot mixture was slowly added 35 g. of the above-described nitro compound. This was boiled for fifteen minutes, 600 cc. of boiling water was added and the mixture filtered hot. The residue was extracted with hot water and the combined filtrates acidified with dilute sulfuric acid, yield, 96.8%. Crystallization from dilute acetone gave long tan-colored needles; m. p. 139–140°.

Anal. Subs., 0.5598, 0.2498: 29 cc. of N_2 at 22" and 731 mm., 10.17 cc. of 0.1 N $AgNO_3$. Calcd. for $C_8H_8O_3NBr$: N, 5.69; Br, 32.52. Found: N, 5.8; Br, 32.57.

2,5-Dibromovanillin.—A smooth paste was made by mixing 33.1 g. of the above-described finely powdered amino compound, 60 cc. of constant boiling hydrobromic acid and 20 cc. of water. This was cooled below 0°, diazotized by adding 9.5 g. of sodium nitrite in small portions and then 15 g. of cuprous bromide in 60 cc. of hydrobromic acid was poured in. After heating on a water-bath for one and one-half hours, an equal volume of dilute hydrochloric acid (1:1) was added and the dibromo compound filtered out, yield, 79%. Crystallization from acetic acid gave colorless needles, m. p. 189°.

Anal. Subs., 0.2018: AgBr, 0.2454. Calcd. for $C_8H_6O_3Br_2$: Br, 51.61. Found: 51.75.

2,5-Dibromo-3-methoxy-4-acetoxybenzal Diacetate.—Ten g. of the dibromo compound just described was suspended in 20 cc. of acetic anhydride and one drop of concentrated sulfuric acid added. When all of the solid had dissolved, the liquid was warmed gently for about two minutes. Addition of water to decompose excess of anhydride precipitated the diacetate in 97% yield. Repeated crystallization from alcohol gave colorless plates, m. p. 157–158°. After drying at 120° it was analyzed for bromine.

Anal. Subs., 0 3046: 13.38 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_{14}H_{14}O_7Br_2$: Br, 35.24. Found: 35.14.

Hydrolysis of the diacetate with potassium hydroxide solution gave a 98% yield of 2,5-dibromovanillin.

Acetyl-2,5-dibromovanillin.—Ten g. of the dibromo compound, an equal weight of sodium bisulfite[18] and 20 cc. of acetic anhydride were mixed and warmed until the dibromovanillin had dissolved. The bisulfite appeared thus far to be unchanged. Fifty cc. of water was added, the mixture stirred and warmed until nearly all was in solution and then filtered hot. The bisulfite addition product that crystallized on cooling was removed, decomposed by sodium carbonate solution and the acetyl derivative separated; yield 74%. Recrystallization from alcohol gave colorless prisms; m. p. 68–70°.

Anal. Subs., 0.3962: 22.46 cc. of 0.1 N $AgNO_3$. Calcd. for $C_{10}H_8O_4Br_2$: Br, 45.46. Found: 45.35.

This dibromovanillin was further characterized by the study of the derivatives indicated in Table I.

---

[18] Attempts to prepare the acetyl derivative by the usual methods failed to give a pure product. One of the impurities was the benzal diacetate described above. Its formation under the conditions was prevented by the bisulfite.

TABLE IA

DERIVATIVES OF 2,5-DIBROMOVANILLIN

No.	Compound	Solvent	Crystal form	Yield, %
1	*p*-Nitrophenylhydrazone	Dil. pyridine	Yellow needles	99
2	Semicarbazone[a]	Dil. acetic acid	Fine colorless needles	95
3	*bis*-Benzidine[b]	Pyridine	Bright orange granules	..
4	Oxime	Benzene	Nearly colorless needles	97
5	Acetate of oxime	...	Uncrystallizable	93
6	Acetate of acetyloxime	Ligroin (140–150)	Colorless needles	72
7	Acetoxynitrile	Dil. acetic acid	Colorless needles	90
8	Dibromovanillic acid	Acetic acid	Colorless needles	91

[a] Drying over potassium hydroxide under partial pressure at room temperature for several days caused loss of some acetic acid of crystallization. *Anal.* Subs., 0.2300: loss in wt. at 120°, 0.0376. Calcd for 2 moles of $C_2H_4O_2$: 24.64. Found: 16.35.

[b] Product changed color and lost pyridine of crystallization when heated at 120°, but the amount was not determined.

TABLE IB

DERIVATIVES OF 2,5-DIBROMOVANILLIN

No	Formula	M. p., °C.	Subs., g	Cc. of 0.1 *N* $AgNO_3$ or wt of AgBr	Halogen, % Calcd.	Halogen, % Found
1	$C_{14}H_{11}O_4N_3Br_2$	249"	0.2034	0.1717 g.	35.96	35.92
2	$C_9H_9O_3N_3Br_2$	233–234	.3085	16.91 cc.	43.60	43.85
3	$(C_{14}H_{10}O_2NBr_2)_2$	<350	.3089	16.16 cc.	41.67	41.85
4	$C_8H_7O_3NBr_2$	154–155	.1784	0.2071 g.	49.23	49.40
5	$C_{10}H_9O_4NBr_2$	184–185	.3299	18.05 cc.	43.60	43.77

7	$C_{10}H_7O_3NBr_2$	89–90	.2996	17.20 cc.	45.85	45.93
8	$C_8H_6O_4Br_2$	179–180	.3376[b]	20.60 cc.	49.08	48.82

[a] After removal of pyridine of crystallization. **Anal.** Subs., 0.2099: loss in wt. at 120°, 0.0319. Calcd. for 1 mole of C_5H_5N: 15.08. Found: 15.20.

[b] After removal of acetic acid of crystallization. *Anal* Subs., 1.0023: loss in wt. at 120°, 0.1447 Calcd. for 1 mole of $C_2H_4O_2$: 15.54. Found: 14.44.

2-Nitro-6-bromovanillin.—Fifty g. of acetyl-6-bromovanillin[19] was gradually added with stirring to 200 g. of fuming nitric acid which was kept between 0 and 6°. When the clear red solution so obtained was poured into ice and water, the oil that separated became solid on standing, The product was heated with potassium hydroxide solution to remove the acetyl group and the free nitro compound was precipitated in 78% yield by the addition of hydrochloric acid. Repeated crystallization from dilute acetic acid gave cream-colored needles that melted at 168–170°, which seemed to be constant.

Anal. Subs, 0.5231: 18.81 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_8H_6O_5NBr$: Br, 28.99. Found: 28.77.

2-Amino-6-bromovanillin.—The above-described nitro compound was reduced by ferrous hydroxide as previously explained, except that an additional 50 cc. of concentrated ammonia water was added just before filtration. The amino compound was obtained in 94% yield. Recrystallization from alcohol gave yellow needles that shrink at 210° and melt at 217–218°.

---

[19] Ref. 7a, p. 1079

Anal. Subs., **0.5205: 21.16 *cc.*** of 0.1 *N* $AgNO_3$. Calcd. for $C_8H_8O_3NBr$: Br, **32.52.** Found: **32.52.**

2,6-Dibromovanillin.—To a solution containing 30 cc of sulfuric acid and **10** cc. of water, 9.8 g. of the above-described amino compound was added and the mixture stirred into a smooth paste. Four g. of solid sodium nitrite was slowly added with continual stirring, while the temperature was kept between **10** and 15° by standing the container in a cooling bath. Five g. of ice was slowly added to the reaction mixture every fifteen minutes during one and one-fourth hours. This was then poured into a solution containing **9** g. of cuprous bromide in 50 cc. of constant boiling hydrobromic acid, the whole heated for some time on a water-bath, **100 cc.** of hydrochloric acid (1:1) added and the mixture filtered. The yield was **85%.** After purification by extraction with benzene, which left a small portion of insoluble material, repeated crystallization from dilute alcohol gave nearly colorless needles; m. p. **155–156°.** The substance was further identified by study of the derivatives indicated in Table II.

Anal. Subs., **0.3378:** 21.86 cc **of** 0 1 **N** $AgNO_3$. Calcd. for $C_8H_6O_3Br_2$: **Br, 51.61.** Found: **51.77**

TABLE IIA

DERIVATIVES OF 2,6-DIBROMOVANILLIN

No	Compound	Solvent	Crystal form	Yield, %
1	Oxime	Benzene	Colorless needles	73
2	*p*-Bromophenylhydrazone	Dil. acetic acid	Flesh-colored needles	56
3	Semicarbazone[a]	Acetic acid	Colorless needles	73
4	*bis*-Benzidine[b]	Pyridine	Yellowish-brown plates	**74**

[a] Drying under partial vacuum over potassium hydroxide for several hours probably caused loss of some acetic acid of crystallization. **Anal.** Subs., **0.3671:** loss in wt. at 120°, **0.0865.** Calcd. for **2** moles of $C_2H_4O_2$: **24.64.** Found: **23.56.**

[b] ***Anal.*** Subs., **0.4141:** loss in wt., **0.0718.** Calcd. for **2** moles of C_5H_5N: **17 06.** Found: **17.34.**

TABLE IIB

DERIVATIVES OF 2,6-DIBROMOVANILLIN

No	Formula	M p, °C.	Subs, g	0 1 *N* $AgNO_3$, cc	Halogen, % Calcd.	Halogen, % Found
1	$C_8H_7O_3NBr_2$	**144–145**	**0 3618**	**22.26**	**49.23**	**49.22**

[b] After removal of pyridine of crvstallization

2,5,6-Tribromovanillin.—A mixture of **12** g. of 2,6-dibromovanillin, 4 ***g.*** of sodium acetate and 40 cc. of acetic acid was warmed until all was in solution, after which **2** 4 cc. of bromine was added and the liquid allowed to stand for a short time The red color disappeared almost immediately. When water was added a 95% yield of the tribromo compound was precipitated. Crystallization from acetic acid gave fine, colorless needles; m. p. 177–178°. The product was further characterized by the preparation of the derivatives indicated in Table III.

Anal. Subs, 0 3150 **24** 25 cc of 0.1 *N* $AgNO_3$. Calcd. for $C_8H_5O_3Br_3$: Br, 61 70. Found 61.59.

TABLE IIIA

DERIVATIVES OF 2,5,6-TRIBROMOVANILLIN

No	Compound	Solvent	Crystal form	Yield %
1	Oxime	*Iso*butyl alcohol	Small, nearly colorless needles	98
2	*p*-Bromophenylhydrazone	Acetic acid	Almost colorless needles	Quant.
3	Semicarbazone[a]	Dilute pyridine	Almost colorless needles	96
4	*bis*-Benzidine[b]	Pyridine	Brown granules	84

[a] Anal. Subs., 0.3274: loss in wt , 0 0489. Calcd. for 1 mole of C_5H_5N: 15.05. Found: 14 94.

[b] Anal. Subs , 0.3382. loss in wt., 0.0535. Calcd. for 2 moles of C_5H_5N: 14.58 Found: 15.82.

TABLE IIIB

DERIVATIVES OF 2,5,6-TRIBROMOVANILLIN

No	Formula	M. p , °C	Subs , g	0.1 *N* AgNO₃, cc	Halogen. % Calcd.	Halogen. % Found

[a] After heating at 120° to remove pyridine.

Summary and Conclusions

1. Nitration of acetylvanillin as directed by Pschorr and Sumuleanu gives mainly the 2-nitro derivative described by them and a small portion of another nitro compound not hitherto recorded, which probably has the nitro group in Position 6.

3. The list of possible bromine substittition products of vanillin has been completed. Each new one has been characterized by the study of several derivatives.

3. In the reactions which involved the aldehyde radical, the presence of one ortho substituent caused no noticeable hindrance; when both these positions were substituted the yields of products were lower but the effect was less pronounced than expected.

4. The hydroxyl and acetoxyl radicals, respectively, as substituents in a benzene derivative may direct entering groups to different positions. This result may depend, in part, on the chemical character of the entering substituent.

5. In no case was there obtained more than one of the oximes demanded by theory. The one obtained, probably the anti form, could not be transmuted by hydrogen chloride, and an attempt to prepare the isomeride from the 6-bromo compound by the Goldschmidt method caused the loss of the methyl radical and the formation of the oxime of the corresponding protocatechuic aldehyde. Thus far the results agree with Brady and Dunn's observations.

6. Further work is in progress in this Laboratory.
