The preparation of unsymmetrical diphenylethane and other hydrocarbons of the type $CH_3CH(C_6H_4R)_2$ from acetylene and the appropriate aryl hydrocarbons has already been described by Reichert and Nieuwland.[1] The same compounds had been obtained by Fischer[2] by the action of paraldehyde and concentrated sulfuric acid. Toluene, so treated, formed the ditolyl derivative where the methyl is supposed to be para to the ethylidene group. These were made in other ways by Anschütz[3] and Haiss.[4] The place of the entering ethylidene group with respect to the alkyl of the nucleus has never been definitely proved by any of the authors mentioned, although it has been assumed that it is in the para position. Condensation is brought about by passing acetylene into the hydrocarbon in the presence of sulfuric acid and mercuric oxide or mercuric sulfate when a reaction represented by the following equation takes place

$$CH{\equiv}CH + 2C_6H_5R \longrightarrow CH_3CH(C_6H_4R)_2$$

In the present paper this series of compounds has been extended by application of the above reaction to several benzene homologs and to other aryl hydrocarbons. Acetylene gives ethylidene hydrocarbons of the above type with normal and isopropylbenzenes, normal and tertiary butylbenzenes, methyl and ethylphenylmethane, methyl*iso*propylphenylmethane, and tetrahydronaphthalene.

Ethylidene-*bis-tert.*-butylbenzene is a white, crystalline solid. The other ethylidene compounds have the general properties of unsymmetrical diphenylethane. They are viscous, amber colored liquids of high boiling points and are better distilled under reduced pressure. They are non-volatile in steam.

Several multinuclear hydrocarbons were subjected to the action of acetylene but no reaction occurred with triphenylmethane, diphenyl, diphenylmethane or dibenzyl. There seemed to be some connection between the character of the substituents in the benzene ring and the facility with which acetylene reacts. Toluene gave a yield of over 40%; benzene somewhat less of the ethylidene compounds.[1] The xylenes, with practically the same molecular weight as ethylbenzene, gave very much higher yields than the latter, while mesitylene with three substitutions in the ring gave 18 to 20% yields and the propylbenzenes were

found to give less than 10% yields. Of hydrocarbons having about the same molecular weight, the di- and trisubstituted ones reacted with greater ease, probably because of the greater compactness and symmetry of the resulting ethylidene compounds. The formation of ring diethylidene compounds was found to occur to a small extent with diphenylethane and ditolylethane giving dimethylanthracene hydride and tetramethylanthracene hydride. None of the hydrocarbons described here, which were all distilled under reduced pressure, was accompanied by such a product except tetrahydronaphthalene.

Naphthalene resembled most benzene derivatives with unsaturation in the side chain in that it did not react with acetylene. But if one of the rings is saturated as it is in tetrahydronaphthalene, condensation readily occurs, with the formation of ethylidene-*bis*-tetrahydronaphthalene. The tetrahydronaphthalene then showed the same behavior as would have been expected of a dialkyl benzene.

Experimental Part

Ethylidene-*bis*-*n*-propylbenzene was prepared from n-propylbenzene obtained by the Fittig reaction from propyl bromide and bromobenzene. Acetylene was passed into a mixture of 130 g. of n-propylbenzene, 25 g. of concentrated sulfuric acid and 5 g. of mercuric oxide, the mixture being kept below 10°. When three-fourths of the theoretical quantity of acetylene had been absorbed the contents of the flask was neutralized with sodium hydroxide solution and was steam distilled until all the unchanged propylbenzene had come off. The ethylidene compound was extracted with ether from the residue, a plastic, grayish brown solid. The ether was evaporated and the residue distilled under reduced pressure; b. p. 192–194" at 42 mm. Anal. Calcd.: C, 89.7; H, 10.27. Found: C, 89.9; H, 9.8.

The solid referred to above was isolated and dried. It is amorphous and insoluble in water and the common organic solvents. When heated

it decomposed without melting. It seemed, therefore, useless to examine it further for the present.

The other ethylidene compounds were prepared in a similar manner. Ethylidene-*bis-tert.*-butylbenzene was separated from the small amount of an oily impurity accompanying it in the distillate by solution with alcohol in which it was less soluble than the oil. It was recrystallized from 95% alcohol.

The boiling points of the new hydrocarbons prepared are given in the accompanying table.

Summary

1. Ethylidene hydrocarbons of the general formula $CH_3CH(C_6H_4R)_2$ have been prepared from acetylene in the presence of concentrated H_2SO_4 and HgO from the following benzene derivatives: propyl- and *iso*propylbenzenes, n-butylbenzene, *tert.*-butylbenzene, methylethylphenylmethane, methylisopropylphenylmethane, diethylphenylmethane. These are all viscous, amber colored liquids of high boiling points, excepting ethylidene-*bis-tert.*-butylbenzene which is a white crystalline solid.

2. Tetrahydronaphthalene gives with acetylene ethylidene-*bis*-tetrahydronaphthalene and also a six-ringed compound in small quantities.

3. Polynuclear hydrocarbons such, for example, as diphenyl, diphenylmethane, dibenzyl, triphenylmethane and naphthalene do not react with acetylene.

THE CATALYTIC CONDENSATION OF ACETYLENE WITH PHENOLS. II. RESORCINOL

BY S. AQUINAS FLOOD AND J. A. NIEUWLAND

RECEIVED JULY 5, 1928 PUBLISHED SEPTEMBER 5, 1928

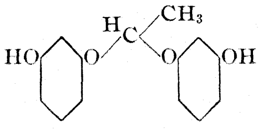
Introduction

In 1923 Wenzke and Nieuwland[1] reported the condensation of acetylene with resorcinol in the presence of sulfuric acid and mercury salts. The product was not separated from the alcoholic reaction mixture until it had undergone a dehydration. This second reaction was induced by diluting with water, whereupon a fine yellow precipitate slowly formed. On oxidation with stannic chloride this precipitate yielded hydroxymethylfluorone (II), indicating that the yellow compound was dihydroxymethylxanthene **(IV).** It was thought desirable, however, to make a more complete study of the reaction in an attempt to secure the primary product in the pure state, and to discover if this reaction resembled other acetylene reactions in giving the same products as acetaldehyde.

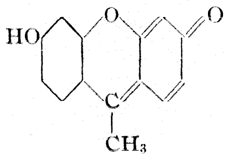
---

[1] Wenzke and Nieuwland, THIS JOURNAL, **46,** 179 (1924).

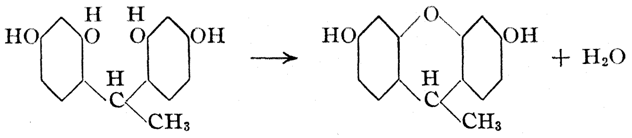
The literature on the reaction of acetaldehyde with resorcinol shows considerable difference of opinion. In 1894 Causse[2] reported the product as being the acetal of resorcinol (I), basing his conclusion largely on analysis and reaction of the diacetate. In the same year Möhlau and Koch[3] stated that resorcinol and aldehyde combined in different proportions at the same time—two moles of resorcinol to one of aldehyde, and two to two (one to one?). The oxidation of the first of these gave hydroxymethylfluorone (II), from which these investigators concluded that the aldehyde residue had been attached to nuclear carbons. Mohlau and Koch came to no conclusion regarding the constitution of the second resorcinol aldehyde compound.



I



II



In 1900 Fosse and Ettlinger[4] attempted to make the acetal of resorcinol by the action of ethylidene chloride on the potassium salt of resorcinol. They found that while their product seemed to be identical with that of Causse, it could not be "saponified" with sulfuric acid as other acetals could be. They concluded that some rearrangement had taken place, that the ethylidene group had become attached to nuclear carbons and that elimination of water had taken place giving dihydroxymethylxanthene (IV). They likewise secured a crystalline acetate which gave practically the same analysis as that of Causse.

Comparison of the products as described and of the methods of procedure shows that while Mohlau and Koch secured a white, microscopically crystalline product from acetaldehyde and resorcinol in aqueous solution acidified with hydrochloric acid, Causse and Fosse and Ettlinger describe their products as being yellow, although the former did the aldehyde condensation in dilute sulfuric acid and the latter heated the ethylidine chloride, aqueous potassium hydroxide and resorcinol in a sealed tube,

Nieuwland[5] used ethyl alcohol acidified with sulfuric acid as a solvent for the resorcinol and aldehyde mixture, which on the addition of water slowly precipitated a yellow substance, identical with that obtained from acetylene reactions.

Many solvents for the acetylene reaction mixture were tried in an effort to secure the primary product in a definitely crystalline form. Methyl alcohol finally was found to give the desired result.

Experimental

Fifty-five grams of resorcinol was dissolved in 400 cc. of methyl alcohol to which the mercury catalyst had been added. After the flask had been tared, washed and dried acetylene was passed in from a gasometer until 13 g. had been absorbed. The solution, originally almost colorless, became reddish brown, while the catalyst darkened and settled on standing. The liquid was decanted from the catalyst and its volume reduced about one-third by evaporation on a water-bath. The flask was tightly stoppered to prevent access of air, cooled and allowed to stand for several hours. In a short time white, needle-like crystals formed in considerable quantity. They were collected on a filter, washed with methyl alcohol and dried at room temperature in the air or in a vacuum desiccator. In some cases it was necessary to recrystallize from hot methyl alcohol in order to remove the last traces of the catalyst. The filtrate and washings were processed a second and a third time, after which they were diluted with water until a slight cloudiness showed and were then allowed to stand. Microscopic yellow crystals slowly precipitated. An average yield was 70 g. of the white compound (83%) and 6 g. of the yellow (10%). These yields are calculated for the formulas given below.

Discussion

Under the procedure described above the large quantity of the white compound seemed to indicate that it was the primary product. It decomposed without melting above 250°. A loss of weight was observed when the air dried crystals were heated in a current of carbon dioxide or under reduced pressure. The loss of weight was found to be constant in various samples between 18.3 and 18.8%. The evolved vapor was condensed and proved to be methyl alcohol. This indicated that alcohol of crystallization was present. Samples dried in a vacuum desiccator showed a lower, and more variable, percentage loss under similar treatment. When fresh, the crystalline product was only moderately soluble in cold alcohol, but very soluble in hot. It dissolved readily in sodium hydroxide solution with deep red coloration. In water, ether, benzene and petroleum ether it showed little solubility. The compound, however, after standing some days, became markedly less soluble even in hot alcohol. Corresponding to this loss of solubility there had been a great increase in molecular weight, as shown by determinations made at intervals of a few days. This change, apparently polymerization, took place even when the sub-

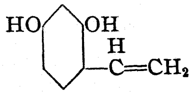
---

[5] Unpublished work, 1925. Read at Organic Section meeting, American Chemical Society at Los Angeles.

stance had been kept in sealed tubes, but was more rapid in the light. The crystals readily crumbled to a powder and if exposed to the air slowly became a yellowish brown. It was necessary to use fresh, air-dried crystals for the determination of the molecular weight as by the time the sample had been perfectly dried it had polymerized to such an extent as to be useless for examination. Samples of the same type were used for combustions.

Anal. Calcd. for $C_8H_8O_2 \cdot CH_3OH$: C, 64.25; H, 7.19. Pound: C, 64.37; H, 6.96. Loss **of weight** on heating. Calcd.: 18.04. Found: 18.3, 18.8 Mcl *wt.* (Ebullioscopic in methyl alcohol). Calcd.: 168. Found: 169.

These results would seem to justify at least a tentative acceptance of formula (V) for this product, vinylresorcinol



V

The polymerization of vinylresorcinol (V) is analogous to the behavior of cinnamic acid, vinylphenol and vinylcatechol, this latter compound never having been secured in the monomolecular form as far as the literature shows.

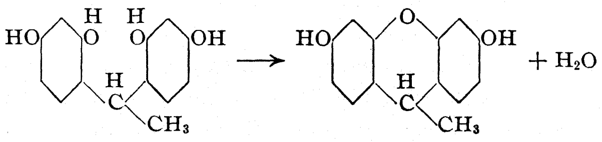
One of the great experimental difficulties encountered in the beginning of this investigation was the readiness with which the reaction mixture solidified to a crumbly, gelatinous mass insoluble in all ordinary solvents. This took place only when an excess of acetylene had been absorbed and was always accompanied by the odor of either dimethyl or diethyl acetal, according to the alcohol used as solvent. It did not occur in the case of other solvents. In order to test the assumption that the formation of this Bakelite-like mass was due to an acetal reaction, acetal was added to an alcoholic solution of resorcinol. No reaction took place until a small quantity of acid had been added, when the action became almost violent, with the formation of a clear, brittle, insoluble Bakelite closely resembling that formed in the acetylene reaction flask.

There is still doubt as to whether the yellow product has been secured in a pure state, free from vinylresorcinol. Its insolubility in water, however, and its oxidation to hydroxymethylfluorone(II) show that dihydroxymethylxanthene (IV) is present at least in considerable proportion. It is readily soluble in alcohol and ether as well as in alkali solutions and shows no tendency to polymerize.

Accordingly, the course of the acetylene-resorcinol condensation would seem to be as follows:

$$HC{\equiv}CH + (HO)_2C_6H_4 \longrightarrow \underset{(V)}{(HO)_2C_6H_3CH{=}CH_2}$$

$$\underset{\text{V}}{(HO)_2C_6H_3CH{=}CH_2} + (HO)_2C_6H_4 \rightleftarrows$$



III IV

This assumes (1) the formation of an intermediate product, ethylidenediresorcinol (III), which has not been isolated, and (2) a reaction between vinylresorcinol (V) and resorcinol. To test this latter assumption, alcoholic solutions of these compounds were mixed. At first practically colorless, the mixture soon turned reddish brown and, on dilution with water, precipitated the yellow compound (IV). Moreover, according to the reaction given above, equilibrium conditions would demand a larger amount of vinylresorcinol (V) in dilute than in concentrated solutions. This, too, was verified experimentally, the more dilute reaction mixtures always giving the higher yield of vinylresorcinol (V).

Derivatives

A. Methyl Ethers.—Attempts have been made to prepare the methyl ethers of vinylresorcinol (V) directly, but have thus far been unsuccessful. In fact, no reaction of vinylresorcinol in basic solution has been entirely satisfactory. It is probable that the base induces some sort of molecular rearrangement which is not reversible, but this point is still being investigated. Consequently the methyl ethers of resorcinol were prepared and their acetylene condensation products investigated.

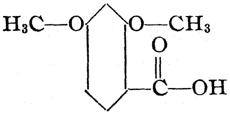
Experimental

One hundred ten grams of resorcinol was dissolved in 500 cc. of methyl alcohol, and then 46 g. of sodium gradually added, the reaction flask being kept under a reflux and frequently agitated. The solution was refluxed on a water-bath for an hour following the addition of the sodium, after which 252 g. of dimethyl sulfate was allowed to drop in slowly from a dropping funnel in the top of the condenser. It was necessary to cool the reaction flask during the addition of the first part of the dimethyl sulfate, and at the end to heat it on a water-bath. After an hour's heating, a sloution of 10 g. of sodium hydroxide was added in order to decompose the dimethyl sulfate completely and the heating was continued for another half hour. The flask was then cooled, the reaction mixture acidified and the methyl alcohol distilled off on a water-bath. Sufficient water to dissolve the salt was then added and the resorcinol ethers were extracted with ether. The ethereal solution was treated with 10% sodium hydroxide solution, which dissolved the monomethyl ether and permitted separation from the dimethyl compound The solvent ether was distilled from the dimethyl ether of resorcinol and this latter distilled. It is a clear, oily liquid boiling at 210°. The caustic solution of the monomethyl ether was acidified, extracted with ether and then treated in the same manner.

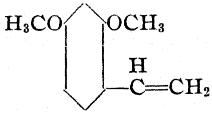
The resorcinol ethers were each dissolved in methyl alcohol and allowed to react with an equimolar quantity of acetylene in presence of the catalyst, as was resorcinol.

From the monomethyl ether only amorphous orange powders have been secured. The variable melting point and the lack of definite crystalline form would seem to indicate that the product is a mixture. Since side chain attachment to nuclear carbons of the monomethyl ether offers considerable opportunity for isomer formation, the condition described above was to have been expected, but not in the case of acetal linkage. moreover, the complete solubility of the product in dilute alkali gave evidence that the hydroxyl group was still free.

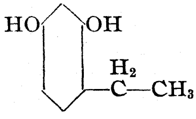
From the dimethyl ether a pale yellow oil boiling with decomposition at 235° was formed. This was oxidized by boiling with dilute nitric acid and also with dilute potassium permanganate. In both cases beautiful monoclinic crystals were formed from a hot water solution. The compound proved to be a monobasic acid melting sharply at 108°. It was identified as the dimethyl ether of β-resorcylic acid (VI); therefore the acetylene condensation product was undoubtedly the dimethyl ether of vinylresorcinol (VII). This is a further corroboration of previous experience that the side chain is attached ortho and para, respectively, to the hydroxyl groups, whether these he free or substituted.



VI



VII



VIII

B. **Ethyl Resorcinol.**—Owing to the slight solubility of vinylresorcinol and to its rapid polymerization, considerable difficulty was experienced in reducing it. The best results were obtained from the use of tin and hydrochloric acid. The product was extracted with ether, which was then evaporated. The residue was recrystallized from boiling benzene in the form of rather large prismatic crystals, melting at 98.5–99°. This product was identified as ethylresorcinol[6] (VIII). Its synthesis from vinylresorcinol is additional evidence of the correctness of the formula assigned to this compound.

C. **Acetate.**—When acetic anhydride in excess was added to vinylresorcinol (V), solution took place accompanied by evolution of heat. On standing, after refluxing about an hour, large rhombic crystals (m. p. 285–286°) slowly formed in the somewhat reddish solution. The product was identical in all respects with that of Causse and Fosse and Ettlinger, while the percentage yield was invariably high. Naturally there is no evidence of free hydroxyls, but in view of the synthesis from vinylresorcinol (V) this cannot be taken as evidence of acetal linkage of the side chain as Causse argues. The empirical formula he assigns to it, $C_{18}H_{18}O_6$, as the diacetate of the acetal (IX), gives the same percentage composition as that of the diacetate of vinylresorcinol (X), $C_{12}H_{12}O_4$, so there is no contradiction from analysis.

$$H_3CCOOC_6H_4\text{—}O\text{—}CH(CH_3)\text{—}O\text{—}C_6H_4\text{—}O\text{—}COCH_3$$

IX

$$(H_3C\text{—}CO\text{—}O)_2{=}C_6H_3CH{=}CH_2$$

X

Aldehyde Condensation

In order to duplicate as nearly as possible the conditions under which vinylresorcinol (V) had been made from acetylene, the aldehyde condensation was tried in methyl alcohol according to the following procedure.

[6] Johnson and Hodge, THIS JOURNAL, 35, **1020** (1913).

Experimental

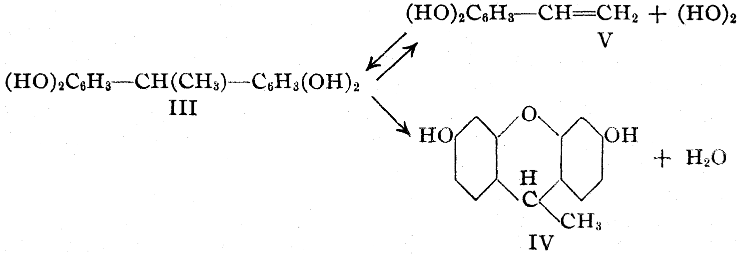
Twelve grams of dry hydrogen chloride was dissolved in 400 cc. of methyl alcohol and 110 g. of resorcinol added; 44 g. of paraldehyde was gradually added to this mixture during the two or three hours it was refluxed on a water-bath. The solution resembled the acetylene reaction mixture in all respects and on partial evaporation a copious precipitate of white, needle-like crystals formed exactly as in the acetylene reaction. Moreover, the filtrate from the third fractional crystallization gave the yellow compound (dihydroxymethylxanthene) on standing after dilution with water. Molecular weight determinations gave results agreeing with those obtained from the acetylene product, while all other properties and reactions of the white product seemed to be identical with those of vinylresorcinol (V).

Attempted oxidations of vinylresorcinol (V) from acetylene or from aldehyde have invariably failed to produce anything which gave even a trace of fluorescence, but the yellow secondary product on heating with stannic chloride gave the highly fluorescent hydroxymethylfluorone (II)

Discussion

There is little doubt but that the condensation of acetylene with resorcinol and the condensation of aldehyde with resorcinol give the same products. However, it is not as clear as to how the aldehyde reaction takes place as it is in the case of the acetylene reaction. The following equation seems the more plausible explanation.

$$2(HO)_2C_6H_4 + CH_3CHO \longrightarrow \underset{\text{III}}{(HO)_2C_6H_3{-}CH(CH_3){-}C_6H_3(OH)_2} + H_2O$$



IV

Schou,[7] however, has recently reported the presence of vinyl alcohol to the extent of $^1/_{830}$ in paraldehyde in the presence of hydrochloric acid and consequently vinylresorcinol may be formed immediately by the reaction of resorcinol with the enolized aldehyde.

Repetitions of Fosse and Ettlinger's ethylidene chloride experiments have been rather unsatisfactory. The reaction was tried in a sealed tube heated to the temperature given by these investigators, and also to much higher temperatures, but in both cases the ethylidene chloride reacted to so small an extent as to make the separation of the small quantity of product almost an impossibility. Yields proved to be equally unsatisfactory when the interacting substances were dissolved in methyl alcohol and refluxed for several hours.

---

[7] Schou, *Compt.* rend., 184, **1452 (1927)**

The probable explanation of the differences of opinion expressed in the literature is that suggested by Mohlau and Koch: that the products reported have been mixtures of the products of condensation in different proportions. In this case derivatives would exhibit different properties according as the reaction with vinylresorcinol (V) or that with ethylidenediresorcinol (III) (dihydroxymethylxanthene (IV)) had predominated.

Summary

1. The primary product of the catalytic condensation of acetylene and resorcinol has been secured in crystalline form and identified as vinylresorcinol (V).
2. The dimethyl ether of vinylresorcinol (VII) has been shown to give the dimethyl ether of β-resorcylic acid on oxidation.
3. Reduction of vinylresorcinol has been effected, the product being ethylresorcinol (VIII).
4. The primary product of the condensation of aldehyde and resorcinol has been shown to be vinylresorcinol (V).
5. The work of previous investigators who showed the presence of dihydroxymethylxanthene (IV) in the products has been corroborated.
6. No evidence whatsoever in support of Causse's acetal formula (I) has been found, but a number of facts which argue against it have been observed.

THE QUANTITATIVE STUDY OF THE PHOTOCHEMICAL ACTIVATION OF STEROLS IN THE CURE OF RICKETS. II

BY STANISLAW-KAZIMIERZ KON, FARRINGTON DANIELS AND HARRY STEENBOCK

RECEIVED JULY 18, 1928 PUBLISHED SEPTEMBER 5, 1928

In an earlier paper from these Laboratories,[1] there were described experiments in which cholesterol was exposed to monochromatic light to determine the minimum number of quanta necessary to secure its antirachitic activation. This work was confined to the use of the 265 m. μ line of the mercury arc. It was followed by an extensive research by Dr. Waldemar Vanselow in which all the important lines of the quartz mercury lamp were studied under a wide variety of conditions.[2] As recent researches from several laboratories have indicated that it is ergosterol rather than cholesterol itself which produces the vitamin D upon irradiation, it seemed desirable to repeat and amplify the experiments, using ergosterol instead of cholesterol.

[1] Fosbinder, Daniels and Steenbock, THIS JOURNAL, **50,923 (1928).**

[2] Unpublished data

Fortunately, in the meantime important improvements have been made in our photochemical technique, so that it is now possible to measure directly the optical absorption as well as the curative effect on animals. In the earlier work an attempt was made to determine the percentage absorption of ultraviolet light by means of a spectrophotometer but the results were too unsatisfactory to publish. By the new technique the percentage absorption was measured directly with a thermopile and galvanometer.

Ergosterol as the Pro-Vitamin

Nearly all of the experimental evidence now available points to the conclusion that ergosterol is the mother substance of vitamin D. Windaus working in collaboratiori with Rosenheim,[3] Hess[4] and Pohl[5] found that ergosterol can be rendered active in much smaller amounts than cholesterol and that it shows exactly the same absorption bands as those considered to be characteristic of the activatable contaminant of ordinary cholesterol. It was found also by these investigators that cholesterol can be freed from the contaminant by various chemical treatments such as bromination and subsequent reduction of the'dibromide, boiling with animal charcoal, treatment with permanganate in acetone and over-irradiation. These results have been commonly interpreted as showing that ergosterol is the mother substance of vitamin D and that it is at present the only substance known to yield an antirachitic substance on irradiation.

A different point of view is held, however, by Bills, Honeywell and MacNair[6] and by Jendrassik and Kenényffi.[7] The former observers reported that highly purified cholesterol is still activatable and concluded that the residual activatability was due to something other than ergosterol. The latter assume an equilibrium between pure cholesterol and pro-vitamin D. Bills, Honeywell and MacNair used cholesterol twice purified by bromination in the laboratory of Windaus as well as cholesterol brominated three times in their laboratory. Cholesterol purified by boiling for three periods of eight hours each with Merck's blood charcoal was used also. All of these preparations after irradiation in the solid state for fifteen minutes gave positive results in feeding tests, but a level of 0.3% of the rachitogenic diet was necessary rather than the 0.01% level used in the case of the ordinary cholesterol. Spectroscopic examination showed that a concentrated solution of the purified cholesterol exhibited three absorption bands identified with ergosterol and two additional ones at 315 and 304 $m\mu$. The ergosterol bands were 150 times weaker after purification but the curative effect was only 30 times weaker.

[6] Bills, Honeywell and MacNair, J. *Biol. Chem.,76,* 251 (1928).

[7] Jendrassik and Kenényffi, *Biochem.* Z., 189,180 *(1927).*

This suggestion that ergosterol is not the only pro-vitamin was so important that it was necessary to put the matter to independent test before continuing with the quantum efficiency tests of the next section on ergosterol. The experiments of Bills and collaborators were repeated using twice brominated cholesterol and cholesterol purified with "Norite" charcoal and with Merck's animal charcoal. Both curative tests and preventive tests were used with several different groups of rats, and although complete cures were not obtained (save in the case of cholesterol purified with Norite of which even 0.06% proved to be active), still there was always a marked lessening of the rachitit condition, confirming the findings of Bills, Honeywell and MacNair.

The results are capable of interpretation in a different way, however. The ergosterol lines were still present in the purified cholesterol of these investigators and the difference between the absorption measurements and the rat tests (150 versus 30) might have been due to the presence of new decomposition compounds absorbing generally in the short ultraviolet, so that the results could still be explained on the assumption that the ergosterol had not been completely removed in the purification. In a recent letter to Nature, Heilbron, Morton and Sexton[8] venture the opinion that the new bands of absorption at 315 and 304 present in the specially purified cholesterol of Bills and co-workers are due to cholesterilene formed in the course of oxidation. We would completely share their opinion inasmuch as a spectrogram taken through 20 cm. of a 10% solution of our inactive cholesterol showed such a heavy absorption below 290 mμ that the presence of various oxidation products absorbing ultraviolet light, but not activatable, cannot be questioned. It must be admitted, as Bills and co-workers point out, that the stability of ergosterol is quite remarkable in the presence of cholesterol and it would be extremely interesting to find the cause of this phenomenon. It is possible that the formation of mixed crystals is effective in this respect.

It was decided to attempt a more drastic purification of cholesterol. Twenty-five grams of commercial cholesterol was dissolved in 437 cc. of boiling acetone and after the addition of 1.25 g. of powdered potassium permanganate, the solution was refluxed for one hour. The manganese dioxide was then filtered off, 1.25 g. of fresh potassium permanganate was added and the solution was refluxed for one hour again and this treatment was repeated five times. The last filtrate was diluted cautiously with water and crystallized at 0°. The crystals were carefully washed with alcohol, taken up in boiling alcohol, filtered through hardened filter paper, the solution was brought to boiling, diluted with water and crystallized; 11.5 g. of snow-white crystals of cholesterol was obtained with a melting point of 147° (uncorr.).

---

[8] Heilbron, Morton and Srxton, *Nature*, **121,452 (1928).**

This material was irradiated, fed and tested as in the preceding experiments, but it was completely inactive, giving no cure and the degree of protection was so small as to be within the limit of experimental error. In the light of these experiments it seems evident that the activatable impurity left in cholesterol after bromination and after boiling with charcoal is ergosterol.

The interesting formation of antirachitic cholesterol derivatives under the action of Floridin[9] described by Bills[10] and MacDonald[11] was also studied. These preparations were made according to the method of Bills and studied in curative and protective experiments. In the protective experiment the animals were evidently stunted. There was almost no growth, though the food intake was sufficient to allow growth at a moderate rate. The development of their bones and especially of the femora and humeri seemed to be out of any proportion to the body weight—in fact the bones would be almost normal for rats of the same age, but twice the weight. The amount of ash was perfectly normal and there was no histological evidence of rickets. The results of the curative test were striking, as they presented much greater variations than is usually encountered when a single preparation is tested on standardized rats. Nearly all of them showed, however, a positive line test. In agreement with Bills and MacDonald it seems certain that the substance formed is different from vitamin D.

Having been convinced that pure cholesterol cannot be rendered antirachitic by ultraviolet irradiation and that ergosterol is at present the only substance known to be specifically activated by radiant energy, a study of the photochemical activation of ergosterol was next undertaken.

Determination of the Quantum Efficiencies

The experimental procedure was similar to that described in the earlier work,[1] but it was markedly improved by the introduction of two new features and the results reported here are more accurate.

Procedure.—The apparatus consisted of a Hilger quartz monochromator and the intensity was measured as before by means of a Coblenz vacuum thermopile and a Leeds and Northrup galvanometer. The commercial quartz mercury vapor lamp was replaced by a water-cooled capillary arc constructed in this Laboratory. A detailed description of this lamp will be published independently. The intensity of isolated lines could be increased ten times by this means over those produced by our previous lamp. A second marked improvement over the original apparatus was obtained by the use of a double absorption cell placed inside of the spectrometer tube immediately in front of the thermopile. It was arranged to slide back and forth on a rack so that either the first cell containing the solvent or the second cell containing the solution of ergosterol could be placed in the path of the light. Each compartment of the cell was 19 mm. long, 1.5

mm. wide and 17 mm high. This arrangement eliminated, completely, errors due to reflection from the windows and absorption by the solvent.

The degree of activation obtained in the different experiments was determined as before by the line test and the amount of calcium deposition was described as negative, positive or very positive. The smallest amount of calcium deposition accepted as a positive test was that corresponding to a condition of the bone described in this Laboratory as indication of a line, provided that the next lower test in the same series showed distinctly less and the next higher distinctly more calcification. If two subsequent members of a series showed the same lowest degree of calcification the one requiring the more energy was taken.

It should be emphasized that although this method is at present the only one which is sufficiently sensitive to detect the exceedingly minute quantities of vitamin D formed, and is far more sensitive than any chemical test, it imposes, nevertheless, limitations on the accuracy of the test. Biological variations are to be expected in all experimental animals, but the rat colony used in these experiments had been so rigorously controlled that the rats may be considered to be as highly standardized as now appears possible.

The ergosterol was prepared by a method similar to that described by Windaus and Grosskopf.[12] The ergosterol was further purified by acetylation, recrystallization of the acetate from glacial acetic acid, saponification and repeated recrystallization from absolute alcohol. The final product melted at 163° (uncorr.). It was beautifully white and crystalline The ergosterol was either irradiated in the dry state back of the slit as in the earlier work, or it was dissolved in optically pure alcohol. It was then placed in one of the compartments of the double cell in front of the thermopile. Two concentrations of the alcoholic ergosterol solution were used: 1/25% and 1/1250%. The results of the experiments carried out on different lines are tabulated below.

Discussion

It will be seen that the threshold value of activation lies for all the lines studied in the neighborhood of 700-1000 ergs (or 10×10^{13}–14×10^{13} quanta). The lower value corresponds to an amount of vitamin D equal to 6×10^{-8} g.

The calculation is similar to that given in the previous paper,[1] and is based on the Einstein law of photochemistry and also on the assumption that vitamin D is the only product formed from ergosterol upon irradiation with monochromatic light. The slight difference in favor of the 256 mμ line when compared with the 293 mμ line is probably not sufficiently marked to be beyond the limits of experimental error. The formation of vitamin

D from ergosterol is thus shown to be independent of the wave length over practically the whole range of selective absorption and to be only a function of the incident energy. The efficiency is also independent of the state in which ergosterol is irradiated for solid ergosterol, a concentrated solution absorbing all the incident rays and a dilute solution absorbing only about 60% of the radiation require all the same number of ergs (or quanta) for activation. When working with crystals it is necessary to use a large excess, otherwise some light passes through the interstices and a lower quantum efficiency is found. For example, 5 mg. of ergosterol placed in the small box used for the purpose (area 70 mm.^{2}) required more than 2500 ergs for activation—calculated on the basis of complete absorption.

In order to determine whether further purification of the light would result in a higher quantum efficiency, a series of irradiations was carried out with one of the slits (between the prism and the double cell) cut down to $^1/_{11}$ of its original width. This change diminished the intensity of the light 3.5 times for the 265 mμ line, but did not alter the quantum efficiency as seen in Table V. A series of irradiations was carried out with ergosterol acetate in $^1/_{25}$% alcoholic solution (prepared in the course of purification of the ergosterol, m. p. 177°, uncorr.) The quantum efficiency is the same as for ergosterol. This fact confirms the statements of other investigators[13] and shows that the hydroxyl group apparently plays no role in the process of activation.

It was thought that some information concerning the mechanism of ac-

---

[13] Rosenheim and Webster, *Lancet*, *II*, 622 (1927); Windaus and Holtz, *Nachr. Ges. Wiss. Göttingen Math.-Phys Klasse*, Heft 2 (1927).

tivation could be gained by exposing ergosterol to intermittent radiation. It was, namely, possible that in the case of one of the stages of the process being a slow reaction the quantum efficiency might be altered by such means. The intermittent irradiation was carried out with a $^1/_{25}\%$ alcoholic solution of ergosterol, wave length 265 $m\mu$. The light was thrown on the cell for the duration of one second at five-second intervals. A photographic camera shutter was used for the purpose. The results are tabulated in Table IV. No change in the quantum efficiency could be detected.

The quantum efficiency of antirachitic activation of ergosterol reported in the present work is smaller than that given in the earlier paper. As already stated the present values are to be considered more accurate and this fact ought not to convey the impression that the activatability of cholesterol is due to a substance having a higher quantum efficiency than ergosterol, A large number of experiments was carried out using various preparations of cholesterol, but lack of space prevents the publication of all of the tables. It is sufficient to say that in no case did we find a higher quantum efficiency than for ergosterol, but for one preparation which had been repeatedly recrystallized and was kept in an ice chest the quantum efficiency was found to be almost the same as for ergosterol, namely 1400 ergs for the 265 line (irradiated in the solid state). Experiments with the original V-1-24 preparation (exposed to air and kept since 1925 at room temperature) showed a lower quantum efficiency—1500 ergs were negative and 5000 distinctly positive. The presence of traces of oxidation products and impurities might easily explain the smaller quantum efficiency of ordinary cholesterol. The chemically purified cholesterols described in the first part of this paper were also exposed in the solid state to monochromatic radiation with the idea that differences in the residual amount of ergosterol present might be detected. These experiments failed in so far as the highest amount of energy used, namely, 200,000 ergs, was insufficient to activate any of them.

Ergosterol was irradiated in a $^1/_{25}\%$ solution in acetone. Acetone shows selective absorption in the same region as ergosterol. The results were negative and energy up to 28,000 ergs was ineffective.

Acetone was used as a solvent also with pure cholesterol with the idea in mind that the energy absorbed by the acetone might possibly be transferred to cholesterol with the formation of vitamin D. A 1% solution of chemically purified cholesterol was used. The results were entirely negative up to 90,000 ergs.

Interesting experiments have been published by Windaus[14] on the sensitization of ergosterol to visible radiation. The products were, however, entirely inactive antirachitically.

---

[14] Windaus and Brunken, *Ann.*, 460, 225 (1928); Windaus and Borgeaud, *Ann.* 460, **235** (1928).

One of us (S.-K. K.) is indebted to the International Health Board of the Rockefeller Foundation for a fellowship during the tenure of which the work here reported was carried out.

Summary

1. Repeated boiling with permanganate in acetone solution removes completely the pro-vitamin from cholesterol. Cholesterol purified in this way and irradiated is inactive antirachitically even in large doses.

2. The photochemical formation of vitamin D from ergosterol under the action of monochromatic light has been studied quantitatively for different lines.

3. The quantity of radiant energy necessary to form an amount of vitamin D sufficient to cause a demonstrable deposition of calcium in the bones of a rachitic rat has been found to be constant over a wide range of radiations, 700–1000 ergs being necessary for the 256, 265, 280 and 293 mμ lines

4. The quantum efficiency was independent of the state in which ergosterol was irradiated, the results being the same for irradiation of the solid or of solutions in alcohol of varying concentration.

5. The quantum efficiency was the same for ergosterol acetate as for ergosterol. The hydroxyl group plays no role in the process of activation.

NEW BOOKS

Crystallographic Tables for the Determination of Minerals. BY VICTOR GOLDSCHMIDT, **Heidelberg, and** SAMUEL G. GORDON, **Philadelphia. Academy of Natural Sciences, Philadelphia,** 1928. **70** pp. **17** × 26 cm. **Price, $1.50.**

In accordance with one of the fundamental principles of crystallography, the angles of every crystallized compound are constant and, except in the cubic system, characteristic of that compound. Angle measurement should accordingly constitute a useful method for the identification of unknown substances. Owing, however, to the existence of freedom of choice as to orientation and as to the unit forms, this method has never come into general use. Previous attempts to arrange crystals in determinative tables have either covered too few compounds or have been too complicated for anyone but the author and his immediate associates to use. In the present publication an effort is made to improve upon existing tabulations (without, however, giving any credit to earlier workers), over a thousand minerals being arranged according to crystal system, with data as to crystallographic constants, composition, specific gravity, hardness and miscellaneous properties.

When any new mineralogic work appears, it is the reviewer's custom, for judging how carefully it has been prepared, to look up at once what composition is given for bornite, boulangerite and chilenite, how "erythrocalcite" is spelled and what specific gravity is assigned to epididymite; for errors, made in these in one of the standard reference works, are usually copied faithfully from one compilation to the next. In the present work three out of five of these errors have been avoided, indicating that more than the average amount of attention has been given to getting the data correct.

The minerals are arranged in these tables, for the most part, in the order of increasing value of some coordinate. Allowance is made for differences in choice of orientation by including the values for several of the orientations possible in each system. No consideration is given, however, to difference in choice of unit forms, so the tables will be most useful to those workers who possess the happy faculty of guessing correctly which forms of a crystal to be identified have been selected as the units by the authors.

EDGAR T. WHERRY

Colloid Symposium Monograph. Papers presented at the Fifth National Symposium on Colloid Chemistry, University of Michigan, June, 1927. Edited by Harry Boyer Weiser, Professor of Chemistry, The Rice Institute. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 394 pp. Illustrated. 16 × 23.5 cm. Price $6.50.

The continued prodigious increase in the extent and variety of our scientific knowledge is, of course, gratifying. To the student of science, however, who is attempting to gain or to maintain a grasp of his subject, this increase is somewhat disconcerting and disheartening. It would be utterly so, were it not that new generalizations and correlations are also being constantly made which, at one stroke, bring whole groups of facts within his comprehension.

Colloid chemistry represents such a generalizing and correlating development in chemistry. It strikes across the whole domain of organic and inorganic chemistry, illuminating many otherwise inexplicable phenomena.

This function of colloid chemistry is particularly apparent in the collection of twenty-four papers read at the Fifth National Symposium on Colloid Chemistry held at the University of Michigan and published in this Monograph. About half of the papers deal with general problems of colloidal chemistry; the others cover applications of colloidal chemistry to the most varied subjects: for instance, to the mechanism by which the kidneys operate, to the coagulation of gelatin, the winter hardiness of insects, the manufacture of photographic film, the eccentricities of molding sand and the nature of Portland cement. It is a useful collection.

One cannot, however, but wonder why this collection is called a monograph.

ARTHUR B. LAMB

Mechanochemistry and the Colloid Mill, Including the Practical Applications of Fine Dispersion. By PIERCE M. TRAVIS, President, Travis Colloid Research Co., Inc. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 191 pp. 17 figs. 16 X 23.5 cm. Price $4.00.

As stated by the author, the book was written in an attempt to help eliminate the guess method in operations that involve the dispersion or deflocculation of substances by mechanical means. The name "Mechanochemistry" was chosen because the subject matter includes a discussion of the principles that underlie such processes, as well as a description of the Colloid Mill and its functions.

The first thirteen chapters are devoted to the usual facts and theories involved in a discussion of the colloidal state of matter, and technical applications are frequently referred to. So much ground is covered in these chapters that the discussion is often necessarily limited; nevertheless, the author's very clear and concise style has permitted the inclusion of a vast amount of valuable information. For the accomplishment of the author's purpose, Chapter XII on the theory of emulsions is worthy of special mention.

While the early chapters, dealing largely with the theoretical side of the question, will be found of very great value to those engaged in technical practice, they are to be highly recommended to the beginner in the study of colloid chemistry.

Chapter XIV is an excellent presentation of the construction and functions of the Colloid Mill. The particular advantages or limitations of the various types for specific purposes are clearly pointed out.

Chapter XV deals with methods and standard practices that may be employed in the testing of colloidal systems. Both the student and the technical chemist will find this chapter very helpful.

ELLWOOD B. SPEAR

Über Konstitution und Zusammenhänge in der Sesquiterpenreihe. (The Constitution and Relationships of the Sesquiterpenes:) BY DR. L. RUZICKA, Professor at the University of Utrecht. Fortschritte der Chemie, Physik und Physikalischen Chemie, Band 19, Heft 5, Serie A. Gebrüder Borntraeger, W 35 Schoneberger ufer 12 a, Berlin, Germany, 1928. iii + 57 pp. 16.5 X 25.5 cm. Price, M 4.80.

In view of the fact that the number of sesquiterpenes discovered in various ethereal oils has increased during the past eight or ten years to over 400, such a résumé as this is timely. No attempt is made to cover the general chemistry of the substances in this field. The author has taken up in particular the reactions leading to a knowledge of the structure of the carbon skeleton of these compounds, the correlation of the various sesquiterpenes, the relationship between the various individuals and the synthesis of a few of the most important ones.

An introductory chapter mentions in brief the work which was accomplished before 1921. The rest of the article comprises, for the most part, a condensation of the author's brilliant researches which have been completed during the past six or seven years. The value for constitutional work of the dehydrogenation method with sulfur has been stressed. A classification and tabulation of the various important groups of sesquiterpenes is included.

For one who may be interested in obtaining a fundamental knowledge of sesquiterpenes from the standpoint of structure, this pamphlet will be invaluable.

ROGER ADAMS

Die Chemie der Zellulose und ihrer Begleiter. (The Chemistry of Cellulose and its Associated Compounds.) By KURT HESS, Member of the Kaiser Wilhelm Institute of Chemistry. Akademische Verlagsgesellschaft m.b.H., Markgrafenstrasse 4, Leipzig C 1, Germany, 1928. xxi + 836 pp. 157 figs. 16 X 23.5 cm. Price, unbound, M 57; bound, **M 59.**

The long expected *magnum* opus from the pen of Professor Hess has finally appeared and will rank for some time to come as the outstanding monograph on the chemistry of cellulose. After a brief introduction and a chapter on the development of the cell wall, the author plunges into a comprehensive review of compounds associated with cellulose, their isolation and analysis, and reactions which throw some light on their possible constitution. Not a little of this long chapter is devoted to lignin and rounds out Fuchs' excellent monograph on lignin by including the very recent and important investigations of Freudenberg, Hagglund, and Herzog.

Subsequently we find a good review of the isolation and purification oi cellulose and its solution and reprecipitation. Here, as we might expect, the cuprammonium solutions are discussed at length, since their polarimetric study first led Hess to the hypothesis that the ultimate cellulose molecule is [$C_6H_{10}O_5$], an hypothesis which he still maintains. Substitution products of cellulose also receive particular attention since Hess' laboratory has systematically studied cellulose esters and ethers, obtaining them in microcrystalline form and determining their molecular weights in various solvents. One of the longest sections in the book is devoted to the degradation of cellulose and here again the work of Hess' laboratory is brought to the fore. An interesting section deals with cellulose acetolysis in which, according to Friese and Hess, cellobiosan acetate is the exclusive product in the earlier stages of the reaction. The final section of Hess' portion of the work is devoted to problems of constitution, in which the author points out experimental methods for determining the possible size of the cellulose molecule. He ends in expressing the hope that researches on the synthesis of glucosans will be forthcoming in the near future.

Professor Hess has been fortunate in his choice of collaborators. Dr. J. R. Katz of the University of Amsterdam has added a thorough and scholarly presentation of the micellar theory and the swelling of cellulose, which is very welcome. A chapter presented historically, on the anisotropy of cellulose, is followed by another which Dr. Katz entitles "Is Cellulose a Crystalline Body?' and which includes detailed x-ray studies on natural fibers and on cellulose derivatives, and a useful supplement on the technique used in this type of work. Subsequently Dr. Katz critically and cautiously discusses various estimates of the size and arrangement of crystallites in cellulose fibers. The final and perhaps the most stimulating part of Dr. Katz' section of the book is devoted to the mechanism of swelling of cellulose, and merits a careful reading by all investigators in the field of cellulose chemistry.

In the very last portion of Dr. Hess' book we find a satisfactory chapter by Dr. R. Haller on the behavior of cotton and artificial cellulose fibers toward dyes.

Some cellulose chemists may take issue with Dr. Hess on certain of his hypotheses and feel that the experimental data presented in their support are quite inadequate. However, these very hypotheses are driving Hess' more cautious colleagues into new and untried fields of investigation, and for this alone he deserves their unstinted praise. He has given them an interesting reference book, the importance of which is beyond question.

LOUIS E. WISE

Fundamentals of Dairy Science. BY ASSOCIATES OF LORE A. ROGERS IN THE RESEARCH LABORATORIES OF THE BUREAU OF DAIRY INDUSTRY, United States Department of Agriculture. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 543 pp. 31 figs. 15.5 × 23.5 cm. Price, $5.50.

This book, it can be safely stated, is the most notable contribution that has been made to the literature of dairy science. It is unique in purpose and plan. It represents the successful accomplishment of a very difficult task. It is eminently satisfactory in filling "a need experienced by advanced students and research workers in the field of dairy science" and in presenting "basic data, fundamental observations and unbiased discussions of researches that contribute to the present status of the dairy industry." It cannot fail in its hope "to stimulate research along lines now lagging, thereby correcting somewhat the lack of balance in our knowledge of the scientific basis of the dairy industry."

In the discussion of milk and milk products, the book, comprising 542 pages, is divided into 4 parts and 15 chapters—(1) the constituents (5 chapters), (2) the physical chemistry (4 chapters), (3) the microbiology (4 chapters) and (4) the nutritional value and the physiology of milk secretion (2 chapters).

Twenty-eight present and former associates of Dr. Rogers contributed to the book. In five chapters there was one writer for each, while in the others the work was divided, two to six writers contributing to each chapter.

A superficial examination without knowing the purposed scope of the book as stated in the preface might lead one to think that some subjects were very inadequately treated as, for example, the composition of milk and milk products, but the book is intended only for those who are already familiar with the elementary facts of dairy science.

When one reads studiously, the impression gains that the editorial committee has shown excellent judgment in compositing the contributions of the different writers for the purpose of unifying the general scheme of the book. To avoid producing an encyclopedia, much restraint must have been exercised by the contributors.

Those interested in dairy chemistry will find a stimulating presentation in the first and second parts, especially the chapters discussing "Acid-Base and Oxidation-Reduction Equilibria of Milk" and "Physical Equilibria of Milk." It is a gratification to find in the chapter on "Metabolism and Growth of Bacteria" more than usual attention given to the chemical reactions taking place in different fermentations.

The reviewer of a book of such exceptional value hesitates to offer any criticism. However, it is his duty to call attention to the erroneous statement on page 211, "The free paracasein in cheddar cheese is soluble in a warm 5 per cent. salt solution, while the paracasein lactate produced by the acid in cottage cheese is insoluble in similar solutions," making reference to Bulletin 261, N. Y. (Geneva) Agr. Exp. Sta., 1905. Later work at the same station annihilated the existence of supposed casein and paracasein lactate (Tech. B. No. 3, 1906), while the substance soluble in warm, dilute solution of sodium chloride was shown in 1012 (Tech. B. No. 26) to be not free paracasein but a compound of paracasein with a minimum amount of calcium.

While the references to literature number over 1300, there are some statements of fundamental facts which are not recognized by proper references.

The book accomplishes an important purpose in revealing how much we do not yet know in the different fields of dairy science. The reviewer, in expressing his own personal gratitude to those who have made possible the preparation of this valuable book, represents the attitude of mind of every one who will have occasion to use it. The dedication of the book to Dr. Rogers in recognition of his twenty-five years of service in his present position is an honor well deserved.

THE EFFECT OF THE POSITION OF SUBSTITUTION ON THE IONIZATION CONSTANTS OF SOME ORGANIC ACIDS

BY D. A. MACINNES

RECEIVED MARCH 14, 1928 PUBLISHED OCTOBER 6, 1928

Since the early work of Ostwald[1] a number of attempts have been made to obtain a definite relation between the ionization constant of a substituted fatty acid and the position, α, β, y, ... of substitution in the carbon chain. Wegscheider,[2] for instance, has given a table of factors by which the constant of an unsubstituted acid may be multiplied to obtain the corresponding constant of a substituted acid. With chlorine substitution, for example, these factors are $\alpha = 90$, $\beta = 6.2$, $\gamma = 2.0$, $\delta = 1.3$. Such factors are, however, admittedly approximate and are entirely empirical. The subject has also been discussed in various papers by Fliirscheim, Michael, Walker, Nelson and Falk, Derick, Simms, and Hixon and Johns.

The following simple relation, which has apparently been overlooked by the writers on the subject, holds for a large number of substituted acids. Briefly, if the logarithm of the ionization constant of each acid is plotted against $1/d$ in which $d = 1$ for the α position, 2 for the β position, etc., remarkably straight lines are obtained for a number of series of substituted acids. For instance, in Fig. 1, the data for the chlorine and hydroxyl substituted acids are plotted as described. The points under consideration are those marked a, β, y and δ corresponding to the equivalent substituted acids: the other points will be discussed later. In this plot the data have been chosen for the longest chain acid for which measurements are available. These straight lines mean, of course, that the data fit an equation of the type

$$\log K_s = C + S\frac{1}{d} \qquad (1)$$

in which K_s is the ionization constant of the substituted acid and C and S are constants. A similar plot, with a slightly greater value for the slope S, is obtained if the data are used for the acids having the substituent

always on the last carbon atom of the chain. Such a series is, for instance, chloro-acetic acid, β-chloropropionic acid, γ-chlorobutyric acid, etc. The agreement is even better in this case than with the long chain series. It appears unlikely that the relation can be accidental. It must have a definite physical origin.

In this connection it is important to recall that if the mutual electric potentials of two charged spheres carrying charges of like sign are plotted as abscissas against the reciprocals of the distances between their centers a straight line is obtained. Thus a system consisting of two like-charged spheres will gain in mutual potential energy, E, by being brought near to each other, according to the relation

$$E = C' \frac{1}{d}$$

the energy E and the constant C' depending on the two charges and the dielectric constant of the space d separating them. It seems, therefore, that it may be more than an analogy that the free energy of ionization, R T log K, is connected with the distance, d, between the carboxyl group and, for instance, a combined chlorine atom by the same function as the energy of a system of two electrical charges is affected by the distance between them.

At an infinite distance, however, the expression for the electrical energy becomes zero, whereas the ionization constant of a long chain acid with the substituent at infinity would have, from Equation 1, an ionization constant

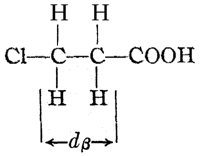
$$\log K_{\infty} = C$$

This is assuming, of course, that the tendencies observed in the change of ionization constants for the first members of the chain would continue without modification for very long chains, which may not be the case.

It might be expected, at first sight, that $\log K_{\infty}$ should be the ionization constant of such an unsubstituted long chain acid. The ionization constant of such an acid is nearly independent of the length of the chain, and varies irregularly between the narrow range 1.4×10^{-5} and 1.6×10^{-5}. The constant C, however, leads to a value of $\log K_{\infty}$ about 65% lower than this for chlorine substitution and about 43% lower for hydroxyl substitution. Though these constants are of the same order of magnitude as the ionization constant of the unsubstituted acid, it is evident that the latter does not fit into the equation or as a point in the plot.

On further consideration, however, it becomes clear that the unsubstituted acid is by no means a member of the series of substituted acids. The attachment of a chlorine or hydroxyl group to the chain can only take place by means of a vigorous chemical reaction or series of reactions, involving the removal of a hydrogen atom and its replacement by another atom or group. That this is attended by a lowering of the total energy of the molecule is shown by the fact that the heat of combustion of the substituted substance is lower than that of the unsubstituted material. It does not seem unreasonable to suppose, therefore, that the primary effect of the halogen or hydroxyl substitution into the molecule is a *lowering* of its free energy of ionization. The second effect is an increase of the ionization constant produced by bringing the negative substituent near to the carboxyl group. According to this point of view $C = \log K_\infty$ is the ionization constant of a hypothetical acid in which the chemical change of substitution has taken place, but in which the substituent is still at a long (theoretically infinite) distance from the carboxyl group. The term $S(1/d)$ is, accordingly, a measure of the potential energy involved in bringing the two negative groups near to each other. In any case, and whatever may prove to be the final interpretation of the physical meaning of the constant C, the effect of change of position of a substituent can, strictly, only be studied with isomeric compounds. Otherwise the results of changes of position of atoms or groups will be confused with the results of chemical reactions.

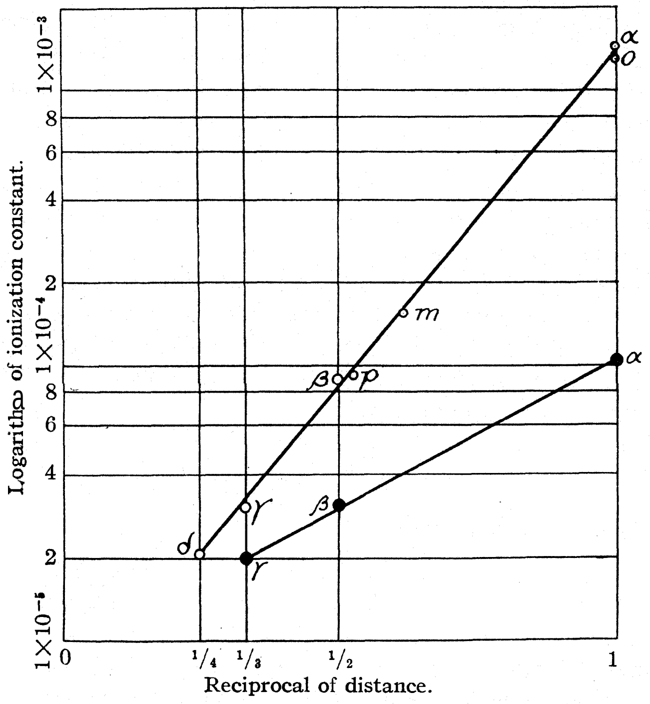
It is of interest to speculate as to the significance of the distance d in terms of atomic dimensions. It is my opinion that it refers to the distance between the polar bond joining the carboxyl to the carbon chain and the polar bond joining the other substituent to the chain, as, for instance, with β-chloropropionic acid



$$\mathrm{Cl{-}\overset{H}{\underset{H}{C}}{-}\overset{H}{\underset{H}{C}}{-}COOH}$$

The movement of a valence electron from a carbon atom to the outer shell of electrons of, for instance, a chlorine atom, probably takes place at such a bond. If the charges involved were situated in the center of the carboxyl carbon and chlorine atoms the series involving d would be $1/(1 + x)$, $1/(2 + x)$, $1/(3 + x)$ (x being the distance between the charges when the two groups are in contact) instead of 1, $^1/_2$, $^1/_3$, . . . as in Fig. 1. Using the available data on the sizes of atoms I have attempted to give values to x, without success. The best agreement with the data is obtained when $x = 0$. The length, d, appears therefore to be the distance between the polar bond joining the carboxyl group to the chain and the polar bond connecting the substituent to the chain, although, if the polar bond is a simple electric dipole, with a constant separation of the charges, the observed relations would not be expected.

Since the simple relation given in Equation 1 applies to the chlorine substituted aliphatic acids, it is important to discover whether the relation also applies to the aromatic series. In this connection it is important to note that o-chlorobenzoic acid and a-chlorobutyric acid have very nearly the same ionization constant. The two values are, respectively, 1.3×10^{-3} and 1.4×10^{-3}. It therefore seems reasonable to suppose that, as a close approximation, the polar bonds of the carboxyl group and of the chlorine atom are the same distance apart in the two molecules. Due to the angular relations imposed on the bonds by the ring structure, this can be nearly true for a flat ring, even though the substituent is on the second carbon atom from the carboxyl group in the ortho acid and on the first carbon atom in the a-substituted acid. With the "puckered" ring structure to be discussed below the bonds can approach still nearer each other. However, if we take the ratios of the o-, m- and p-distances as 1,2 and 3, respectively, we obtain a decided curvature on a plot similar to Fig. 1. More nearly straight lines, which are shown in Fig. 2, are obtained for the chlorine and methyl substituted benzoic acids, if the ratios of the distances across a regular hexagon, through the intervening space for the meta and para position, are used. With a regular hexagon, the ratios for the o-, m- and p-positions become $1 : \sqrt{3} : 2$. Though the plots in Fig. 2 are nearly straight lines, there is, nevertheless, a distinct bend upward in both.



○ = Cl substitution; ● = OH substitution.

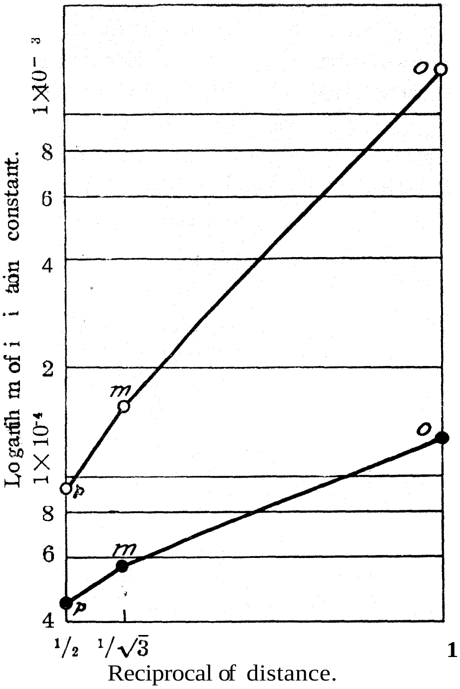
Fig. 1.—Chlorine and hydroxyl substituted acids.

A more probable structure for benzene seems to be, however, a "puckered" ring, that is to say, one in which the carbon atoms, and therefore the bonds to the hydrogen or other radicals, are in two parallel planes each containing three carbon atoms.[3] According to this conception the polar bonds would be at the corners of two equilateral triangles which are at a distance, we will call y, apart. The spacial arrangement is shown in Fig. 3. Considering the radius of a circle in which the triangles can be inscribed as unity the ratios of the *o*-, *m*- and *p*-distances are readily seen, in such a model, to be

$$d_o : d_m : d_p = \sqrt{1 + y^2} \ : \ \sqrt{3} \ : \ \sqrt{4 + y^2}$$

By assuming successive values for the distance y, a value 0.36 was found at which the curves in Fig. 2 become straight lines. This empirical procedure would be of little interest except that, dividing these newly computed ratios by $\sqrt{1 + y^2}$ (so that the ortho distance now equals unity) *the points for the three chlorobenzoic acids fall on the line containing the points for the long chain aliphatic chloro substituted acids.* The resulting points are marked o, *m* and *p* on Fig. 1. The equation

$$\log (K \times 10^5) = -0.30 + 2.44\,(1/d)$$



○ = ClC_6H_4COOH; ■ = $CH_3C_6H_4COOH$.

Fig. 2.

---

[3] Attempts to explain the structure of benzene by positions of electrons led to the arrangement described. See, for instance, Huggins, THIS JOURNAL, 44, **1607** (1922), and 45, **264** **(1923)**; Lewis, "Valence and the Structure of Atoms and Molecules," Chemical Catalog Company, New York, 1923, p. 92; Morse, *Proc. Nat. Acad. Sci.*, **13**, 789 **(1927)**. Nendricks and Bilicke, THIS JOURNAL, 48, 3007 (1926), and Dickinson and Bilicke, *ibid.*, 50, **764** (1928), have arrived, by analysis of x-ray measurements, at a structure for benzene hexabromide having the bromine atoms in two parallel planes each containing three atoms, as in Fig. 3. Victor Henri, *Compt. rend.*, **174**, **809** **(1922)**; *J. Phys. Radium*, **3**, **181–214** (1922), has arrived at the same conclusion as a result of his extensive measurements on absorption spectra. On the other hand, the workers in the field of electric moments of molecules favor a flat molecule for benzene (Smyth and Morgan, THIS JOURNAL, 49, **1030** (1927), and Williams, *ibid.*, 50, **2350** (1928)), although the evidence seems inconclusive.

therefore, holds for both series of acids provided the distances d are computed as just described for the benzene substituted series. It is not impossible that the data are insufficiently accurate to decide between the two structures for the benzene ring, and the computations do not preclude the possibility of other structures. However, it is of interest to note that the data for these ionization constants at present in the literature favor the structure in which the carbon atoms are in two planes, provided, of course, that the underlying assumptions of this paper are accepted.

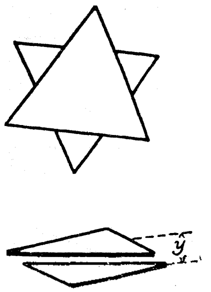


Fig. 3.

Most of the relatively few substituted benzoic acids that have been measured in the o-, m- and *p*-forms show at least fair agreement with the relations observed for the chlorine and methyl substituted acids. An exception, if the present data can be trusted, is the nitrobenzoic series. The hydroxyl acids agree reasonably well with the relation, but there is apparently no connection between the aromatic and aliphatic acids as is found for the chlorine series.

Turning our attention to the bromine and iodine substituted compounds, it has been found that the ortho and meta acids have, very closely, the same ionization constants as the corresponding chlorine compounds. This is shown in Fig. 4 in which the solid line, it will be observed, has the same ordinates and abscissas as in Fig. 1. (The data for the para-iodo and para-bromo acids have not yet been obtained.) With the aliphatic bromine and iodine compounds there seems to be a secondary effect producing systematic deviations from this line. Except for the a-substituted iodo acids, this effect is relatively small, and the solid line is the best that can be drawn through the points. A perceptible effect of the kind may possibly be seen in the slight deviations of the aliphatic chlorine compounds and it increases with the weight or complexity of the halogen atom. This effect may be due to the same cause that produces the other well-known systematic changes in carbon chains.

In these computations it has been assumed that the aliphatic carbon chains are straight, or, at least, that the distance d increases by regular increments as the substituent is moved out on the chain. This would be expected to be the case if the groups at each end strongly repel each other. If, however, a basic group such as NH_2 is substituted in the chain, this group and the carboxyl group can apparently attract each other, producing distorted molecules. Thus a basic group far out on a carbon chain may, by bending, get very near the carboxyl group, resulting in a lowering of the ionization constant and possibly inner salt formation. The ionization constants of amino substituted fatty acids are in fact found to be very small. On the other hand, the effects of substitution by basic groups in benzoic acid follow closely what would be expected from an undeformable benzene ring. The experimental data are particularly uncertain in this field and they are difficult to interpret since the acids are amphoteric and the ionization "constants" change rapidly with dilution. However, plots of the average "constants," as given by Scudder,[4] for amino- and N-methylaminobenzoic acids, give straight lines within the large experimental error when plotted as described above. It is found that the basic groups yield acids which increase with the distance of the substituted group from the carboxyl group. The CH_3NH-group, being probably more strongly basic than the NH_2-group, gives a weaker ortho acid and the effect of removal to the meta and para positions is greater than is the case with the amino group. Both of these effects would be expected from the theory as outlined above.

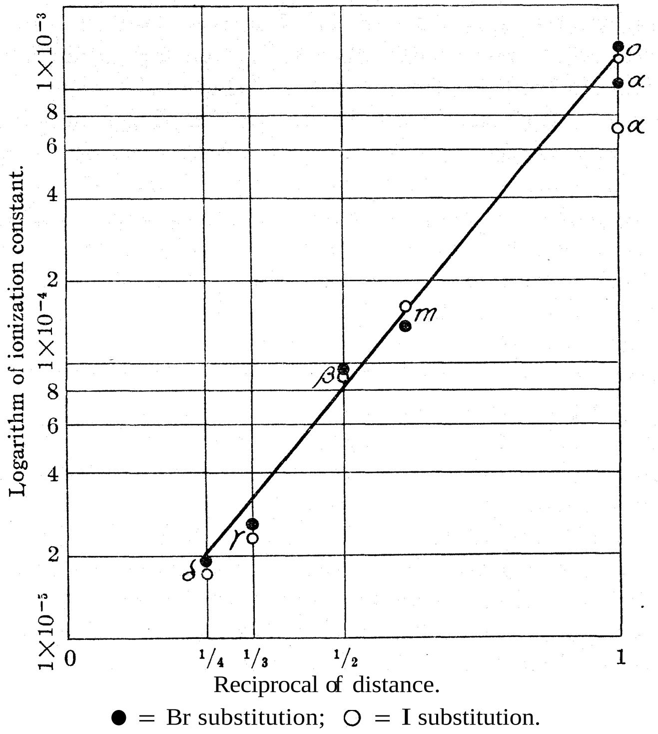

Fig. 4.—Bromine and iodine substituted acids.

It is an interesting fact that the aliphatic and aromatic data fall on the same line when the structure of the aliphatic molecule is such that a straight carbon chain is to be expected. The necessary condition is a strong electronegative group on each end of the chain. With com-

pounds containing a carboxyl and a basic group there is no relation yet evident between the behavior of the aliphatic and aromatic series. The data for the latter fit Equation 1 at least roughly, as has just been stated. The aliphatic compounds, however, have very small ionization constants, which would be expected if bending and a consequent close approach of the positive and negative groups should occur. This appears to be evidence that the benzene ring is a stable system, and that the aliphatic chains are comparatively flexible.

Through the kindness of Dr. E. W. Washburn and Dr. James Kendall I have had access, before publication, to the recomputations of ionization constants made by the latter for the International Critical Tables. In these recomputations the best value for the limiting conductance of the hydrogen ion was used, and the data were otherwise, as far as possible, brought to the same standards for necessary fundamental constants. The plots in this paper were prepared from these recomputed constants which, as a matter of fact, differ but little, on the scale of precision which concerns us here, from those found in the last edition of Landolt and Bornstein. The constants used are all at 25°.

No attempt has been made in this paper to recompute the constants to allow for interionic attraction and ionic activities, as the author has done in a previous paper.[5] In the first place, sufficiently accurate data are not available for the recomputation for any except the few acids dealt with in that paper. Also such computations have shown that the value of a constant found by the older method of computation, for more dilute solutions, is not very different, due to a compensation of two factors, from a corresponding value computed on the newer basis. The latter, however, holds over a far wider range of concentrations even for relatively strong acids. The small difference between the two methods of computation may be illustrated by the constants for o-chlorobenzoic acid. The older method gives 1.28 X 10^{-3} as a limiting value and the newer 1.23 X 10^{-3}, the difference hardly appearing on a plot of the scale of Pig. 1. Provision is, however, already being made to redetermine the conductances of solutions of the chlorine substituted acids in order to obtain constants based on the more modern conceptions.

Brief mention may be made of some of the conclusions reached by others in this field. Derick[6] has proposed a "rule of thirds," which may be stated as follows. If K_u and K,, K_β, K_γ are the ionization constants of the unsubstituted acid and the *a*-, *β*- and y-substituted acids, respectively, Derick finds that

$$\frac{(\log K_u)}{(\log K_\alpha)} - 1 : \frac{(\log K_u)}{(\log K_\beta)} - 1 : \frac{(\log K_u)}{(\log K_\gamma)} - 1 : \ldots. = 1 : \frac{1}{3} : \frac{1}{9} \ldots$$

---

[5] MacInnes, THIS JOURNAL, 48, 2068 (1926).

[6] Derick, *ibid.*, 33, 1152, 1167, 1181 (1911); 34, 74 (1912).

approximately, for several series of substituents. It is difficult to find a physical basis for this observation, especially as the chemical effect of substitution and the effect of shifting the substituent are both included, as has been shown above, when the formula contains K_u. Hixon and Johns[7] have, in an interesting paper, shown that the logarithms of the ionization constants for a large series of substituents can be plotted on smooth curves and expressed as empirical equations, as functions of an arbitrary "electron combining capacity," and also that the effect of the distance along the chain at which substitution takes place can be dealt with according to empirical formulas of the same form.

Summary

The ionization constants K_s of chlorine and hydroxyl substituted aliphatic acids follow the formula

$$\log K_s = C + S\frac{1}{d}$$

in which C and S are constants and $d = 1$ for the a-position, *2* for the β-position, etc. Theoretically this equation would follow if, in the first place, the substituting and carboxyl groups repel each other according to the inverse square of the distance between their polar bonds, and, secondly, the free energy of ionization is increased in proportion to the mutual potential energy of the two groups.

The ionization of the chlorine substituted benzoic acids follows the same formula accurately if the ortho distance is equal to the a-distance and a slightly "puckered ring" structure for the benzene nucleus is assumed.

The constants for bromine and iodine substituted aliphatic acids show small systematic deviations from the equation, although the corresponding aromatic compounds agree with it closely.

PHOTOCHEMICAL OZONIZATION AND ITS RELATION TO THE POLYMERIZATION OF OXYGEN

BY OLIVER R. WULF[1]

RECEIVED MARCH 14, 1928 PUBLISHED OCTOBER 6, 1928

It is a familiar fact that ozone is formed photochemically by irradiating oxygen gas with ultraviolet light. However, the assumption has always been made that this results from the absorption of radiation by the molecule O_2. The researches on photochemical ozonization, combined with related ones on the absorption of light by oxygen, afford evidence that the latter is not always the case, and that, rather, depending on the wave length used, the absorption may be due to another molecule, a polymer of O_2.

Most of our knowledge of this photochemical reaction has been gained through the quantitative researches of Warburg,[2] who studied ozonization at the wave lengths 2070 Å. and 2530 Å. in oxygen gas at high pressures, and measured the photochemical efficiency of ozonization for each of them. At wave length 2070 Å. he found conditions which nearly satisfied the photochemical equivalence equation, approximately two molecules of ozone being formed per quantum absorbed. This was not the case at 2530 Å. He concluded that the quantum corresponding to the former wave length was sufficient to dissociate the molecule 02, and that this process was in reality the primary photochemical act.

The above wave lengths, however, lie to the red of the familiar ultraviolet absorption of oxygen at room temperature and ordinary pressures. The author has recently discussed the absorption of the O_2 molecule in relation to that occurring at 2530 Å. and 2070 Å. in oxygen at high pressure.[3] It does not appear that either of the two known electronic levels in the O_2 molecule can account for the absorption at 2530 Å. nor for the major part of that at 2070 Å. The absorption of oxygen gas at these wave lengths resulting in ozonization is thus evidence for the existence of another molecular species than O_2 in oxygen gas.

A second point directly related to the above is evidence in this same direction. It was originally assumed by Warburg that, in those cases where unit quantum efficiency is found in endothermic photochemical processes, the primary act is the dissociation of the absorbing molecule. The results of recent experiments have borne out Warburg's point of view.[4]

[3] Wulf, *Proc. Nat. Acad. Sci.*, **14**, 609 (1928).

[4] This does not mean necessarily that the longest wave length yielding unit quantum efficiency is a measure of the energy of dissociation of the molecule. In general it may be considerably greater, as discussed for instance in ref. **3.**

Where it has been possible to test this experimentally, it appears to be true, and stoichiometrical considerations make it plausible. Thus we know today that the primary act in the photochemical dissociation of hydrogen bromide and of hydrogen iodide is indeed dissociation of the molecule,[5] and these are classical illustrations, as a result of Warburg's researches,[6] of reactions in which the conditions of the photochemical equivalence equation are apparently met. Yet so far as we now know, neither of the two wave lengths used by Warburg are sufficient to dissociate the molecule O_2, the most probable value for its dissociation energy being 7 volts,[7] corresponding to a quantum of wave length 1751 Å. Here, then, is further indication that there exists in oxygen gas a molecular species other than O_2, which is actually absorbing the light, and for which in the absorption of wave length 2070 Å. the primary act is dissociation of the molecule.[8]

Professor G. N. Lewis[9] has given evidence that there is polymerization in oxygen and from the data on the magnetic susceptibility of oxygen at low temperatures has computed a value for the change in heat content accompanying this polymerization. He concludes that at the temperature of liquid air, or at room temperature and a pressure of several hundred atmospheres, a considerable fraction of the oxygen is in the form of the molecule O_4.

A series of researches on the absorption of light in gaseous oxygen at high pressures and in liquid oxygen bear out this point of view. These have been enumerated, and discussed in part, by the author in the articles mentioned under references 3 and 8. New absorption enters whose character and behavior with changing pressure indicate that it is not due to the molecule O_2. It increases in intensity more nearly as the square of the pressure, rather than directly as the pressure. Its character and position afford evidence that in the region of 2400 Å. the molecule O_4 is undergoing dissociation by the absorption of light into the components O_3 and O. Calculation of the energy of this dissociation supports the point of view; and at the same time a plausible explanation is afforded of the

See Born and Gerlach, *Z physik.*, 5, 433 (1921), and Warburg, *Z. Elektrochem.*, 26, 58 (1920).

[9] Lewis, THIS JOURNAL, 46, 2027 (1924).

results of Warburg's quantum efficiency measurements. The wave length 2530 Å., which is to the red of this limit, would not be expected to give conditions approximating the equivalence equation, as has been discussed above, and indeed Warburg found that it did not, while λ 2070 Å., which is well to the short wave length side of this limit, did give conditions approximating the equivalence equation.

Thus there is evidence that the molecule O_4 is the absorbing molecule in photochemical ozonization at wave lengths 2530 Å. and 2070 Å., and that in the region of 2400 Å. a continuous absorption begins and stretches to shorter wave lengths, representing the dissociation of O_4 molecule into O_3 molecule and oxygen atom.

The behavior of this absorption with changing pressure is further evidence that it is due to the molecule O_4, and affords the possibility of making a quantitative estimate of the degree of polymerization. It is evident that the existence of the equilibrium between O_4 and O_2 gives at once a qualitative explanation of the tendency for this absorption to increase more rapidly than as the first power of the pressure. For low total pressures there would be predicted an increase proportional to the square of the pressure, as was recorded by early investigators. Liveing and Dewar suggested two possible explanations: (1) the existence of the molecule O_4 in equilibrium with O_2; and (2) an alteration of the O_2 spectrum by the influence at high pressures of neighboring molecules on those absorbing. Quantitative absorption measurements made by Warburg will now be considered.

For the two wave lengths 2070 Å. and 2530 Å., Warburg[10] measured the absorption over a range of pressures, in the case of the first wave length extending from 27.5 kg./cm.^{2} to 392.5 kg./cm.^{2}, and both for 95% oxygen and for air. Wave length 2530 Å. lies in the discontinuous spectrum,[3] that is, in the midst of the band progression that precedes the continuous spectrum. The change of the absorption of this wave length with pressure might be complicated by the pressure broadening of the band spectrum. Wave length 2070 Å., however, lies in the continuous spectrum, and the assumption that the absorption due to it is proportional to the number of absorbing molecules will probably be approximately true even to fairly high pressures. Warburg found that the absorption increased more rapidly than the pressure, but somewhat more slowly than the square of the pressure. He believed that there was sufficient evidence against polymerization as a possible explanation; at least this appears to be the case from a previous paper[11] in which he considered this absorption in liquid oxygen. Nernst had pointed out, for instance, that oxygen obeyed Trouton's rule and that this was evidence against the

[10] Warburg, *Berl. Ber.*, 1915, **230.**

[11] Warburg, *Verhandl. deut. physik. Ges.*, *17*, 194 (1915).

opinion[12] that liquid oxygen was appreciably polymerized.[13] Warburg felt rather that this failure of oxygen to obey Beer's law showed that the molecular absorption was influenced by neighboring molecules, an effect which Ångstrom[14] had ascribed to the action of collisions. Warburg treated his results entirely from this point of view.[15]

In view of the considerable amount of evidence pointing to the existence of the polymer O_4, it is our purpose to apply the idea of the polymerization to Warburg's results. Before passing to the calculation of the equilibrium constant, however, it must be mentioned that, as had been noticed by earlier observers, Warburg also found there was a considerable difference between the absorption of the oxygen in compressed air and that in compressed oxygen, the former being approximately two-fold greater than that in 95% oxygen for the same partial pressure. It seems probable, however,

---

[12] See, for example, Hunter, **J.** *Phys. Chem.*, 10, **330** (1906); Dolezalek, *Z. angew. Chem.*, 222,2460 (1909); *Z. physik.* Chem., *71*, 191 (1910).

[13] The argument with regard to Trouton's rule would apply, however, only if the degree of polymerization in the liquid state were considerable and if the change in heat content accompanying depolymerization were large. At the normal boiling point oxygen appears to be about one-quarter polymerized, and Lewis (ref. 9) finds the change in heat content accompanying depolymerization to be 128 calories. The molal heat of vaporization of oxygen at the normal boiling point is 1632 cal. Dana, *Proc.* ***Amer.*** *Acad.*, **60**, 241 (1925).

[14] K. Angstrom, *Arkiv. Mat. Astron.* ***Fysik***, *Bd. 4* (1908).

[15] **A** brief discussion regarding this type of explanation seems necessary. According to it, the molecule acquires the ability to absorb through the influence of impacts by other molecules, this dying away with time after each impact. Thus this absorption depends not only on the number of molecules of this kind present, but also upon the number of times they are struck per unit of time. There is some similarity between such an explanation and the idea of polymerization. It would seem, however, that the new absorption, as it decays with time, might reasonably be expected to change not only in intensity but also in character, reverting toward that of the unstruck molecule. This new absorption in oxygen, while somewhat diffuse, as would be expected of any absorption at high pressures, bears the characteristics of clear-cut molecular absorption. It would seem more in keeping with present ideas to attribute it to some definite molecular species having a definite electronic configuration of its own, and in this way polymerization seems a more acceptable explanation. In long paths of oxygen the new spectrum appears at relatively low pressures and its general form is preserved even into the liquid state. That this absorption is some of the known absorption of O_2 in a displaced or distorted form appears not to be the case. The character of this spectrum has been discussed by the author under reference **3.** There is also a little evidence against the collisional point of view in the observation of Liveing and Dewar that this new absorption of oxygen appeared if anything to be slightly weakened in passing from normal temperature to 100°. The number of impacts per unit of time increases ***as*** the square root of the temperature, and thus, barring other complications, this would lead to ***a*** slight increase in the absorption from the point of view of Warburg's treatment. On the basis of the second suggestion of Liveing and Dewar, which depended on the average proximity of the molecules, no change would be expected, while from the point of view of polymerization one would predict a slight decrease in the O_4 concentration and hence in the absorption.

that the equilibrium $O_4 \rightleftarrows 2O_2$ may be considerably different in a solvent. At the highest pressure used by Warburg the concentration of nitrogen is less only by a factor of six than that of the solvent in water solution. That there is a difference in the amount of O_4 in pure oxygen and in air containing oxygen at the same partial pressure is not out of accord with the idea of polymerization.

Using Warburg's absorption data, the author had calculated the equilibrium constant in terms of partial pressures.[16] However, the assumption upon which the entire calculation rests is that the absorption is proportional to the number of O_4 molecules present. The absorption being thus employed as a measure of concentration (which is not proportional to partial pressure at these high pressures), it is evidently consistent to use units of concentration in the calculation and to express the equilibrium constant as

$$K_\rho = \frac{\rho_2^2}{\rho_4} = \frac{(\rho - \rho_4)^2}{\rho_4} = \frac{16c_2^2}{c_4}$$

where ρ_2, ρ_4 and p are the densities of O_2, O_4 and of the mixture, respectively in grams per cc., and the c's indicate concentrations in moles per cc. In the region where ρ_4 is small compared to ρ_2, one may write as a close approximation

$$\rho_4 = \frac{\rho^2}{K_\rho + 2\rho}$$

but above this, where the degree of association is appreciable, the expression is

$$\rho_4 = \frac{1}{2}\left(K_\rho + 2\rho - \sqrt{K_\rho^2 + 4\rho K_\rho}\right)$$

The absorption observations at the lower pressures are at higher concentrations than the pressure would indicate on the basis of perfect gas behavior, while just the reverse is true concerning the observations at the highest pressure, these being at a lower concentration than the pressure would indicate. Both these facts tend to raise the value of the constant compared with that calculated in terms of partial pressures and as will be seen make a very considerable difference in the final value.

For wave length 2070 Å. Warburg gives at seven different pressures the value of $z = \log_{10} J_0/J$ for 95% oxygen, where J_0 and J are the initial intensity and the intensity after passing through a length d of the gas. Assuming that Beer's law holds for the absorbing molecular species, O_4,

---

[16] Wulf, Yroc. *Nat. Acad. Sci.*, **14**, 356 (1928). Over this range of pressures oxygen shows considerable deviation from the perfect gas law, the pv product passing through a minimum in the vicinity of 150 atmospheres and at 400 atmospheres being appreciably greater than its value at one atmosphere. The calculation was looked upon, however, as an approximate estimation. The result $K_\rho = 531$ atm. or, in other units, $K_\rho = 0.35$ g./cc., appeared not unreasonable, even though this indicated a rather surprisingly large degree of polymerization, considering that assumptions had been made which could be only approximately true.

we may write

$$z = \log_{10}\frac{J_0}{J} = d\cdot\mu_4\cdot c_4\cdot\log_{10} e = \beta\cdot p_4$$

where μ_4 is the molal absorption coefficient of the molecule O_4 for this wave length, and c_4 is the number of moles of O_4 per unit volume. It is evident that values of z for two values of p will afford a determination of K_p and the proportionality factor β.

In the following table the first and fifth columns are taken directly from Warburg's paper. The third and fourth columns give the corresponding pv product and density of the gas mixture which the author has obtained from the available data on the pressure–volume relations in oxygen at 20°.[17] The last column contains the values corresponding to the absorption of pure oxygen.[18] These are plotted in the figure against the corresponding densities of the gas mixture.

TABLE I

RESULTS

Pressure Kg/cm.²	Pressure Atm.	pv pa = 1 at 0° and 1 atm.	Density, g./cc.	z 95% O_2	z 100% O_2
27.5	26.6	1.056	0.0360	0.144	0.154
47.5	46.0	1.043	.0630	.382	.409
67.5	65.3	1.031	.0905	.736	.788
97	93.8	1.017	.132	1.30	1.39
195	188.6	1.014	.266	4.69	5.02
293.5	284.0	1.053	.385	9.84	10.53
392.6	380.0	1.127	.482	13.9	14.87

The curve inserted in the figure corresponds to the equation

$$z = \frac{\beta}{2}\left(K_p + 2p - \sqrt{K_p^2 + 4pK_p}\right)$$

---

[17] Below 100 atm. there are recent data: above this the earlier measurements of Amagat have been used. The nearest temperature at which the latter measurements were made is 15.65°; but those also made by Amagat at 0 and 99 5° showed that above 100 atm. a linear interpolation would be quite justifiable and the values for pv at 100 atm. and above were so determined. These two sets of data do not meet exactly. The discrepancy is not great, however, and in the plotting of the 20" pv–p curve up to 500 atm. a smooth joining of the data has been made. The difference in the value of pv at 100 atm. as given by the two sources of data is only about 1%.

[18] Warburg deduced a formula to convert the absorption of 95% oxygen to the case of pure oxygen. This resulted in a uniform 7% increase at any pressure. Since in treating this work from the viewpoint of the polymerization we apply an equation of different form to Warburg's results than that which he used, it is evidently the experimentally observed absorption which we must consider rather than the equation which Warburg finally arrived at as expressing best his results on the basis of the theory mentioned in footnote 15. But it is advisable to apply the correction to the observed values, since the absorption for pure oxygen will be greater than for 95% oxygen at the same total pressure, and by an amount which is at least approximately given by the 7% correction.

with the values of $K_p = 1.2$ g./cc. and $\beta = \mathbf{133}$ cc./g. The percentage deviations of the observed from the calculated values about cancel one another. It should be noted that there is, however, a tendency for the values of z at low values of p to lie above the computed ones, while at high values of p the reverse is true. The cause of this is not evident. It may be due to deviations from the fundamental assumption of the proportionality between the absorption and the number of molecules of O_4 per unit volume. It may also be due to the fact that a small amount of absorption due to the molecule O_2 is also present at this wave length. If the curve were lowered somewhat in the vicinity of $c = 0.1$, holding the value at $c = 0.4$ as it is, for instance, this would result in an increase in the value of K_p. The reduction of the observations from 95% oxygen to pure oxygen by the factor 1.07 does not greatly affect the result.

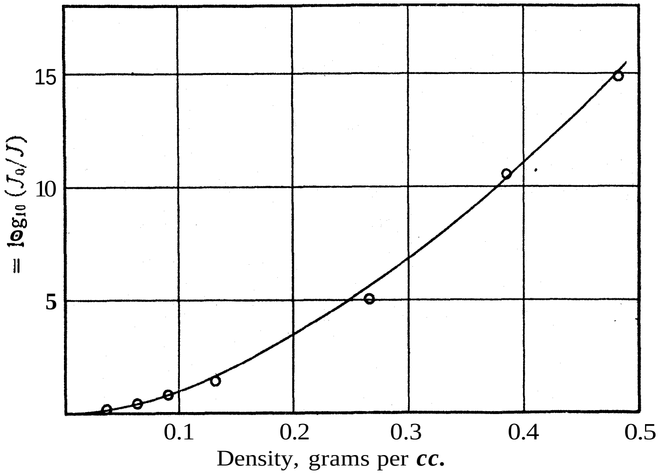

Fig. 1.

The value of the equilibrium constant obtained by Professor Lewis from the magnetic susceptibility measurements of Perrier and Onnes is $K_p = 4$ g./cc. Thus the value obtained in the present work is a little more than three-fold smaller, but the author feels that the agreement is satisfactory considering that assumptions which could only be approximately true have entered into this treatment of the absorption data. It may be that only the order of magnitude of the present result is significant.

The molal absorption coefficient of the molecule O_4 for this wave length may also be estimated. Warburg's values of z given in the table were for a thickness of gas of 1.72 cm. From the above

$$\mu_4 = \frac{\beta\cdot\rho_4}{d\cdot c_4\cdot\log_{10} e} = \frac{\beta\cdot M_4}{d\cdot\log_{10} e} = \frac{133 \times 64}{1.72 \times 0.434} = 1.1 \times 10^4 \text{ cm.}^2 \text{ per } mole$$

It might be suggested that the extent of polymerization indicated above, although small, should make itself evident in the observed pressure–volume relations. A moment's reflection shows that in the absence of any knowledge of the independent behavior of O_2 and O_4, no quantitative conclusions can be drawn. It may be pointed out, however, that the *pv* value for oxygen falls markedly below that for nitrogen, and at high pressures by an amount that is of the order to be expected if the difference is due in a considerable degree to the decrease in the number of molecules. Furthermore, the constant b of the van der Waals equation is smaller for oxygen than for nitrogen, which is suggestive in view of a tendency for this quantity to increase with increasing molecular weight, within a series of molecules built of the same number of atoms. It is not meant to imply that the molecule O_2 should behave at high pressure just as the molecule N_2, but the difference might not be expected to be great and the observed difference is in the direction to be accounted for by the polymerization. It is true that the ratio of pa for nitrogen and oxygen varies very little from 500 atm. to 3000 atm. Yet at these pressures the concentration is no longer even approximately proportional to the pressure and the increase in the total gas concentration will be small, the composition of the mixture changing only slowly in the direction of being richer in O_4. But again, the molecular size determined from viscosity measurements also gives a value for oxygen smaller than for nitrogen, and it is not evident that this should be affected by the polymerization. The paramagnetism of oxygen is undoubtedly also a factor in conditioning its behavior. There appears, at least, to be nothing in the pressure–volume relations inconsistent with the idea of polymerization, while the latter affords a plausible explanation of some points. The present work rests upon the facts of photochemical ozonization in connection with the new absorption of oxygen, which appears in the liquid and in the gas at high pressures and which shows so striking a departure from Beer's law.

This work had its origin in discussion with Professor T. R. Wogness of this Laboratory, and the author gladly acknowledges his indebtedness to him for valuable suggestions.

Summary

The characteristics of photochemical ozonization at wave lengths 2070 Å. and 2530 Å. afford important evidence for the existence of a polymer of the molecule O_2 in oxygen gas.

Related experiments on the absorption of light by oxygen gas at high pressures and in liquid oxygen support this, and indicate that this polymer is the molecule O_4.

Qualitatively, the change of the absorption with the pressure agrees with the idea that the absorption is due to the molecule O_4. Quantita-

tively the data afforded by the absorption measurements of Warburg lead to a value of the equilibrium constant $K_p = 1.2$ g./cc. Probably this is significant only in order of magnitude owing to the approximations entering into the treatment of the data.

THE INFLUENCE OF ACIDS AND BASES ON THE INHIBITORY EFFECT OF GELATIN UPON THE CATALYTIC DECOMPOSITION OF HYDROGEN PEROXIDE BY COLLOIDAL PLATINUM

BY H. V. TARTAR AND N. K. SCHAFFER

RECEIVED MARCH 15, 1928 PUBLISHED OCTOBER 6, 1928

Introduction

Roth Groh[1] and Iredale[2] have stated that the inhibitory effect of protective colloids upon the catalytic decomposition of hydrogen peroxide by colloidal platinum is approximately proportional to their protective properties as measured by Zsigmondy's "gold number." Tartar and Lorah[3] and later Reinders,[4] using proteins as protective colloids, investigated the influence of different degrees of acidity and alkalinity on the "gold number" and concluded that the variation of the protective action was in accordance with the known amphoteric character of the proteins.

The work presented herein is a study of the influence of different degrees of acidity and alkalinity on the inhibitory effect of gelatin upon the catalytic decomposition of hydrogen peroxide by colloidal platinum. It was undertaken in order to determine whether or not under these ,conditions the variation of the inhibitory effect is similar to that of the protective effect, as shown by Zsigmondy's "gold number."

Experimental Part

***(a)* Preparation of Materials.**—The colloidal platinum was prepared by Bredig's arc method using a direct current, 110 volts and 8 amperes. The platinum was dispersed in a solution of 0.001 M potassium hydroxide as a peptizer. After standing for a few weeks in clean Pyrex flasks to permit the larger platinum particles to settle, the sol was carefully decanted and made uniform by mixing. The concentration then determined was 12.5 mg. of platinum per liter.

The gelatin ("Silver Label" brand) was purified and made isoelectric according to the procedure recommended by Loeb[5] and dried *in vacuo* at 65–70'. The gelatin sol used was prepared by adding 0.05 g. of gelatin to 100 cc. of water and heating the mixture

at 50° for four hours to permit the sol to come to "equilibrium."[6] The sol was then diluted to 250 cc. and allowed to cool slowly to 25°. Five cc. of this sol in 100 cc. of the reaction mixture gave a concentration of 0.001% of gelatin. This concentration was used in all experiments. The gelatin sol was used a few hours after its preparation to eliminate any effects due to aging.

The hydrogen peroxide (Merck's) was purified by distillation under reduced pressure.

(b) Method of Procedure.—The reactions were run in uniform, calibrated, 100cc. volumetric flasks, kept in a thermostat at 25°. The desired quantity of platinum sol was pipetted into the fiask and the gelatin, acid, or base added; then the mixture was immediately diluted to 95 cc. and shaken. At this time the flask was placed in the thermostat and after exactly fifteen minutes, 5 cc. of the hydrogen peroxide solution was added, the time observed and the mixture shaken. The initial concentration of the hydrogen peroxide was determined in a separate flask containing none of the catalyst At subsequent intervals 5 cc. of the reaction mixture was pipetted into dilute sulfuric acid and titrated rapidly with potassium permanganate, 0.03 N.

It was found expedient to express the results in terms of the time required for half of the peroxide used to decompose, the half period, since the velocity constant is inversely constant proportional to the time for 50% decomposition.

Although the order of the reaction is uncertain, reaction constants using the unimolecular formula, $K = 1/t \log_{10} (a/(a - x))$, were calculated for a few typical acid and alkali runs with and without gelatin, to afford some idea of the progress of the reactions. The data are given in Table I. With

sulfuric acid without gelatin the value for K fell rapidly, showing that the colloidal platinum quickly became less active as a catalyst. At this same acid concentration in the presence of gelatin, however, the value for K decreased very much more slowly, indicating a stabilizing action of the gelatin. With the alkalies, K increased both in the presence and absence of gelatin.

The hydrogen-ion concentration was determined electrometrically. Very little difficulty was experienced from the presence of the gelatin and the colloidal platinum.

Results and Discussion

(a) Reproducibility.—In general, under carefully controlled conditions the reproducibility of the experimental results was excellent with alkalies, but only fair with acids. It was better with than without gelatin. Preliminary experiments showed that the period during which the platinum sol remained diluted and the time that the acid or alkali was in contact with the platinum, before the addition of hydrogen peroxide, had to be controlled. Immediate dilution of the platinum sol and addition of hydrogen peroxide gave extremely poor results. Bredig and Muller von Berneck[7] have reported like findings in their studies of the catalysis of the decomposition of hydrogen peroxide. It was found that the method given above gave the best results with acids; however, the half period even in this method had to be shortened (by increasing the concentrations of platinum and hydrogen peroxide) to give results of quantitative significance. The smaller the time of the catalysis, the less the time for the action of foreign influences.

Reproducibility of results with acids below a PH of 3.5 equaled that with alkalies; however, from a PH of 3.5 to 8,[8] deviations of 15% or more occasionally occurred. Similar discrepancies have also been noted by Bredig and Ikeda,[9] who in studying the effect of various substances on the hydrogen peroxide catalysis with platinum, report that, "between parallel runs sometimes there occur errors of more than 20 per cent. in the velocity constants, which by no means are accounted for by errors of manipulation; but are explained by very slow changes in the condition of the platinum sol, due to its extremely great sensitiveness toward traces of certain poisons, which cannot be excluded from the air of a large chemical laboratory."

(b) Experiments **with** Acids.—The results are given in Table II and presented graphically in Fig. 1 for acetic, sulfuric and phosphoric acids, respectively. In all these runs, 50 cc. of the platinum sol was used, the concentration in 100 cc. of the reaction mixture being 6.25 mg. of platinum

per liter. The initial concentration of the hydrogen peroxide was 0.076 *N*. The per cent. of inhibition at any *Pa* was calculated by subtracting the half period without gelatin from that with gelatin, dividing the result by the half period without gelatin and multiplying by 100.

○, sulfuric acid. □, phosphoric acid; ×, acetic acid.

Fig. 1.—Influence of acids on the inhibitory effect of gelatin upon the catalytic decomposition of hydrogen peroxide.

Inspection of the curves for the acids shows that in all cases the inhibition increases rapidly to a PH of 3.5 to 4, but beyond this PH it constantly increases with acetic acid, decreases with phosphoric acid and first decreases then increases with sulfuric acid. However, the noteworthy conclusion to be drawn from these results is that the inhibitory effect in the acid range is not completely comparable to the protective effect, for if it were, we should expect the inhibitory effect to increase not at a PH of **3.5** but at 4.7, the isoelectric point of gelatin, as was the case of the "gold number."[3] Apparently the acids affect not only the gelatin but also the catalysis. The different shapes of the curves are perhaps attributable to the specific effects of the acid anions.

(c) Experiments **with** Alkalies.—The experiments with alkalies convincingly disclose a dissimilarity between inhibition and protection. The data are presented in Table III and Fig. 2 for potassium hydroxide, barium hydroxide and sodium hydroxide, respectively. Reinders[4] has shown that the protective effect of gelatin from a PH of 5.5 to 11 is large and constant, whereas it is here shown that the inhibitory effect in the alkaline range is small, variable and even becomes accelerative at certain concentrations. The smallest recorded inhibition in the acid range is even greater than the largest inhibition in the alkaline range. Groh[1] reported less efficient protective action of gelatin in 0.1 N sodium hydroxide than in neutral solution. Rocasolano,[10] studying inhibition, found an increase of catalytic power beyond a certain concentration of sodium protalbinate, which he attributed to its alkaline reaction.

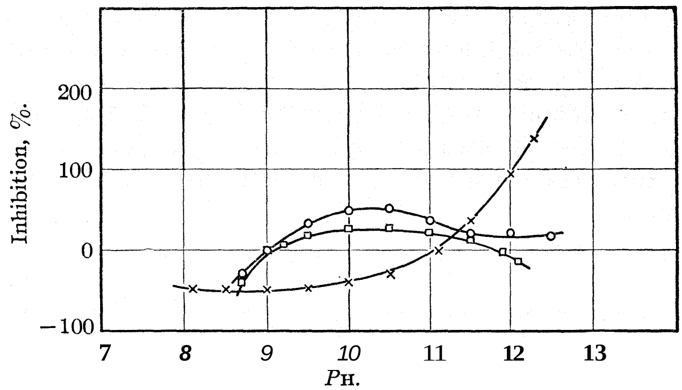
---

[10] Rocasolano, *Compt.* rend., **173,** 41 (1921).

The potassium hydroxide and barium hydroxide curves are very similar, indicating that the hydroxyl ion is the dominant factor in the catalysis. The hydroxyl ion apparently promotes the catalysis by its peptizing action on the platinum and also by directly decomposing the hydrogen peroxide." Since in alkaline solution the reaction is markedly accelerated, a smaller quantity of platinum sol had to be used. With potassium hydroxide and barium hydroxide, 10 cc. of the platinum sol was used, giving a concentration of 1.25 mg. of platinum per liter. The initial concentration of the hydrogen peroxide was 0.075 N. In the runs with sodium hydroxide only 5 cc. of the platinum sol was used, a concentration of 0.625 mg. of platinum per liter. The initial concentration of the hydrogen peroxide was 0.0077 N and titrated with 0.001 N potassium permanganate. The divergencies between the potassum hydroxide and barium hydroxide curves on the one hand and the sodium hydroxide on the other are undoubtedly chiefly due to the different proportions of the materials used. Thus from Fig. 2 barium hydroxide at a *PH* of 9.5 and potassium hydroxide at a PH of 9.6 give per cent. inhibitions of 17.9 and 37.5, respectively, whereas using the concentrations of hydrogen peroxide and platinum as in the sodium hydroxide runs and keeping the *PH* the same, the per cent. inhibitions were found to be —7.9 and —20.9, respectively.



○, potassium hydroxide; □, barium hydroxide; X, sodium hydroxide.

Pig. 2.—Influence of bases on the inhibitory effect of gelatin upon the catalytic decomposition of hydrogen peroxide.

In conclusion the writers wish to point out that the catalysis of hydrogen peroxide by colloidal platinum will be markedly influenced by the extent and character of the platinum surface. Zsigmondy[12] specifies very fully how the gold sol must be prepared for the determination of the "gold

number." In any use of the catalysis by platinum of the decomposition of hydrogen peroxide for the measurement of protective action, there should be a careful standardization of the method.

Summary

1. A study has been made of the influence of different concentrations of acid and alkalies on the inhibitory effect of gelatin upon the catalytic decomposition of hydrogen peroxide by colloidal platinum.

2. In the acid range the variation of the inhibition is evidently a function of the specific effect of the acid anion as well as of the hydrogen-ion concentration.

3. In the alkaline range the variation of the inhibition depends chiefly upon the hydroxyl ion concentration.

4. At any P_H the inhibition depends upon the concentration of the hydrogen peroxide and platinum used.

5. The results indicate that not only the gelatin but also the catalysis itself is influenced by the acids and alkalies; therefore the variation of the inhibitive effect is not similar to the protective effect as shown by the "gold number."

THE EQUILIBRIUM BETWEEN HYDROGEN-CARBON MONOXIDE AND METHANE-CARBON DIOXIDE IN THE CORONA DISCHARGE

BY GERALD L. WENDT AND GREGG M. EVANS

RECEIVED MAY 2, 1928 PUBLISHED OCTOBER 6, 1928

Introduction

The subject of chemical reaction in the electrical discharge has long been of interest. Andrews and Tait,[1] Brodie,[2] Thenard,[3] and Berthelot[4] seem to have been the earliest workers. Since then a large number of investigators[5] have studied various reactions, and many others have worked on

the electrical considerations. In general two types of apparatus have been used: the ozonizer, with the discharge taking place between two concentric cylinders, and the type here used, with the discharge between a central wire and a concentric cylinder. Although both of these have been called by the name of corona, the name having been applied as early as 1872 by Reynolds[6] to the phenomenon on the balls of a static machine, the wire-in-cylinder type corresponds more closely to the corona of the electrical engineer,[7] and will be so called in this paper.

Since the gases are important commercially, and since from at least one side the reaction has been studied catalytically, it seemed worth while to study the effect of the corona discharge upon the reaction, $2H_2 + 2CO = CO_2 + CH_4$. This reaction has accordingly been investigated with emphasis upon the gaseous phase, and this has been found to reach a constant composition from both sides of the reaction. The method of constant pressure has been used to avoid any influence of pressure changes upon the course of the reaction. Since the gas volume continues to contract even after this constant composition is reached, it is evident that some other reaction accompanies or follows the one given, and probably goes to completion.

The Experiments

Gases Used.—Carbon monoxide was generated from sodium formate and concentrated sulfuric acid, stored over saturated brine containing sodium hydroxide, analyzed and transferred as soon as possible to the gas holder. Hydrogen and carbon dioxide were taken from tanks, the former being led over hot copper for removal of oxygen. Natural gas[8] was used for methane. This contained about 0.4% of carbon dioxide and 3.4% of ethane.

Hydrogen and carbon monoxide, or methane and carbon dioxide, whichever pair was being used, were mixed in as nearly equal proportions as possible by means of approximate calibrations on a gas holder of the type suggested by Burrell, Seibert and Jones,[9] but constructed entirely of glass, mercury being used as the confining liquid.

The mixture was analyzed after standing for several hours and the calculated amount of gas added to correct the composition of the mixture to equality in the two constituents. After standing overnight a check analysis was made to determine the final composition of the mixture. Preparing gas mixtures of equal parts was difficult and it was impractical to make corrections to within 1% of the exact amounts. Special efforts were made to exclude oxygen from the mixture because of pronounced effects on the reaction caused by even small quantities of this gas. The mixture was drawn off from this holder with a gas buret, dried over concentrated sulfuric acid in a Hempel gas buret and loaded into the corona tube.

The Corona Tube.—The corona tube is shown in Fig. 1. It was constructed of Pyrex glass, the foundation being a twenty-inch, sealed-in Liebig condenser. To the ends of the inner tube were sealed as shown the 3-way stopcocks for manometer, vacuum and loading connections, and to the lower end the large cylinder D. In this latter was inserted a piston made from a rubber stopper and a jointed rifle cleaning rod, by means of which the volume of the apparatus could be varied. The total length of the main tube was 103.5 cm. The length of the short top segment was 6.5 cm., and its volume 16.7 cc. The length of the tube within the condenser jacket, to which the discharge was confined, was 51 cm. and its diameter 1.15 cm. Its actual volume was **53.8** cc. The distance from the lower end of the jacket to the center of the stopcock B was 8.5 cm. The length of the large cylinder was **37.5** cm. and its internal diameter **2 cm.** The 85cc. calibration mark was slightly below the lower stopcock, and with the piston inserted at its lowest possible point the total volume was 175 cc. The reaction space was then approximately one-third of the total volume. This is small, but experiments showed that diffusion of bromine from the lower end of the tube was practically complete in five minutes; nor could any difference greater than the experimental error be found in the analysis of samples taken from the top of the tube immediately after cessation of the discharge, and the next sample from lower down in the tube. The volume of the tube could be varied from about 83 cc. to the maximum by movement of the piston. The 2mm. capillary connecting the stopcock **A** with the main tube was 4 cm. long and that for C, 8 cm. The manometers were both of 2mm. capillary. The amount of dead space was therefore negligible. The high potential electrode consisted of a platinum wire 0.51 mm. in diameter (B. and S. gage 24), centered in the inner tube and

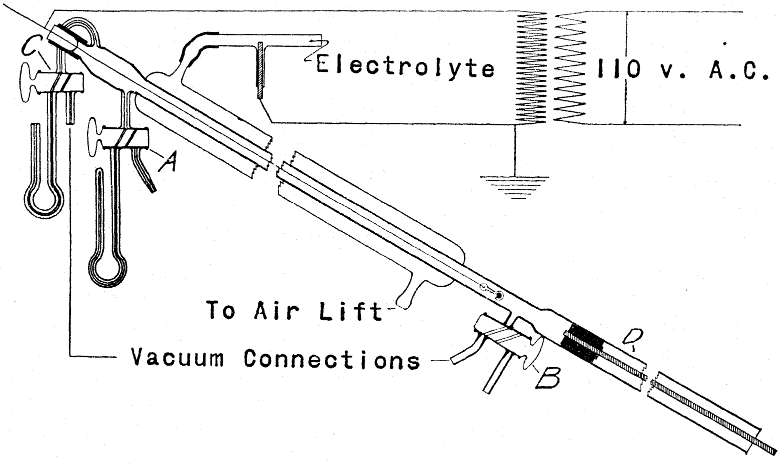

Fig. 1.

fastened at its lower end to a heavy platinum wire hook, which in turn engaged a glass cross bar in the tube about two centimeters above the lower stopcock. At the upper end it was sealed through the lower end of a short cylinder of glass tubing of the same size as the corona tube, a flexible connection for the purpose of centering and putting tension upon the wire being obtained by means of a piece of heavy rubber tubing, wired and shellacked. A cord from the top of the wire was led over a pulley to a weight. A dilute solution of acid was circulated by means of an air lift through the outer jacket and a reservoir set above the tube and served both as the grounded electrode and a cooling medium. A thermometer for measuring the temperature of the electrolyte was inserted at the lower opening of the condenser jacket.

Electrical Equipment.—The power was taken from the 110-volt, 60-cycle lighting circuit, through a Thordarsen transformer with a secondary rating of 20,000 volts. The line voltage was subject to fluctuations of at times as much as 10%, so that it was impossible, even with careful watching of the meters, to keep the input absolutely constant. The primary amperage, the voltage drop across the transformer and the secondary milliamperage were measured by means of appropriate Weston instruments. The secondary voltage was obtained by means of a 10,000 volt Braun electrostatic voltmeter with a series condenser, the effect of the condenser being obtained by means of low voltage measurements with and without the condenser inserted. These measurements are believed to be accurate to within 5%.

Manipulation.—Each time before using the reaction tube was cleaned with boiling dichromate-sulfuric acid cleaning solution, washed with distilled water until the washings no longer tested acid to methyl orange, and dried by means of air which had been run through two wash bottles of concentrated sulfuric acid and a tube filled with glass wool to remove acid spray. To make a run the piston was lubricated with a small amount of paraffin stopcock grease (which did not measurably absorb the gases used) and inserted in the cylinder D to its upper end. The mercury in the open manometer was drawn to the stopcock at C and the stopcock was turned to connect with the vacuum. The open end of B was cbnnected by means of a rubber tube with a leveling bottle of mercury, the mercury raised just to the stopcock and held by turning the cock. The stopcock at A was connected with the vacuum manometer and evacuation begun. A pressure as low as twenty millimeters was ordinarily easily obtainable with the water pump used. The tube was then shut off from the vacuum line and held under vacuum to test for leaks. The gas buret containing the dried mixture was next connected with the opening at A and the gas allowed to enter the tube. The buret was then disconnected and the end of the capillary capped. This evacuation and filling were twice repeated, evacuating once from C and once from B, so as to sweep out as completely as possible all air in the side tubes. After the last filling a second buret-full was drawn in by pulling the piston carefully down to the calibration mark for the desired initial volume. This was ordinarily 160 cc. The stopcock C was then connected with the open manometer, the gases were brought down to atmospheric pressure by momentarily opening A, and the power was turned on. During the run the pressure was kept constant by changing the volume as required by means of the piston. At the end of the run the analytical buret was connected with A and the sample forced out by means of the piston, or by running in the mercury at B, first sweeping out the capillary at A. To get samples of the tube washings a few cubic centimeters of the solvent were drawn in at A and run up and down in the tube by means of the mercury, finally being ejected into a container.

As a milliameter was available only toward the latter part of the work, the runs were made unless otherwise stated with a constant primary current of two amperes. This gave a primary voltage drop of 87 to 88 volts, corresponding to fifteen kilovolts in the secondary circuit, as calibrated. The secondary current increased during an experiment from 6 4 to somewhat over 7.0 milliamperes, depending upon the length of the run.

Analytical Methods.—The Hempel type of gas analysis apparatus was used, as any of the Orsat types suitable for complete analysis were found insufficiently portable for use in this connection. A calibrated 50cc. buret was employed, made from an Exax titration buret, with mercury as the confining liquid. Carbon dioxide was absorbed in potassium hydroxide, oxygen in alkaline pyrogallol, carbon monoxide in ammoniacal cuprous chloride, and hydrogen and methane were determined by combustion over mercury. In the preliminary analyses of the carbon dioxide and methane mixtures the ethane could be determined separately, but in the final analyses both ethane and methane show under methane. In the preliminary analyses of the hydrogen and carbon monoxide mixtures carbon monoxide was more conveniently determined by combustion. No unsaturated compounds beyond the error of the analytical methods could be found, so that after the first ten or fifteen experiments this determination was omitted. The formaldehyde titrations were made with potassium iodide, 0.01 N dichromate and 0.01 *N* thiosulfate solutions.

The Results

The Equilibrium.—The initial expansion due to the "corona pressure," as recorded by former investigators in this field, was evident on closing the switch. This was followed by a slower expansion caused in part by temperature increase. An expansion would be expected when carbon dioxide and methane were used for the starting gases. Actually this lasted for only about twenty-five minutes and a correction for the temperature increase taking place during that time showed that the actual corrected maximum came after fifteen minutes. From then on the gas contracted. When starting with hydrogen and carbon monoxide, and correcting for temperature, an almost linear contraction began at once.

The analyses of a series of runs are shown in Table I and plotted in Fig. 2, No exact analysis of the starting mixture is shown because the runs were made from several mixtures differing slightly in composition. All contained, however, from 48 to 49% of each of the gases used. It will be seen that the same percentage composition of the resulting gas mixture is obtaiaed from both' sides of the reaction. Averaging the results from runs of 180 minutes and longer gives this composition as 13.3% carbon dioxide, 37.1% carbon monoxide 8.7% methane, and 37.6% hydrogen.

Since contraction continued even after attainment of this constant composition, the record of the actual volumes throughout the reaction is also important. In Table II are shown the volumes as actually recorded in the longest run in each part of Table I, and for each gas the number of

cubic centimeters which may be assumed to have been present at the times stated, judged by the analyses of the individual runs stopped at those points. These amounts are plotted in Fig. 3. It will be seen that the amounts of the gases being formed in the reaction reach a maximum and then decrease, the slope of the line finally being the same as-that of the same constituent when starting from the opposite side of the reaction. Due to difference in starting volume and to the initial increase in volume from the carbon dioxide and methane side, they would not be expected to reach the same actual amount. It is evident then, that some other reaction takes place simultaneously with the one we are discussing and causes

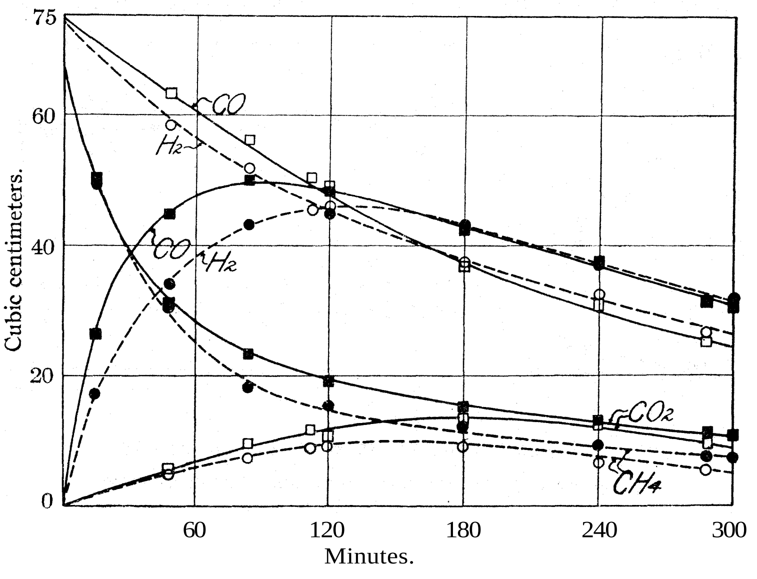
the contraction in volume. This was confirmed by the formation of a solid deposit. It is important that there is no further change in gas composition during this change in volume.



□, ○—from H_2 and CO; ■, ●—from CO_2 and CH_4.

Fig. 3.—Gas volumes during reaction.

The equation for the equilibrium constant for the reaction $2CO + 2H_2 = CO_2 + CH_4$ would be written $K_p = [CO_2]\,[CH_4]/[H_2]^2\,[CO]^2$. Inserting the average percentages given above, the actual value would be $K = (0.133 \times 0.087)/(0.1413 \times 0.1377)$. This gives for the experimental value of the equilibrium constant $K = 0.5946$. Using the equation for the free energy change in this reaction as given by D. F. Smith,[10] A F = --56,950 + 15.07.5 T ln T − 0.01078 T^2 + 0.00000031 T^3 − 30.34 T, and substituting the free energy values calculated therefrom for the temperatures 900 and 950° absolute in the Equation, $\Delta F = -RT \ln K$, we have, $K_{900} = 0.7686$ and $K_{950} = 0.20\%$. The equilibrium point for this reaction reached under the conditions of this investigation would therefore seem to correspond to an absolute temperature of between 900 and 950°. Lunt[5p] and Wendt and Farnsworth[5v] have previously found evidence of a high temperature effect in the corona discharge.

Other reactions are possible from the mixture of gases employed in these experiments, for instance, $3H_2 + CO = CH_4 + H_2O$. All such reactions, however, involve the formation of water. A number of experiments mere made in which a vessel containing phosphorus pentoxide was inserted in the reaction tube, being attached to the piston. In no case did this result in a change in the composition of the equilibrium gas mixture. If water had been a component of the equilibrium its removal in this manner should have had a marked effect on the equilibrium concentrations. The presence of even a small quantity of free oxygen, for instance, entirely altered all the concentrations. The fact that phosphorus pentoxide had no effect indicates that these reactions involving water need not be considered in this equilibrium.

The intensity of the electric discharge influences the rate at which equilibrium is obtained. In order to measure the effect of changes in the corona, runs were made with carbon dioxide and methane with the secondary milliamperage at 6.4, and at 4.0. The first was a two-hour run and the second was run until the volume contracted to that reached by the first. The volume loss in the first run for the last linear part of the time-volume curve was at the rate of 8 cc. per hour, and for the second run, 4.9 cc. per hour. The secondary voltage in the first run was 14,000 and in the second 9700. The reaction velocity seems more nearly proportional to the secondary current than to voltage or volt-amperes. There is, of course, an unknown amount of surface leakage involved but as the milliameter was in the grounded line this was reduced to a minimum. Neither of the analyses differed by more than the experimental error from that for the corresponding two-hour run shown in Table I.

To study the effect of the proportion of the total gas mixture which was actually in the discharge region upon the velocity of the reaction, a run was made with a starting volume of only 82 cc. of carbon dioxide and methane, and run to the maximum volume at fifteen minutes. The final volume was 92 cc., and the composition of the resulting gas mixture was as follows: CO_2, 25.3%; O_2, 0.1%; CO, 24.3%; CH_4, 26.3%; H_2, 19.8%;

[10] D F. Smith, *Ind. Eng Chem.*, **19,** 801 **(1927).**

N_2, 5.2%. This, when compared with the fifteen-minute run in Table I in which 160 cc. was used, shows that the rate of reaction is roughly proportional to the fraction of the total volume exposed to the discharge.

Non-Gaseous Products.—The continued reduction in volume indicated that other products besides the above gases were formed. In fact some of them were visible. In from five to ten minutes from the closing of the electrical circuit brown spots appeared on the central wire, which soon blackened, and by the end of three hours the wire was entirely covered. Location of the original spots seemed to coincide with the position of the negative beads of the discharge. In runs of more than two hours' duration a brown deposit appeared on the inside of the glass tube itself. In preliminary work when aluminum carbide was used as the source of methane, so that hydrogen as well as methane and carbon dioxide were present in the starting mixture, there was evidence of drops of clear liquid on the walls of the glass tube; this was no longer obtained after the use of the natural gas began. Investigation of the brown deposit showed that the greater part of it was carbon suboxide, as it had the properties attributed to that substance by Brodie[2] and Crespi and Lunt[5e] as prepared under slightly different circumstances. In addition, however, the water solution from washing the tube gave a decisive though weak test for aldehyde with Schiff's solution, although the water which had stood in contact with the gaseous phase alone showed only a very faint trace. A slight roughening of the wire due to sputtering was visible after the removal of the deposit.

The Decrease in Volume after Equilibrium.—In order to study the continuous decrease in volume after the composition of the gases had reached equilibrium a number of possibilities were investigated. To determine whether the contraction continues indefinitely or comes to an end while reactive gases are still present, a mixture of methane and carbon dioxide was exposed to the action of the corona for a total of forty-five hours. The discharge was confined to a length of about two and a half centimeters of the upper end of the wire by emptying the jacket of electrolyte and using for a grounded electrode a strip of aluminum foil of the above width wrapped around the tube where the two upper stopcocks are attached. An air blast was used to cool the tube and sweep away ozone. During a run totaling forty-five hours with this small discharge, 170 cc. of gas contracted to less than 17 cc. The last part of the contraction was followed by allowing mercury to flow up into the region inside the condenser, as was done in taking samples for analysis. The stoppage of the reaction was necessitated only by the approach of this mercury, which was, of course, at high potential, to the outer aluminum electrode. The contraction had not up to that time shown any signs of stopping, and probably would have gone to completion had it been possible to continue the experiment. As deposition of solids took place only in the discharge region, such products were in this case thus left within the influence of the corona throughout the run. The deposit on the walls as well as on the wire was black, indicating considerable carbonization of the primary deposit. It was not possible to obtain a sufficiently large sample of gas for an accurate analysis, but it was possible to determine that all four gases of the equilibrium mixture were still present.

The effect of the corona on pure carbon monoxide and on pure methane was tested in order to determine whether either gas alone was responsible. Hydrogen alone could not be responsible, and Wendt and Farnsworth[5v] have investigated carbon dioxide alone and found no such effect. The contraction might have been due to the formation of carbon suboxide according to the equation $4CO = C_3O_2 + CO_2$. Crespi and Lunt[5e] studied this reaction in an ozonizer under constant volume conditions and found that contraction stopped after 225 minutes. Carbon suboxide was the principal solid product. We made a run with pure carbon monoxide and contraction in our case stopped after eight hours, when an original volume of 173 cc. had contracted to 133 cc. The analysis of the gas was as follows: CO_2, 10.7%; O_2, 0.1%; CO, 86.3%; CH_4, 0.0%; total absorbed, 97.1%. The deposit on the walls of the tube was similar in appearance and properties to the deposit formed on the glass during the regular reaction, but was lighter in color, indicating that while the deposit in the regular reaction was principally carbon suboxide, some carbonization had taken place. This reaction of carbon monoxide alone, therefore, could not account for the continued contraction, both because the deposit appeared to be different and because contraction did not continue indefinitely.

A run was made with methane alone in the tube, but in this case, also, equilibrium was reached, indicated by a stoppage of expansion when an original volume of 80 cc. had expanded to 88 cc. The composition of the final gas was as follows: CO_2, 0.0%; unsaturated compounds, 0.5%; O_2, 0.5%; CO, 0.8%; CH_4, 38.4%; H_2, 57.2%; total absorbed, 97.4%. The deposit on the tube in this case took the form of droplets of viscous liquid, probably polymerization products similar to those found by Lind and Glockler[11] in their experiments with ethane in electrical discharges. The action of methane alone thus fails to explain the large contraction taking place in the experiments with gas mixtures.

Since no single constituent accounts for the contraction, those reactions which give condensed products deserved further study. Two possible reactions which might cause a complete contraction without affecting the proportions of the four gases present at equilibrium are, $H_2 + CO = HCHO$, and $H_2 + CO = C + H_2O$. Schiff's solution, as mentioned above, showed the presence of aldehyde, but a titration with thiosulfate, potassium iodide and potassium dichromate of a solution of the deposit from a five-hour run

---

[11] Lind and Glockler, Preprint No. 6, *Trans. Am. Electrochem. Soc.*, Sept. 22, 1927.

reduced only half a cubic centimeter of the 0.01 N dichromate, an amount hardly above the error of the method. Contardi[12] has shown that polymers of formaldehyde which would be insoluble in water are not stable in the electrical discharge. It is evident, then, that the influence of the formaldehyde reaction is small.

To study the possibility that the formation of carbon and water is involved, an attempt was made to produce the reaction $2C + 2H_2O = 2H_2 + 2CO = CO_2 + CH_4$, by depositing carbon on the wire from methane and running the discharge with the tube filled with steam. We were unable to keep the discharge region sufficiently hot to prevent condensation of the steam, even though boiling salt solution was used in the jacket; the vacuum so created caused air leakage through the melted stopcock grease and only a trace of methane was found.

The calculation of the carbon, hydrogen and oxygen balances in the remaining gaseous constituents during the course of the contraction gives an indication of the nature of the volume loss and the fate of the gaseous materials apparently lost. Table III shows a balance of the gaseous constituents at the beginning and end of the long runs in Table I. Inasmuch as these losses appear to be very close to the proportions in CH_2O, or C and H_2O, and the amount of formaldehyde formed has been found to be very small, carbon and water seem the most probable end products of the reaction under these conditions. Losanitsch and Jovitschitsch[50] state that their final product from hydrogen and carbon monoxide in the ozonizer at seventy volts was glycolaldehyde. Due to the higher voltage used in this investigation and the greater current density at the small diameter

wire electrode, different results might well be expected from those obtained in the ozonizer type apparatus at the low voltage. It is interesting to note, however, that in glycolaldehyde, as well as in formaldehyde and with carbon plus water, the ratio of carbon, hydrogen and oxygen is the same, namely, $C_nH_{2n}O_n$, and that this is the same as the ratio in either pair of starting gases, hydrogen and carbon monoxide, or methane and carbon dioxide. Hence the contraction and condensation do not change this ratio. The fact that the removal of water during the reaction by means of phosphorus pentoxide does not change the equilibrium concentrations indicates that water can take part only in this final reaction, whereby all gaseous constituents are removed in the form of carbon and water, a reaction which is under the experimental conditions apparently irreversible.

Summary

The reaction $2CO + 2H_2 = CO_2 + CH_4$ has been studied under the conditions existing in a corona discharge. The reaction reaches an equilibrium when approached from either side in which the composition is 13.3% carbon dioxide, 37.1% carbon monoxide, 8.7% methane, and 37.6% hydrogen. This equilibrium would under purely thermal conditions correspond to an absolute temperature of 900 to 950°. The gas volume continues to contract after the equilibrium is reached and the most probable end products are carbon and water according to the equation $CO + H_2 = C + H_2O$.

OXIDATION-REDUCTION POTENTIALS OF THE PENTACYANO-FERROATES

BY DAVID DAVIDSON[1]

RECEIVED MAY 7, 1928 PUBLISHED OCTOBER 6, 1928

Baudisch and his coworkers[2] have shown that sodium pentacyano-aquo-ferroate[3] (I) and sodium pentacyano-ammine-ferroate[4] (II) may act as catalysts in the oxidation of pyrimidines, purines and hydantoins by means of oxygen or air. The present paper deals with the oxidation-reduction potentials of mixtures of the ferrous and ferric forms of these salts as well as of sodium pentacyano-nitrito-ferroate[3] (III) as compared with the ferrocyanide (IV) electrode.

Previous investigators[5] have found that the potential of the ferrocyanide electrode depends on the concentration of potassium ions. For a given solution of potassium chloride, however, the potential of the electrode followed the equation

$$\text{E.m.f.} = E_0' - RT/F \ln C_o/C_i$$

C_o and C_i were the total concentrations of the ferrous and ferric salt, respectively. $C_o + C_i$ was small compared with [KCl].

$$\left[\begin{array}{ccc} \mathrm{CN} & & \mathrm{H_2O} \\ & \mathrm{II} & \\ \mathrm{CN} & \mathrm{Fe} & \mathrm{CN} \\ \mathrm{CN} & & \mathrm{CN} \end{array}\right] \mathrm{Na_3} \qquad \left[\begin{array}{ccc} \mathrm{CN} & & \mathrm{NH_3} \\ & \mathrm{II} & \\ \mathrm{CN} & \mathrm{Fe} & \mathrm{CN} \\ \mathrm{CN} & & \mathrm{CN} \end{array}\right] \mathrm{Na_3}$$

$$\left[\begin{array}{ccc} \mathrm{CN} & & \mathrm{NO_2} \\ & \mathrm{II} & \\ \mathrm{CN} & \mathrm{Fe} & \mathrm{CN} \\ \mathrm{CN} & & \mathrm{CN} \end{array}\right] \mathrm{Na_4} \qquad \left[\begin{array}{ccc} \mathrm{CN} & & \mathrm{CN} \\ & \mathrm{II} & \\ \mathrm{CN} & \mathrm{Fe} & \mathrm{CN} \\ \mathrm{CN} & & \mathrm{CN} \end{array}\right] \mathrm{K_4}$$

III IV

Similar results have been obtained with the molybdo- and tungstocyanides.[6] The preliminary study was therefore limited to solutions of the iron salts in normal potassium chloride.

Apparatus and Methods

The electrode vessel consisted of a glass cup of 75 cc. capacity, fitted with a rubber stopper which bore a dropping funnel, nitrogen inlet, gold plated platinum electrode, salt bridge containing *N* KCl, 5 cc. buret (when employed) and a mechanical stirrer equipped with mercury seal and driven by an air turbine. The second leg of the salt bridge was placed in a beaker containing *N* KCl, into which a normal calomel electrode dipped. Weighed quantities of the salts were placed in the cup, the stopper was affixed and the air rinsed out with nitrogen. Fifty cc. of N KCl was placed in the dropping funnel. By properly regulating the nitrogen pressure and opening the cock of the dropping funnel, the potassium chloride solution could be de-aerated just before use. Finally the solution was allowed to run into the cup, stirring was begun and readings were taken at intervals. The potentiometer used was a Leeds and Northrop Student Type with a needle galvanometer. The measurements were carried out at room temperature (21°).

The solutions studied were prepared by dissolving a total of 0.2 millimole of the two salts in 50 cc. of N KCl. Usually three ratios of ferrous to ferric salt were measured: (a) 0.15 ferrous + 0.05 ferric (3:1); (b) 0.10 ferrous + 0.10 ferric (1:1); (c) 0.05 ferrous + 0.15 ferric (1:3).

Potassium Ferrocyanide

The apparatus and method were checked by measuring the ferrocyanide electrode. The potentials given in Table I remained constant during the twenty minutes they were observed.

TABLE I

POTENTIALS OF THE FERROCYANIDE ELECTRODE

Soln.	*N* KCl cc.	Ferrous, millimole	Ferric, millimole	E m f.	E m.f. $- E_0'$ Pound	Calcd.
(a)	50	0.15	0.05	0 171	−0.029	−0.028
(b)	50	.10	.10	.198	..	..
(c)	50	.05	.15	.225	.027	.028

The value of 0.198 volt is practically identical with that obtained by Butler and Davies,[5f] the difference in temperature being allowed for.

Sodium **Pentacyano-Ammine-Ferroate**

Solutions containing ferrous and ferric "ammine" salt gave potentials which varied with time as shown in Fig. 1. Moreover, at no time was the difference between the potentials of solutions (b) and (a) or of (b) and (c) equal to the value of 0.028 volt calculated from the electrochemical equation given above. It was constantly greater. Thus, for example, ten minutes after the solutions were prepared, (b) − (a) = 0.040 volt and (c) − (b) = 0.041 volt. Since this anomalous behavior of the electrode could be attributed to the hydrolysis of the "ammine" salts[3]

$$Na_3Fe(CN)_5{\cdot}NH_3 + H_2O \rightleftharpoons Na_3Fe(CN)_5{\cdot}H_2O + NH_3$$
$$Na_2Fe(CN)_5{\cdot}NH_3 + H_2O \rightleftharpoons Na_2Fe(CN)_5{\cdot}H_2O + NH_3$$

a second series of measurements was made in which the solvent contained 0.5 cc. of concentrated ammonia, the total volume and normality in potassium chloride being maintained by using the proper quantities of *N* and 2*N* potassium chloride.

As is seen from Fig. 2, this had the effect of stabilizing the potentials except in solution (c), in which case, apparently, reduction of the ferric salt by the added ammonia caused a gradual fall in the potential, which fall became uniform after five minutes. The extrapolation indicated in the figure yielded a value which harmonized with those of (a) and (b) which are given in Table II.

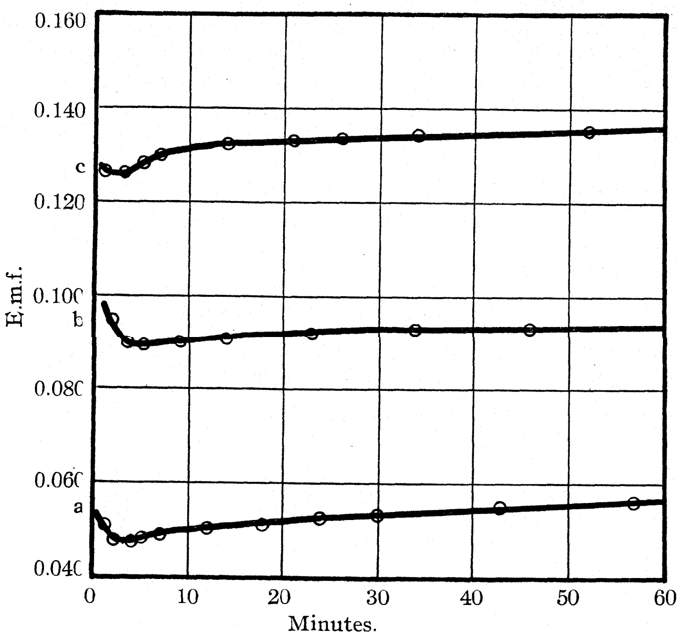

Fig. 1.—Variation of the pentacyano-ammine-ferroate electrode with time. [Ferrous]/[ferric] = a, 3; b, 1; c, $^1/_3$.

[a] Extrapolated.

As Fig. 3 indicates, the results with different concentrations of ammonia were practically identical as long as the disturbance caused by the oxidation of the ammonia did not occur. Of the (b) solutions, that containing 2.0 cc. of ammonia, (b''), displayed a falling potential. The readily extrapolated value, however, agreed with those obtained in the other (b) solutions. In the (c) solutions the potentials fell increasingly rapidly so that extrapolation was hardly feasible in the last case, (c''). Nevertheless, it is evident that within the limits of ammonia concentrations employed the potential of the electrode is independent of the ammonia concentration,

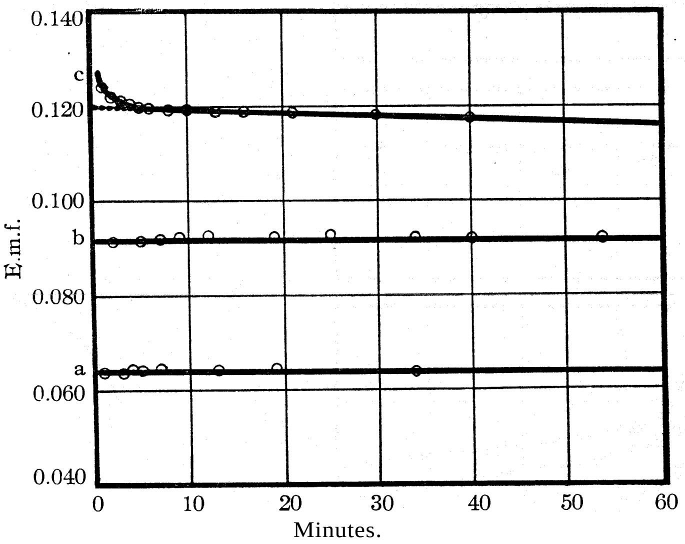

Fig. 2.—Stabilizing effect of ammonia on the pentacyano-ammine-ferroate electrode.

although with increasing ammonia concentration the solutions become increasingly unstable.

Sodium Pentacyano-Aquo-Ferroate

Application of the method described above to sodium pentacyano-aquo-ferroate gave the following results.

TABLE IV

POTENTIALS OF THE PENTACYANO-AQUO-FERROATE ELECTRODE

Soln.	*N* KCl, cc	Ferrous. millimole	Ferric, millimole	E.m.f.	E.m.f $-E_0'$ Found	E.m.f $-E_0'$ Calcd
(a)	50	0 15	0.05	0.100	−0.069	−0.028
(b)	50	.10	.10	.169	..	..
(c)	50	.05	.15	.294	.125	.028

The color of the solutions indicated, however, that compound formation was occurring between the ferrous and ferric salts, since the deep blue color of the ferric salt was only apparent in (c), while solutions (a) and (b) were only slightly darker than solutions of the ferrous salt alone. That compound formation actually occurs was demonstrated by titrating the ferrous salt with a solution of the ferric compound.

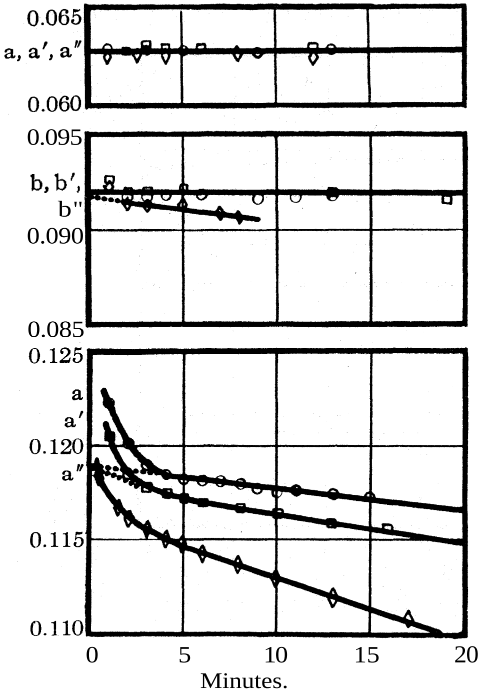

Fig. 3.—Effect of [NH_3] on the pentacyano-ammine-ferroate electrode. a, b, c contain 0.5 cc. of concd. NH_3 in 50 cc. of solution; a′, b′, c′, 1.0 cc.; a″, b″, c″, 2.0 cc.

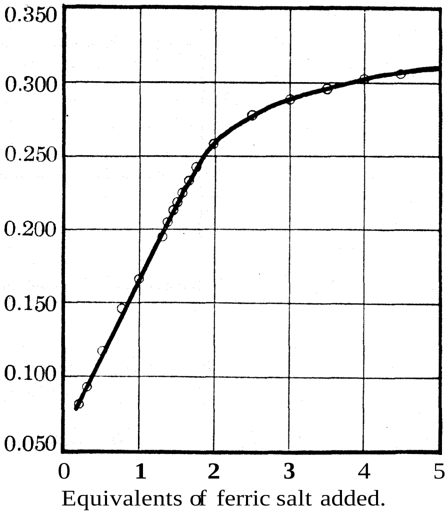

Fig. 4.—Titration of $Na_3Fe(CN)_5\cdot H_2O$ with $Na_2Fe(CN)_5\cdot H_2O$.

A quantity of the ferric salt (approximately 0.25 millimole) was weighed into a 5cc. volumetric flask, while a weight of ferrous salt equivalent to one-fifth of the ferric salt (approximately 0.05 millimole) was weighed into the cup. Fifty cc. of *N* KCl was introduced into the cup in the usual way. The ferric salt was made up to **3** cc. with *N* KCl, the solution introduced into the buret and the titration begun. Fig. 4 is a plot of this titration. More information is obtained from a plot of e.m.f. against log C_o/Ci (Fig. 5). This curve shows an inflection point at e.m.f. = 0.219

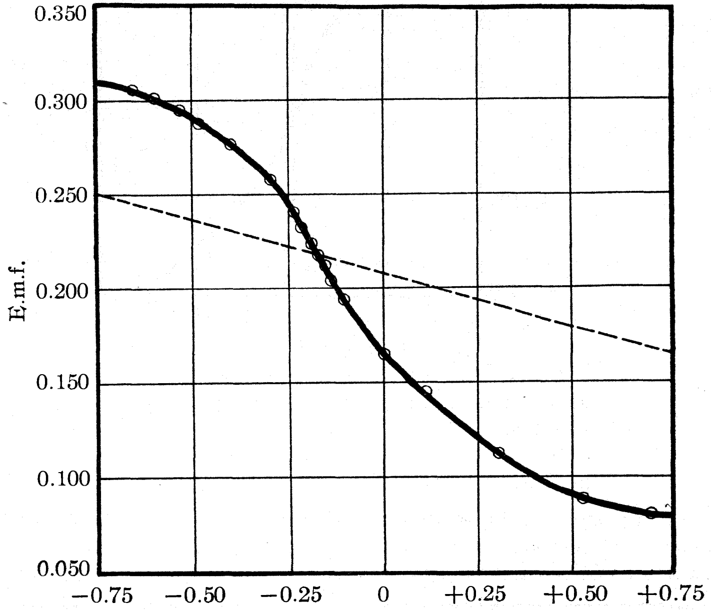

Fig. 5.—Titration of $Na_3Fe(CN)_5 \cdot H_2O$ with $Na_2Fe(CN)_5 \cdot H_2O$. The dotted line is the curve of e.m.f. = $E'_0 - 0.058 \log([\text{ferrous}]/[\text{ferric}])$.

and log C_o/Ci = −0.176. This point corresponds to the composition of the compound.[7] Hence, the ratio of ferrous to ferric salt in the com-

---

[7] This becomes more evident by considering the simpler case of a system in which the reductant, *red.*, and the oxidant, *ox.*, form a compound, *red.ox.* A solution of the "pure" compound will contain *red.ox.*, as well as the two components, *red.* and *ox.* arising from its dissociation.

Let [*red.*] = concentration of uncombined reductant
[*ox.*] = concentration of uncombined oxidant
[*Red.*] = concentration of total reductant
[*Ox.*] = concentration of total oxidant
concentration = activity.

If one adds an excess of *red.* to a solution of the compound its dissociation is depressed; that is to say, a small proportion of this excess combines with a large proportion of the free *ox.* present. In other words. [*red.*] is slightly less than the sum of that originally present and that added, while [*ox.*] has been greatly decreased. Therefore, [*red.*]/[*ox.*] > [*Red.*]/[*Ox.*], and the e m f.-log [*Red.*]/[*Ox.*] curve lies below the normal curve;

that is, below that of Equation 1. Moreover, since equal increments in log *Red.* cause diminishing decrements in log *[ox.]*, (d log *[red.]*/*[ox.]*)/(d log *[Red.]*/*[Ox.]*) diminishes as log *[Red.]*/*[Ox.]* increases. Similar reasoning applies to additions of excess of *ox.* Hence, the resulting curve, Fig. 6, has an inflection point at log *[Red.]*/*[Ox.]* corresponding to the compound. This point also lies on the straight line which normally obtains in the absence of compound formation. In general, for a compound *m·red.·n·ox.*, the inflection point will occur at log *[Red.]*/*[Ox.]* = log *m*/*n*. Fig. 7 represents the curves calculated for a titration, during which, of course, the quantity of the compound varies widely.

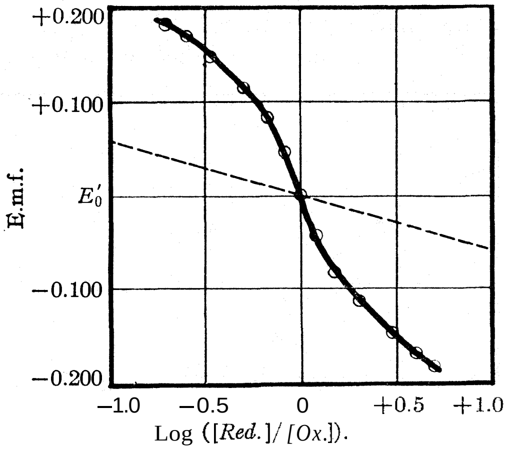

Fig. 6.—Calculated curve for the effect of excess of *red.* or *ox.* on the potential of *red.ox.*, whose dissociation constant = 0.011. [*red.ox.*] = 1. The dotted line is the curve of e.m.f. = E_0' − 0.058 log ([*Red.*]/[*Ox.*]).

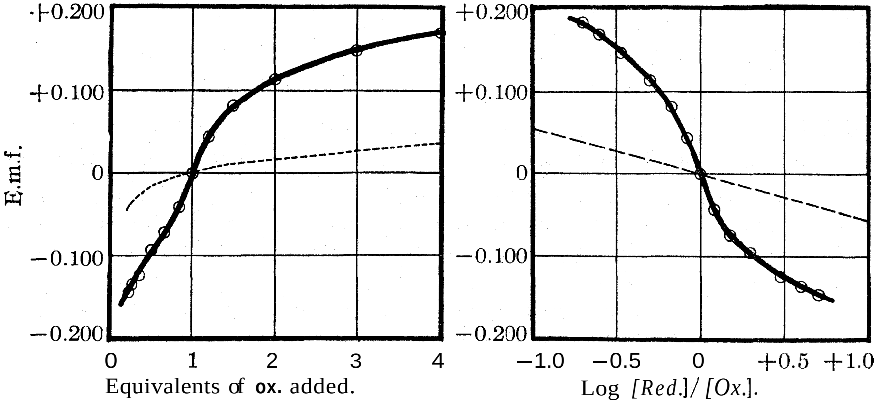

Fig. 7.—Calculated titration curves of one mole of *red.* in one liter of solution titrated with *ox.* Ox. and *red*, form a compound, *red.ox*, whose dissociation constant is 0.011. The volume of the solution is not appreciably altered during the titration. The dotted curves represent the equation e.m.f. = E_0' − 0.058 log ([*Red.*]/[*Ox*]).

plex is antilog $-0.176 = 0.67$, or 2:3, and the formula of the compound[8] is $2Na_3Fe(CN)_5H_2O \cdot 3Na_2Fe(CN)_5H_2O$. The value of E'_0 is obtained from the coordinates of the inflection point since this is the only point at which the ratio of uncombined ferrous salt to uncombined ferric salt is equal to the ratio of the total ferrous salt to the total ferric salt. Thus

$$0.219 = E'_0 - (0.058)(-0.176); \quad E'_0 = 0.209 \text{ volt}$$

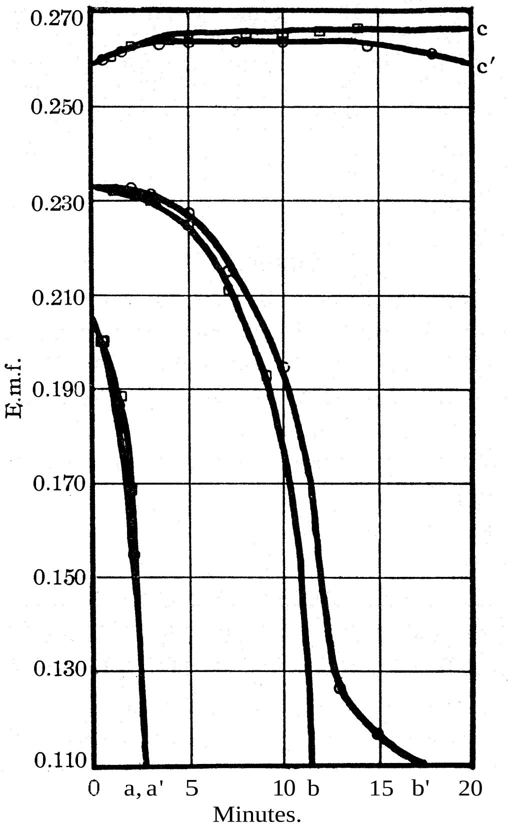

Fig. 8.—Variation of the pentacyano-nitrito-ferroate electrode with time. a', b', c' contain added nitrite.

Sodium Pentacyano-Nitrito-Ferroate

Solutions of this system gave potentials which varied rapidly with time (Pig. 8), parallel with a change in color from red (the color of the ferric salt) to yellow. Addition of 1 cc. or more of N $NaNO_2$ made little difference in the behavior of the electrode. Nevertheless, if the curves (except

---

[8] Complex formation between the iron cyanides has also been noted by Briggs, *J. Chem. Soc.*, 117, 1026 (1915).

the (c) curves, which were constant for several minutes) are extrapolated to zero time, values are obtained which differ from each other in agreement with Equation 1.

[a] Extrapolated.

Summary

Under comparable conditions, the oxidation-reduction potentials of the following complex iron cyanides against the normal calomel electrode were: $K_4Fe(CN)_6$–$K_3Fe(CN)_6$, 0.198 volt; $Na_3Fe(CN)_5{\cdot}NH_3$–$Na_2Fe(CN)_5{\cdot}NH_3$, 0.092 volt; $Na_3Fe(CN)_5{\cdot}H_2O$–$Na_2Fe(CN)_5{\cdot}H_2O$, 0.209 volt; $Na_4Fe(CN)_5NO_2$–$Na_3Fe(CN)_5NO_2$, 0.234 volt.

Indication was obtained of the formation of the compound, $2Na_3Fe(CN)_5{\cdot}H_2O{\cdot}3Na_2Fe(CN)_5{\cdot}H_2O$.

THE USE OF GELATIN OLEATE MIXTURES FOR THE DEMONSTRATION OF SMALL AMOUNTS OF CALCIUM[1]

BY SAMUEL AMBERG,[2] JOHN LANDSBURY[3] AND FRANCES SAWYER[4]

RECEIVED MAY 21, 1928 PUBLISHED OCTOBER 6, 1928

In a study of the penetrability of gelatin by dyes added to blood serum, Bennhold[5] found that it was impossible to use oxalated plasma because the calcium in the gelatin formed a precipitate of calcium oxalate which interfered with the experiments. Although this difficulty can be overcome by the use of ash-free or isoelectric gelatin,[6] it seemed probable that the formation of a stabilized ring reaction might furnish a method for the

[6] Obtained from the Eastman Kodak Company.

detection of minute amounts of calcium or other alkaline earths. It was also decided that results of interest might be obtained by a study of the effect produced by the addition of oxalate, oleate and other anions to a gelatin solution in contact with a solution of the alkaline earths.

Technique

Solutions of ash-free gelatin were so prepared that the final concentration was 5%. These solutions contained substances such as ammonium oxalate, sodium oleate, potassium oleate, sodium fluoride and sodium citrate. Freshly prepared tubes are preferable.

To insure as nearly as possible uniform conditions of temperature the tubes were kept in an ice chest at about 40°. They were read usually after standing from one to four hours, and again on the next day. The tubes, which were 9 mm. in inner diameter, were charged with about **3** cc. of gelatin mixture. The solutions were prepared roughly and the figures are approximate. The solutions to be tested were always added in the amount of 1 cc. The reactions which occurred may be characterized as stabilized ring reactions.

The gelatin in these experiments, as in others in which alkali was added, was dissolved in water, with enough space left in the tube for additions. When dissolved, 20 cc. of 0.01 N solution of oleate for each 100 cc. was added, followed immediately by 12.5 cc. of 0.1 N sodium hydroxide or potassium hydroxide. Then sufficient alkali was added to bring the reaction to a hydrogen-ion concentration of about P_H 7.4, using phenol red as the indicator. The alkalinity varied from about P_H 7.2 to 7.8, but was always greater than P_H 7. In later experiments potassium oleate[7] replaced the sodium oleate. The potassium oleate has the advantage of greater clearness, although both salts behaved similarly.

The water used for, the solutions was redistilled in an all-glass apparatus and only ash-free filter paper was used. Tubes with distilled water were used as controls, in none of which was there a reaction. Such controls are necessary for the detection of faint reactions. Reactions which could readily be distinguished from those of the controls were accepted as positive.

The solutions tested were lithium sulfate, sodium chloride, sodium sulfate, sodium nitrate, potassium chloride, potassium iodide, potassium sulfate, magnesium sulfate, strontium chloride, barium acetate, calcium hydroxide, calcium sulfate, calcium acetate, calcium oxalate, sodium hydroxide and potassium hydroxide. These solutions, with the exception of the hydroxides, were brought to a hydrogen-ion concentration of P_H 7.4 to *7.6.*

Slight or negative reactions were obtained with the sodium, potassium

---

[7] Obtained from Kahlbaum.

and lithium salts in solutions stronger than 0.02 N, with reference to the metal; with 0.002 *N* solutions reactions were not obtained. Sodium and potassium hydroxide in concentrations of 0.02 *N* or greater produced some reaction.

The reactions of magnesium solutions were similar to those of the sodium solutions. With concentrations of $M/400$ the reactions were always positive, whereas with concentrations of $M/4000$ they became questionable or negative. Strontium chloride reacted definitely at a concentration of $M/4000$ and questionably at $M/40,000$, whereas barium acetate always reacted at a concentration of $M/80,000$, perhaps even more regularly than the calcium solutions. At a concentration of $M/160,000$ the reaction was questionable or absent.

The calcium compounds, as a rule, also reacted in concentrations of $M/80,000$; occasionally a reaction was questionable or negative. With concentrations of $M/160,000$ a questionable reaction was occasionally seen. Solutions made by exposing freshly precipitated and thoroughly washed calcium oxalate to redistilled water and then brought to a hydrogen-ion concentration of about P_H 7.4 also reacted promptly.

When calcium solutions were added to a watery solution of oleate of the same strength and reaction as in the gelatin tubes, in concentrations lower than $M/4000$, the tubes containing calcium could not be distinguished from the controls. A stratification of the solution could not be produced, as would be expected.

Solutions of gelatin containing 0.001 N potassium oleate gave the same results as the usual concentration of 0.002 *N* but with a concentration lower than 0.001 *N* the potassium oleate solutions did not react with the lower concentrations of the calcium solutions.

When ammonium oxalate, sodium fluoride or sodium citrate was added to the gelatin in place of the oleates, it required a greater concentration of calcium solutions to obtain reactions, and in these reactions the precipitate showed peculiar differences in distribution.

Summary and Conclusions

1. Gelatin may be used under certain conditions to obtain ring reactions when a stratification of solutions cannot be accomplished. This method can be amplified.
2. Sodium or potassium oleate mixtures can be used for the detection of small amounts of calcium, the limit being approximately 0.0005 mg. of calcium in 1 cc.
3. The reaction is not specific for calcium.

[CONTRIBUTION FROM THE JOHN HARRISON LABORATORY OF THE UNIVERSITY OF PENNSYLVANIA]

THE ACTIVITY COEFFICIENTS OF SODIUM AND POTASSIUM HYDROXIDES IN THEIR CORRESPONDING CHLORIDE SOLUTIONS AT HIGH CONSTANT TOTAL MOLALITY

BY HERBERT S. HARNED AND JOHN MCARTHUR HARRIS, JR.

RECEIVED JUNE 15, 1928 PUBLISHED OCTOBER 6, 1928

The logarithm of the activity coefficient of hydrochloric acid' in solutions of an alkali halide at constant total molality has been found to vary linearly with the acid concentration. Thus, if γ is the activity coefficient, and m the molal concentration of the acid

$$\log \gamma = \alpha m + \log \gamma_0 \qquad (1)$$

γ_0 is the activity coefficient of the acid at zero acid concentration in the salt solution of a given total molality and α is a constant.

In an extraordinarily careful study, Güntelberg[1] has shown that at 0.1 M total concentration this law is valid for the activity coefficient of the acid in lithium, sodium, potassium and cesium chloride solutions to within 0.04%. Harned[2] has shown that at 1 M and 3 M total molalities the above expression is valid to within ±0.2% for sodium and potassium chloride–hydrochloric acid mixtures. Results more recently obtained indicate that this law is valid for hydrochloric acid–sodium chloride mixtures at 6 M total molality.

The object of this investigation was to find whether equation (1) is also valid for the activity coefficients of all univalent alkaline hydroxides in their corresponding chloride solutions.

The thermodynamic properties of the alkali metal hydroxides differ from those of the corresponding chlorides. For example, sodium chloride has a higher activity coefficient than potassium chloride but the opposite is true of the corresponding hydroxides. As previously pointed out,[3] the hydroxides occupy a somewhat anomalous position in comparison with other strong electrolytes. If, therefore, deviations from the law expressed by Equation 1 are to be found, it is to be expected that they will be observed in the cases of the hydroxide–salt mixtures and will be more pronounced for sodium hydroxide–chloride than for potassium hydroxide–chloride mixtures. These latter mixtures have already been investigated at constant hydroxide–varying salt concentrations. From the few results obtained at constant total molality, indications were obtained that there was but little if any departure from the linear relation-

ship. Since these previous studies did not constitute an exhaustive test, the electromotive forces of cells of the type

$$H_2 \mid MOH(m_1), MCl(m_2) \mid M_xHg \mid MOH(m_0) \mid H_2 \qquad (2)$$

in which $(m_1 + m_2)$ was kept constant, were measured.

Experimental Results

The experimental technique as well as the methods of preparation of the amalgams, solutions and electrodes was with minor alterations the same as that developed by Knobel,[4] Harned[5] and Åkerlöf,[6] and will require no further discussion. The electromotive forces are given in Table I. All measurements were made at 25°.

Calculation of the Activity Coefficients

The activity coefficients of the hydroxides in the salt solutions were calculated according to the equation

$$E = 0\ 05915 \log \frac{\gamma_{M(s)}\gamma_{OH(s)}\, a_{H_2O(m_0)}\, (m_1 + m_2)\, m_1}{\gamma_{M(m_0)}\gamma_{OH(m_0)}\, a_{H_2O(s)}\, m_0^2} \tag{3}$$

where the subscripts (s) and (m_0) refer to the salt solutions and to the reference solutions, respectively. In all of the subsequent discussion, we let

$$\gamma = \sqrt{\frac{\gamma_{M(s)}\gamma_{OH(s)}}{a_{H_2O(s)}}} \text{ and } \gamma_0 = \sqrt{\frac{\gamma_{M(m_0)}\gamma_{OH(m_0)}}{a_{H_2O(m_0)}}}$$

and Equation 3 becomes

$$E = 0.1183 \log \frac{\gamma \sqrt{(m_1 + m_2)m_1}}{\gamma_0\, m_0} \tag{4}$$

The values employed for γ_0 were taken from the data of Harned and Åkerlöf.[7] Thus, for potassium hydroxide, $\gamma_{0\ 108}$ was taken to be 0.776, and in the case of sodium hydroxide, $\gamma_{0\cdot 106}$ and $\gamma_{0\cdot 108}$, were taken to equal 0.758 and 0.757, respectively. The final values computed in this manner are given in Table I.

Discussion of the Results

Figure 1 contains the plot of log γ_{KOH} against m_{KOH} in the solutions of 3.5 total molality. The upper plot is a straight line drawn through the points at 0.5 M and 3.5 M potassium hydroxide concentrations, and the lower curve is drawn through all the points. A slight curvature is noticeable although it should be remarked that if we had drawn the straight line through the 0.5 M and 3 M points, all points except that at 3.5 M hydroxide would have fallen on it with an error of about ±0.2 mv. In this case, however, the 3.5 M point would have been over a millivolt off the curve. We regard the results, therefore, as indicating a very small curvature. On the other hand, a pronounced curvature is observable in the case of sodium hydroxide–sodium

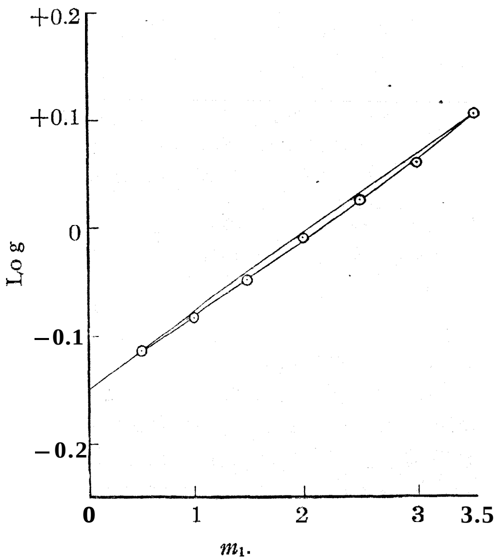

Fig. 1.—Log γ–m_1 of potassium hydroxide–chloride mixtures.

---

[7] Harned and Åkerlöf, *Physik. Z.*, 27, 411 (1926).

chloride mixtures at a total concentration of 3, and a very pronounced deviation from the straight line is apparent at a total molality of 5. This is shown by the graphs in Fig. 2. It should be noted that we have plotted $\sqrt{\gamma_M\gamma_{OH}/a_{H_2O}}$, not $\sqrt{\gamma_M\gamma_{OH}}$, owing to our lack of knowledge of the activity of water in these mixtures. The small change in a_{H_2O} in passing from the pure hydroxide to the pure salt solution would be expected to be approximately linear, and in any case would not be responsible for the pronounced curvatures. The points at 0.01 M and 0.1 M sodium hydroxide concentrations at a total concentration of three were obtained from the data of Harned.[3b]

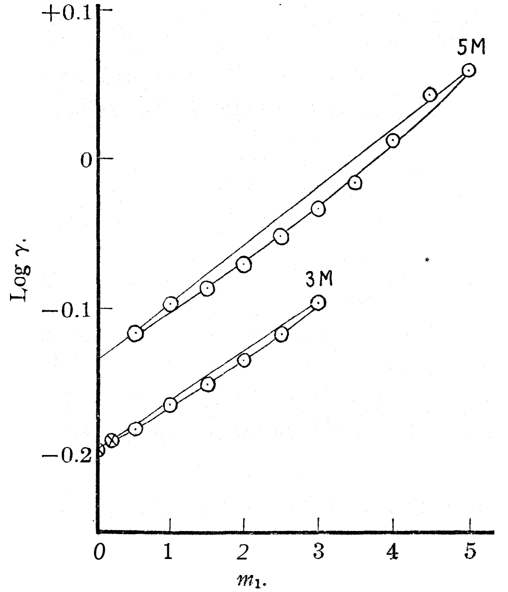

Fig. 2.—Log γ–m_1 plots of sodium hydroxide–chloride mixtures

The extent of the deviations from the straight lines shown in the figures is made apparent by the last two columns in Table I. The calculated values of γ were obtained from the equations for the straight lines, namely

$$\begin{aligned}
&\text{(a)}\quad \text{KOH–KCl } (3.5\ M);\ \log \gamma = 0.0728m - 0.150\\
&\text{(b)}\quad \text{NaOH–NaCl } (5\ M);\ \log \gamma = 0.0387m - 0.135 \qquad \text{(1a)}\\
&\text{(c)}\quad \text{NaOH–NaCl } (3\ M);\ \log \gamma = 0.0320m - 0.192
\end{aligned}$$

The differences between the calculated and observed values have been computed by the equation

$$\Delta = 118.3 \log \frac{\gamma_{\text{calcd.}}}{\gamma_{\text{obs.}}} \qquad (5)$$

and are, therefore, in millivolts.

These results leave little doubt that in the case of these solutions at these high concentrations there is a definite departure from the linear relationship. The maximum deviation is 0.88 mv. in the potassium hydroxide series. This corresponds to a 1.76% difference between the observed and calculated activity coefficients. The same maximum difference is obtained in the case of the sodium hydroxide–chloride mixtures at 3 *M* total molality. The 5 *M* total sodium hydroxide–chloride series indicates a maximum difference of 1.95 mv., which corresponds to a 3.9% difference between the calculated and observed activity coefficients.

Summary

1. Measurements at 25° of the cells

$$H_2 \mid KOH(m_1), KCl(m_2) \mid K_xHg \mid KOH(m\ ) \mid H_2$$

in which $(m_1 + m_2)$ was kept at a constant molality of 3.5 have been made.

2. Similar measurements of the cells

$$H_2 \mid NaOH(m_1), NaCl(m_2) \mid Na_xHg \mid NaOH(m_0) \mid H_2$$

at total molalities of 3 and 5 have been presented.

3. From these data the activity coefficients of the hydroxides in the chloride solutions have been computed.

4. The linear relationship given by Equation 1 does not hold for the activity coefficients of the hydroxides in these mixtures. The differences between the observed and calculated activity coefficients were not very large. The maximum difference which occurred with the 5 M sodium hydroxide-chloride mixtures was 3.9%.

THE CATALYTIC OXIDATION OF CARBON MONOXIDE.
IV. THE PORE VOLUME OF THE CATALYSTS MANGANESE DIOXIDE, COPPER OXIDE AND MIXTURES OF THESE OXIDES

BY HAL D. DRAPER

RECEIVED JUNE 22, 1928 PUBLISHED OCTOBER 6, 1928

In this paper are presented the results of experiments, completed in 1922, on the pore volume and related physical properties of the catalysts investigated and reported on in the first papers of this series.[1] Results of tests upon the catalytic efficiency of related series of catalysts, in which the composition varied between MnO_x (where x is less than 2) and CuO, showed that all the mixtures were more catalytically active than either of the pure components, whether the mixing was effected by thorough kneading of the moist hydrated oxides with subsequent drying,[1a] or by stirring together finely ground portions of the previously dried or ignited components.[1c] These results point to the conclusion that the component oxides retain their characteristic properties in the mixtures and that the "mixture effect" is due to a speeding up of the electronic rearrangement postulated in the mechanism for the catalytic reaction.[2]

As in the previous papers, the members of the three series reported on here (Almquist's Series 1, 2 and 3) will be referred to by the numbers from 1 to 6, in the order of decreasing manganese dioxide content. The compo-

sitions of these catalysts with respect to CuO, MnO_x, H_2O, CO_2 and impurities are given in the first paper.

Definitions of Terms Used.—In the following, "true density" shall indicate that value of the density obtained by immersing the evacuated granules beneath gas-free water and determining the loss of weight sustained. This value will represent the actual density of the solid only if there is no expansion or contraction of the water in the pores of the granule and if all the pores are completely filled. Neither of these conditions is actually fulfilled in all probability.

"Granule density" will indicate the mass in grams of a granule having the volume of one cubic centimeter. This volume will consist of the volume of the solid plus the intra-granular volume (pore volume).

"Apparent granule density" or "apparent density" will indicate the value obtained by filling a vessel with granules, settling them by gentle tapping, and dividing the mass of the granules by the volume of the vessel.

The entire intra-granular free space will be called the "pore volume," which consists of "micro-capillaries," "macro-capillaries" and "cavities."

Part I of the paper will give the results of the determination of the total pore volume and the related properties of the granules; Part II will give the results from which a knowledge of the distribution of the pore volume between micro-capillaries, macro-capillaries and cavities can be obtained.

Part I

Experimental.—The true densities of the granules of Series 1 and 2, and the three samples prepared at Washington, were determined by the method of Hulett.[3]

From 4 to 8 g. of the granules was placed in a Pyrex tube constructed as shown in Fig. 1, which was then sealed off at A. Tube B was then sealed to a vacuum line and the granules were evacuated at about 200° for from three to seven hours. Eight tubes were sealed to a ring close enough together to be immersed in the same heating bath, thus insuring that all of the granules of a given series received uniform treatment. When the pressure had fallen to about 0.003 mm., the tubes were sealed off at C.

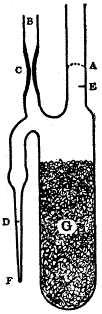

Fig. 1.

After cooling, each tube was cleaned, scratches were made at D and E and its weight reduced to *vacuo* was determined. Tube F was then inserted in tube H of the Pyrex "wash-bottle," Fig. 2, which contained distilled water, the two tubes being joined together by tight fitting rubber tubing. The water in the wash-bottle was then freed from dissolved gases by boiling under reduced pressure, and the gas-free water introduced into the granule tube by breaking the capillary at D.

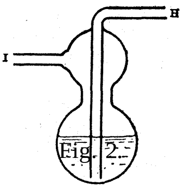

Fig. 2.

The density and pore volume of the granules was then determined as described by Cude and Hulett.[3]

Since it appeared from the results of Series 1 and *2* that a high degree of precision

---

[3] Cude and Hulett, THIS JOURNAL, **42,391 (1920).**

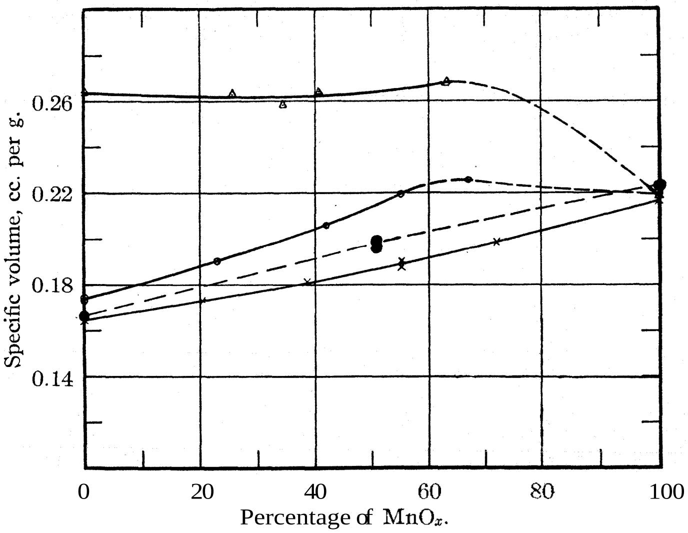
in the true density was not essential, a somewhat simpler method was used in this determination for Series 3.

Duplicate determinations made upon different specimens of the same sample gave a satisfactory check, as shown below.

Check Results on Two Specimens or Sample 5, Series 1 (Washed)

True density, g. per cc.	4 436	4 433
Specific volume, cc. per g.	0.2255	0.2256
Pore volume, cc. per g. of solid	0 49	0.50
Pore volume, cc. per cc. of solid	2.16	2.21
Granule density, g. per cc.	1 41	1.38

All the granules (Series 1 had to be washed free of soluble salts[4]) showed an initial "drift" in the density such as Hulett[3] and Harkins[5] found in experiments with charcoal, but of much smaller magnitude and of much shorter duration. None of these oxide granules required more than a



○ Series 1 (washed); X Series 2; △ Series 3, ● Washington samples.

Fig. 3.

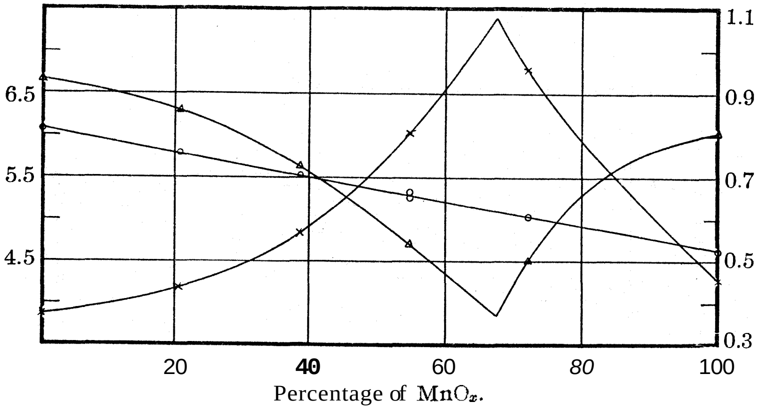
---

[4] Granules of Series 1 gave an unexpected result in showing a large drift almost exactly as described by Hulett and Harkins *but in the opposite direction.* Thus a 7g. specimen of Sample 6 changed from a density of 5.68 to 4.69 between Sept. 23 and Jan. 26, a change of 21%. From its mode of preparation, Sample 6 is presumably contaminated with sodium sulfate. The initial rapid decrease in density is due to the hydration of the salt to form the decahydrate. This then slowly goes into solution and diffuses out of the tube, causing the later slow decrease in density. A calculation based on this assumption indicated that 4.8% of sodium sulfate in the sample would account for the 21% change in density. Almquist[1a] found by analysis, 4.5% impurities, the nature of which he did not ascertain.

[5] Harkins and Ewing, This journal, 43, 1787 (1921).

few days before coming to a constant density, whereas with some of the charcoals several months elapsed before the "drift" disappeared. Hulett and Harkins attribute this drift to the slowness of penetration of the liquid into the micro-pores. Our results would indicate that the micro-pores of the oxide granules constitute a much smaller proportion of the total pore volume (a conclusion borne out by results described in Part II of this paper), or else that the oxides are more easily wetted by the water than is the charcoal.

Part of the results of these determinations are summarized in Table I and shown graphically in Fig. 3. It is believed that the determinations of true density in Series 1 and 2 are precise to a few hundredths of a per cent., but that the homogeneity of the samples is not greater than a few tenths of a per cent. The pore volume and apparent density are probably not precise to much better than 2%. The results given in the tables are expressed so that the last figure given is likely to be in error by not more than 3 or 4 units.



⊙ True density, g. per cc. (use left-hand ordinates). X Pore volume, cc. per g. of solid (use right-hand ordinates). △ Apparent granule density, g. per cc. (use right-hand ordinates).

Fig. 4.

Fig. 4 shows some of the properties of Series 2, which are typical of those obtained with Series 1 and 3. The sharp maxima and minima shown are probably not real, but some kind of maxima arid minima unquestionably exist in all three series between the composition of 50 and 70% MnO_x.

Discussion of Results.—One of the chief purposes of this investigation was to obtain an explanation of the "mixture effect" in the oxidation of carbon monoxide by gaseous oxygen as catalyzed by the oxide granules. As stated in the opening paragraphs of this paper, it was found that all of

[a] All of the sample was used up in the various tests so that the apparent density could not be determined; assumed to be the same density as Sample 1, Series 2.

[b] Tube 35 was prepared at the same time as Tube 31, but had stood (sealed) for three months. No great change in the condition of the granules is produced by this treatment, judging from the satisfactory check.

[c] Samples were in the form of fine powders; the pore volume could not be determined by centrifuging.

[d] This sample had been put through the density determination before, and had been allowed to stand in water for four or five weeks. The slightly increased density probably means that the granules contained *a* small amount of soluble impurity which was dissolved out by this treatment. Some results obtained with this sample in **Part** II of this paper seem to indicate the presence of soluble impurities.

the mixtures were much **more** active catalysts than either of the pure components alone. One of the possibilities that needed investigation was whether the two oxides on mixing formed some definite compound. Since compound formation is generally accompanied by a departure from linearity in the specific volume–composition curve, we are now in a position to apply this criterion to the present case.

Compound Formation.—The granules of Series 2 and 3 were prepared with considerably greater care than those of Series 1, both in the washing of the component oxides free from soluble salts and in the mixing of the moist oxides before drying. Sample 1 (and probably 2) of Series 1 suffered a profound chemical and physical change when they were first wetted. In the case of Series 3, results of analysis'" indicate that the various samples lost carbon dioxide unequally upon drying. As for the Washington samples, the three bear no relation to one another in their origin, being taken from different batches of stock oxides. Series 2, therefore, is the only complete series tested, and we are confined to a consideration of results from this series alone in drawing conclusions as to the possibility of compound formation between the oxides.

An inspection of the specific volume–composition curve for Series 2 in Fig. 3 shows that the departure from linearity is very small, the maximum departure being about 2%. This result therefore indicates that there is probably no definite compound formed between the oxides. The work of Bray and Doss[1c] furnishes additional evidence against compound formation.

Correlation of Physical Properties of Granules and their Catalytic Activity.—In attempting to find a relationship between the physical properties thus far determined and the catalytic activity, results of Series 1 must be ruled out, since the determinations of catalytic activity were made with the unwashed granules, while the results given above were made upon granules which were washed free of soluble salts. The other granules, however, are comparable.

Since Almquist's results were obtained with 5.0 cc. of granules in each case, the properties of a *fixed volume* and not of a *fixed mass* of the granules must be considered. An inspection of the results calculated on this basis fails to reveal any marked break in any of the properties between the mixtures and the pure oxides corresponding to the great difference in catalytic activity. In the case of the mixtures, rough parallelism exists between catalytic activity and pore volume for Series 2, but the parallelism fails completely in Series 3 and the entire group of samples (Series 2, 8 and the Washington samples) considered as a whole.

It would appear, therefore, that the physical properties thus far discussed bear a very minor part in determining the catalytic activity of the granules.

An explanation of the marked maxima and minima in the properties other than the specific volume is found in the colloidal character of the pastes as discussed in Part II.

Part II

With the idea that compound formation could be detected by heat effects produced on mixing these oxides in a finely divided condition, samples of MnO_x and CuO were prepared for this purpose.

The MnO_x was prepared by the Fremy method, that is, by adding potassium permanganate to a concentrated solution of sulfuric acid and allowing the permanganic acid thus formed to decompose spontaneously. The copper oxide was prepared by adding a moderately dilute solution of copper sulfate to a solution of sodium hydroxide, the latter in slight excess; both solutions were at room temperature. Upon standing, the gelatinous, blue-green precipitate of hydrated copper oxide slowly changed to brownish black. (Incidentally, it is interesting to note that a sample prepared in the same way, but with an excess of copper sulfate, has been kept for several months with no apparent change in color.) Both precipitates were washed by decantation until no trace of sulfate could be detected in the washings. The precipitates were rendered semi-colloidal by this treatment; several weeks were required for the precipitates to settle out after being stirred up. This was especially marked in the case of the copper oxide, indicating either that the copper oxide particles were smaller than the MnO_x particles, or that they were less compact (average density less), or else they had adsorbed a greater number of ions per particle upon being peptized.

Quantities of these suspensions which contained about the same amount of solid were brought together in a calorimeter and stirred by hand for about five minutes. The sensitive thermometer showed only 0.001° rise in temperature, part of which was due to stirring. Later analysis showed in a total volume of 150 cc. 2.872 g. of solid consisting of 1.175 g. of copper oxide and 1.697 g. of MnO_x (by difference). The observed heat effect corresponds to only 10 calories per mole of one of the oxides. This result furnishes strong evidence against the formation of a definite compound between the two oxides.

However, it was noticed that the precipitate settled out much more rapidly after mixing, the supernatant liquid being clear after standing overnight, although, as mentioned before, several weeks were required for the settling of the pure oxide suspensions. This result indicated that the two colloidal oxides are of opposite sign—their properties and method of formation making it probable that the copper oxide is negatively, the MnO_x positively, charged due to the adsorption of hydroxyl and hydrogen ions, respectively.

The application of the above considerations has an extremely important bearing upon the whole theory of the formation of a porous granule. Almquist and Bray[6] give the following picture of the process. The terms in italics are inserted by Draper.

"The formation of the firm, porous granule may be thought of as follows. Each hydrated oxide is precipitated in the form of minute particles, the size *and configuration* of which are determined by the *nature of the substance* and the method of precipitation, *and also* by *the thoroughness of washing;*

---

[6] Ref. 1 a, footnote, p. **2311.**

the more completely the soluble salts are removed, the finer the particles become through peptization of the precipitate. The filter cake, before it is dried, consists of particles surrounded by films of water which enable the relative positions of the particles to be easily changed, for example in a kneading process. In the preliminary drying as the water is slowly expelled, the particles are gradually drawn together, and in many places contact is sufficiently close to allow valence forces to come into play between the molecules of the different particles. The plastic material has now been transformed into a solid. Finally, as the water of hydration is gradually expelled, the body becomes porous."

Gelatinous and semi-gelatinous precipitates such as hydrated copper oxide, from the ease with which they may be peptized by washing, are thought to be composed of very small particles held together in a branching network, partly at least by the adsorbed substances on their surfaces. As such a precipitate is washed, the large flocks are progressively broken down into smaller and smaller particles, which must still be quite irregular in configuration until they approach the size of the ultimate particles which are of colloidal dimensions.

Now if a granule is formed from such a precipitate by the process given above, the pore volume (cc. per cc. of solid) will evidently be less the smaller and more regular the ultimate particles, that is, the more thoroughly the precipitate is washed. Comparison of the results for Sample 6 of Series 1 and 2 offers confirmation of this conclusion.

In the case of the pulverulent precipitates of MnO_x, the evidence given above indicates that the particles are considerably larger than the *ultimate* particles of copper oxide. As with most pulverulent precipitates, the particles are compact, rounded grains, which made a compact, dense granule. With particles which are nearly spherical, the pore volume might be expected to be nearly independent of their size,[7] but the proportion of macro-pores in the total pore volume will be less the smaller the particles.

The more irregular the particles of a given size, the larger the proportion of macro-pores might be expected to be.

From a comparison of the physical properties of the two oxides, one should expect the particles of the semi-gelatinous copper oxide in the thoroughly washed paste to be considerably smaller and considerably more irregular than the particles of the pulverulent MnO_x. Granules made from the pure copper oxide alone may therefore have a total pore volume which is greater or less than that of the granules made from the MnO_x, depending upon which of the two factors (size and irregularity)

---

[7] It can be shown that the total free space in a given cube filled with close-packed spheres whose radius is small in comparison to the dimensions of the cube is independent of the radius of the spheres.

predominates. If the pore volume is approximately the same (as is the case in Series 2, Samples 1 and 6, Table I), we would predict that the proportion of cavities and macro-pores in the copper oxide granules would be greater, a prediction verified by results given later.

If our assumption as to the adsorption of ions of the opposite sign by the particles of the two oxides is correct, bringing the two pastes together will bring about peptization between the particles. This should have the effect of increasing both the size and the irregularity of the particles in the mixture. If the maximum effect is obtained in the case where the number of oppositely charged particles is the same, which appears logical since the peptization must take place particle by particle, the granule of maximum porosity should contain a large proportion of that oxide whose particles are the larger. Results given in Table I show that, from this standpoint also, the MnO_x particles are larger than those of copper oxide in Series 2. In Series 1, where the oxides were not so thoroughly washed, we find as predicted that there is less difference in the size of the oxide particles. In Series 3, the results indicate that the MnO_x particles are smaller; the copper oxide of this series was made from basic copper carbonate, which is much more pulverulent than the product made from the hydrated oxide.

It seemed desirable, in the light of the above considerations, to attempt to gain some idea as to the distribution of the pore volume between micro-capillaries, macro-capillaries and cavities in the various granules. A study of the adsorption curves for a vapor up to the saturation pressure should give us such information, since a relation can be developed connecting the vapor pressure and the curvature of the liquid surface in equilibrium with the vapor. For a liquid which wets the granules, the curvature of the liquid surface gives us a measure of the radius of the capillaries in which the liquid is condensed, and adsorption isotherms for the vapor will give the volume of all capillaries whose radius is equal to or less than that corresponding to each measured pressure. Since water had been used in determining the total pore volume, this liquid was used in determining the adsorption isotherms. A rather hasty run was made upon Sample 6 of Series 2 using ether instead of water. The isotherm had the same general shape as that for water, but the calculated value of the radius of the capillaries did not check closely for the smaller values, a result for which a number of explanations has been advanced[8,9,10,11] some assuming that the liquid in the capillaries is under relatively enormous positive or negative pressure; some that the "true adsorption"

may consist of single or multiple layers of the adsorbate, depending upon the nature of the adsorbent and the adsorbate.

Since capillary condensation is preceded by "true adsorption,"[12] the calculated values for the radii of the capillaries will differ for different adsorbates if the molecular dimensions of the latter are different. This difference may be relatively great in the event that one adsorbate forms a monomolecular and the other a multimolecular adsorbed film. It is not assumed, therefore, that the radii calculated below represent the actual dimensions of the pores; it is enough for our purpose to assume that the results obtained from the various granules, with water as adsorbate, are comparable.

To calculate the effect of curvature of the liquid surface upon the vapor pressure, the following well-known formula has been derived from the rise of a liquid in a capillary. A capillary of circular cross section, the walls of which are wet by the liquid, and whose radius is so small that the liquid surface is circular is assumed in the derivation.

$$r = \rho = \frac{2\gamma M}{DRT \ln p_0/p_1} = \frac{K}{\ln p_0/p_1} \tag{1}$$

K being a constant for constant temperature. In this formula ρ = the radius of curvature of the liquid surface, r = the radius of the capillary, D = the density of the liquid, p_0 = the vapor pressure of the liquid at a plane surface, p_1 = the vapor pressure of the liquid from the concave surface, M is the molecular weight of the vapor, R = the molecular gas constant, γ = the surface tension of the liquid and ln is the logarithm to the base e.

The volume of liquid condensed in a capillary of radius r and length l, closed at one end, and where $\rho > r$, is

$$\pi r^2 l - \pi \left[2/3\, \rho^3 - \rho^2 (\rho^2 - r^2)^{1/2} + 1/3\, (\rho^2 - r^2)^{3/2}\right] \tag{2}$$

Suppose that we have a system consisting of a network of capillaries threading a solid which is wet by water. If a volume, v, of water is absorbed at constant pressure, p, we know that the radius of curvature of the water surfaces in the capillaries has not changed during the absorption. If ρ is the radius of curvature of the water surface corresponding to the pressure p, the absorption is equivalent to that produced in circular cylindrical capillaries of radius ρ and total length L, where $\pi\rho^2 L = v$. The entire capillary volume of the solid can thus be represented by an aggregation of circular, cylindrical capillaries, at least as far as the volume and capillary properties are concerned. The actual shape of the pore will have a large effect upon the extent of surface exposed in the walls, but not upon the capillarity. The actual volume of water condensed in a porous body at any pressure of water vapor less than the saturation

---

[12] *Bray and Draper, Proc. Nat. Acad. Sci.*, 12, 295 (1926).

pressure will depend largely upon the *average* length of capillaries having uniform cross section rather than the *total* length of pores having this cross section, as can be seen from Equation 2.

Consider a system composed of n_1 pores of uniform radius, r_1, and average length l_1, n_2 pores of uniform radius r_2 and average length l_2, ... n_k pores of uniform radius r_k and average length l_k. If water vapor is introduced at a pressure corresponding to a curved surface of radius ρ where $r_k < \rho < r_{k+1}$, the volume of water condensed when equilibrium is reached is evidently, from (2)

$$V = \pi\{n_1[l_1r_1^2 - 2/3\ \rho^3 + \rho^2\ (\rho^2 - r_1^2)^{1/2} - 1/3\ (\rho^2 - r_1^2)^{3/2}] + n_2[l_2r_2^2 - 2/3\ \rho^3 + \rho^2\ (\rho^2 - r_2^2)^{1/2} - 1/3\ (\rho^2 - r_2^2)^{3/2}] + \ldots\ldots + n_k[l_kr_k^2 - 2/3\ \rho^3 + \rho^2\ (\rho^2 - r_k^2)^{1/2} - 1/3\ (\rho^2 - r_k^2)^{3/2}]\} \qquad (3)$$

or

$$V = \pi \sum_{i\,=\,l}^{i\,=\,k} n_i[l_ir_i^2 - 2/3\ \rho^3 + \rho^2\ (\rho^2 - r_i^2)^{1/2} - 1/3\ (\rho^2 - r_i^2)^{3/2}] \qquad (4)$$

If, now, $p = r_{k+1}$, the volume condensed at equilibrium is the same as that given in (4) plus an additive term, $\alpha\pi[n_{k+1}\,l_{k+1}\,r_{k+1}^2 - {}^2/_3\,n_{k+1}\,r_{k+1}^3]$ (5), where α is the fraction of the capillaries of radius r_{k+1} which are filled.

Differentiating (4) with respect to ρ, we obtain

$$\frac{\mathrm{d}V}{\mathrm{d}\rho} = \pi\rho \sum_{i\,=\,1}^{i\,=\,k} n_i \left[\frac{\rho^2}{(\rho^2 - r_i^2)^{1/2}} + (\rho^2 - r_i^2)^{1/2} - 2\rho\right] \qquad (6)$$

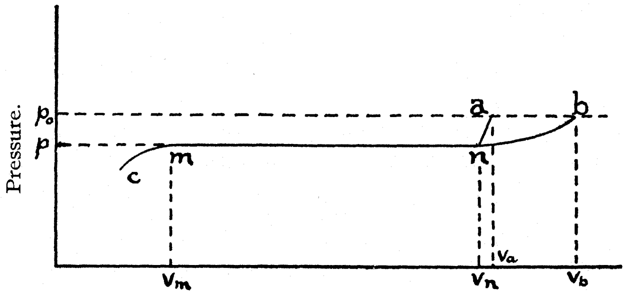
and since $\mathrm{d}V/\mathrm{d}p = (\mathrm{d}V/\mathrm{d}\rho)/(\mathrm{d}\rho/\mathrm{d}p)$, and from (1) $\mathrm{d}\rho/\mathrm{d}p = K/[p(ln\ p_0/p)^2]$

$$\frac{\mathrm{d}V}{\mathrm{d}p} = \frac{\pi K^2}{p(ln\ p_0/p)^4} \sum_{i\,=\,1}^{i\,=\,k} n_i \left\{\frac{K^2}{[K^2 - (r_i\ ln\ p_0/p)^2]^{1/2}} + [K^2 - (r_i\ ln\ p_0/p)^2]^{1/2} - 2K\right\} \qquad (7)$$

An inspection of (5) tells us that any considerable volume of water condensed at constant pressure may indicate either a very large number of short capillaries of uniform radius and length, $l > {}^2/_3\ r$, or else **a** relatively small number of long tube-like capillaries, or anything between these extremes. Equation 7 gives some important information about the adsorption curves, as follows: the slope of the pressure–volume curve is not dependent upon the average length of the capillaries; the contribution to the slope at any given point by capillaries of any given radius is directly proportional to the number of these capillaries present. This contribution is smaller the smaller the radius of the capillary; the slope of the curve is greater (other variables being constant) the larger p becomes. (Note that when V is plotted against p as the ordinate, $\mathrm{d}V/\mathrm{d}p = 0$ indicates a vertical tangent, and $\mathrm{d}V/\mathrm{d}p = \infty$ indicates a horizontal tangent.)

The actual condition of any porous body cannot be determined from the sorption curve alone, but in some cases we can obtain a valuable comparison between porous bodies by making use of the generalizations derived from the equations just developed.

In Fig. 5, cmna and cmnb represent theoretical sorption curves for such amounts of two porous granules A and B, that the same volume of water ($v_n - v_m$) is absorbed at the same pressure p, and in which the distribution of pores of various *radii less than that corresponding to the pressure* p (r_p) *is the same* (since the branches cm coincide in the two curves). Granules A and B thus have the same total volume of pores of radius r_p. Granule A differs from Granule B in having few *pores of radius greater than* r_p, the volume $v_a - v_n$ thus representing the water necessary to fill up the menisci of a relatively *small number of capillaries.* The much larger volume $v_b - v_n$ in the curve for Granule B indicates one of two conditions: (1) *a much larger number of* capillary menisci to be filled or (2) a smaller number of capillaries of uniform radius r_p, with funnel or trumpet shaped ends.



Volume of water absorbed, *cc.*

Fig. 5.

The following conclusion therefore seems justified: for a given volume of liquid condensed at constant pressure, p, the more abrupt the transition from the horizontal to the high pressure branch of the sorption curve, the fewer are the capillaries of radius r_p present in the granule and, therefore, the greater is the average length of these capillaries. For a granule whose sorption curve has a long, horizontal branch with a rather abrupt transition to the high pressure branch, we are justified in assuming that. there must be a rather small number of relatively long tube-like capillaries present.

Curves of type cmna were obtained by Lowry and Hulett[13] for sorption of water vapor by charcoal, in which we might expect to find a considerable number of tube-like pores.

Sorption curves were determined for Samples 1, 2, 3, 4 and 6 of Series 2 for water vapor up to saturation pressure at 25° (23.53 mm. of mercury at 45°), the results for better comparison being plotted for that weight of each sample which has a total pore volume of 1 cc. as determined in Part I. These results are shown in Fig. 6 and a typical run with calcula-

---

[13] Lowry and Hulett, THIS JOURNAL, **42, 1403, Fig.** 6 **(1920).**

tions is given in Table II. It should be noted that the form of Equation 1 is such that values of p become rapidly less accurate as the value of p increases. Thus, an error of 0.005 cm. of mercury in the measurement of the pressure produces the following errors in the calculated values of p: at p = 1.00 cm. of Hg, p = 12.1 Å., dp = 0.07 Å., < 1% error; at p = 2.00 cm. of Hg, ρ = 60.0 Å., dp = 0.86 Å., 1.4% error; p = 2.35 cm. of Hg, p = 755 Å., dp = 116 Å., 15% error.

The measurements recorded in the last two lines were taken when the tube was heated to 200°. In Column 10, the volume of liquid absorbed by 1.245 *g.* of the granules is calculated since 1.245 g. of these granules have a pore volume of 1.00 cc.

Experimental

The sorption curves were determined by means of the apparatus shown diagrammatically in Fig. 7. All of the glass parts were made of Pyrex glass. That part of the apparatus within the dotted lines was enclosed in an automatically controlled air thermostat, the temperature of the gas in the 2-liter bulb D being maintained at 45.00 ±0.02°. After assembling, the volume of the various parts of the apparatus was carefully determined, either by adding a known amount of air and measuring the pressure change produced or by adding distilled water from a buret. The volume of the catalyst bulb A and connecting tubes to a point a on manometer B was 97.9 cc., and that of D and connecting tubes between point a on manometer B and point b on manometer E was 2233 cc.

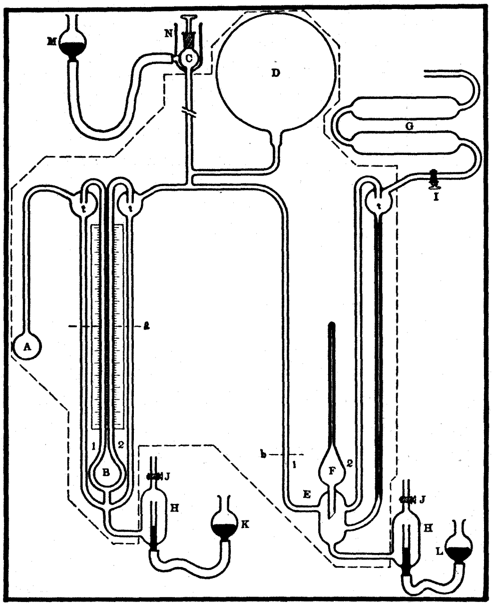

Fig. 7.

A 0.05 to 2.0 g. sample of the dried granules was placed in A, heated to 200° and evacuated through I for from three to seven hours. The small auxiliary thermostat (Fig. 8) was then adjusted to the catalyst tube and the temperature of the latter brought to 25.0 ± 0.1°, evacuation continuing until the pressure dropped to about 0.002 mm. as shown by McLeod gage F. The catalyst bulb was then cut off from the main apparatus, and the latter from the vacuum line by raising leveling bulbs K and L, respectively.

Gas-free water was then introduced into the apparatus by means of the device N, whose construction and operation have been described by Lamb and Coolidge,[8] the amount admitted being adjusted so that no vapor will condense. The amount of water present in the apparatus was then determined by measuring the pressure at manometer E, and applying the perfect gas laws. All pressures were measured by means of a cathetometer reading to 0.001 cm. Lowering K then admitted any desired amount of water into the catalyst bulb, the traps t serving to prevent any mercury from being thrown over into bulb A.

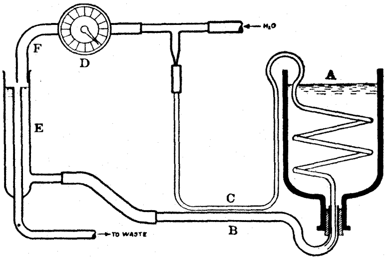

Fig. 8.

It was found simpler in practice, and the results were more reproducible when running desorption cycles. The majority of runs were made in this way. Experiments were made which demonstrated that the "zero point" could be checked to within 1% upon running an adsorption cycle, followed by a desorption cycle. It was also shown that the same curve was traced on both the adsorption and desorption cycles, no evidence of hysteresis appearing. The method of measuring the pressure probably involved the vaporization of a little of the sorbed water, so that final equilibrium may have been approached always from the same side, whether portions of water were being added or withdrawn.

The operation of the thermostat, Fig. 8, is almost self-evident from the diagram. A stream of water from the tap was passed through the tube marked "H_2O." Pinch clamp D (fitted with a dial and pointer) served to by-pass enough water through the small copper tube C to carry off just as much heat from A as entered by conduction from the air-bath.

Upon applying the principles developed from theoretical considerations to the individual curves, we arrive at the following conclusions.

Sample 1. Poorest catalyst.—A long, nearly horizontal portion of the curve with rather abrupt change near the saturation volume indicates the presence of long, tube-like pores in the granule. About 30% of the total volume sorbed is held in capillaries of radius 85 to 90 Å.; 80% is sorbed by capillaries less than 150 Å. in radius. This granule, as was predicted, is the finest grained of all those tested.

Sample 2. Most porous, second best *catalyst.*—Curve shows little evidence of either long, tube-like pores or large cavities. About 30% of the total volume is held in capillaries of 200 to 300 Å. radius.

Sample 3. Best catalyst.—No evidence of tube-like pores; a large number of rather large cavities. About 40% of the total volume is held in capillaries larger than 700 Å. in radius.

Sample 4.—The curve seems to give evidence of two sets of pores of nearly constant radius but rather short, one group having a radius of about 75 Å., and the other about 160 Å. This evidence is, however, rather doubtful.

Sample 6.—There is evidence, from the sharpness of the break in the curve, that there are relatively few capillaries of about 275 Å. radius and that a large number of large cavities exist in the granule. Twenty-five per cent. of the total volume is held in pores of radius greater than 300 Å. Nearly 30% of the volume is held in capillaries of radius between 75 and 110 Å. but there seems to be little evidence of tube-like pores in this range.

The generalizations that may be drawn connecting the porosity and the catalytic activity from the foregoing are:

1. The poorest catalysts are those which have the finest grained structures or, stated in another way, the poorest catalysts are those which sorb the greatest amount of water at relatively low pressures.

2. The best catalyst is one having high porosity (large total pore volume) with the smallest number of fine pores and the largest number of cavities.

3. For the mixtures, the slight difference in catalytic activity may be due to differences in the accessibility of the surface; the mixture *effect* still fails to find an explanation in the physical properties studied.

An additional result, for which it has been impossible to suggest an explanation that appears reasonable, may be pointed out at this point. In the region of "true adsorption" (vapor pressure less than half the saturation pressure) all the curves except that for Sample 1 coincide within the limits of error in the measurements. This would seem to indicate that the ratio of surface exposed to pore volume of the granules is the same for Samples 2 to 6, but is greater for Sample 1. Assuming cylindrical capillaries, their surface $S = 2\pi rl$, and their volume, $V = \pi r^2 l$, so that the ratio of surface to volume is $S/V = 2/r$, so that it would appear the material having the finest structure should have the greatest surface. Since Sample 1 has been shown by considerations enumerated above to have much the finest grained structure, it is to be expected that it should possess the largest adsorbent surface; the result that is hard to explain is that two granules which show such great differences in distribution of pore sizes as, say, Samples **3** and 6, should have the same surface.

In conclusion, I wish to express my gratitude for the help and encouragement given me by Professor W. C. Bray in the above investigation, and to my father for his assistance in making the sorption measurements.

Summary

It has been shown in the present investigation that: 1. The determination of the density of porous granules of certain oxides gave reproducible results by the immersion method of Hulett. No slow "drift" in the density of the granules similar to that encountered in determinations with charcoal was discovered. This indicates that there are few very small micro-capillaries in the former or else the resistance to filling of these pores is less. Adsorption curves prove the oxide granules to be much more coarse grained than the charcoal.

2. The porosity of the pure oxides is less than that of any of the mixtures made from them. This enhanced porosity is explained by colloidal phenomena.

3. There is no evidence of compound formation between the well washed oxides upon mixing.

4. An expression has been derived giving the volume of water sorbed by *a* porous body in terms of the radius of curvature of the water surface corresponding to the equilibrium pressure of the water vapor, the number and the radii and average length of the capillaries of the solid. The slope of the volume–vapor pressure curve depends upon the number and the radii of the capillaries present and the ratio of the saturation to the equilibrium pressure but not upon the average length of the capillaries. The sorption curves are shown to yield evidence as to the existence of long, tube-like capillaries in the granules in some cases.

5. Sorption curves have been determined for certain oxidation catalysts

in the form of porous granules. The poorest catalysts have the finest grained structure. No explanation for the "mixture effect" is discovered.

6. An apparent anomaly in the results has been pointed out. In the region of true adsorption, all the sorption curves except that for Sample 1 coincide, indicating nearly equal surface exposure per unit pore volume for all these granules, in spite of great difference in pore size.

THE HEAT CAPACITY AT LOW TEMPERATURES OF ZINC OXIDE AND OF CADMIUM OXIDE[1]

BY RUSSELL W. MILLAR[2]

RECEIVED JUNE 30, 1928 PUBLISHED OCTOBER 6, 1928

Research on the heat capacities of the oxides of metals previously reported by the author[3] has been continued. For the sake of a comparison of results with those of Parks and his co-workers,[4] the heat capacity of zinc oxide was redetermined.

Materials.—The zinc oxide used was the Sample 2 described by Maier, Parks and Anderson. It had been kept in an evacuated silica flask at 1100° for sixty hours. The product was microcrystalline and contained, according to them, less than 0.1% of impurities.

The cadmium oxide used was prepared by heating pure cadmium oxide in an open platinum dish at 1100° for three days. The product was finely crystalline and of much higher apparent densitv than the original powder.

The values of C_p, the heat capacity in calories per mole per degree, are presented in Tables I and II and in Fig. 1 opposite the corresponding temperatures in degrees Kelvin.

The entropy was calculated, as described previously, by extrapolation to the absolute zero by means of the sum of suitable functions of the form of Debye and of Einstein. For zinc oxide a Debye function with $\beta\nu$ = 295.5 and an Einstein function with $\beta\nu$ = 753 fitted the data with an accuracy of 0.5% to 250°K., although C_v and C_p begin to deviate at much lower temperatures. At higher temperatures the experimental values fall below those given by the theoretical functions. Using C_p and log T as coördinates, the curve was extrapolated to 37.58°K., where it joined the Debye curve at $C_v = 0.860$. Below this temperature the tables of Mieth-

ing[5] give the entropy as 0.308 cal. per mole. The area above this temperature represents 9.97 entropy units, so that for ZnO, $S°_{298} = 10.28$. The error is probably not over 0.05 unit.

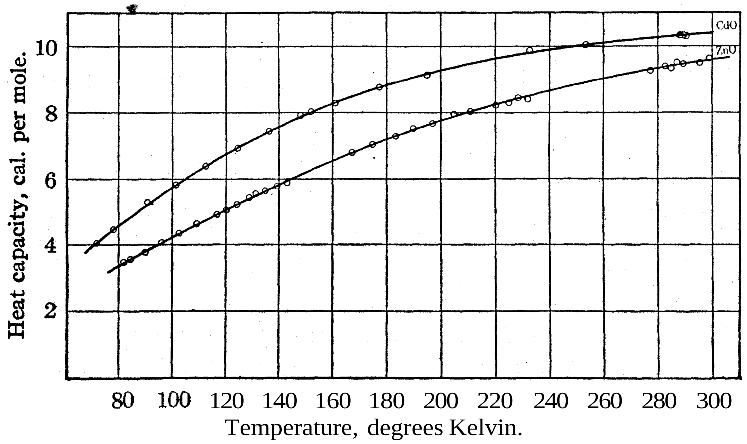

Fig. 1.—The molal heat capacities of cadmium oxide and zinc oxide.

A similar calculation for cadmium oxide, with $\beta\nu = 236$ and 478.5 for the Debye and Einstein functions, respectively, gives 0.36 entropy unit

---

[5] Published in Nernst, "Die theoretischen und experimenteller Grundlagen des neuen Wärmesatzes," Wilhelm Knapp, Halle, 1918.

at 31.84°K. and, by graphical integration, 12.81 units between 31.84 and 298°K. Thus for CdO, $S°_{298} = 13.17$. The sum of these functions agrees with the data within 0.2% to 160°K., and exceeds the experimental values at higher temperatures. Obviously the theoretical values would exceed the values of C_v, if necessary data for their calculation existed, at still lower temperatures.

The values of the heat capacity of zinc oxide agree with those of Maier, Parks and Anderson within 0.2% at their lowest temperature, 88°K., but become appreciably lower at higher temperatures. At room temperature the deviation is 2%. Although widely different methods of calculation were employed, the entropy which they give, $S°_{298} = 10.4$, differs but little from the present value of 10.28.

No significance is to be attached to the agreement of various combinations of theoretical curves for heat capacity with the experimental values of this quantity, for all such mathematical treatments rest upon hypotheses not entirely true and, furthermore, are designed to give values of C_v and not C_p. However, extrapolations by means of these curves cannot be far from correct when the last measured value of the heat capacity is not more than 4 calories per mole, and they undoubtedly approach the absolute zero correctly.

After reviewing the direct determination of the heat of formation of zinc oxide and comparing the values obtained from the temperature coefficients of the equilibrium constant of the reaction $ZnO + CO = Zn + CO_2$ and of the e.m.f. of the cell $ZnO + Zn | Ba(OH)_2$ soln. $| H_2$, Maier, Parks and Anderson[4b] give 83,000 cal. as the best value. Roth and Chall[6] have recently obtained 82,905 cal. for dense zinc oxide and 82,825 for less dense material at 50°, while Parks, Hablutzel and Webster[7] give 83,240 cal. at 20°. We shall choose for $Zn_{(s)} + {}^1/_2 O_{2\,(g)} = ZnO_{(s)}$; $\Delta H = -83{,}000$.

Maier after a review (to be published soon) of the data, has chosen 62,000 as the probable value of the heat of formation of cadmium oxide.

For zinc and cadmium, Lewis, Gibson and Latimer[8] give $S°_{298} = 9.83$ and 11.80, respectively, and for O_2 we may use, as before, Millar's[3] value 49.2.

We have $Zn_{(s)} + {}^1/_2 O_{2(g)} = ZnO_{(s)}$, $\Delta H_{298} = -83{,}000$, $\Delta S°_{298} = -24.15$, $\Delta F°_{298} = -75{,}800$; and $Cd_{(s)} + {}^1/_2 O_{2(g)} = CdO_{(s)}$, $\Delta H_{298} = -62{,}000$, $\Delta S°_{298} = -23.23$, $\Delta F°_{298} = -54{,}200$.

Since the value of the free energy of zinc oxide which Maier, Parks and Anderson obtained from cells, –75,930, is doubtless much more nearly accurate than our knowledge of the heat of formation, it is more logical to calculate the latter from the entropy of formation. We obtain $\Delta H = -83{,}130$, a value probably accurate to within 100 calories.

Summary

1. The heat capacities of zinc and cadmium oxide from 70 to 300° Kelvin have been determined.

2. The entropy of zinc oxide at 298°K. is 10.28 ± 0.05 cal./mole/degree, and of cadmium oxide is 13.17 ± 0.1 cal./mole/degree.

3. For zinc oxide we find from an accurate value of the free energy and the entropy of formation $\Delta H = -83{,}100 \pm 100$, and for cadmium oxide we find from the entropy of formation and a somewhat uncertain value of the heat of formation, $\Delta F^\circ_{298} = -54{,}200$.

THE EQUILIBRIUM $2K_3Fe(CN)_6 + 2KI \rightleftharpoons 2K_4Fe(CN)_6 + I_2$ IN AQUEOUS POTASSIUM CHLORIDE SOLUTIONS

BY VICTOR K. LA MER AND KARL SANDVED

RECEIVED JULY 10, 1928 PUBLISHED OCTOBER 6, 1928

I. Introduction

This paper comprises one phase of a study of the kinetics of ionic reactions which proceed to a measurable equilibrium state, the purpose of the study being to investigate the velocity of the reaction not only in its initial stages but also in the neighborhood of equilibrium.

The reaction between ferricyanide and iodide ions yielding ferrocyanide and iodine, as follows

$$2Fe(CN)_6^{---} + 2I^- \rightleftharpoons 2Fe(CN)_6^{----} + I_2 \qquad (1)$$

possesses certain advantages for such a study since

1. The reaction reaches an equilibrium state after 2–13% conversion, depending upon the composition and the amount and character of added neutral salts. The equilibrium state is therefore accessible to experimental measurement and is well adapted for a study of salt effects.

2. The velocity of the reaction is also highly sensitive to neutral salt catalysis, a subject of considerable theoretical interest at the present time.[1]

3. Previous studies[2,3,4] have shown that the velocity of the reaction, unlike most reversible ionic reactions, is of a magnitude that can be followed.

In the investigations of Donnan and Le Rossignol,[2] Just[3] and Wagner,[4] the reaction was followed by adding measured amounts of thiosulfate and

starch and noting the time of appearance of the blue color. Although this very simple technique, known as the compensation method of Harcourt and Esson,[5] has the advantage of continuously regenerating the iodide ion as fast as it is converted to iodine by ferricyanide, so that the concentration of iodide is constant throughout the course of the reaction, it is impossible to study the equilibrium state by this method since the reaction is forced to completion by the addition of thiosulfate.

We have accordingly adopted the method of titrating the liberated iodine in aliquots removed at definite time intervals. The kinetic measurements will be reported later and only data on the equilibrium state and its relation to the component potentials of the ferro–ferricyanide and iodine–iodide systems will be considered in the present paper.

II. The Equilibrium Constant in Salt Solutions

The thermodynamic mass action function for Reaction (1) may be written as follows

$$\frac{c^2_{\mathrm{Fe(CN)_6^{----}}} \cdot c_{\mathrm{I_2}}}{c^2_{\mathrm{Fe(CN)_6^{---}}} \cdot c^2_{\mathrm{I^-}}} \times \frac{f^2_{\mathrm{Fe(CN)_6^{----}}} \cdot f_{\mathrm{I_2}}}{f^2_{\mathrm{Fe(CN)_6^{---}}} \cdot f^2_{\mathrm{I^-}}} = K_a \qquad (2)$$

$$K_c \times K_f = K_a \qquad (3)$$

where c refers to the stoichiometric concentration and f to the stoichiometric activity coefficient of the participating components. K_a is a true constant for any given temperature and pressure and is independent of changes in concentration. The value of K_a is calculated in Section (V). To avoid the cumbersome quotients the abbreviated symbols given in (3) corresponding to (2) are introduced.

From what is known of the behavior of the activity coefficient as a function of valence and the total electrolyte concentration in dilute solution,[6] it is evident that the ratio

$$K_f = f^2_{\mathrm{IV}} \cdot f_0 / f^2_{\mathrm{III}} \cdot f^2_{\mathrm{I}} \qquad (4)$$

where the roman subscripts refer to the valences of the ions involved in (1) and (2), should presumably decrease with increasing salt concentration, which means that the equilibrium state will be displaced to the right. Constant values for the stoichiometric equilibrium "constant" K_c therefore can only be expected when the ratio of the coefficients in (4) is constant, that is, when a constant thermodynamic environment[7] is maintained.

Although measurements exist for computing an estimate of the change of the component activity coefficients in K_f as a function of salt concen-

tration, in no case do the measurements correspond to the exact environment which is produced by the simultaneous presence of both systems, and particularly for concentrated solutions.

In their studies on the equilibrium

$$2Fe^{+++} + 2I^- \rightleftharpoons 2Fe^{++} + I_2^- \qquad (5)$$

Bronsted and Kai Pedersen[8] showed that a constant environment could be obtained by the addition of an excess of neutral salt. They found 1.65 *M* KCl + 0.1 M HCl to be sufficient for the conditions under which they studied their reaction.

In view of its importance for our further studies, it seemed desirable to determine whether or not the general principle enunciated by Brönsted,[9] namely, "That the simple gas laws hold good for ions or salts when other salt solutions are employed as solvents, the concentration being large in comparison with the concentration of the dissolved ion or ions," would also hold good for the present reaction where tri- and tetravalent ions were involved and at considerably higher concentrations than those employed in the experiments of Bronsted and Pedersen.[8] The highly specific behavior[10,11] of ferro- and ferricyanides in dilute solutions makes it especially desirable to test the principle with these ions.

III. Experimental Procedure

Weighed amounts of potassium ferricyanide corresponding to the concentrations given in Col. 2 of the tables were dissolved in boiled distilled water in a volumetric flask, calibrated to deliver 50 cc., and immersed in a thermostat at 25°. The potassium iodide and potassium chloride (also potassium ferrocyanide in Expts. 21 and 22) were weighed out, dissolved in 250 cc. of distilled water and brought to 25° in a 500cc. Erlenmeyer flask. When both solutions had acquired the temperature of the bath, the reaction was started by adding the 50 cc. of ferricyanide solution to the potassium iodide. A series of Erlenmeyer flasks containing definite amounts of *N*/100 $Na_2S_2O_3$, weighed out from a weight buret and diluted to 125 cc. with boiled water containing 0.08 g. of dissolved starch, were in readiness before the start of the reaction. Samples were withdrawn at 2.5-minute intervals in a 10cc. measuring pipet calibrated to a 0.1cc. graduation and allowed to flow rapidly into these flasks until the color change due to iodine was retained on stirring

From four to six titrations were made on the system after equilibrium was reached and the average was recorded in Col. 8 of the tables in terms of the concentration of potassium ferrocyanide formed. The maximum deviation from the average was about 0.3%. It required about forty to sixty minutes to reach equilibrium in the presence of excess potassium chloride and a somewhat longer time in its absence.

[10] La Mer and Mason, THIS JOURNAL, 49, 410 (1927)

[11] G. N. Lewis, Z. *physik. Chew.*, *70*, 212 (1909), points out that the classical dissociation constant of potassium ferricyanide changes about one million fold in passing from 0.0001 *M* to 1.0 *M*.

There are several factors which contribute to make this method an accurate one for determining the concentrations at equilibrium. The forward reaction is of the second and first orders, respectively, for iodide and ferricyanide. Fifteen-fold dilution alone is thus amply sufficient to check the reaction. Furthermore, this dilution displaces the equilibrium almost completely to the left and the instantaneous removal of iodine by the thiosulfate prevents the reverse reaction from proceeding. That this is really the case was proved by allowing samples at the titration end-point to stand overnight., No perceptible color change occurred.

All salts employed were of c. p. grade and the potassium ferricyanide was recrystallized twice from water. The potassium chloride used in Expts. 1 to 16 was recrystallized twice.

IV. Discussion of Results

The Tri-iodide Equilibrium

Cols. 5, 6 and 7 of Table I give the concentrations of the solutions, respectively, in terms of the sum of the KI and KCl, the total equivalent concentration or ΣK, and the ionic strength μ defined as $\mu = {}^1/_2\ \Sigma c_i z_i^2$. Since the concentrations of I_2 and $I-$ are influenced by the well-known equilibrium

$$I_3^- \rightleftarrows I_2 + I^- \tag{6}$$

the amount of iodine titrated is recorded in Col. 9 in terms of its stoichiometric equivalent potassium ferrocyanide.

In the most recent investigations for the constant

$$L = \frac{c_{I^-} \cdot c_{I_2}}{c_{I_3^-}} \cdot \frac{f_{I^-} \cdot f_{I_2}}{f_{I_3^-}} \tag{7}$$

is given as 0.00153 for water as solvent by Bray and MacKay,[12] whereas Bronsted and Pederson found 0.00502 at 15° and 0.00540 at 18.5°, and give an extrapolated value of 0.00611 for 25° using 1.65 M KC1 + 0.1 M HCl as solvent. The latter value appears to be quite trustworthy and was used in all the further calculations.

By applying the law of mass action to Equations 1 and 6, the following expression for the concentration of the complex ion I_3^- results

$$c_{I_3^-} = \frac{b + L - x/2 - \sqrt{(b + L - x/2)^2 - 2\,x\,(b - x)}}{2} \tag{8}$$

where b = initial concentration of KI, x = concentration of $K_4Fe(CN)_6$ formed, and $x/2$ = concentration of I_2 formed.

It is at once apparent from the I_3^- values tabulated in Col. 9 of the table that almost all of the iodine formed exists in the form of the complex ion, since the values in Col. 8 are only a little more than twice those of Col. 9. For this reason it is more convenient to compute the equilibrium constant (Col. 11)

$$K_c' = \frac{x^2 \cdot c_{I_3^-}}{(a - x)^2(b - x - c_{I_3^-})^3} \tag{9}$$

---

corresponding to the reaction

$$2Fe(CN)_6^{---} + 3I^- \rightleftharpoons 2Fe(CN)_6^{----} + I_3^- \qquad (10)$$

where a = initial concentration of ferricyanide. The mass action function for (10) will be designated by primes to distinguish it from (3); namely,

$$K_c' \cdot K_f' = K_a' \text{ where } K_f' = \frac{f_{IV}^2}{f_{III}^2} \cdot \frac{f_{I_3^-}}{f_{I^-}^3} \qquad (11)$$

The equilibrium constants for the original Equation 1 can be obtained when desired by multiplying the figures in Col. 11 with the appropriate value of L for the solvent employed. We have not done this because systematic studies on the variation of *L* for potassium chloride additions have not been made. That L changes markedly when chlorides are added is evident from the values given by Bray and MacKay and by Bronsted and Pedersen. For an accurate calculation the L value used in (8) should of course correspond with the measured value for the particular solvent employed. However, we have proved to our satisfaction that the $c_{I_3^-}$, as computed from (8), is not appreciably affected by using either the Bray or the Brönsted value. For example, $10^3K'_c$ in Expts. 1 and 23 is changed from 0.637, and 17.8 to 0.649, and 18.3 when L is assigned the values 0.00611 and 0.00143, respectively. Since the p value of 1.63 lies intermediate in our range of salt concentrations, the value L = 0.00611 is more appropriate for the calculations in Tables I and II.

A comprehensive study of the behavior of L in salt solutions, particularly the halides, by the method given by Bronsted and Pedersen, is needed since this constant enters into the interpretation of all kinetic and equilibrium studies involving iodine.

V. Determination of K_a and K'_a from e.m.f. Data

Although we cannot measure K'_c at sufficient dilution to extrapolate safely to infinite dilution to determine K'_a, we can by a combination of existing free energy data arrive at what should be very trustworthy values for K'_a and K,.

Linhart's[13] careful measurements on the cell

$$\mathrm{Hg, HgCl\,(S) + KCl\,(M)}, \left(\begin{matrix}\mathrm{K_3Fe(CN)_6(c_1)}\\ \mathrm{K_4Fe(CN)_6(c_2)}\end{matrix} + \mathrm{KCl\,(M)}\right)\mathrm{Au} \qquad (12)$$

give, when corrected for the activity of potassium chloride as Wnhart has done using the measurements of Harned, the free energy of the reaction

$$\mathrm{Hg\,(S) + Fe\,(CN)_6^{---} + Cl^- = Fe(CN)_6^{--} + HgCl\,(S)} \qquad (13)$$

$$\mathrm{E_0} = 0.2188 \pm 0.0002;\ \Delta F^{\circ}_{298.1} = -5049 \pm 5$$

In these experiments no liquid junction potential exists since the potassium chloride was in great excess and of the same concentration in both half-cells. Eight molalities of potassium chloride were used, ranging between 0.05 M and 4.284 M. The concentration ratio c_1/c_2 was varied between 2 to $^1/_2$ and $(c_1 + c_2)$ between 0.0005 to 0.02 M at the highest concentrations of potassium chloride.

When the concentration of potassium chloride was greater than 0.1 M, Wnhart found that the activities of potassium ferrocyanide and potassium ferricyanide were proportional to their concentrations, a result which Bronsted's principle demands. The greatest variation which $\mathrm{E_0}$ exhibited is only 0.4 mv. in changing from $c_1/c_2 = 2$ to $^1/_2$, which corresponds to a change of 2.5% in K'_c. Linhart speaks of this result as in accord with the view that potassium ferrocyanide and potassium ferricyanide are

---

[13] Linhart, THIS JOURNAL, 39,615 (1917).

undissociated or at least that the ionization of intermediate ions is completely repressed. This is not necessarily true. Linhart's results only prove that both salts are dissociated to the same extent in potassium chloride solutions. The data may be taken equally well as proof for the hypothesis of complete dissociation as for any definite degree of incomplete dissociation.

Linhart also shows that Lewis and Sargent's[14] data yield the same average value for $\mathbf{E}_0$ when the differencesin potassium chloride concentration in the oxidation cell and normal calomel cell are taken into account. Lewis and Sargent's measurements consequently serve as a good check upon his results.

On the other hand, the measurements of Schoch and Felsing[15] involve concentrations of ferro- and ferricyanide relative to potassium chloride which are too large to determine $\mathbf{E}_0$ accurately. Nevertheless, the trend of their values is also consistent with a value $E_0 = 0.2188$.

The other data needed for the calculation are taken from Lewis and Randall's "Thermodynamics" with the exception of cell (14). For 25°

$$\mathrm{Hg\,Cl\,(S)} + \mathrm{E}^- = \mathrm{Hg} + \mathrm{Cl}^-;\ \mathbf{E}_0 = 0.2676;^{16}\ \mathrm{AF}^\circ = -6175 \qquad (14)$$

$$\mathrm{I}^- = \mathrm{E}^- + \frac{1}{2}\mathrm{I}_2\,(\mathrm{S});\ \mathbf{E}_0 = -0.5357 \pm 0.0004;\ \mathrm{AF}^\circ = 12{,}361 \pm 10 \qquad (15)$$

$$\frac{1}{2}\mathrm{I}_2\,(\mathrm{S}) = \frac{1}{2}\mathrm{I}_2\,(\mathrm{aq.});\ \mathbf{E}_0 = -0.0851;\ \Delta F^\circ = 1963 \qquad (16)$$

$$\frac{1}{2}\mathrm{I}_3^- = \frac{1}{2}\mathrm{I}^- + \frac{1}{2}\mathrm{I}_2(\mathrm{S});\ \mathbf{E}_0 = +0.0010;\ \mathrm{AF}^\circ = -23 \qquad (17)$$

By combining (13) and (14), we get (18)

$$\mathrm{Fe(CN)_6}^{---} + \mathrm{E}^- = \mathrm{Fe(CN)_6}^{----},\ \mathbf{E}_0 = +0.4864;\ \mathrm{AF}^\circ = -11{,}224 \qquad (18)$$

with an uncertainty which should be less than 1 mv.

Similarly, by combining (18) and (15)

$$\mathrm{Fe(CN)_6}^{---} + \mathrm{I}^- = \frac{1}{2}\mathrm{I}_2(\mathrm{S}) + \mathrm{Fe(CN)_6}^{----};\ \mathbf{E}_0 = -0.0493;\ \Delta F^\circ = 1137 \qquad (19)$$

or by combining (18), (15) and (16), we obtain

$$\mathrm{Fe(CN)_6}^{---} + \mathrm{I}^- = \frac{1}{2}\mathrm{I}_2\,(\mathrm{aq.}) + \mathrm{Fe(CN)_6}^{----};\ \mathbf{E}_0 = -0.1344;\ \Delta F^\circ = 3100 \qquad (20)$$

To take into account tri-iodide .formation, we have on combining (19) and (17)

$$\mathrm{Fe(CN)_6}^{---} + {}^3/_2\,\mathrm{I}^- = \frac{1}{2}\mathrm{I}_3^- + \mathrm{Fe(CN)_6}^{----};\ \mathbf{E}_0 = -0.0503;\ \Delta F^\circ = 1160 \qquad (21)$$

By introducing the well-known formula

$$-\mathrm{AF}^\circ = \mathbf{N\,F\,E}_0 = RT \ln K$$

we obtain the following values for the equilibrium constants K_a and K'_a, corresponding to Equations 1 and 10 for N = 2 when the activities of all components are one (hypothetical) molal; namely,

$$K_a = 2.89 \times 10^{-5} \tag{22}$$

$$K'_a = 0.199 \times 10^{-3} \tag{23}$$

which corresponds to

w $$L_a = \frac{a_{I_2} \cdot a_{I^-}}{a_{I_3^-}} = \frac{K_a}{K'_a} = 0.00143 \tag{24}$$

in substantial agreement with Bray and MacKay's value.[17]

VI. The Influence of Environment

In Col. (12), K'_f is computed by dividing K'_a by the stoichiometric quantity, K'_c, and in accordance with expectation K'_f decreases markedly with increasing salt concentration. The most striking result of the investigation is the marked dependence of K'_c, in the absence of foreign neutral salts, arising from comparatively small variations in the initial ferricyanide and iodide concentrations, and the almost complete obliteration of this dependence in the presence of excess potassium chloride. Thus Expts. 1–4 show a change in K'_c or K'_f of 35% when potassium iodide is varied from 0.15 to 0.20 M in the absence of potassium chloride and the concentration of potassium ferricyanide is held constant at 0.075 M.

In the next group of experiments (5–9), potassium chloride is added to maintain the sum of potassium chloride and potassium iodide constant at 1.20 M. K'_c now shows a variation of less than 2% which is within the experimental error. Expts. 5–9, 12–14 and 16–17 may therefore be taken as an excellent confirmation of Bronsted's principle. Expts. 18–20 indicate that 0.50 M potassium chloride is hardly sufficient to maintain a constant environment, a change in potassium iodide from 0.10 to 0.20 causing K'_c to increase by about 20%.

In Expts. 27 and 28, the same change in potassium iodide produces a 6% change in K'_c in the presence of 2.00 *M* potassium chloride. This variation is about three times as great as the probable error in K'_c and is most likely to be ascribed to the fact that the value of L employed does not correspond to this salt concentration and therefore does not yield exactly comparable results for $c_{I_3^-}$ when potassium iodide is varied as is the case for the experiments where $\mu = 1.65$ for which environment L has been determined.

Considering now those experiments in which ferricyanide is varied, it is evident that the ionic strength does not function as an entirely satis-

---

[17] The minor difference between Lewis and Randall's value for L_a and Bray and MacKay's value is due to a slightly different assumption in regard to the behavior of the activity coefficients of I^- and I_3^- ions. See Lewis and Randall, "Thermodynamics," p. 527.

factory measure of the electric environment, although it is perhaps the best of all proposed measures. Comparing Expt. 10 with Expts. 5–9, and Expt. 15 with Expts. 12–14, it is seen that for constant ionic strength produced by interchanging potassium chloride for potassium ferricyanide K'_c becomes smaller as potassium ferricyanide is increased.

The principle of ionic strength assumes that the square of the valence is the appropriate function to take into account changes in the concentration of ions of different valences. The Debye-Hückel theory yields this theorem as a limiting law for extreme dilution, but it is certainly not universally true when any appreciable concentrations of high valence ions are present.[18] This inadequacy of the principle of ionic strength has already been demonstrated for other systems of high valence ions and for far more dilute solutions than those now under consideration, namely, as low as 0.0005 μ.[19]

If we compute the appropriate valence exponent in order to maintain constant values of K'_c by changing the c_{KCl} when the ferricyanide concentration changes from 0.075 M to 0.10 M, we find that an exponent of 1.75 is satisfactory for Expts. 5–9 and 12–14, but groups 12–14 and 16–17 require an exponent of 1.1 for a corresponding change in ferricyanide concentration from 0.10 to 0.05 M. It will be of interest to carry out experiments with the ferricyanide concentration at still lower values to see if in the limit the equilibrium constant is determined by the equivalent concentration which demands a valence exponent of unity.

The addition of 0.003 M potassium ferrocyanide, although of considerable influence upon the percentage conversion and the observed rate of reaction, is without influence upon K'_c, as is to be expected (Expts. 16 and 22). A qualitative experiment using 0.5 M HCl + 1.00 M KCl showed a percentage conversion about 5 times that found in the absence of hydrochloric acid, and a few experiments were accordingly undertaken to determine the influence of P_H. Expts. 7, 26, 32 and 33 show that although acidity has no effect up to a P_H of about 3.7, a very noticeable increase in the oxidizing action of ferricyanide is apparent as the hydrochloric acid is increased above 0.001 M. Kolthoff[20] states that hydroferrocyanic acid is a weak acid with a dissociation constant of about 5.10–4 and the oxidation potential of the ferro–ferricyanide system is increased

owing to removal of ferrocyanide ion in acid solution. Our experiments are consistent with this prediction but hardly support Kolthoff's statement that ferrocyanide will *quantitatively* reduce iodine in neutral solution, except, of course, the presence of excess ferrocyanide. The validity of his empirical expression for the influence of hydrochloric acid, upon which this statement seems to be based is restricted to the concentration range studied, namely, 0.0125 N to 1.00 N HCl, and should be modified to take in the influence of the dissociation constant.[20]

We wish to acknowledge the grant of a DuPont Fellowship which enabled one of us (K. S.) to engage in this research.

Summary

The equilibrium state for the reaction

$$2Fe(CN)_6^{---} + 3I^- \rightleftharpoons 2Fe(CN)_6^{----} + I_3^-$$

has been studied analytically for the potassium salts in pure water as well as in aqueous potassium chloride solutions as solvents.

Using water as solvent the value of $K_{eq.}$ changes 35% when the concentration of potassium iodide is increased from 0.15 *M* to 0.20 M, but the corresponding change is less than 2% in the presence of 1.0 M KCl. The data confirm the principle that the law of mass action holds for ionic systems when a sufficient excess of neutral salts is present to maintain a constant electrical environment, although this law fails completely in the absence of excess of neutral salts.

The inadequacy of the principle of ionic strength for high valence ions is also evident in this system.

The equilibrium constant in the absence of salt effects has been computed from e.m.f. data and found to be $0.199 \cdot 10^{-3}$.

Addition of hydrochloric acid up to a PH value of about 3.5 is without influence upon $K_{eq.}$ but is of marked influence in more acid ranges.

THE THEORY OF ACIDITY

BY LOUIS P. HAMMETT

RECEIVED JULY 14, 1928 PUBLISHED OCTOBER 6, 1928

During the past five years there has been published by Hantzsch a series of papers[1] on the nature of acidity, whose results are markedly at variance with accepted ideas on the subject. In the recent papers of Hall and Conant[2] on "superacid solutions" there is presented evidence from much more precise indicator studies and from potential measurements of the essential correctness of some of Hantzsch's conclusions. These results may be completely explained by methods which derive from Brönsted's important treatment of the problem,[3] and which will be developed in the present article.

According to the classical ionization theory the quantitative measure of acidity is hydrogen ion concentration, and a non-ionized solution cannot have the properties of an acid. The experimental evidence for this conclusion is the unquestionably close parallelism between ionization and acidity in solutions in a single solvent, and the fact that such non-ionized solutions as hydrogen chloride in benzene do not react or react only very slowly with metals and carbonates.[4] Hantzsch's conclusion, on the other hand, is that practically non-conducting solutions may be acid, even that such solutions may be much more acid than highly ionized aqueous solutions. His evidence is that dilute solutions of certain acids in non-ionizing solvents produce the same effect upon indicators as do more concentrated solutions of the same acid in water; and that the rate of decomposition of diazoacetic ester, an acid catalyzed reaction, is greater in the non-ionized solution than in an equally concentrated aqueous solution of the same acid.

The evidence for high acidity in the non-ionizing solvent depends upon homogeneous reactions; the evidence against high acidity depends upon heterogeneous reactions for which both reactant and product are insoluble in the medium. The formation of protective coatings seems almost certain, and it is clear that Hantzsch's conclusions rest upon sounder evidence than do the accepted theories.

The essential features of Hantzsch's results may be summarized as

follows: 1. Acids (HCl, HBr, $HClO_4$) which are both highly ionized and strongly acidic in aqueous solutions, are even more strongly acidic yet practically un-ionized in hydrocarbons and similar solvents, and differ among themselves greatly in their acidity; whereas dilute aqueous solutions of the different acids have the same acidity at the same concentration. 2. Acids (acetic, formic) which are weak in water are much weaker in the hydrocarbon type of solvent. 3. Many solvents containining oxygen, notably ether, give solutions of extremely low acidity. Some acids which are strong in water (nitric, trichloro-acetic) are quite weak in ether, and only those acids (HBr, $HClO_4$) which are the most acid in chloroform and similar solvents have an acidity in ether which approaches the value in water.

Hantzsch's explanation of the first of these results seems very probable: that water is a base in much the same way that ammonia is a base; that an acid dissolved in water exists as an oxonium salt just as an acid dissolved in ammonia exists as an ammonium salt.[5]

Strong acids are then less acid in water than in solvents of lower basicity, and still less acid in the more basic ammonia, and they all have the same acidity in a given basic solvent, because this is now the acidity of oxonium (OH_3^+) or ammonium ion regardless of the acid used. This may be better expressed in terms of Bronsted's adaptation of Werner's theory in the light of the principle of complete dissociation. The formation of ions and the resultant conductivity, according to Brönsted, are due not ~~to~~ the reaction $HClO_4 \rightleftarrows H^+ + ClO_4'$ but to the reaction $HClO_4 + H_2O — OH_3^+ + ClO_4'$. This process can take place only by virtue of the fact that oxonium ion holds its hydrogen ion more firmly than does perchloric acid, that OH_3^+ is less acid than $HClO_4$.

These conclusions are further supported by the work of Hall and Conant, and the significance of the concept of basicity of solvent for the question of acidity is very clearly presented in their diagram and discussion.[6]

---

[5] Aside from Hantzsch's work, the theory that water is a base in this sense is supported by the following lines of evidence. The overwhelming similarity in the properties of water and ammonia, which shows so clearly for instance in Franklin's work on ammonia solutions, indicates strongly that the acidity relations are similar in the two solvents. But acids in ammonia solution are ammonium salts. There is evidence in the work on oxonium salts that the maximum coordination number of oxygen is three; that saturated oxygen compounds can add one hydrogen ion just as can ammonia and its substitution products. Fajans and Joos, *Z. physik*, 23, 1 (1924), have shown that the interpretation of the refractive index of aqueous acids demands the assumption of the existence of such an ion as OH^+_3. Hantzsch, *Z. physik. Chem.*, *65*, *41* (1908), has shown that the cryoscopic effect in sulfuric acid of water and ammonia is the same. Volmer, *Ann.*, 440, 200 (1924), has demonstrated by x-ray analysis the crystallographic identity of ammonium perchlorate and the monohydrate of perchloric acid, which is therefore shown to be oxonium perchlorate.

[6] Ref. 2 b, page 3069.

If, however, basicity of solvent were the only factor, all acids, and not merely the strong ones, should appear stronger in chloroform than in water, which is not true. Bronsted'' has already suggested the importance of dielectric constant in this connection, and it is possible to account for Hantzsch's results as they have been enumerated by taking this into account.

It has been clearly shown by Brönsted[3a] that the only logically consistent general measure of acidity is hydrogen-ion potential (which is proportional to PH) or the closely related hydrogen-ion activity. The use of activities instead of potentials is convenient, but it should be made very clear that this use does not express or even imply any knowledge of concentration. Hydrogen-ion activity is by definition an exponential function of hydrogen-ion potential, and hydrogen-ion potential represents the work concerned in the reversible removal of hydrogen ions (protons) from a given system, or their addition to it. High activity means loosely bound hydrogen ions, low activity firmly bound hydrogen ions. Reaction proceeds by the transfer of hydrogen ions from higher to lower activity, and we have no means of knowing whether actual protons are ever present either as an intermediary or as a by-product in such transfers. It may, however, be reasonably expected that the concentration of free hydrogen nuclei in a solution should be at least as small as the concentration of free electrons, that is, negligible; and this point of view will be taken in what follows.

Since it is only the ratios of activities that can be measured, it is necessary always to set up a purely arbitrary scale of numerical values of activity. It has been convenient when considering the variation of activity with concentration in a single solvent to set up a different arbitrary scale for each solvent, in such a way that the activity coefficient, the ratio of activity to concentration, approaches one as the solution becomes infinitely dilute. This usual convention is, however, very unsatisfactory when solutions of the same solute in more than one solvent are considered,[7] and the quite different convention is adopted in this paper that the same scale of activities is used for all solvents. It follows then that two solutions of the same hydrogen-ion potential, that is, of the same true acidity, will have the same hydrogen-ion activity, no matter what the solvent, but it follows also that the activity coefficient will not in general approach one for infinitely dilute solutions. When numerical values become available it will probably be desirable to define the scale of activities in such a way that the activity coefficient approaches one for very dilute solutions in some one solvent, say water; the activity coefficient in another solvent will then approach a value which will in general be greater or less than one.

With this understanding it is possible to attack mathematically the

---

[7] *See* Scatchard, THIS JOURNAL, **47,** 2105 **(1925).**

problem of the effect of solvent upon acidity. The following symbols will be used: HX = acid, for example HCl, or $HClO_4$; S = solvent, for example water, ether, chloroform; c = concentration; a = activity; f = activity coefficient; c_a = stoichiometric concentration of HX.

Regardless of the solvent we have

$$a_{H^+} = K_{HX} \frac{a_{HX}}{a_{X'}} = K \frac{c_{HX}}{c_{X'}} \frac{f_{HX}}{f_{X'}} \tag{1}$$

but if the solvent is basic, we have also

$$a_{H^+} = K_S' \frac{a_{SH^+}}{a_S} = K_S\, c_{SH^+} \frac{f_{SH^+}}{A} \tag{2}$$

If, as seems probable, c_{H^+} may be taken as negligibly small

$$c_a = c_{HX} + c_{X'} = c_{HX} + c_{SH^+} \tag{3}$$

since the reaction between acid and solvent is $HX + S \longrightarrow X' + SH^+$. Combination of 1, *2*, and **3** gives

$$ant = \frac{1}{2} K_{HX} \frac{f_{HX}}{f_{X'}} \left\{ -1 + \sqrt{1 + 4c_a \frac{K_S}{K_{HX}} \frac{f_{SH^+}\, f_{X'}}{f_S\, f_{HX}}} \right\} \tag{4}$$

Since a_{H^+} increases with increasing K_S, this equation records the principle that *decreased basicity* of *solvent* (greater K_S) *means greater acidity, although it also means less ionization.*

In order to see more clearly the effect of changes in the f terms, which record the effect of changes in dielectric constant, it is advisable to consider the forms to which Equation 4 reduces in the two limiting cases.

When the second term under the radical sign is large compared with one, the equation becomes

$$a_{H^+} = \sqrt{c_a\, K_S K_{HX} \frac{f_{SH^+}\, f_{HX}}{f_S\, f_{X'}}} \tag{5}$$

This is the case of weak acid or weakly basic solvent; the reaction of ionization, $\mathbf{HX} + S \rightleftarrows X' + \mathbf{SH^+}$, is incomplete, and the acidity depends upon both K_S and K_{HX}, that is, upon the properties of both acid and solvent.

When the same term is small the radical may be expanded and using the linear term only we have

$$a_{H^+} = c_a K_S \frac{f_{SH^+}}{f_S} \tag{6}$$

Ionization is large and the acidity depends only upon the properties of the solvent. This represents the leveling effect of the solvent, mentioned by Hantzsch and by Conant and Hall.

We can now make at least a qualitative prediction of the effect of dielectric constant from the known effect of this property upon the activity coefficients. The activity coefficient of an ion is unquestionably greater in solvents of low than in solvents of high dielectric constant. This is demonstrated by the extremely low solubility of true salts in solvents of low dielectric constant, and is predicted by the interionic attraction theory of electrolytes. The changes in the activity coefficients for uncharged molecular species from solvent to solvent are much smaller than the changes of the ionic activity coefficients. It therefore follows of necessity that such a ratio as $f_{HX}/f_{X'}$ or f_S/f_{SH^+} will decrease with decreasing dielectric constant. We shall asume as an admittedly rough approximation that the change in this ratio between two different solvents is independent of the acid or base concerned. There is indeed some reason for believing that specific effects upon the ratio will be considerably smaller than the effect upon the individual activities. This corresponds to the impression that those acids or bases which are themselves much more soluble in organic solvents than in water will have salts which are relatively soluble in organic solvents.

It follows then that the ratio $f_{SH^+}\, f_{HX}/f_S\, f_{X'}$ in Equation 5 will be approximately one for all solvents; that *the hydrogen-ion activity of a weakly ionized acid is independent of the dielectric constant of the medium.* It follows from Equation 6 that *the hydrogen-ion activity of a highly ionized acid will be greater in solvents of low than in solvents of high dielectric constant.* For the intermediate cases decrease in dielectric constant will result in a more or less large increase in hydrogen-ion activity.

But hydrogen-ion activities cannot be measured directly unless or until we know very much more than we do at present about diffusion potentials. Verification of the theory depends upon its extension to some such measurable phenomenon as salt formation with indicators. We shall let I represent the molecular substance of some indicator base (dimethylamino-azobenzene, benzalacetophenone, etc.), and IH+ the ion which it forms with acids. Then

$$\frac{a_{H^+}\, a_I}{a_{IH^+}} = K_I \tag{7}$$

Suppose an amount of indicator be added which is insufficient to displace materially the acid solvent equilibrium. Then the salt base ratio of the indicator, which determines the color, is given by

$$\frac{c_{IH^+}}{c_I} = \frac{1}{K_I}\frac{f_I}{f_{IH^+}}\sqrt{K_{HX}\, K_S\, c_a} \tag{8}$$

for weakly ionized solutions, and by

$$\frac{c_{IH^+}}{c_I} = \frac{K_S\, f_{SH^+}\, f_I}{K_I\, f_{IH^+}\, f_S}\, c_a \tag{9}$$

for highly ionized. The same considerations already used concerning the effect of dielectric constant upon the activity coefficients lead to the conclusion *that decrease in dielectric constant will have little effect upon salt formation when ionization is large, and will decrease salt formation when ionization is small. For all except very highly ionized solutions the result of decreased dielectric constant will be a decrease in apparent acidity as measured by a basic indicator.*

We may now explain the conclusions drawn previously from Hantzsch's work. 1. Acids which are highly ionized and strong in water give increased salt formation with indicators in solvents of negligible basicity like chloroform and the hydrocarbons because these solvents are less basic than water, 2. Acids like acetic and formic which are weakly ionized in water give very little salt formation with indicators in these solvents of low dielectric constant because a reaction like $HX + I = IH^{+} + X'$ which produces ions from neutral molecules takes place to a smaller extent the smaller the dielectric constant. **3.** Acids, except the very strongest, which are presumably highly ionized in both ether and water, give less salt formation with basic indicators in ether than in water because of the low dielectric constant. Ionization is frequently much less in ether than in water, as with HCl, again because the reaction $HCl + S = SH^{+} + Cl'$ is displaced toward the left by lowered dielectric constant. Salt formation is, of course, always less in ether than in chloroform or similar solvents of about the same low dielectric constant because of the basicity of the ether.[8]

It will be seen that acidity as measured by a basic indicator does not run parallel to hydrogen-ion activity when there is a change in dielectric constant. It is only necessary to change to an acid indicator to see how unreliable indicator measurements must be for determining relative acidities in different solvents. Thus ordinary glacial acetic acid gives an intermediate shade with dimethylamino-azobenzene. From this one may estimate its P_H on the water scale to be about **3.5.** With picric acid it gives a colorless solution, indicating an acidity greater than that of molar aqueous hydrochloric acid, that is a P_H less than 0.[9]

Presumably the true acidity lies between the values indicated by the basic and by the acid indicator. For the color determining ratio acid over salt for an indicator HI (such as picric acid) is given by

$$\frac{c_{\mathrm{HI}}}{c_{\mathrm{I}'}} = \frac{1}{K_{\mathrm{HI}}}\frac{f_{\mathrm{I}'}}{f_{\mathrm{HI}}}\sqrt{K_{\mathrm{HX}}\,K_{\mathrm{S}}\,c_{\mathrm{a}}} \qquad (10)$$

for weakly ionized solutions, and by

$$\frac{c_{\mathrm{HI}}}{c_{\mathrm{I}'}} = \frac{K_{\mathrm{S}}}{K_{\mathrm{I}}}\frac{f_{\mathrm{SH^+}}\,f_{\mathrm{I}'}}{f_{\mathrm{S}}\,f_{\mathrm{HI}}}\,c_{\mathrm{a}} \qquad (11)$$

for those highly ionized. The effect is to increase the apparent acidity with decrease in dielectric constant, the change being greater the higher the ionization. A tabulation shows that the effect of decreased dielectric constant upon hydrogen-ion activity lies always between the effect upon apparent acidity by basic indicator and apparent acidity by acid indicator.

---

[8] If we may drive the analogy between water and ammonia a little farther, the basicity of ether should differ from that of water to about the same extent as that of an aliphatic amine differs from that of ammonia.

[9] It is only with the strongest alkalies that the medium permits, such as sodium acetate, that the picric acid indicator gives a yellow color in acetic acid as solvent.

Ionized system	Basic indicator	Hydrogen-ion activity	Acid indicator
Weakly	Decreased acidity	No effect	Increased acidity
Highly	No effect	Increased acidity	Greatly increased acidity

The best we can say about relative acidities in water and ether and water and acetic acid, then, is that they are approximately the geometric mean of the hydrogen-ion activities estimated by the use of basic and acid indicators.

The superacid solutions of Hall and Conant are probably even more acid than their own figures indicate. Their tentative choice of a scale of P_{H} in acetic acid amounts to the same thing as the assumption that two solutions in which a basic indicator gives identical colors have the same hydrogen-ion activity regardless of the solvent. They assume that two solutions with the same ratio of concentrations of an anhydro base and the salt which it forms by addition of hydrogen ion should have the same hydrogen-ion activity. From the equation $a_{\mathrm{H}^+} = K\ (c_{\mathrm{BH}^+}/c_{\mathrm{B}})\ (f_{\mathrm{BH}^+}/f_{\mathrm{B}})$ it will be seen that of two solutions with a given ratio of salt to base $c_{\mathrm{BH}^+}/c_{\mathrm{B}}$ the solution in the solvent with lower dielectric constant has the greater hydrogen-ion activity.

If the true P_{H} relative to aqueous solutions is two to three units less than the values given by Hall and Conant, it is unnecessary to assume such abnormal values for the diffusion potential in their salt bridge,[10]

It is true that salt formation, a concrete, measurable thing, is more important than a concept like activity, which is not susceptible to direct measurement; but it remains extremely important to call the thing we measure salt formation and not hydrogen-ion activity if it is salt formation and if it is not parallel to activity.

If we were to confine our interest in acidity to aqueous solutions the subject matter of the present article would be of little value. It is only when comparing acidities in different solvents that the basicity and dielectric constant of the solvent need be considered. Probably the greatest reason for an interest in acidity outside of the bounds of aqueous solutions is the great importance of catalysis by acids and bases in organic reactions. This becomes particularly important since the appearance of Meerwein's[11] evidence that zinc chloride and aluminum ethylate have acidic properties and that their catalytic properties are probably closely related to their acidity.

According to Hantzsch there is a close and far-reaching parallelism between salt formation with basic indicators and the rate of decomposition of diazoacetic ester, a reaction which has been a classical one for the study of acidity in aqueous media. The reaction is not an ideal one for the purpose of studying acidity in different media, for the product of the

---

[10] I am indebted to Professor H. A. Fales for pointing out that a diffusion potential of 0.15 volt is much greater than any previously known or suspected.

[11] Meerwein, *Ann.*, **455,** 227 (1927)

decomposition may be different with different acids and different solvents. Nevertheless it is possible, as Hantzsch supposes, that the reaction velocity depends in any case upon salt formation by addition of hydrogen ion to the ester, and that the final steps of the reaction, leading to the different possible products, do not affect the velocity. This would account for the observed parallelism of reaction velocity and indicator acidity.

It should be of great importance to investigate other, less ambiguous reactions to see if this parallelism can be generalized.

Summary

A generalized theory of acidity is proposed and given mathematical expression. In this the effect of the basicity and of the dielectric constant of the solvent are both considered.

The predictions of the theory are in agreement with the available evidence on acidity in non-aqueous solutions, notably with the work of Hantzsch and with that of Hall and Conant.

A BALLISTIC GALVANOMETER METHOD OF POTENTIOMETRIC MEASUREMENT FOR HIGH RESISTANCE CELLS

BY H. T. BEANS AND GEORGE H. WALDEN, JR.

RECEIVED JULY 18, 1928 PUBLISHED OCTOBER 6, 1928

Introduction

A recent publication by Jones and Kaplan[1] contains a description of a method of potentiometric measurement for high resistance cells which uses a condenser and ballistic galvanometer as a null point indicator. A deflection method for high resistance cells which used the condenser and ballistic galvanometer was used in this Laboratory by Beans and Oakes.[2] Since then we have developed a more exact method[3] which is in many respects similar to that of Jones and Kaplan but differs in that it is a semi-deflection method. We have experimentally demonstrated that our method may be used successfully with cell resistances as high as 50 megohms. The cells which Jones and Kaplan used had internal resistances no higher than 1.6 megohms. At higher resistances the null point method, while still possible, becomes very cumbersome due to the time required to charge the condenser sufficiently to cause a noticeable throw upon discharge. Our method overcomes this difficulty, at the same time retaining an accuracy of 0.1 to 0.5 millivolt.

Apparatus

A diagram of our apparatus is shown in Fig. 1. Our circuit is the same as that of Jones and Kaplan except in two particulars. We do not use a tapping key to discharge the condenser but a discharge switch, so that the ballistic galvanometer G_b receives the total discharge of the condenser, not the instantaneous discharge. Also the discharge switch has a third contact which automatically removes the damping shunt R_d at the moment of discharge. We also have a current galvanometer G_c for comparison purposes which may be substituted for the condenser-ballistic galvanometer system by means of a double pole double throw switch. G_b has a sensitivity of about 0.0007 microcoulomb per millimeter throw. C is a mica dielectric condenser of approximately 10 microfarads capacity. All switches have mercury contacts supported on hard rubber pedestals. Connections are made with wires supported by glass insulators or silk cord.

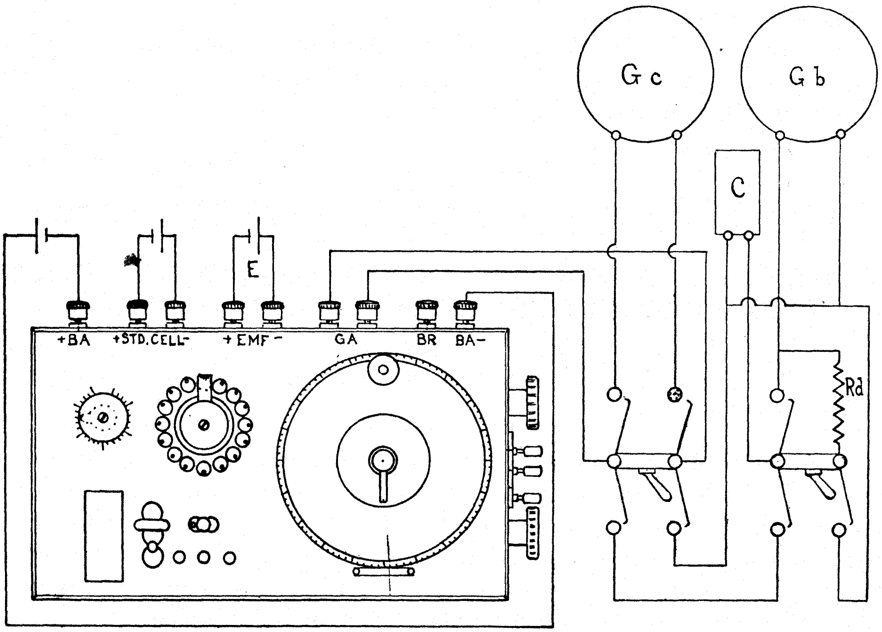

Fig. 1.—Working circuit diagram as used in connection with a Leeds and Northrup Type K potentiometer.

Method

Instead of locating the exact null point of the potentiometer by successive trials we locate it by this method within 10 millivolts. Then we measure the difference between the voltage of the potentiometer and the electromotive force of the cell by the throw of the galvanometer. To do this we need to determine the relationship between galvanometer throws and voltages between the condenser plates. This is accomplished as follows. We connect together the potentiometer binding posts marked "E.M.F." Then if the discharge switch is set to charge the condenser the applied potential difference will instantly be that of the potentiometer, since there is little resistance in the circuit. By charging and discharging with different settings of the potentiometer data are obtained with which to plot galvanometer throws against condenser voltages. Thus we empirically avoid all trouble due to a non-linear galvanometer characteristic and also from dielectric absorption. Data for this curve may be obtained in about fifteen minutes. It is necessary to check this curve occasionally since ballistic galvanometer constants change slowly. To measure the difference between the voltage of the potentiometer and the electromotive force of the cell, we may charge the condenser until it has attained its equilibrium charge nearly enough, discharge and observe the galvanometer throw, and read the difference directly from the curve. The required charging time becomes very long when cell resistances are high. For such cases we have devised a method of determining the equilibrium voltage by measuring the voltages between the condenser plates after two measured charging times. This cuts the time required to make a measurement about in half. When cell resistances are very high leakage through the dielectric of the condenser becomes a factor of importance. Our method considers this possibility and corrects for it where necessary.

Time Required to Charge a Condenser.—Let C = the capacity of the condenser; R = the resistance of the circuit; e = the charging electromotive force; v = the potential difference between the plates, of the condenser at any instant; q = the charge in the condenser at any instant; L = the resistance through the dielectric of the condenser and T = the elapsed time since the circuit was closed. As the condenser is charging

$$dq = \left[\frac{e - v}{R} - \frac{v}{L}\right] dT$$

$$T = RLC \int_0^q \frac{dq}{eLC - q(L + R)} = RC\,\frac{L}{L + R} \ln \left[\frac{e}{e - v\,\frac{L + R}{L}}\right] \qquad (1)$$

If L is very much larger than R, Equation 1 reduces to

$$T = RC \ln \frac{e}{e - v} \qquad (2)$$

If $v = 0.99e$ (corresponding to an error of 0.1 millivolt in a measurement of 10 millivolts), it has been found that if the condenser is moderately well constructed Equation 2 is a sufficiently close approximation. When R = 50 megohms, C = 10 microfarads and $v = 0.99e$; T, by Equation 2, is equal to 38.4 minutes. This large charging time is very objectionable since in the absence of exact knowledge of the resistance of the cell the only way to tell when the charging time has been sufficiently long is to obtain the same result after a longer period. Therefore, when R is large we do not measure e directly but calculate it from two measurements of v obtained after different time intervals.

Method of Calculating e when T is Large.—If v is measured after two time intervals, we have from Equation 1

$$T_1 = RC\,\frac{L}{L + R} \ln \left[\frac{e}{e - v_1\,\frac{L + R}{L}}\right]$$

$$T_2 = RC\,\frac{L}{L + R} \ln \left[\frac{e}{e - v_2\,\frac{L + R}{L}}\right]$$

Solution of these equations leads to the expression

$$e = \frac{v_2^2}{2v_2 - v_1} \times \frac{L + R}{L} \tag{3}$$

if $T_1 = 2T_2$. If e is never greater than 10 millivolts, L can be as small as $100R$ before error from neglect of the leak correction factor $(L + R)/L$ becomes greater than 0.1 millivolt. We have found that leak resistances in a well constructed condenser are sufficiently high so that this correction need not be used.

Elimination of Error from Dielectric Leakage.—If it may be assumed that the dielectric resistance L is constant, the value of the factor $(L + R)/L$ may be experimentally determined by means of Equation **3.** Two measurements of v are made after two time intervals, one twice as long as the other. Then the potentiometer setting is changed, changing e by a known amount to e', and two similar measurements of v' are made. Then

$$\frac{L + R}{L} = \frac{e - e'}{\dfrac{v_2^2}{2v_2 - v_1} - \dfrac{v_2'^2}{2v_2' - v_1'}} \tag{4}$$

from which it can be seen that if the difference between the values of e and e' calculated by Equation **3** neglecting the leak correction factor is equal to the difference between the potentiometer settings within the precision sought $(L + R)/L$ may be considered nearly enough equal to 1. If this is not the case it seems advisable to use another condenser with smaller leakage, since L may be expected to vary with the temperature and humidity. We have found that a sufficiently good condenser may be made by connecting 10 of the Western Electric Company's 1 microfarad condensers.

Error Introduced by Calculating e.—If v_1 and v_2 are measured after time intervals which are too short a very large error may be introduced. Since it is desirable to keep the charging times as short as possible in order to cut down the time required to make a measurement, some method of estimating this error is necessary. If Δv_1 and Δv_2 are the errors in the two measurements, the errors introduced by each into the calculation of e by Equation **3,** neglecting the factor $(L + R)/L$, will be

$$\frac{\delta e}{\delta v_1}\,\Delta v_1 = \frac{v_2^2}{(2v_2 - v_1)^2}\,\Delta v_1 = \frac{1}{(2 - r)^2}\,\Delta v_1$$

and

$$\frac{\delta e}{\delta v_2}\,\Delta v_2 = \frac{2v_2(v_2 - v_1)}{(2v_2 - v_1)^2}\,\Delta v_2 = \frac{2(1 - r)^2}{(2 - r)^2}\,\Delta v_2$$

where

$$r = \frac{v_1}{v_2}$$

Since the two errors are of opposite sign, the maximum error which can be introduced by this calculation is

$$\Delta e_m = \pm \Delta v \left[\frac{1}{(2 - r)^2} - \frac{2(1 - r)^2}{(2 - r)^2}\right] = \pm \Delta v\,\frac{2r - 1}{(2 - r)^2} \tag{5}$$

where Δv is the maximum error expected in measuring a. This relationship may be plotted for any given apparatus, arid the operator can then decide whether sufficiently long charging times have been taken by calculating r and finding Δe_m from the curve.

Error Caused by Leakage between the Poles of the Cell.—When electromotive force measurements are made on cells with large internal resistances very serious error may be caused by leakage between the poles of the cell. If R_L is the leakage resistance, R_I the internal resistance of the cell, E the electromotive force of the cell and AE the error caused by the leakage through R_L, it follows from Ohm's Law that $R_L = [(E - \Delta E)/E]$ R_I. If the measurement of E is to be accurate to 0.1 millivolt and if E may be as large as 1 volt, it is evident that R_L must be 10,000 times R_I. If R_I is of the order of several megohms, great care must be exercised in the design of the cell and its connections to the measuring instrument.

Experimental

Since it is not easy to construct a high resistance cell of known electromotive force, an analogous system consisting of a low resistance standard cell in series with a high resistance was used for testing purposes. The high resistance and cell were placed side by side, connected together with a short lead, and connected to the potentiometer with the same leads which were afterwards used to connect the actual high resistance cell. The high resistance consisted of the requisite number of megohm resistance units connected in series. The units were made by spattering platinum on mica.[4] The resistance of each unit was measured and found to be correct within a few per cent.

Table I shows a series of measurements made on a cell in series with resistances from 1 to 10 megohms. Over this resistance range it is not

necessary to calculate e since the time required to approach equilibrium closely enough is never more than ten minutes.

Table II shows a series of measurements over a resistance range of 10 to 50 megohms. Here e was calculated by Equation 3, neglecting the correction factor for leakage through the condenser. Charging times were chosen so that Δe_m from Equation 5 was about 1 millivolt if Δv is 0.1 millivolt.

Summary

1. We have described a semi-deflection method of potentiometric measurement which may be used with cells having internal resistances as high as 50 megohms.
2. We have discussed the precautions necessary with work of this kind.
3. We have shown that when full precautions are taken measurements may be made with a precision of ±0.1 millivolt when cell resistances are as high as 10 megohms, and with a precision of ±0.5 millivolt with cell resistances as high as 50 megohms.

TERNARY SYSTEMS. VII. THE PERIODATES OF THE ALKALI METALS

BY ARTHUR E. HILL

RECEIVED AUGUST 3, 1928 PUBLISHED OCTOBER 6, 1928

Following the discovery of periodic acid and the periodates, it was observed at an early date that the acid differed widely from the analogous perchloric acid in being distinctly polybasic and in the varying degrees of hydration of its hypothetical anhydride I_2O_7. The nomenclature most commonly adopted for classifying the various acids is, with slight modification, that of Blomstrand.[1] H_5IO_6, the hydrate of greatest water content, is known as para-periodic acid, $H_8I_2O_{11}$ as di-para-periodic acid, H_3IO_5 as meso-periodic acid, $H_4I_2O_9$ as di-meso-periodic acid and HIO_4 as meta-periodic acid. Although but two, or possibly three, of these acids are definitely known, salts derived from all of them have been reported; of these, the silver salts and the salts of the common alkali metals have been most thoroughly studied.[2] It does not appear, however, that the studies have been systematic in this nature; slight modifications in the conditions of preparation have given to the various investigators salts differing in their analyses and which were on that evidence assigned to the corresponding one of the five acids enumerated above. By such

methods the possibility of mixtures being regarded as pure salts is by no means excluded, It has seemed worth while to make a systematic investigation of the periodates of the two alkali metals, sodium and potassium, in order to determine with certainty just how many of those reported are true compounds. This can be completely determined, as far as salts crystallizing from water are concerned, by a study of the three component systems consisting of water, periodic acid and sodium hydroxide or potassium hydroxide, respectively, and the finished study should leave no doubt as to the compounds existing at the temperature selected. For reasons of convenience, however, since periodic acid is not easily prepared, the studies have been made with use of the meta-periodate of sodium or potassium (the most highly acidic salts known in each series) with water and the appropriate base; these show therefore all stable periodates more basic in composition than the meta-salt chosen. The possibility of more acidic salts will be mentioned later.

Materials.—The sodium periodate used in the experiments was prepared from pure sodium hydroxide, passing through the stage of the tri-sodium-para-periodate, $Na_3H_2IO_6$, which was eventually converted into the meta-periodate, $NaIO_4$. To a solution of pure sodium iodate five equivalents of sodium hydroxide was added and the solution stirred mechanically while a rapid stream of chlorine gas was passed through. The very insoluble sodium salt begins to precipitate within a few minutes. The stream of chlorine was continued until the solution gave an odor of hypochlorites and was nearly neutral; after the treatment with chlorine was interrupted, an additional equivalent of sodium hydroxide was added and the mixture well stirred for several hours. In the presence of an excess of base, which is essential to the formation of the tri-sodium salt, the reaction occurring is represented by the equation $NaIO_3 + Cl_2 + 4NaOH \longrightarrow Na_3H_2IO_6 + 2NaCl + H_2O$; yields averaged above 80%. The solid salt was filtered on a Büchner funnel and washed repeatedly; because of its very low solubility, the loss on washing is negligible. In order to convert this salt to the meta-periodate. $NaIO_4$, it was treated with water and nitric acid in the ratio of 150 cc. of water and 45 cc. of concd. nitric acid to 100 g. of salt; the solution was heated until the salt dissolved completely, and then allowed to stand for twenty-four hours at room temperature. The crystals thus formed are of large size and even contour; because of their low rate of dissolving they could be washed rapidly on a Büchner funnel without considerable loss, and they analyze within 0.1% of the theoretical composition; the yields varied from 60 to 85%, dependent largely upon the time allowed for crystallization.

The potassium meta-periodate was likewise prepared from the iodate with four to five equivalents of base by oxidation with chlorine. Unlike the case of the sodium salt, the potassium salt is freely soluble in excess base, and does not appear in solid form until the solution has become nearly neutral. It was then, after cooling, rendered acid with a slight excess of sulfuric acid and allowed to stand until the insoluble meta-periodate, KIO_4, had precipitated. The yields obtained, after washing and drying, ran as high as 95%. As in the case of the sodium salt, the well-washed product analyzed always within 0.1% of the theoretical composition without the necessity for recrystallization.

The periodic acid used was prepared by the method used by Wells, Lamb[3] and others: the sodium salt was converted into (supposedly) Ag_3IO_5 by long stirring with

---

[3] (a) Wells, *Am. Chem. J.*, 26, 278 (1901); (b) Lamb, *ibid.*, 27, **134** (1902).

three equivalents of silver nitrate solution, and the precipitate decomposed, after thorough washing, by a slow stream of washed chlorine gas passed into a cold aqueous suspension. After filtration from the silver chloride, the solution was evaporated to a small volume over a free flame and finally in a desiccator over sulfuric acid; the periodic acid crystallizes in the form of its hydrate $HIO_4 \cdot 2H_2O$, which may be dried over sulfuric acid without loss of water. Since no data have been recorded as to the solubility of this acid, it may be of use to state that analysis of the mother liquor shows the solubility to be about 53% at room temperature, and the density about 2.3.

The sodium hydroxide and potassium hydroxide used were Kahlbaum preparations, which were dissolved in water to a suitable concentration and standardized by titration against analyzed hydrochloric acid solutions, using methyl orange as indicator. The small carbonate content of the base was left out of consideration as having but a negligible influence upon the solubilities measured.

The periodates were analyzed by measuring their oxidizing action upon potassium iodide in acid solution; the thiosulfate solutions used were standardized against recrystallized potassium iodate. The free alkali present in the ternary solutions was determined by titration with standard sodium hydroxide solution, using methyl orange as indicator; the meta periodates are neutral to that indicator, as previously shown by others,[4] so that any excess alkali can be accurately determined.

The Periodates of Potassium

The determination of the periodates of potassium consisted in the study of the action of potassium hydroxide upon the solubility of potassium meta-periodate. The experiments were conducted in a thermostat at 25°; weighed quantities of the meta-periodate were treated with measured quantities of potassium hydroxide solution and of water and rotated in glass stoppered test-tubes of Pyrex glass until equilibrium was attained; the time required did not exceed twenty-four hours in any case. Pipetted samples of the clear supernatant liquid were analyzed for periodate and for free base; from the volume of the pipetted liquid, density determinations of moderate accuracy could be calculated. The results are given in Table I.

[4] Rosenheim and Loewenthal, *Kolloid. Z.*, 25, 53 (1919); Loewenthal, "Inaugural Dissertation," Berlin, 1918.

From Table I and Fig. 1 the facts as to the periodates of potassium which are stable in contact with solution can easily be deduced. The sparingly soluble salt KIO_4 has its solubility rapidly increased by the addition of potassium hydroxide; no common-ion effect in lessening its solubility can be detected. At the point *b* in Fig. 1, representing line 4 in the table, there is a change of solid phase, giving an isothermally invariant point. Further additions of potassium hydroxide give increasing concentrations of the second solid, which will be shown to be the ennea-hydrated potassium di-meso-periodate, $K_4I_2O_9{\cdot}9H_2O$. The increase in solubility of this salt upon addition of potassium hydroxide is striking; in line 13 we have a total solubility increased to 87 times that of the original saturating salt.

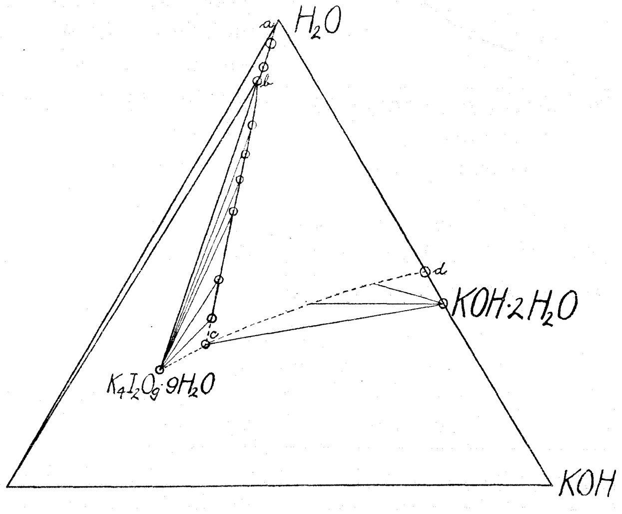

Fig. 1.—25° isotherm, KIO_4–KOH–H_2O.

Further additions of base caused the system to gelatinize, which of course put an end to further solubility measurements. It is clear, however, that the last experiment indicates a solution not far from the saturation point with respect to potassium hydroxide, which is shown schematically as the point c, with the solubility curve c-d drawn schematically for the hydrated base. It is accordingly clear that two and only two periodates of potassium can be formed from aqueous solutions at 25°, and it is probable that at higher temperatures the same limitation exists as far as aqueous solutions are concerned. Kimmins'[5] salt, $K_3HI_2O_9$, and Ihre's[6] $K_3IO_5{\cdot}4H_2O$ are not confirmed; it is probable that both are mixtures represented by the point *b* in Fig. 1, since they were formed in solutions in which the concentration of free base was not accurately known.

[6] See Blomstrand, *Ber.*, 3, 316 (1870).

Some study was given to each of the two potassium salts prepared. The meta-periodate, KIO_4, has a strikingly low solubility for a potassium salt; the figure at 25°, calculated as moles per liter, is 0.0238; that of the corresponding perchlorate, $KClO_4$, is 0.152,[7] over six times as great. The advantages of the use of this salt for the determination of potassium are clearly evident, especially because of the ease with which the periodate radical can be determined volumetrically and because of the high solubility of the corresponding sodium salt, which will be discussed later. It is understood that the details of such a method have been worked out at the laboratories of the University of Michigan. The solubility of the salt at a number of temperatures is given in Table II and shown in Fig. 2; measurements were made from solutions stirred by hand for brief periods, immersed in a water-bath with hand controlled temperature regulation.

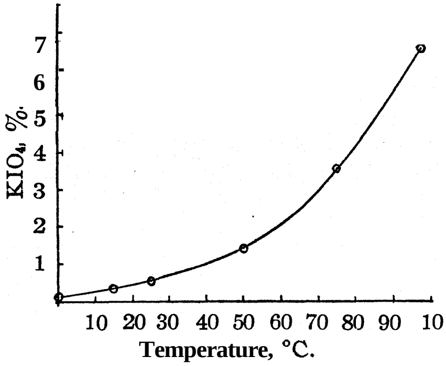

Fig. 2.—Solubility of KIO_4.

TABLE II

SOLUBILITY OF KIO_4 IN WATER

Temp., °C.	0.2	5.4	15.0	25.0	50.0	75.0	97.0
KIO_4, %	0.169	0.21	0.334	0.510	1.44	3.59	6.83

The di-meso-periodate, $K_4I_2O_9{\cdot}9H_2O$, should be congruently soluble according to Fig. 1, and therefore capable of recrystallization, which was found to be the case. For the analysis of the salt, including the water of hydration, the crystals were dried to constant weight in a miniature desiccator over the anhydrous salt;[8] the water content was then determined by heating in an electric oven at 110°, KIO_4 by the usual iodimetric method, and the excess base by titration with standard acid. The results follow.

Anal. Calcd. for $K_4I_2O_9{\cdot}9H_2O$: KIO_4, 64.21; K_2O, 13.15; H_2O, 22.63. Found: 64.32, 13.23, 22.34.

There can be no question therefore, as to the composition of the salt. Its solubility was then determined as shown in Table III and in Fig. 3, the temperatures above 25° being hand controlled.

It is evident that the di-meso salt has both a high solubility and a high temperature coefficient of solubility. The figure found at 25° for the pure salt is in reasonably close agreement with the point b of Fig. 1, indicating

78	61.7	...	$K_4I_2O_9 \cdot 9H_2O + K_4I_2O_9$
98.6	61.1	...	$K_4I_2O_9$

that the salt does not form as a solid phase until the ratio of base to acid in the solution is almost exactly that which occurs in the salt itself. The solubility curve shows a sharp break at about 78°, which is the temperature of the transition $K_4I_2O_9 \cdot 9H_2O \rightleftarrows K_4I_2O_9$ + solution. This temperature was obtained by a study of cooling curves, but could not be obtained with high precision, owing to delayed transformation and also possibly to slight decomposition, since the hot solutions gradually acquired a slightly yellow tinge, although free iodine could not be detected in them by the starch test. That the compound existing above 78° is the anhydrous form and not some lower hydrate is indicated by the evidence (just short, it may be claimed, of proof) that the moist ennea-hydrate, placed over the anhydrous form, does not lose water to form any lower hydrate, as shown above. If this evidence be accepted, it follows that the ennea-hydrate is to be regarded as a true salt-hydrate, and not in any sense an acid salt of the para series, as has been sometimes proposed.

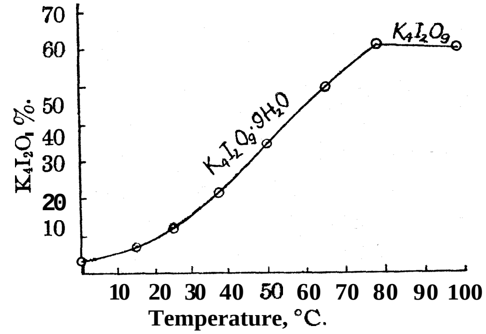

Fig. 3.—Solubility of $K_4I_2O_9$.

The Periodates of Sodium

To determine the periodates of sodium which are stable in contact with aqueous solution, the 25" isotherm was studied by the same method used for the potassium salts. The results are given in Table IV.

The results are in striking contrast with those of Table I. First, with regard to the experiments themselves, it was found that a very long time is required for equilibrium to be attained; from one to three weeks' stirring was used for the experiments in which $Na_2H_3IO_6$ is the solid phase and it is by no means certain that complete equilibrium was always reached. For this reason the figures for $NaIO_4$ content of the solution, while showing a

high absolute accuracy, do not show a high relative accuracy. Since the solutions were made up from the side of supersaturation, the result showing the lowest solubility was taken in all cases as most nearly correct. With

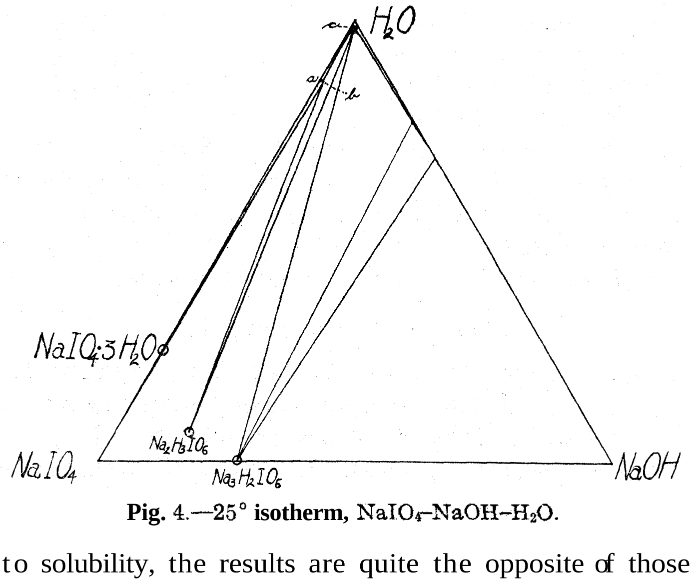

Fig. 4.—25° isotherm, $NaIO_4$–$NaOH$–H_2O.

respect to solubility, the results are quite the opposite of those for the potassium salts; the meta salt, $NaIO_4$, has a relatively high solubility, as shown in line 1, and is changed to the very insoluble para-periodate,

$Na_2H_3IO_6$, upon addition of the smallest quantity of sodium hydroxide (line 2). In the solution obtained no free base could be detected, although the titration would easily show amounts smaller than 0.01%. The isothermally invariant point *b*, shown in Fig. 4, is therefore too close to the side of the triangle to be shown to scale. Further additions of base give $Na_2H_3IO_6$ as the solid phase until the point *c* of Fig. 4 is reached, corresponding to line 10 of Table IV, beyond which the stable phase is the more basic para-periodate, $Na_3H_2IO_6$. The experiments were discontinued at the point where there was present 30% of sodium hydroxide, without the appearance of any new phase; there are, therefore, three and only three sodium periodates found by precipitation from aqueous solution, namely, $NaIO_4{\cdot}3H_2O$, $Na_2H_3IO_6$ and $Na_3H_2IO_6$. Col. 6 of Table IV shows the sodium hydroxide content of the salts, by algebraic extrapolation of the tie lines; the results are in good agreement with the calculated values of 14.71% and 27.22% for the two salts, taking into consideration the great length of the lines extrapolated. The partial isotherm shown in Fig. 5 shows in greater detail the pitch of the tie lines for the two compounds.

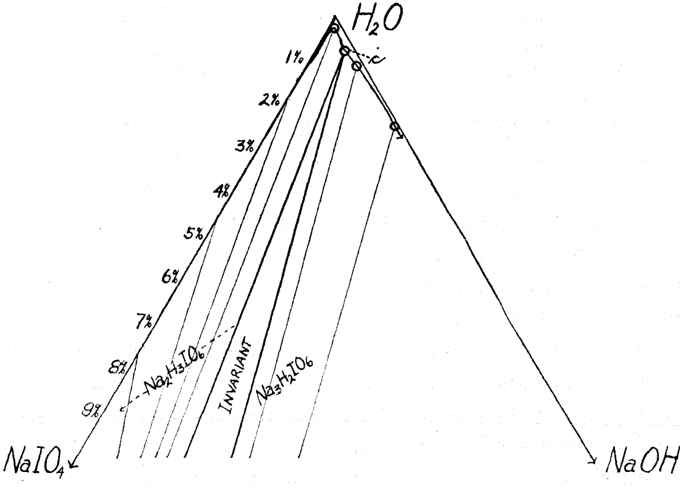

Fig. 5.—Partial isotherm at 25°, $NaIO_4$–$NaOH$–H_2O.

Each of the three sodium salts has been studied. The meta-periodate exists as a trihydrate and in anhydrous form as shown in Table V.

It was found that this salt is very slow in coming to equilibrium with its aqueous solutions and that the transition from the anhydrous form to the hydrate is also greatly delayed; the experiments, therefore, were conducted in the usual thermostat at the lower temperatures and at the higher temperatures in an electric oven, containing a large vessel of glycerin as a temperature buffer, into which the test-tube of solution was dipped and stirred mechanically from outside the oven. By making the heating

element of the oven appropriate in size, the temperature changes in the glycerin bath were kept within 0.1'. The time required for equilibrium, if the stable solid phase is present, varies from one to two days; but if a change of phase is to be completed, a week or more may be necessary. The results of lines 9 and 10 were obtained after twenty-four hours and forty-eight hours' stirring, respectively; in line 9 the solubility is in perfect alignment with the results for the anhydrous salt, though metastable at this temperature, while in line 10 there has been a slight fall from that required for the metastable curve, indicating the very slight transformation to the hydrate which has occured in two days. The transition temperature, 34.5°, is obtained from the intersection of the two curves, using the equation Solubility $= 8.53 + 0.37t$ for the anhydrous form and Solubility $= 4.017 - 0.0758t + 0.0167t^2$ for the hydrate. Efforts to find the transition by cooling or warming curves gave no indication of the transition at any temperature, however carefully managed.

The composition of the hydrate, as previously shown by Barker,[9] was confirmed by bringing a sample of moist crystals to constant weight over the anhydrous form. Analysis gave the water by loss on heating as 20.0%; calcd. for $NaIO_4 \cdot 3H_2O$, 20.17%.

The secondary sodium para-periodate, $Na_2H_3IO_6$, has a very low solubility; by independent experiments made with a recrystallized sample, the solubility at 25° was found to be 0.23%, somewhat higher than the figure (0.157%) given by Rosenheim and Loewenthal.[4] This is, as far as I am able to find, the least soluble sodium salt known, and its use for the detection and estimation of sodium is easily possible; the sharp contrast with the solubilities of the potassium salt is favorable for such a separation,

[9] Barker, *J. Chem. Soc.*, 93, 15 (1908).

since in neutral or acid solution the potassium salt (KIO_4) is insoluble and the sodium salt ($NaIO_4$) soluble, while in alkaline solution the potassium salt ($K_4I_2O_9$) is freely soluble and the sodium salt ($Na_2H_3IO_6$) very insoluble.

In the study of the properties of this secondary sodium salt, some interesting facts as to its hydration were observed. When formed by precipitation from $NaIO_4$ and NaOH solutions, the precipitate is usually amorphous in part, and upon drying over sulfuric acid to a constant weight it is found to contain from 2 to 3% of water in excess of that calculated by formula. This finding is in accordance with the results of Rammelsberg,[10] whose analysis shows the salt to be low in periodate and therefore high in water, but not in accord with the analyses of Loewenthal,[4] who worked, however, with exceedingly small samples of the salt (0.030 to 0.099 g.), which may have resulted in obscuring the fact of high water content. On putting the samples in a drying oven at 100°, it was observed that there was a somewhat rapid loss of water for the first two days (0.4 to 0.6%), and following that a quite regular loss continuing for at least three months, at a rate of about 0.01% per day, during which time the composition passed through that of the para-periodate and evidently the formation of a pyro salt began. The results of analyses of two 10g. samples are given in Table VI. Sample 1 was apparently amorphous, and showed continuous loss of water while Sample 2, more definitely crystalline, lost water only up to the point of the composition of the di-sodium salt.

TABLE VI

DEHYDRATION OF $Na_2H_3IO_6$

Sample No. 1 (amorphous)

Water lost at 100°	...	...	0.68	1.12	1.30	1.30

During this entire period the samples were weighed weekly. It is apparent, therefore, that the salt (at least in its amorphous form) can contain more than the stoichiometrical proportion of water, that the loss of water (both the excess and that of the stoichiometric compound) is appreciable at 100° under atmospheric conditions of aqueous pressure and that the vapor pressure of the excess water and that of the true

---

[10] Rammelsberg, *Pogg. Ann.*, 134, 368 (1868).

compound are sensibly the same. The loss of water was not observed by Rammelsberg[10] to occur until a temperature of 185° had been reached. With well crystallized samples of the salt, however, no excess of water, within the limits of the analysis, could be found. Recrystallization was accomplished by dissolving the salt by lengthy boiling in water (its solubility at 100° being about 0.4%) and evaporating the saturated solution to about one-fourth its original volume; because of the well-developed property of forming supersaturated solutions, this could be accomplished without any precipitation. On standing at room temperature for a period of days, the salt precipitated in well-formed, small crystals; analysis of these samples gave the calculated stoichiometric composition for all three components within ± 0.1%. It is also to be deduced from the low vapor tensions here indicated that the water in the stoichiometric compound is held by primary valence as water of composition, and not by secondary valence as water of hydration; the compound is therefore to be classed as a para-periodate and not as a hydrated di-meso-periodate, as has sometimes been proposed.[11]

In order to determine whether the ratio of the two components, $NaIO_4$ and NaOH, varies in the compound, through adsorption from an excess in solution, four experiments were conducted similar to those of Table IV, but with quantities of the components chosen so that the extrapolation of the tie lines should be subject to smaller error, that is, with a larger proportion of solid phase in the complex. Arranging to have about 10% of solid present, the four tests were made to contain the following molar ratios of NaOH to $NaIO_4$: 0.8, 1.0, 1.1 and 1.2, respectively. After agitation in the thermostat for ten days, the liquid phases were carefully analyzed; algebraic extrapolation of the tie lines showed that the solid phases contained the following slight variations from the theoretical quantities of NaOH: −0.40%, + 0.24%, + 0.07%, −0.07%. These figures contain the error of the analysis of the solution multiplied nearly ten times, and because of their small magnitude and irregular direction seem to me to be negligible and to prove that there is no sensible variation of these two components in the compound. Analysis of these solids, and of others, gave a molar ratio of $NaIO_4$ to NaOH of 1 to 1 ± 2%. These findings are in agreement with those of Loewenthal.[4]

Passing to the tertiary sodium salt, $Na_3H_2IO_6$, it will be seen from Fig. 5 that the salt does not possess congruent solubility. It can be formed only when there is excess sodium hydroxide in the solution, which excess can be calculated from the results of Table IV, line 10; expressed as a molar ratio of $NaIO_4$ to NaOH, it has the high value 1:9.2. The pure salt, therefore, cannot be recrystallized from water; depending upon whether the amount of water is greater or less, it will either be completely

[11] Rammelsberg, *Ber.*, **1**, 70 **(1869).**

hydrolyzed to the secondary salt, or (if the total complex falls within the invariant area of Pig. 5) to a mixture of the two salts. This fact as to influence of the excess base explains why the preparation of sodium periodate by action of chlorine upon sodium iodate in presence of sodium hydroxide has sometimes given the secondary sodium salt,[12] sometimes the tertiary,[13] and sometimes a mixture;[5] no other explanation is needed to clear up the discrepancies. In order to confirm these conclusions as to the hydrolysis of the tertiary salt, independent experiments were carried out; a sample complex of $Na_3H_2IO_4$ and water falling within the area of saturation for the salt $Na_2H_3IO_6$ (Fig. 5) was agitated for a week's time at 25°; the supernatant liquid showed upon analysis a ratio of 2.3 moles of NaOH to 1 of $NaIO_4$, indicating that the hydrolysis had occurred. Since it was found that the hydrolysis was slow at room temperature, a similar complex was boiled with water for two and one-half hours and then allowed to stand overnight at room temperature; the liquid phase showed upon analysis substantially the same ratio of the components as given above, and the solid phase, filtered and dried, was found to contain 78.16% of $NaIO_4$, corresponding to a 91.5% conversion into $Na_2H_3IO_6$.

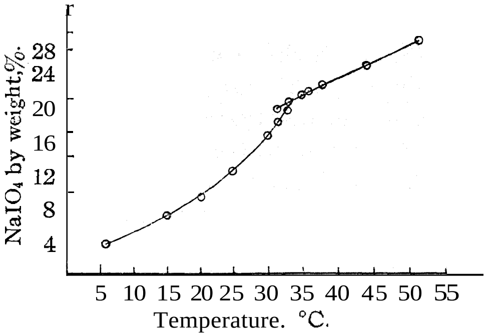

Fig. 6.—Solubility of $NaIO_4$.

The water content of the tertiary salt was found, as in the case of the secondary salt, to depend upon the crystalline character of the solid. If precipitated rapidly and in amorphous condition, it may contain up to 2% of water, which is not lost over sulfuric acid; moreover, it is driven off at 100° much more slowly than in the case of the secondary salt. Experiments continued over several months gave an average daily loss of only 0.002%. If the salt is allowed to precipitate from only moderately supersaturated solutions, formed from $NaIO_4$ and NaOH, a crystalline form occurs which has the stoichiometrical composition. As a matter of interest, the preparation of the salt by action of chlorine upon the iodate, as given earlier in the paper, apparently occurs at a rate giving a crystalline precipitate, which analyzes as practically 100% pure. The ratio of NaOH to $NaIO_4$ in various samples was found to be stoichiometric within the errors of the analysis. It was found also, in accordance with the experiments of Loewenthal,[4] that there is no detectable adsorption of sodium

[13] Ihre (Blomstrand), Her., **3,** 316 (1870).

hydroxide from solution containing the base in excess; the figures of Col. 6 of Table IV indicate, indeed, a deficiency of base, but this variation is probably due to the method of experimentation necessary for solubility determinations; an excess of the solid meta-periodate was present, which on treatment with sodium hydroxide solution doubtless became crusted with the very insoluble trisodium salt, preventing further action upon the interior parts of the crystals. Material formed by precipitation, however, never showed variation in this direction.

It is also to be deduced that the trisodium salt, which shows so very low an aqueous tension, is to be regarded as a salt of the para series, and not a hydrated meso salt ($Na_3IO_5 \cdot H_2O$). It appears, then, that the only stable sodium periodates forming from aqueous solution are the meta-periodate (as a trihydrate and in anhydrous form) and the disodium salt and the trisodium salt of para-periodic acid; the several others listed in Mellor's "Treatise"[12] cannot be confirmed. In view also of the very low aqueous tension of the two last named salts, it seems necessary to classify them as stated, and Mellor's preference for regarding them as hydrated di-meso salts or meso-salts cannot be sustained. Walden's[14] measurements of the electrical conductivity of solutions made from periodic acid and sodium hydroxide are in solutions supersaturated with respect to the two salts described above and illustrate the marked metastability of these solutions; however justified may be his deductions as to the condition of the dissolved salts, they have no bearing upon the composition of the solid phases and there is therefore no evidence for the existence, as a solid, of the salt Na_5IO_6.

Acid Periodates

It being well known that the nearly related alkali salts of iodic acid form double compounds or acid salts with free iodic acid, such as $KIO_3 \cdot HIO_3$, experiments were conducted to determine whether a similar condition exists in the case of the periodates. Samples of the two meta-periodates were agitated in the thermostat with varying amounts of periodic acid and the solutions analyzed after equilibrium had been attained, as shown in Table **VII.**

TABLE VII

SOLUBILITY OF META-PERIODATES IN THE PRESENCE OF PERIODIC ACID AT 25°

Saturating salt	Complex taken		Saturated solution		
	Wt. % of salt	Wt. % of HIO_4	Wt. % of salt	Wt. % of acid	Density
KIO_4	Excess	0.0	0.51	0.00	1.000
KIO_4	0.982	1.171	0.355	1.157	1.014

[14] Walden, Z. *physik. Chem.*, 2, 49 (1888).

It will be seen that the addition of free acid produces a marked diminution in the solubility of potassium periodate, qualitatively in accord with the common-ion effect of the periodate ion but in direct contrast with the effect of free base previously shown to cause an increase in solubility. Such a decrease in solubility indicates the probable non-existence of a double compound of the nature of an acid periodate of potassium. The results in the case of the sodium salt are to be interpreted in the same fashion. It did not seem worth while, with this evidence, to complete the isotherms through all possible concentration ranges.

The Periodates of Lithium and Ammonium

Periodates of lithium have previously been prepared only by action of periodic acid upon lithium hydroxide. Attempts were made[15] to prepare such salts by action of chlorine upon lithium iodate in the presence of lithium hydroxide, in imitation of the methods so successful for the sodium and potassium salts. The products of the reaction were certain very insoluble substances, proved to be periodates by the correct ratio of oxidizing oxygen to iodine content, but containing large and irregular quantities of lithium hydroxide, so that stoichiometrical formulas were not to be thought of. The explanation probably lies in the fact, clearly demonstrated by Rosenheim and Loewenthal,[4] that lithium periodate adsorbs the hydroxide very strongly from its solutions. It appears, therefore, that this method of preparing lithium periodate is not possible, unless devices for maintaining a correct concentration of base during the preparation were worked out, which would be a matter of some difficulty.

Attempts[16] to prepare ammonium periodate by action of chlorine on ammonium iodate in the presence of ammonium hydroxide were wholly unsuccessful; no periodate was obtained and the iodate remained unchanged. It seems probable that in ammonia solutions the hydroxyl-ion concentration is insufficient to permit the oxidation of iodate ion to periodate ion, a reaction which thus far has been found to occur only in strongly basic solutions.

The conditions for the formation of pyro-salts of sodium periodate, by dehydration of the para-periodates, are being studied in this Laboratory, and the composition of the periodates of silver is also under investigation.

Summary

1. A 25° isotherm has been studied for the system consisting of KIO_4, potassium hydroxide and water. The stable salts of potassium found to

---

[15] Experiments by Mr. H. E. Wolf, thesis for the B.S. degree, New York University, 1928.

form from aqueous solutions are two only, and of the formulas KIO_4 and $K_4I_2O_9 \cdot 9H_2O$.

2. The solubility of the two potassium salts in water has been measured between the temperatures of 0 and 100°. The latter salt undergoes a transition to the anhydrous form at about 78°.

3. A 25° isotherm has been studied for the system consisting of $NaIO_4$, sodium hydroxide and water. The stable sodium salts which form from aqueous solution are three only, and of the formulas $NaIO_4 \cdot 3H_2O$, $Na_2H_3IO_6$ and $Na_3H_2IO_6$.

4. The solubility of sodium meta-periodate, $NaIO_4$, has been measured between the temperatures of 5 and 50°. A transition point between the hydrate and the anhydrous form occurs at 34.5°.

5. The wide difference in the solubilities of the sodium and potassium salts may be used as a means for the analytical separation of potassium and sodium.

6. The secondary sodium periodate, $Na_2H_3IO_6$, is found, when in an amorphous condition, to hold a few per cent. of water with a vapor tension apparently as low as that of the compound; at 100° the rate of loss of water, adsorbed or of composition, averages about 0.01% per day under atmospheric aqueous pressures. The tertiary sodium salt also adsorbs water, and the rate of loss of water adsorbed or of composition is about one-fifth as great.

7. Action of periodic acid upon the meta-periodates was not found to produce acid salts.

8. Lithium periodate could not be formed in a pure state, and ammonium periodate could not be formed at all by the oxidation of the iodates by chlorine in presence of the appropriate base.

THE FREEZING POINT-SOLUBILITY RELATIONS OF GEOMETRICAL ISOMERS. I. THE β-CHLOROCROTONIC ACIDS[1]

BY EVALD L. SKAU[1a] AND BLAIR SAXTON

RECEIVED AUGUST 3, 1928 PUBLISHED OCTOBER 6, 1928

If the freezing point-solubility data of any component of an ideal solution are plotted $1/T$ against log N, the slope of the line at any point is proportional to the molal heat of fusion of the component.[2] Alternately, we may take as our criterion that the activity, *a*, or N calculated by means of this equation from a calorimetrically determined value of ΔH, should be equal to the actual value of N. With these criteria of ideality, a number of cases have been cited in which two substances are substantially mutually ideal and these seem to show that ideality is realizable when, and only when, the substances are quite similar in chemical constitution,[3] but not similar enough, especially in crystallography, to form mixed crystals to a pronounced extent.[4] For example, certain isomeric *ortho*, *meta* and para disubstituted benzenes form practically ideal binary and ternary systems.[5]

It seemed reasonable to suppose that isomers of the cis-trans or the *syn-anti* type might form ideal solutions of the simple eutectic type, since there appears to be a marked resemblance in structure between the *cis* and *ortho* on the one hand and the *trans* and para on the other.[6] Further, it appears from the rather meager data which are available that geometrical isomers show substantially the same percentage differences between their heats of combustion as are shown by *ortho*, *meta* and para isomers. At their melting points the molal heat capacities of the geometrical isomers studied in this paper do not show a greater difference than the differences

---

[1] From a dissertation submitted by Evald L. Skau to the Graduate School of Yale University, June, **1925,** in candidacy for the Degree of Doctor of Philosophy.

[1a] Du Pont Fellow, **1924-1925.**

[2] From the equation $(d \log N_A)/[d(1/T)] = -\Delta H_A/4.575$, where log N_A is the common logarithm of the mole fraction of *A*, the component crystallizing at temperature T, and ΔH_A is its molal heat of fusion at that temperature. For a bibliography and discussion of this equation see Johnston, *J. Phys. Chem.*, 29, 882 **(1925).**

[3] For a more detailed discussion see Hildebrand, "Solubility," The Chemical Catalog Co., New York, 1924, p. **59** ff.

[4] In such a case the equation must be modified. For example, see Van Laar, *Z. physik. Chem.*, *55*, *435* **(1906); 63, 216 (1908); 64, 257 (1908).** In some cases where limited solid solutions are formed nearly straight lines are obtained by plotting log N against $1/T$, but this alone is not a criterion of ideality in the liquid phase.

[5] Narbutt, *Z. physik. Chem.*, *53*, **697 (1905);** Holleman, Hartogs and van der Linden, *Ber.*, 44, **704 (1911);** Andrews, *J. Phys. Chem.*, 29, **1041 (1925);** Kohman, *ibid.*, **1048.**

calculated for the *ortho, meta* and para isomers investigated by Andrews, Lynn and Johnston.[7] Indeed, Andrews[8] found practically no differences in the molal heat capacities of the solid isomers of the type C_6H_4XY from 30° below the lowest melting isomer to 110°K. Hence he concluded that they would give substantially the same free energy change of formation. Probably this can also be said for geometrical isomers. Furthermore, it was hoped that a study of such systems might aid in the solution of the nature of this type of isomerism, which, following Wislicenus, has been called geometrical isomerism. If it could be shown that the *cis-trans* isomers of a substance form systems of the simple eutectic type, whereas the *cis-cis* or the *trans-trans* forms of two closely related substances form solid solutions,[9] the structure of such isomers might be referred to fumaric and maleic acids, whose structures are conceded to be reasonably well established.

A search of the literature reveals only one system of geometrical isomers for which the temperature–composition diagram has been constructed with sufficient accuracy for use in testing ideality by these methods. This is the system crotonic acid–isocrotonic acid as given by Morrell and Hansen.[10] These investigators undoubtedly used pure acids but their experimental method is open to criticism. They made their solutions of different compositions by starting with a known amount of each pure component and adding, successively, small amounts of the other form. The freezing points were determined in the usual way without correcting for the amount of solid separating. Thus the error in composition was accumulative and the freezing points were all lower than the true values. In the course of one series of determinations "it was necessary to substitute a mercury thermometer for the alcohol thermometer." Although correction was made for the solid removed by the thermometer, a considerable error must have been introduced since there is a break in the solubility curve between the points in question. Using their data, we have plotted $(1 + \log N)$ against $1000/T$. On the crotonic acid branch of the plot, the points lie both above and below a nearly straight line drawn from $1000/T_f$ (T_f is the freezing point of pure crotonic acid) with an initial slope calculated

[7] Andrews, Lynn and Johnston, THIS JOURNAL, 48, 1274 (1926).

[8] Andrews, *ibid.*, 48, 1287 (1926).

[9] This does not seem improbable since, judging from a survey of the literature and from results obtained in this Laboratory by E. P. Jones [Johnston and Jones, *J. Phys. Chem.*, 32, *593* (1928)] and by Myer Solomon (unpublished), the disubstituted derivatives of benzene seem to form solid solutions only in the *meta-meta, ortho-ortho* or *para-para* systems. Further, Bruni [Bruni and Gorni, *Atti. accad. Lincei* (5) *8*, 454, 570 (1899); Bruni, *Gazz. chim. ital.*, *I*, 30, 64 (1900)] claims to have shown that the *trans* form of two geometrical isomers forms a solid solution with the corresponding saturated compound, whereas the cis form gives a freezing point–solubility diagram of the ordinary eutectic type.

[10] Morrell and Hansen, J. Chem. *Soc.*, 85, 1520 (1904).

from the molal heat of fusion.[11] Though the experimental points show considerable divergence from this line, the fact that the deviation is not in one direction indicates that experimental error rather than non-ideality is the cause. The points on the isocrotonic acid branch fall remarkably close to a straight line corresponding to a calculated heat of fusion of 3100 cal. per mole. Although this heat has not been determined calorimetrically, we may conclude that the two forms of crotonic acid probably form a nearly ideal solution.

The temperature–composition diagram of another system, *syn*- and anti-benzaldoxime, has been constructed by Cameron,[12] but due to the partial transformation on heating above the melting point, the freezing points could be determined only roughly by means of the capillary tube method. On plotting the values of $(1 + \log N)$ against $1000/T$ for this system, decidedly curved lines, concave upwards, are obtained for both branches, which would ordinarily point toward non-ideality.[13] Due to the inaccuracy of the data, however, and since the true heats of fusion are unknown, it would be unsafe to draw any conclusions from this evidence.

In order to secure some definite evidence concerning the ideality of cis-trans systems, it was decided to construct accurately the freezing point–solubility diagram for the system β-chlorocrotonic acid-β-chloro-isocrotonic acid and to determine their heats of fusion. These compounds can be synthesized with relative ease; furthermore, proof of the ideality of this system would strengthen the indications as to the ideality of the crotonic acid–isocrotonic acid system, since they are structurally quite similar to the latter.

Experimental Part

Method of Synthesis

Preparation of *cis* and *trans* Forms.—A mixture of the two forms of β-chlorocrotonic acid was prepared from acetoacetic ester by Geuther's method as modified by

---

[11] Determined in this Laboratory by Lynn (*Dissertation*, 1925) using the method described by Andrews, Lynn and Johnston (ref. 7). In the neighborhood of the melting point this can be expressed by the empirical equation $\Delta H = 3695 - 13.56t + 0.0736t^2$. At the melting temperature, 71.4°, this becomes 3100, or 924 cal. higher than the value obtained by Bruner [Ber., 27, 2102 (1894)], who probably used impure acid since he gave the melting point as 67.4°. The new value for the heat of fusion corresponds to an entropy of fusion of 9.0 cal. per degree at the melting point instead of 6.4 from Bruner's data. Crotonic acid can no longer be cited as the organic compound with the lowest entropy of fusion (Roozeboom, "Die Heterogenen Gleichgewichte," II, 1, 279). As far as the present authors are aware this position should now be assigned to cyclohexane with a value of 1.75 cal. per degree.

[12] Cameron, J. Phys. *Chem.*, 2, 413 (1898).

[13] The change in slope of such a curve is determined by $d\,\Delta H/dT$; hence this evidence alone does not exclude ideality.

Michael, Wislicenus, Jr., and Scheibler.[14] The ester, in benzene solution, was treated with phosphorus pentachloride and the reaction mixture was added to water. The acids were removed from the benzene layer as their sodium salts by extracting with sodium carbonate solution and were then precipitated by acid and extracted with ether. In removing the ether it was found advisable to use a fractionating column to hold back the volatile β-chloro-isocrotonic acid; the last portions are best removed by evaporation at room temperature from a shallow crystallizing dish. The yield was 36.5%. The two acids were then separated as well as possible by fractional steam distillation.

Purification

β-Chlorocrotonic Acid.—The crude residue from the steam distillation was decolorized with Norite and was then recrystallized once from water and fractionally crystaliized from carbon disulfide. It was finally sublimed[15] at 105° at atmospheric pressure. The melting point was at first followed by means of the ordinary capillary tube method and later by means of cooling curves. The final product froze at 93.6°.

β-Chloro-isocrotonic Acid.—The crude product was first fractionally steam distilled. Subsequent sublimation[15] at 105° and atmospheric pressure gave a pure product which gave a "flat" on a cooling curve at 60.5°.

The Freezing Points

The freezing point determinations were made by means of the apparatus described by Andrews, Kohman and Johnston,[16] with some further refinements developed in this laboratory since the publication of their work. The apparatus is sketched in Fig. 1. A cylindrical copper tube or shield (14 cm. long, 5cm. outside diameter, 2.5cm. inside diameter) closed at one end is set on a cushion of asbestos in the silvered pint Dewar flask A. K is a heating coil consisting of a 25-ohm nichrome resistance wound tightly around the metal cylinder and insulated from it by means of a thin layer of mica. A thin-walled freezing point tube G (65 mm. long, 8 mm. diameter) containing the sample, H, fits quite snugly over the end of a thin glass tube. The latter extends up through the cork stopper from which the small unsilvered Dewar tube C[17] is suspended by means of a wire not shown in the diagram. I is an inlet for a stream of hot air,[18] used in melting the sample *in situ,* and E an outlet. The temperature of the shield B is measured by means of the copper–constantan thermoelement J set in hard solder in a hole drilled for the purpose. A plug of cotton wool prevents too rapid radiation from the top of the shield. The thermoelement D, in the melt, is constructed of No. 46 (B. and S. gage) copper and No. 40 constantan wire, the copper being wound around the insulated constantan for a distance of about 4 cm. above the junction In order to minimize the heat conductivity. It is of course an advantage to have the thermoelement directly in the melt but in some cases this is impossible due to the solvent action of the liquid. However, the element responds to *a* change in temperature with no appreciable lag when

[15] Rejecting and resubliming all but the long needle-like crystals that projected from the sides of the sublimation tube.

[16] Andrews, Kohman and Johnston, *J. Phys. Chem., 29,914* (1925).

[17] Later work showed this tube to be superfluous.

[18] Produced by passing air through a small iron pipe loosely filled with copper turnings and wound with a heating element. The sample may also be melted by using a small resistance heater fitting loosely around tube G.

protected by a thin-walled capillary tube containing vaseline or some high-boiling liquid (for example, benzophenone). We have therefore used this method exclusively since it has the added advantage that the glass around the thermoelement is much more easily cleaned than the bare thermoelement.

The thermocouples were calibrated at the ice point and at the boiling points of water, naphthalene and benzophenone. Temperatures were read to the nearest microvolt (ca. 0.02°) by means of a Leeds and Northrup type K potentiometer. The freezing points were corrected by using the extrapolation method of Andrews, Kohman and Johnston.[16] The freezing points of the pure substances are correct to within about ±0.05° and, with the solutions, the maximum error, near the eutectie point, is about 0.25°.

The freezing point data for the system are given in Table I, the points marked with an asterisk being values interpolated from the $(1 + \log N)$ *vs.* $1000/T$ plots. In this table are included the ideal values of N, or the activities, a, calculated from the heats of fusion and the changes in heat capacity as measured by us. The ratio a/N, given in the last column for each component, represents the deviation from ideality at the temperature t and mole fraction N.

The system is of the simple eutectic type and on plotting $(1+ \log N)$ against $1000/T$ for the two branches on a large scale it is found that, within the accuracy of our experimental values, straight lines are obtained in both cases. The values of $(d \log N)/[d(1000/T)]$ for these lines are 1.1427 for the β-chlorocrotonic acid branch and 0.0009 for the β-chloro-isocrotonic acid branch, from which the calculated heats of solution are 5220 and 4120 cal. per mole, respectively.[19]

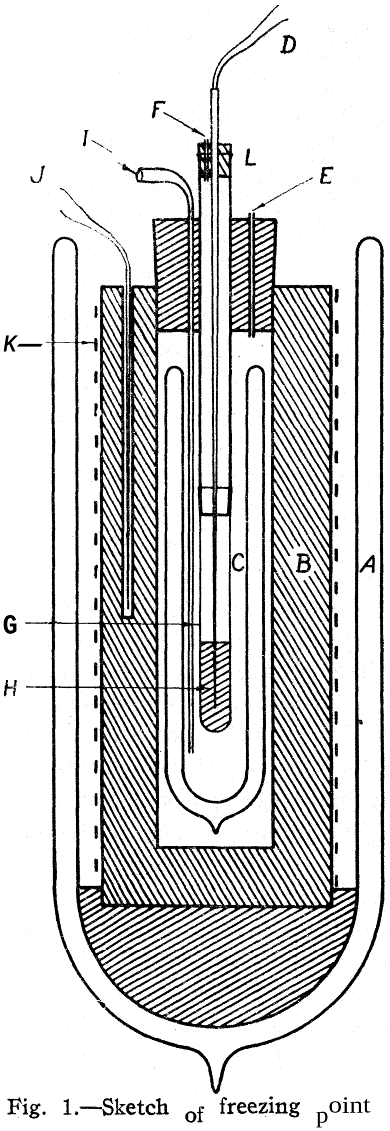

Fig. 1.—Sketch of freezing point apparatus.

---

[19] Since $(1 + \log N)$ is plotted against $1000/T$, $s = \dfrac{d \log N}{1000\ d(1/T)} = -\Delta H/4575$, from which $\Delta H = -4575\,s$.

The Heats of Fusion

Direct calorimetric measurements of the differences between the heat contents of each form[20] at several temperatures and that of the solid at 22° were made by the method described by Andrews, Lynn and Johnston.[7]

Following their usage, we have expressed the heat content of the solid and of the liquid by empirical equations, valid over a short temperature range in the neighborhood of the melting point, of the form $H = a + bt + ct^2$. In these equations H is expressed in gram-calories per mole at t°, referred to the heat content of the solid at 22° as zero. The value of *H* for the liquid minus that for the solid is the heat of fusion, ΔH. For β-chlorocrotonic acid this is $\Delta H = 20{,}300 - 94.15\ T + 0.1426\ T^2$; and for β-chloro-isocrotonic acid it is $\Delta H = 11{,}660 - 61.26\ T + 0.1085\ T^2$. These equations have been used in calculating the activities given in Table I. This involves the assumption that the heat content equations for the liquids are valid down to the eutectic temperatures, but this seems preferable to considering the heats of fusion as constant. The values of ΔH, calculated to the freezing temperatures, are given in Table II.

By differentiating the heat content equation with respect to temperature, C_p can be expressed over a limited temperature range. Since the heat content equations are necessarily empirical, the heat capacity equations derived from them are only approximate. The heat capacities of the solids and liquids have been calculated to the freezing temperatures and are given in Table II. The difference, $C(l) - C(s) = \Delta C_p$, approximately expressing the variation of ΔH with temperature in the neighborhood of the freezing point, is about the same for the two isomers. The

---

[20] The sample of β-chlorocrotonic acid was not quite so pure as that used in the freezing point experiments, hence its freezing point was about 0.3° lower. In attempting to carry the curve to higher temperatures, it was found that decomposition of some kind took place, as was shown by the heat content values of the sample when redetermined at lower temperatures. The β-chloro-isocrotonic acid, on the other hand, was of the highest purity and the heating curves run on this sample afterwards proved that there had not been the slightest decomposition.

values **are** of the same order of magnitude as those found by Andrews, Lynn and Johnston[7] for the organic acids studied by them. The results are summarized in Table II. In addition to the quantities above described we have included A , and A„ expressing the maximum and the average (disregarding sign) differences between the experimental values of H and those calculated from the empirical equations.

TABLE II

HEAT CONTENTS OF THE β-CHLOROCROTONIC ACIDS

	No of obs.	Temp. range, °C.	*a*	*b*	*c*	A	A,	ΔH_f at t_f	C_p at t_f	ΔC_p
β-Chlorocrotonic acid										
solid	9	33	—756	36 68	0 0303	62	**31**	4950	39.4	
liquid	4	121	4470	17.42	.1729	14	9		49 8	10 4
β-Chloro-isocrotonic acid										
solid	6	33	—712	31 45	0 0416	48	22	3300	36 5	
liquid	9	121	2308	29 44	1501	71	24		47 6	11.1

It will be noted that the values for the heats of fusion calculated from the freezing point data and those experimentally determined differ by 270 cal. per mole in the case of the β-chlorocrotonic acid and by 820 cal., per mole in the case of the β-chloro-isocrotonic acid, both deviations being in the same direction. That these differences are due to experimental error is out of the question. The freezing points calculated from the experimentally determined heats of fusion are ***lower*** by **3** and 5°, respectively, near the eutectic composition, than the observed freezing points. This is many times the probable error in the freezing point determinations. The experimental accuracy in the calorimetric determinations is about 50 cal. per mole, so that the error in the heats of fusion so determined would be 100 cal. per mole at the greatest. Inasmuch as the experimental measurement of the heat of fusion involved the sudden cooling of the molten sample to about 22°, it seemed possible that under these conditions the substances may have solidified in some unstable crystalline modification whose heat of fusion was smaller. In order to test this possibility three successive heating curves were run on the same sample of β-chloro-isocrotonic acid and for the data so obtained the relative heats of fusion in the three cases were calculated, by evaluating the appropriate area under the temperature–time curves,[21] with a reproducibility of about 5%. The first and third curves were run on the sample after melting it and chilling it suddenly to room temperature; the second after inoculating it just below the melting point and then allowing it to cool very slowly, thus duplicating the conditions in the freezing point determinations. The results are as follows.

[21] See Andrews, Kohman and Johnston, who have applied this method to cooling curves (ref. 16).

TABLE III

EFFECT OF RATE OF COOLING ON HEAT OF FUSION OF β-CHLORO-ISOCROTONIC ACID

No.	Previous treatment	% deviation from mean of I and III
I	Suddenly chilled	+3.8
II	Seeded and slowly cooled	– 1.9
III	Suddenly chilled	– 3.8

Since the difference to be accounted for is of the order of 20%, this evidence shows that only one modification of β-chloro-isocrotonic acid was involved. Further, inasmuch as no break was detected in the heat content–temperature curve of the solid until the melting point was reached, it seems reasonable to conclude that it undergoes no transition above 22°.

Conclusion

The only plausible conclusion to be drawn from the data, therefore, seems to be that the system is not entirely ideal. That no complexes are formed in appreciable amounts by association or reaction seems to be probable since the $(1 + \log N)$ *vs.* $1000/T$ plots are substantially straight lines throughout the whole range considered for both branches of the freezing point diagram. Neither would mixed crystal formation explain the discrepancies satisfactorily. On the other hand, the non-ideality might be explained by a slight difference in the internal pressures or polarity of the two substances.[22] That is, there may be a slight heat of mixing in the liquid state for the two forms which deviates from constancy at the various compositions in such a way that when it is added to the heat of fusion, which also changes, it gives practically a straight line for the $(1 + \log N)$ vs. $1000/T$ plot.

If this explanation is correct, one would predict a slight volume change on mixing the two liquids.

Summary

A modification of the freezing point apparatus as given by Andrews, Kohman and Johnston[16] has been described.

Accurate freezing point measurements for the system β-chlorocrotonic acid–β-chloro-isocrotonic acid have been made and calorimetric data, including heat contents, specific heats and heats of fusion, have been determined for each of these two compounds. The heat of fusion of crotonic acid has been reported. An examination of these data and those existing for the crotonic acid–isocrotonic acid system has been made to test the ideality of these two systems. It was found that in the former system the values for the heats of solution based on freezing point measurements are higher than those determined calorimetrically and the activities calculated from the thermal data are, for each component, greater than the corre-

---

sponding mole fraction to the maximum extent of about 8% at the eutectic point. Judging from our present knowledge of such systems, geometrical isomers seem to show slight deviations from mutual ideality but not such as would indicate complex or mixed crystal formation.

It is possible that similar studies made on less polar isomers of this type may show them to be more nearly ideal than those discussed in this paper.

THE SURFACE ENERGY OF SOLID SODIUM CHLORIDE. III. THE HEAT OF SOLUTION OF FINELY GROUND SODIUM CHLORIDE

BY S. G. LIPSETT, F. M. G. JOHNSON AND O. MAASS

RECEIVED AUGUST 6, 1928 PUBLISHED OCTOBER 6, 1928

In previous papers[1] it was shown that finely divided sodium chloride had a heat of solution different from that of coarsely ground sodium chloride. This difference was attributed to the energy bound up in the surface of the finely divided salt, and from the measurement of the difference in the heat of solution, the actual value of the surface energy of solid sodium chloride was calculated. In these experiments the finely divided salt had been obtained by sublimation.

In the present paper an account is given of similar measurements but here the finely divided salt is obtained by grinding. It has been found in this case also that the finely divided material had a lower (negative) heat of solution than the coarsely ground sodium chloride.

Experimental Procedure

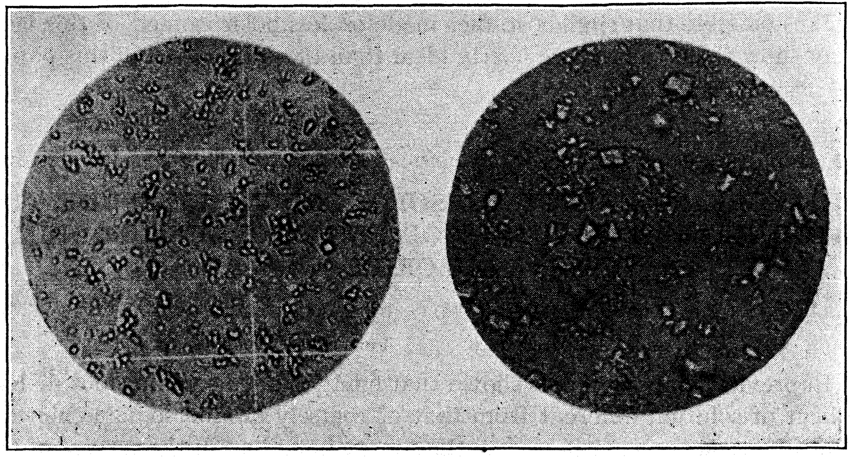
Pure sodium chloride was ground in a mechanically driven agate mortar for fifteen minutes. The ground salt was then placed at the bottom of a vertical glass tube about 1 m. long and 4 cm. in diameter and dry air, at a constant pressure, was blown into the tube through a fine nozzle at the bottom. The air was admitted so as to impinge on the ground salt. The current of air carried up the fine particles of salt which then passed into a series of settling chambers[1b] where they were sorted out according to size. The vertical glass tube was jarred continuously by an automatic tapper to prevent salt from adhering to the walls of the tube. The salt in the tube was recharged every fifteen minutes.

In order to see whether the salt was contaminated by silica rubbed off the agate mortar, samples of the product were analyzed but no weighable amount of silica was found in them.

---

[1] *(a)* Lipsett, Johnson and Maass, THIS JOURNAL, 49, 925 (1927); (b) 49, 1940 (1927).

The heat of solution of the finely divided salt was determined using the apparatus described previously[1b] and the diameter of the particles was measured by means of photomicrographs.[1b]



Sublimed. Ground.

Fig. 1.—Finely divided sodium chloride. (805 diameters).

Experimental Results

The heat of solution was determined at 25° at a concentration of 4.62% with three different samples of salt. The results are given in Table I.

TABLE I

HEAT of SOLUTION OR FINELY GROUND SODIUM CHLORIDE:

Sample	Heat of soln., cal. per mole	Diff. in heat of soln., cal. per mole	Diameter of average particle, μ
I	−903.7	24.9	1.3
II	−903.6	25.0	1.2
III	−887.9	40.7	1.4

In Col. 3 is given the difference between the heat of solution of coarsely ground sodium chloride (−928.6 cal. per mole) and of the finely ground salt measured, of course, at the same temperature and concentration. This difference is far larger than that obtained with finely divided salt obtained by sublimation. It may be calculated from the previous work[1b] that sublimed salt whose particles were 1.3μ in diameter would have approximately a heat of solution only 11 cal. less than that of coarse salt. The exceptionally large difference obtained with the finely divided salt obtained by grinding is probably due to the uneven surface of the ground salt whereby the actual surface of the particles is much larger than the apparent surface.

The fine salt obtained by sublimation, when examined under the microscope, is seen to be definitely cubic in appearance. It is reasonable to suppose that crystals of salt formed by sublimation would have smooth surfaces and be fairly regular in shape. On the other hand, the fine salt obtained by grinding is distinctly irregular in appearance under the microscope and the crystals show many jagged fractures. This is shown in the accompanying photomicrographs of the finely divided salt prepared by the two methods. Calculation of the surface area of the finely divided ground salt from the measurement of the diameter of the particles, assuming that the particles are cubic in shape, will almost certainly give a result which is less than the actual surface, since no account will have been taken of the irregularities in the surface and the small projecting fragments which may be assumed to be present even when not visible under the microscope.[2]

For the above reason, the results obtained by using the ground material have been taken as more or less qualitative in nature and as supporting the previous work, but the actual calculation of the surface energy is believed best to be derived from the results obtained using the finely divided sublimed salt, since in the latter case the surface area is probably more accurately obtained.

The present work shows, however, that finely divided salt whether obtained by sublimation or by grinding has a lower (negative) heat of solution than coarsely ground salt.

Grateful acknowledgment is made to the National Research Council of Canada for a grant to aid in this work and also for a Studentship held by one of us, during the tenure of which this work was carried out.

Summary

The heat of solution of finely divided salt prepared by grinding has been determined and has been found to be less in magnitude than the heat of solution of coarsely ground sodium chloride.

THE OXALATE METHOD FOR SEPARATING CALCIUM AND MAGNESIUM

BY WILLIAM T. HALL

RECEIVED AUGUST 27, 1928 PUBLISHED OCTOBER 6, 1928

The use of the oxalate anion for the quantitative precipitation of calcium in the presence of magnesium cations probably dates from Bergmann, the father of analytical chemistry, for it is mentioned in a Latin paper covering the work of Bergmann, which was published in 1778. Bucholz in a paper written in 1812 casually mentions the reaction as if it were well known to chemists at that time.

C. R. Fresenius, in his classic text on analytical chemistry, recommended, at about 1850, a dilute solution, the presence of sufficient ammonium chloride to prevent the precipitation of magnesium hydroxide and sufficient ammonium oxalate to combine with both calcium and magnesium. Fresenius stated that more oxalate than that required by the calcium is necessary because magnesium tends to prevent the precipitation of calcium oxalate. He recommended that the precipitate be allowed to stand twelve hours to insure complete precipitation of the calcium and that the precipitate be dissolved in hydrochloric acid and again treated with ammonia and oxalate in order to obtain a pure precipitate free from magnesium.

Down to the beginning of the nineteenth century, the statements of Fresenius regarding the oxalate precipitation of calcium were for the most part regarded as authoritative, although a number of chemists criticized the method, notably Sherer, who in 1858 preferred to separate calcium and magnesium ions by means of dilute sulfuric acid and considerable alcohol.

In 1901, Richards, McCaffrey and Bisbee[1] studied the ammonium oxalate separation from the standpoint of the physical chemist, and succeeded in avoiding the double precipitation. According to Richards, the hot, slightly acid solution of calcium and magnesium chlorides is first treated with an excess of oxalic acid and is then neutralized slowly during about fifteen minutes. Then the solution is made distinctly ammoniacal and a large excess of ammonium oxalate is added.

A careful study of Richards' paper fails to show exactly what is meant by a "large excess of ammonium oxalate" and the reason for the excess appears to be the idea of making the calcium oxalate less soluble in accordance with the solubility product principle and the common ion effect.

Blasdale[2] subsequently modified the procedure of Richards and obtained good results with much less oxalate. For a solution containing the equiv-

---

[1] Richards, McCaffrey and Bisbee, *Proc. Am. Acad. Arts Sci.*, **36**, 375 (1901); *Z. anorg. Chem.*, 28, 71 (1901).

[2] Blasdale, THIS JOURNAL, 31, 917 (1909).

alent of not more than 0.6 g. of the mixed oxides in a volume of 300 cc. Blasdale recommended adding to the boiling solution 3.5 g. of ammonium chloride and only one gram of oxalic acid. If the content of magnesium is very high, only enough oxalate to precipitate the calcium is added at the start and the rest only after the solution has been slowly neutralized and allowed to stand for ten minutes. A double precipitation is advised when ten times as much magnesium as calcium is present and when the content of ammonium salts is high it is advised to remove them before precipitating the magnesium.

Dede[3] determined the calcium content of burnt magnesia and held that the addition of 2 g. of ammonium oxalate was necessary. Luff[4] avoided the use of excess ammonium oxalate and Bach[5] states that a bad separation of a little calcium from considerable magnesium always results if the ammonium chloride content is low or the ammonium oxalate content is high.

Recently two very contradictory papers have been written on the separation of small quantities of calcium from considerable magnesium. Hahn and Weiler[6] claim that a good separation is obtained when only a *slight excess* of ammonium oxalate is used while Bobtelsky and Frau Malkowa-Janowskaja[7] obtained excellent results by adding 20 g. of ammonium oxalate to 100 cc. of hot solution containing calcium and magnesium. In this way, prompt precipitation of 20 mg. of calcium was obtained in the presence of 2.70 g. of magnesium chloride.

The above citations represent but a very small part of the voluminous literature on the separation of calcium and magnesium. It is clear that chemists differ widely with respect to how much ammonium oxalate should be used to accomplish the best results. In order to settle this matter in our own minds, we have made quite a number of experiments, the enumeration of which would be very boring but the results seem quite clear.

The statement by Fresenius that more oxalate is required when magnesium is present than would be necessary in a solution of pure calcium chloride is true. Thus, with a sample of pure calcium carbonate weighing 0.5 g. (10 milliequivalents), correct results were obtained by using 50 cc. of 0.5 *N* ammonium oxalate solution as precipitant. When, however, 0.5 g. of calcium carbonate was present together with 0.5 g. of basic magnesium oxalate, only 4.06 and 4.12% of calcium were obtained when 7.40% of calcium was present by using 5 cc. of the reagent. In fact, with only 0.05 g. of calcium carbonate in the mixture, the results were low with 50 cc. of reagent. Correct results were obtained when one milliequivalent of cal-

---

cium was present together with five milliequivalents of magnesium only by adding 35 milliequivalents of oxalate. In every case the precipitate was allowed to stand overnight before filtering.

Fresenius' statement that magnesium oxalate is likely to be formed if considerable ammonium oxalate is added, does not appear to be true when the solution is fairly dilute and the precipitation is accomplished as recommended by Richards or by Blasdale. With a sample weighing 0.5 g. and containing 24.5% of magnesium, the magnesium results were high when the precipitation of calcium was incomplete but were correct when 25–125 milliequivalents of ammonium oxalate was added to precipitate one milliequivalent of calcium.[8] The method of Bobtelsky and Frau Malkowa-Janowskaja is based on some solubility studies which show that ammonium chloride solutions dissolve more magnesium oxalate than pure water does and that the solvent effect of ammonium oxalate on magnesium oxalate is much more marked. A number of experiments were made[9] using 20 grams of ammonium oxalate to precipitate a small quantity of calcium in the presence of considerable magnesium. The results obtained were in close agreement with those obtained by the method of Richards or by a double precipitation of calcium. The statement that there is no precipitation of magnesium when this very large excess of oxalate is used to precipitate a little calcium appears to be correct.

The presence of this large excess of ammonium oxalate has, however, a decidedly unfavorable effect upon the subsequent determination of magnesium. In the first experiment by Mr. Gardner in which 20 g. of ammonium oxalate was used, there was absolutely no precipitation of magnesium ammonium phosphate by the method of Smitz, although the solution was allowed to stand for several days. In another experiment a solution was used from which 0.1775 g. of magnesium pyrophosphate should have been obtained, as it was when only 5 g. of ammonium oxalate was used. This solution, when 20 g. of ammonium oxalate was present, yielded only 0.0154 g. of magnesium pyrophosphate by the Smitz method but after evaporating the filtrate to dryness, expelling ammonium salts and taking up in dilute acid, an additional 0.1618 g. of magnesium pyrophosphate was obtained on repeating the precipitation.

Recently it has been recommended to determine magnesium by precipitation with *o*-hydroxyquinoline.[10] This precipitant gives a crystalline precipitate, easy to handle, in solutions which are slightly alkaline. Our

---

[8] These conclusions are based on the results of twenty-two experiments by Arnold A. Smith. The experiments were carried out in duplicate and consistent values obtained with each duplicate.

[9] Experiments of Howard S. Gardner.

[10] R. Berg, *J. prakt. Chem.*, **115**, 18, 178–185 (1927); Hahn and Vieweg, *Z. anal. Chem.*, 71, 122–130 (1927).

experiments[11] show, however, that the presence of a large excess of ammonium oxalate prevents the complete precipitation of this organic salt of magnesium. All the results were too low when much oxalate was present.

Neubauer,[12] Gooch and Austin,[13] Järvinen,[14] and Smitz have all found that the precipitation of magnesium succeeds in the presence of considerable ammonium salt, but it is evident that they never tried the experiment with as much ammonium oxalate present as recommended by Bobtelsky. In giving beginners a sample of dolomite to analyze for calcium and magnesium, the results obtained are usually good when the directions of Richards or of Blasdale are followed and a single precipitation of calcium oxalate made, or when, according to the directions of Fresenius,[15] a double precipitation of calcium oxalate is made. Occasionally, however, we have noticed that a student fails to get all of the magnesium precipitated as magnesium ammonium phosphate. In the light of these experiments it seems probable that this is the result of using too large an excess of ammonium oxalate. These experiments indicate that 75 cc. of 0.5 N ammonium oxalate solution is sufficient for the precipitation of 0.3 g. of calcium ions in a volume of 500 cc., but the same quantity of reagent should be used when only 0.02 g. of calcium is present in the presence of considerable magnesium (0.12 g.).

Summary

For the precipitation of calcium oxalate in the presence of magnesium ions an excess of ammonium oxalate is necessary. If this excess is properly regulated, it is possible to precipitate pure calcium oxalate. If, however, a very large quantity of ammonium oxalate is present, the precipitation of magnesium ammonium phosphate is incomplete even after long standing.

zinc vapor and carbon monoxide should react to give zinc oxide and carbon at about 700°, the temperature of the condenser in zinc smelter practice. Viewed otherwise, carbon monoxide should at 700° change to carbon dioxide and carbon almost completely, and the carbon dioxide should oxidize the zinc to zinc oxide. As the formation of carbon dioxide and carbon from carbon monoxide is, in the absence of a catalyst, extremely slow at 700°, it appeared to be of interest to determine whether or not the rate of the direct reduction of carbon monoxide by zinc was appreciable. The appearance of some carbon during experiments of Maier and Ralston at higher temperatures suggested that zinc oxide might catalyze the decomposition of carbon monoxide into carbon and the dioxide.

Pure zinc was made by fractional distillation of electrolytic zinc in *vacuo*. Pure carbon monoxide was made from concentrated sulfuric acid and 60% formic acid, passed over soda lime, and allowed to stand for two days in contact with molten sodium at 130°.

In a system of about 200 cc. in volume, 20 g. of zinc was distilled in two hours through carbon monoxide at 0.5 atm. Vaporization took place in the center of a horizontal silica tube furnace, the gas passed through about 20 cm. of the tube kept at 750° by a separate winding, and condensation took place near the end of the furnace. The distilled zinc contained no free carbon detectable when 1 g. was dissolved in hydrochloric acid, and no zinc oxide could be found on the walls of the tube. The hydrogen evolved was not tested for hydrocarbons. The pressure did not drop.

About 5 g. of zinc was refluxed in a silica tube in 0.5 atm. of carbon monoxide for five days. The volume of the system was about 100 cc. and the temperature was 690°. A total decrease in pressure of 0.006 atm. occurred. Some zinc condensed in the section of the tube at the upper end of the furnace, changing to a finely divided solid in the colder part of the tube and to large crystals in the hotter part.

A silica tube containing 0.1 g. of zinc and 3 pieces of red fire brick about 1 mm. in diameter was evacuated, heated to 680°, and filled with carbon monoxide at 0.4 atm. The volume of the system was about 100 cc. In five days the pressure dropped 0.06 atm. The fire brick became sooty, and a coating of zinc oxide covered the inner wall of the tube. Fire brick freed from iron showed no catalytic effect whatever; negative results were also obtained with aluminum oxide and zinc oxide.

Zinc containing 0.04% of iron was refluxed in carbon monoxide in the same way as the pure zinc, with the same result.

These experiments indicate (1) that the reaction $CO + Zn_{(l \text{ or } g)} = ZnO + C$ is extremely slow at 600 to 700° in the absence of a catalyst, (2) that it is possibly slower than the reaction $2CO = CO_2 + C$ under the same conditions and (3) that zinc reduces carbon dioxide rapidly at the given temperatures.

The production of zinc oxide in the zinc condenser is due, then, to the oxidation of the zinc by carbon dioxide, or water vapor, both of which are present in considerable quantities in the gases issuing from the retort when reduction first starts. Additional carbon dioxide may be produced by the reaction $2CO = CO_2 + C$, which is catalyzed by the clay present in the condenser walls. Pure carbon monoxide is an excellent atmosphere in which to distil zinc, provided the walls of the apparatus are free of iron.

A MODIFICATION OF THE SKRAUP SYNTHESIS OF QUINOLINE

BY BYRON E. COHN AND R. G. GUSTAVSON

RECEIVED FEBRUARY 21, 1927 PUBLISHED OCTOBER 6, 1928

The Skraup synthesis of quinoline occupies a position of interest in organic chemistry because it offers a ready method of synthesis of the quinoline group of compounds.

Several modifications have been proposed since the method was inaugurated in 1880. The most important advance has been the enlargement of the yield. The ferrous sulfate modification is outstanding in this phase of the development.[1] The original Skraup method and all of the modifications to date possess one disadvantage in common. The reaction is usually vigorous and at times violent. Clarke and Davis writing in "Organic Syntheses" say, "In the Skraup synthesis of quinoline the principal difficulty has always been the violence with which the reaction generally takes place; it occasionally proceeds relatively smoothly, but in the majority of cases gets beyond control."[1] The occasional violence of the reaction renders the experiment objectionable as a routine laboratory experiment. The authors have succeeded in eliminating this danger by the addition of acetic acid to the reaction mixture, and have studied the effect of variations in the conditions upon the yield of quinoline obtained.

The safety attained by this modification is attested by the fact that the reaction has been carried out in our Laboratories by large classes of students observing no special precaution and the reaction has never become violent.

During the course of the investigation an unsuccessful attempt was made to render the reaction safe by dilution of the sulfuric acid. The method

[4] Associate chemist.

[1] H. T. Clarke and Anne W. Davis, "Organic Syntheses," John Wiley and Sons, New York, **2, 79** (1922).

used to obtain an equivalent dehydrating power of the sulfuric acid can be applied in many types of reactions and is therefore of interest. The method consists of the assumption that the dehydrating power of sulfuric acid is directly proportional to the heat of dilution. A curve very well adapted for the computation of the equivalent amount of the dilute sulfuric acid necessary may be found in a paper by Zeisberg.[2]

Acetic Acid Modification

The acetic acid modification of the original Skraup method is conducted as follows. The following reagents are weighed out and placed in a liter flask in the order given: aniline, 38 g.; nitrobenzene, 24 g.; glycerol, 100 g.; acetic acid (80%), 60 cc.; sulfuric acid (95%), 54 cc.

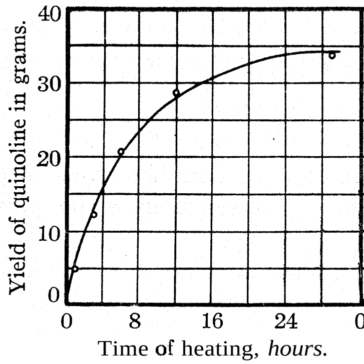

Fig. 1.

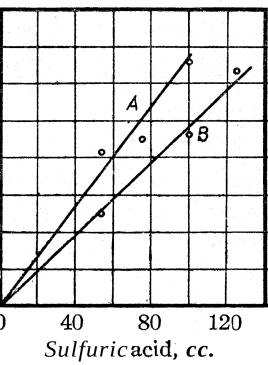

A, six *hours; B, three hours.*

Fig. 2.

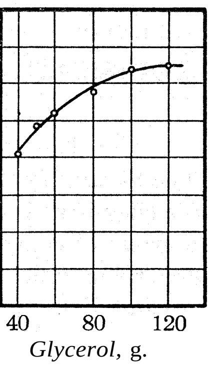

Fig. 3.

The flask is connected with a water reflux condenser and is heated with a Bunsen flame until the boiling point is reached. (In this modification it is not necessary to remove the flame while the reaction is taking place.) The contents of the flask are then kept simmering for a period of sixteen hours. The flame is removed, the contents are diluted with water and steam is passed through the contents of the flask until the distillate is clear, which shows that all of the nitrobenzene has been removed.

The contents of the flask are cooled, made alkaline with a concentrated solution of sodium hydroxide and again distilled with steam. When the distillate is clear, the current of steam is discontinued. The distillate is next dissolved in sulfuric acid, cooled and sodium nitrite solution is added until a drop of the solution causes a starch–potassium iodide spot to turn blue. The material is allowed to stand for about an hour and is then heated to about 100°, being kept at this temperature until thoroughly steamed out. This usually requires about an hour.

The contents of the flask are allowed to cool, are made alkaline with

---

[2] Zeisberg, *Chem. Met. Eng.*, 27, 23 (Fig. 4) (1922).

sodium hydroxide and again steam distilled. As in the preceding cases, the steam is passed in until the distillate comes over clear. The distillate is extracted with ether, the ether is evaporated and the resulting quinoline is weighed. Although in the various processes the material is usually further purified by distillation, in our work the results are based on comparisons of the yield at this stage.

Graphs.—The effect of the time of heating upon the yield of quinoline is shown in Fig. 1. The effect of varying the amount of sulfuric acid is shown in Fig. 2. The effect of the quantity of glycerol upon the yield of quinoline is shown in Fig. **3.** The concentration of the acetic acid has no decided effect upon the yield of quinoline.

Theory of Modification

The authors believe and experiments indicate that the violence of the ordinary Skraup reaction is due to the sudden liberation of acrolein resulting from the action of sulfuric acid upon the glycerol. The acetic acid was introduced in an effort to form a glycerol mono or diacetate and thereby remove a large proportion of the glycerol from the reaction sphere. Acetic acid was used because it is quite stable and relatively cheap.

Summary

1. A modification of the Skraup process which may be conducted with safety has been developed.

2. The variation of the yield under different conditions has been studied.

THE NITRATION OF PIPERONAL

BY JOHN B. EKELEY AND MARGARET S. KLEMME[1]

RECEIVED MAY 1, 1928 PUBLISHED OCTOBER 6, 1928

In a former paper[2] it was reported that commercial o-nitropiperonal yielded two benzylidene derivatives when treated with anthranilic acid in alcohol solution. The one was a yellow crystalline compound melting at 128° and the other yellowish-brown crystals melting at 185'. These two benzylidene products, in turn, reacted with acetic anhydride to form the corresponding nitropiperonylacet-keto-dihydrobenzmetoxazines melting at 206 and 165°, respectively. The conclusion was that Kahlbaum's

---

[1] Extract from a thesis by Margaret S. Klemme submitted to the Graduate School of the University of Colorado in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Ekeley, Rogers and Swisher, THIS JOURNAL, 44, 1756 (1922). The *o*-nitropiperonal used was Kahlbaum's product. Material from the same lot was used in these experiments.

o-nitropiperonal contained a small amount of a second isomeric nitropiperonal. Further study of the matter was desirable. To this end the above reactions were repeated and verified. The two benzylidene anthranilic acids melting at **128** and 185°, respectively, were hydrolyzed, the former yielding o-nitropiperonal melting at 98.5° and the latter a compound melting at 143° which showed the reactions of an aldehyde and gave the following analysis: calcd. for $C_8H_5NO_5$: N, **7.18.** Found: N, **7.17.** In addition fractional crystallizations were carried out with a quantity of Kahlbaum's o-nitropiperonal melting as an impure substance at 80°. The fractionations were carried out in ethyl alcohol, with the result that a yellow crystalline product was obtained melting at 143° and another, the major portion, melting at 98.5°. Both were nitropiperonals and yielded the above described benzylidene compounds with anthranilic acid which, in turn, were transformed into the benzmetoxazine derivatives. The one melting at **143°** gave the following analysis: calcd. for $C_8H_5NO_5$: N, 7.18. Found: N, 7.22. The benzmetoxazine derivatives made from it gave the following analysis: calcd. for $C_{15}H_{10}N_2O_6$: N, **8.91.** Found: N, **8.89.**

We are unable to find anything in the literature on the nitration of piperonal since Fittig and Remsen's paper of **1871.** A systematic study of the nitration products of piperonal then seemed advisable and this paper is a report of the results from the nitration of piperonal under twenty-one different experimental conditions. In no case was it possible to isolate from the reaction product a nitropiperonal melting at 143°. We have been unable to obtain from Kahlbaum the method of nitration used in preparing their product, so that we do not know the conditions under which it was formed. Our experiments show that besides o-nitropiperonal, there were formed in varying quantities, according to the nitration method used, nitropiperonylic acid, mononitromethylenecatechol, dinitromethylenecatechol, and under one set of conditions an isomeric mononitromethylenecatechol, hitherto unknown.

Experimental

The nitrations were carried out by adding small portions at a time of powdered piperonal to the nitration mixture at the temperatures indicated in each case. The raw nitration product after removal from the nitration mixture was washed and first treated with potassium hydroxide solution to obtain any acid product. Next it was treated with sodium bisulfite solution to remove aldehydes. The remaining solids were then subjected to distillation with steam. The non-volatile residue was purified, examined qualitatively and identified. In case two products were found, they were separated by fractional crystallization. The yields of the several nitration products were determined by weighing the product. The original filtrate was evaporated to dryness and oxalic acid determined.

I. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.31) at 23°, stood for two hours when temperature finally rose to 40°. Yields: nitropiperonal, 40 g.; mononitromethylenecatechol,[3] m. p. 144°, 5 g., obtained by Jobst and Hess by nitrating piperonylic acid.

II. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.31), at 2–4°. Yields: nitropiperonal, 50 g.; mononitromethylenecatechol, 4 g.; oxalic acid, small amount.

III. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.38), without cooling, temperature rising finally to the boiling point, 91° at Boulder. Yields: nitropiperonal, 35 g.; mononitromethylenecatechol, 5 g.; oxalic acid, 7.7 g.

IV. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.38), below 45°. Yields: nitropiperonal, 51.7 g.; mononitromethylenecatechol, 10 g.; oxalic acid, 2.6 g.

V. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), at 0–10°. Yields: nitropiperonal, 50 g. Non-aldehyde portion gave mononitromethylenecatechol, 8 g., and a small amount of a compound melting at 100°, and shown by properties and analysis to be dinitromethylenecatechol,[4] obtained by Jobst and Hess by nitrating piperonylic acid.

VI. Fifty g. piperonal, 500 cc. HNO_3 (sp. gr. 1.403), at 0–10°. Yields: nitropiperonal, 49.1 g.; mononitromethylenecatechol, 13.3 g.; a trace of dinitro, a trace of a compound melting at 172° (see IX) and a small amount of oxalic acid.

VII. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), at 0–10° in sunlight. Yields: nitropiperonal, 46.6 g.; mononitromethylenecatechol, 10 g.; a trace of the dinitro; a trace of the compound melting at 172°; oxalic acid 2 g.

VIII. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.43), below 40°. Yields practically the same as in VII.

IX. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.43), on ice for a week. Yields: nitropiperonal, trace; nitropiperonylic acid, m. p. 172°, 35 g.; oxalic acid 7.5 g. Nitropiperonylic acid was obtained by Jobst and Hess[5] by the nitration of piperonylic acid.

X. Fifty g. piperonal, 250 cc. fuming HNO_3 at 30–70°. As was to be expected, there was severe oxidation, the yields being nitropiperonal, 25 g.; dinitromethylenecatechol, 4 g.; oxalic acid, 30 g.

XI. Fifty g. piperonal, 250 cc. fuming HNO_3, on ice three days. Yields, nitropiperonal, 16.5 g.; dinitromethylenecatechol, 20 g.; a small amount of the mononitro; oxalic acid, 10 g.

XII. Fifty g. piperonal, 250 cc. fuming HNO_3, at 0°, the piperonal being added very slowly during ten hours. Yields: nitropiperonal, 9 g.; dinitromethylenecatechol, 8 g., oxalic acid, 14 g.; 20 g. of a yellow crystalline compound melting at 70°. This was separated from the dinitromethylenecatechol by fractional crystallization and was shown by its properties and analysis to be an isomer of mononitromethylenecatechol.

Anal. Calcd. for $C_7H_5O_4N$: N, 8.40. Found: N, 8.44.

XIII. Fifty g. piperonal, 250 cc. fuming HNO_3, at -5°. Yields: nitropiperonal, 45 g.; dinitromethylenecatechol 13.3 g.; oxalic acid, 1 g.

XIV. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), 250 cc. H_2SO_4 (sp. gr. 1.82), below 10°. Yields: nitropiperonal, 15 g.; dinitromethylenecatechol, 32.5 g.; a trace of nitropiperonylic acid, a small amount of oxalic acid.

XV. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), 250 cc. H_2SO_4 (sp. gr. 1.82) below 0°. Yields: nitropiperonal, 25 g.; dinitromethylenecatechol, 12 g.; some oxalic acid.

XVI. Fifty g. piperonal, 250 cc. fuming HNO_3, 250 cc. H_2SO_4 (sp. gr. 1.48), at 0". Yields: nitropiperonal, 20 g.; dinitromethylenecatechol, 5.8 g.; oxalic acid, 35 g.

---

[4] Jobst and Hess, *Ann.*, 199, 75 (1879).

[5] Jobst and Hess, *Ann.*, 199, 70 (1879).

XVII. Fifty g. piperonal, 250 cc. fuming HNO_3 into which SO_2 had been led for twelve hours, at 0°.[6] Yields: nitropiperonal, 38.3 g.; dinitromethylenecatechol 20 g.; oxalic acid, 1 g.

XVIII. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), 250 cc. glacial acetic acid[7] at 25°. Yields: nitropiperonal, 40 g.; mononitromethylenecatechol, 10 g.; a trace of the dinitro; oxalic acid, 1 g.

XIX. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), acetic acid, 166 g., acetic anhydride,[8] 166 g. at 25°. Yields: nitropiperonal, 47 g.; mononitromethylenecatechol, 8.3 g.; a trace of the dinitro; some oxalic acid.

XX. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403) and $HgNO_3$[9] 11.8 g. at 20°. Yields: nitropiperonal, 50 g.; mononitrocatechol, 13.3 g.; a trace of oxalic acid. No phenolic compounds were formed.

XXI. Fifty g. piperonal, 250 cc. HNO_3 (sp. gr. 1.403), 250 cc. H_2SO_4 (sp. gr. 1.48), $HgNO_3$, 11.8 g., at 0°. Yields: no nitropiperonal; mononitromethylenecatechol, 6.6 g.; dinitro, 26.6 g.; some oxalic acid.

It was noticed that nitropiperonal on exposure to sunlight changes to a brown color. Since the isomeric nitropiperonal isolated from Kahlbaum's product is brownish-yellow, it was thought that it might have been formed from the ordinary form through a light reaction. Ordinary nitropiperonal was, therefore, exposed in thin layers to sunlight and to ultraviolet light, but on recrystallizing the brown product only nitropiperonal, m. p. 98.5°, and a brown tarry residue were obtained.

Summary

1. An isomer of the ordinary nitropiperonal has been isolated and found to melt at 143°. It was found in the commercial Kahlbaum nitropiperonal, m. p. 80°, both by means of derivatives made therefrom and by fractional crystallization of the Kahlbaum product.

2. In an attempt to prepare the isomeric nitropiperonal, piperonal was nitrated under varying conditions of temperature and of nitric acid concentrations with and without sulfuric acid in the presence and absence of catalytic agents and in the presence and absence of sunlight.

3. Besides o-nitropiperonal, mononitro and dinitromethylenecatechol, nitropiperonylic acid and an isomeric mononitromethylenecatechol may be obtained by nitrating piperonal.

4. Increase in temperature in general causes an increase in oxidation products.

5. Beyond a nitric acid of sp. gr. 1.38, increase in acid concentration causes an increase in oxidation products.

6. The presence of nitrosulfonic acid causes a decrease in oxidation and an increase in nitration, the presence of glacial acetic acid causes an

increase in the nitration, but the best yield of nitropiperonal was obtained with nitric acid of sp. gr. 1.38 at 45°.

7. No trace of the isomeric nitropiperonal, m. p. 143°, present in Kahlbaum's commercial product, m. p. 80°, was obtained in any of the experiments.

8. That the isomeric nitropiperonal was probably formed as an intermediate product in the experiment using fuming nitric acid at 0° is indicated by the isolation of an isomeric mononitromethylenecatechol from the reaction mixture.

EQUILIBRIUM IN THE REACTION $C_2H_6 \rightleftarrows C_2H_4 + H_2$[1]

BY ROBERT N. PEASE[2] AND ELFORD S. DURGAN[3]

RECEIVED MAY 11, 1928 PUBLISHED OCTOBER 6, 1928

Bone and Coward[4] have shown that ethane is rather rapidly decomposed at 675°, and that the primary products of decomposition are ethylene and hydrogen; and it is well known that ethylene and hydrogen combine quantitatively to form ethane in the presence of catalysts from room temperature up to at least 350°.[5] The indications are, therefore, that the reaction $C_2H_6 \rightleftarrows C_2H_4 + H_2$ is reversible somewhere within the temperature region between 350 and 675°, and that equilibrium should be determinable. Indeed, Berthelot[6] has reported that dissociation and formation of ethane both occur at a low red heat. These results have encouraged us to attempt the measurement of equilibrium in this reaction.

Methods and Apparatus

The work of Bone and Coward having proved that prolonged heating of ethane or ethylene gives rise to by-products such as methane, it was necessary to show that the reaction under consideration was the main reaction under the conditions of our experiments. We therefore carried out forward and reverse reactions at each temperature, making a check-up of

---

[1] This paper contains the results of an investigation carried out as part of Project No. 7 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund donated by Mr. John D. Rockefeller. This fund is being administered by the American Petroleum Institute with the cooperation of the Central Petroleum Committee of the National Research Council. Professor Hugh S. Taylor of Princeton University is Director of Project No. 7.

[4] Bone and Coward, J. Chem. *Soc.*, 93, **1197 (1908).**

[5] Sabatier and Senderens, ***Ann.*** *chim.* phys., [8] **4, 344** (1905).

[6] Berthelot, **Ann.** *chim.*, [4] 9, 431 **(1886).**

reactants and products, and selecting times for heating such that side reactions constituted only a small fraction of the total. From these measurements the approximate position of equilibrium could be estimated. In order to obtain a more accurate value, mixtures of ethane, ethylene and hydrogen were made up to correspond to the calculated equilibrium, and were heated for the same lengths of time as the gases in the preliminary experiments. These measurements furnished the basis for our final values of the equilibrium constants.

Our method of experimentation was essentially as follows. The desired gas mixture was made up in a buret and delivered to an evacuated silica bulb which was heated electrically. After heating for the desired length of time, the pressure was determined, and a "snap" sample of the gas was transferred by means of a Topler pump to a gas analysis apparatus. From the volume and composition of the gas admitted, the volume of the bulb together with the temperature and pressure, and the analysis of the gas sample, the amount of reaction could be determined.

The silica reaction bulb was connected to a gas buret, a mercury manometer and a Topler pump through suitable stopcocks. The bulb occupied the middle third of a resistance furnace, the ends of which were packed with loose magnesia. The volume of the bulb was **207.5** cc. The temperature of the central portion of the furnace was determined by means of a calibrated two-junction chromel-alumel thermocouple. This central portion contained a sheath of sheet iron to insure uniformity of temperature.

The gas analysis apparatus was of the Bureau of Mines precision type. Ethylene was determined by absorption in dilute bromine water, the bromine subsequently being removed by absorption in a 30% solution of potassium hydroxide to which had been added sodium thiosulfate in order to minimize the evolution of oxygen. Fuming sulfuric acid proved very unsatisfactory because of the simultaneous absorption of ethane. No sharp end-point could be obtained. Oxygen was absorbed in alkaline pyrogallol. Hydrogen was determined by preferential combustion with copper oxide at 350°. The saturated hydrocarbons were determined by preferential combustion with copper oxide at 550° followed by absorption of carbon dioxide in **30%** potassium hydroxide solution.

Hydrogen and ethylene were obtained from tanks of the pure gases. Ethane was prepared in 500cc. lots from ethylene and hydrogen by passage of a 50% mixture of these over a supported nickel catalyst at room temperature. The only purification consisted in freezing out moisture at −79°. The hydrogen contained 1.0% of nitrogen; the ethylene, 1.6% of nitrogen.

Results

Our equilibrium measurements were made at 600, 650 and 700°. Observations were also made at 500 and 550°, but the extreme slowness of the reactions and other factors rendered the measurements unsatisfactory. At 600° and above equilibrium could be approached more rapidly. Methane formation could not be avoided entirely, and at 700° would seem to have reached serious proportions. However, the consistency of our results inclines us to the belief that our final equilibrium values are not far from the truth.

Our final experimental results are presented in Table I. For each experiment we give the composition and pressure of the gas mixture as introduced into the reaction bulb, and the composition and pressure after heating.

Three other experiments carried out at 600° with mixtures initially close to equilibrium gave for the equilibrium constant the values 0.0309, 0.0307, 0.0315.

Our data indicate that the equilibrium constants at 600, 650 and 700° are 0.0310, 0.082 and 0.20, respectively. The plot of the corresponding values of log K against I/T gives a straight line. The data are satisfactorily reproduced by the Equation $\Delta F = -RT \ln K = 31{,}244 - 28.88T$.

According to the above equation, the heat of dissociation of one mole of ethane into ethylene and hydrogen at 600–700° is —31,244 cal. From the combustion data of Thomsen and of Berthelot[7] the heat of dissociation of ethane may be calculated to be —31,200 cal. (Thomsen) or —37,100 cal. (Berthelot), the average being —34,200 cal. Although adequate specific heat data are lacking, the indication is that our value at 600–700°

---

[7] Thomsen and Berthelot, Landolt-Börnstein, "Tabellen," 1923, p. **1588**.

might be reduced by 1000–3000 cal. at room temperature, making it approximately 28,000–30,000 cal. as compared to the above average of —34,200 cal., which also is for room temperature.

It is difficult to estimate the accuracy of our results. The most serious source of error is indicated by the presence of considerable amounts of methane among the products of some of the experiments. The corresponding side reaction undoubtedly has displaced equilibrium to some extent. However, in view of the facts that approximately the same end-point is reached from either side and that our calculated heat of reaction is not unreasonable, we are inclined to believe that our data are not greatly in error.

Summary

The position of equilibrium in the reaction $C_2H_6 \rightleftarrows C_2H_4 + H_2$ has been measured at 600, 650 and 700°. Equilibrium was approached from both sides. Some uncertainty exists owing to the simultaneous formation of methane, but the indications are that the equilibrium constants at the three temperatures are 0.0310, 0.082 and 0.20, respectively, partial pressures being expressed in atmospheres.

THE MECHANISM OF THE ACETAL REACTION. THE EXPLOSIVE REARRANGEMENT OF HYDROXY-ETHYL VINYL ETHER INTO ETHYLIDENE GLYCOL[1]

HAROLD S. HILL[2] AND LLOYD M. PIDGEON

RECEIVED MAY 28, 1928 PUBLISHED OCTOBER 6, 1928

In a previous paper[3] dealing with the formation of cyclic acetals by the action of acetylene on polyhydroxy compounds in the presence of a catalyst, some speculations as to the mechanism of this interesting reaction were brought forward. Taking the reaction between ethylene glycol and acetylene as an example, it was assumed that the first change involves intermolecular addilion of one glycol hydroxyl to the unsaturated acetylene carbons, giving hydroxy-ethyl vinyl ether, (A)

$$\begin{array}{l} HC{\equiv}CH \\ H{-}OCH_2CH_2OH \end{array} \longrightarrow \underset{\textbf{A}}{CH_2{=}CHOCH_2CH_2OH}$$

---

[1] This paper represents one of a series of publications carried out under the joint auspices of the Canadian Pulp and Paper Association, the Pulp and Paper Division of the Forest Products Laboratories of Canada and the Department of Industrial and Cellulose Chemistry, McGill University. The authors wish to express their appreciation of the facilities placed at their disposal by the three cooperating agencies.

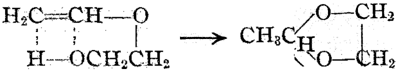
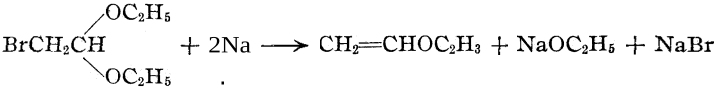
which, undergoing the same general reaction *intra* molecularly, rearranges at once to form ethylidene glycol.



B

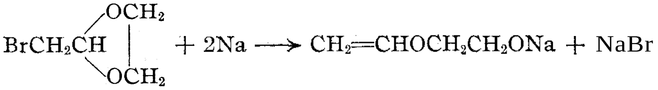
The present communication deals with the synthesis of the intermediate vinyl derivative (A) and shows that its rearrangement into the acetal (B) takes place in a most striking manner.

For the synthesis of hydroxy-ethyl vinyl ether recourse was had to a scheme proposed in an earlier paper.[4] Since Wislicenus[5] had obtained vinyl ethyl ether by the action of metallic sodium on bromo-ethylal, according to the equation



$$\mathrm{BrCH_2CH}\begin{matrix}\diagup\mathrm{OC_2H_5}\\ \\ \diagdown\mathrm{OC_2H_5}\end{matrix} + 2\mathrm{Na} \longrightarrow \mathrm{CH_2{=}CHOC_2H_3} + \mathrm{NaOC_2H_5} + \mathrm{NaBr}.$$

it was considered probable that a similar reaction with bromo-ethylidene glycol would yield the sodium salt of the desired intermediate (A)



$$\mathrm{BrCH_2CH}\begin{matrix}\diagup\mathrm{OCH_2}\\ \vert\\ \diagdown\mathrm{OCH_2}\end{matrix} + 2\mathrm{Na} \longrightarrow \mathrm{CH_2{=}CHOCH_2CH_2ONa} + \mathrm{NaBr}$$

and this is now found to be the case. When metallic sodium is added to a dry ether solution of bromo-ethylidene glycol, a smooth but vigorous reaction takes place accompanied by the gradual accumulation of sodium bromide and the sodium salt of hydroxy-ethyl vinyl ether. The latter compound is obtained by hydrolyzing the sodium salt with water and extraction as described in the experimental part.

Hydroxy-ethyl vinyl ether is a colorless oil, soluble in water, ether and benzene but insoluble in ligroin. It adds bromine readily at the double bond, and the presence of a free hydroxyl group is shown by the evolution of hydrogen on reaction with sodium and by the formation of a monobenzoate.

Rearrangement of Hydroxy-ethyl Vinyl Ether into Ethylidene **Glycol.**—When this vinyl derivative, freshly prepared as above, is brought in contact with a trace of 50% sulfuric acid, an explosive reaction takes place and the unsaturated ether rearranges quantitatively into cyclic ethylidene glycol. The violence and velocity of this transformation are remarkable. Using small amounts, however, and by strong cooling, it may be modified somewhat, although even under these conditions cyclization is complete within a very short time. Any strong acid suffices to effect this rapid change and less dissociated acids cause the same reaction but at a slower rate. In fact, heating hydroxy-ethyl vinyl ether

---

[4] Hibbert and Hill, THIS JOURNAL, 45, 740 (1923).

[5] Wislicenus, *Ann.*, **192**, 112 (1878).

alone in the air is sufficient to bring about gradual rearrangement as well as other changes. It is impossible, therefore, to redistil the vinyl derivative after it has been exposed to the air for any length of time. The reason for this may possibly be the formation of traces of acetic acid by slight hydrolysis and oxidation. Distillation is best carried out in the presence of a small amount of carbonate, or traces of sodium hydroxide. The product is quite stable in the presence of alkalies, although long boiling with dilute alkalies causes hydrolysis. The same change takes place with great ease in dilute acids, the products being acetaldehyde and ethylene glycol.

A trace of dry hydrogen bromide added to the vinyl derivative produces the same instantaneous rearrangement that was caused by concentrated sulfuric acid, which, together with the fact that in no case could the presence of free acetaldehyde be detected during or after the change, would seem to preclude the possibility that this transformation involves preliminary hydrolysis to vinyl alcohol, its rearrangement to acetaldehyde and the recombination of the latter product with ethylene glycol to give the cyclic acetal (B).

In this connection, it should be noted that the benzoate of hydroxyethyl vinyl ether, $CH_2{=}CHOCH_2CH_2{-}OCO{-}C_6H_5$, shows no tendency to rearrange or to react in any way in the presence of small amounts of acid, thus indicating a specific role of the hydroxyl group in this interesting transformation.

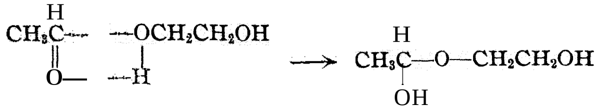
The quantitative nature of the rearrangement is proved not only in a recovery of over 90% of pure ethylidene glycol, but also by the fact that immediately after the reaction there is no trace of remaining unsaturation against bromine in carbon tetrachloride solution.

The identity of the ethylidene glycol formed was established beyond question by its boiling point, refractive index, solubilities, and its quantitative hydrolysis into acetaldehyde and ethylene glycol. It compared in every way with the product obtained from the interaction of acetaldehyde (as paraldehyde) or of acetylene with ethylene glycol.

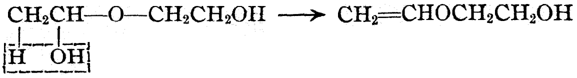
Theoretical Discussion

There would seem to be considerable theoretical significance attached to the above transformation, especially in view of the marked ease with which it takes place. Involving as it does the addition of a hydroxyl group to a *vinyl* double bond, it leads to the suggestion that intermediate unsaturation of this sort may precede many of the reactions of hydroxy compounds. Besides being the mechanism through which ethylene glycol reacts with acetylene, it may also serve as an explanation of acetal formation in general.

Thus, for example, the reaction of ethylene glycol with acetaldehyde may be represented as taking place in three stages: (1) addition of one glycol hydroxyl to the unsaturated C=O group to form a half acetal.[6]

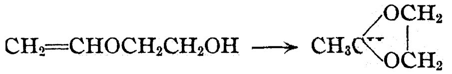


(2) dehydration



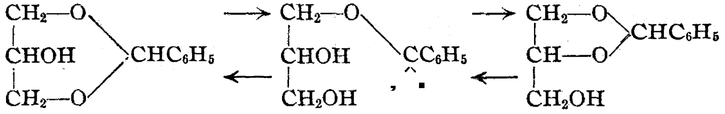
$$CH_2CH{-}O{-}CH_2CH_2OH \longrightarrow CH_2{=}CHOCH_2CH_2OH$$

(3) rearrangement of the vinyl derivative as shown in this paper

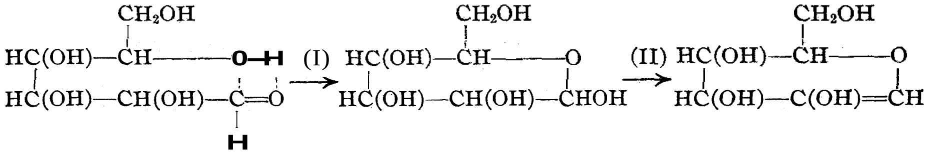


With monohydric alcohols instead of ethylene glycol, the scheme would be the same except that in the last stage the reaction would be intermolecular rather than intra molecular. Substituting formaldehyde or benzaldehyde for acetaldehyde, the dehydration in stage (2) would be from the same carbon. Such an unsaturated carbon compound has never been isolated, but there is much evidence that they occur as intermediates.

For example, it has recently been found[7] that a trace of dry hydrogen chloride causes the interconversion of 1,3-benzylidene glycerol to its 1,2-isomer and *vice versa,* a reaction probably taking place through an unsaturated intermediate



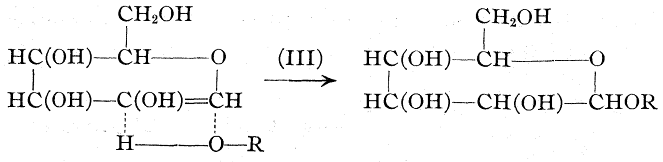
It is of special interest to apply this mechanism to reactions of the sugar and polysaccharide groups, in which the cyclic half acetal configuration is of such common occurrence. Thus, in glucoside formation, starting with the more unstable aldehydic form of glucose, the three identical stages of the acetal reaction above may occur.



---

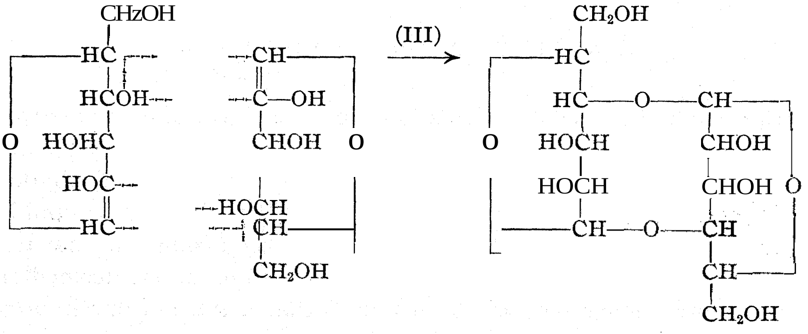
[6] Since this work was completed, Adkins and Broderick, THIS JOURNAL, 50, 499 (1928), have brought forward evidence indicating that the formation of a half acetal, as in Equation 1 is, in fact, the first stage in the acetal reaction. From changes in refractive index it is shown that this initial addition takes place on merely bringing together a pure alcohol and an aldehyde.

[7] Hill, Whelen and Hibbert, THIS JOURNAL, 50, 2238 (1928).



If (R) is another sugar residue, a polysaccharide results, and sugar metabolism in general may well proceed along these lines.

Assuming, for example, cellulose to be based on a unit of a biose anhydride, the latter might be formed from the -ene-1,2-glucose derivative (C) as follows



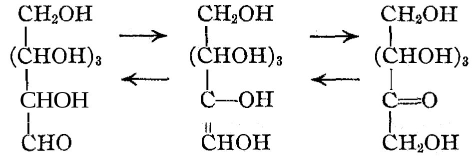
In like manner it is possible to interpret many other transformations of sugar derivatives.[8]

The fact that such an unsaturated sugar (C) does not appear in the course of these reactions is no more surprising than that the corresponding vinyl derivative is not apparent in the preparation of acetals from acetylene.

Dehydration between adjacent carbons, however, is a very commonly occurring reaction in many classes of hydroxy and polyhydroxy compounds. This fact, coupled with the experimental evidence brought forward above, leads to the conclusion that among these unsaturated vinyl

---

[8] Somewhat different unsaturated intermediates have been proposed as a basis for the explanation of certain transformations of sugar derivatives in alkaline solution. Thus Wohl, *Ber.*, 33, 3095 (1900), postulated a scheme in which the glucose-mannose fructose interconversion takes place through an intermediate "enediol" form



Recent investigations of Evans and his co-workers have yielded much experimental evidence in favor of this mechanism, THIS JOURNAL, 47, 3085, 3098, 3102 (1925); 48, 2665, 2678, 2703 (1926); 50, 486 (1928); see also Wolfrom and Lewis, *ibid.*, 50, 837 (1928).

derivatives there may prove to be the key to the mechanism of many of the reactions of this group, including such important changes as occur in natural metabolism of sugars and polysaccharides.

Experimental Part

Preparation of **Bromo-ethylidene** Ethylene **Glycol.**[9]—One hundred and twenty-five g. of paraldehyde was brominated at –12" as described[4,10] with 315 g. of bromine. After stirring the brominated mixture at –10° for ten hours, a slight excess of bromine was removed by bubbling in sulfur dioxide with stirring. One hundred and thirty-five g. of ethylene glycol was added during two hours through a dropping funnel, keeping the temperature below –10°. The cooling bath was then removed and efficient stirring continued for six hours at room temperature. The mixture was extracted with ether, neutralized with sodium carbonate, washed successively with small amounts of concentrated sodium bisulfite solution, 10% sodium hydroxide, water and dried over solid potassium carbonate After removal of the ether, fractionation under reduced pressure yielded 260 g. of bromo-ethylidene glycol, b. p. 68–71" (15 mm.). The yield is 80% of the theoretical calculated on the basis that all of the bromine was available as bromo-acetaldehyde.

The product obtained by this method shows a tendency to darken on standing. It may then be purified by shaking with 10% sodium hydroxide solution, followed by redistillation.

Bromo-ethylidene glycol may also be prepared by the interaction of ethylene glycol with crystalline dibromoparaldehyde[10] in the presence of 40% sulfuric acid as a catalyst.

One hundred and forty g. of ethylene glycol with 2 cc. of 40% sulfuric acid was added to 185 g. of dibromoparaldehyde (m. p. 57°) in a three-necked flask equipped with a stirrer, mercury seal and reflux condenser. The mixture was heated on the steam-bath with stirring for ten hours, after which it was worked up as in the above experiment. Fractionation gave some low boiling ethylidene glycol, followed by bromo-ethylidene glycol; b. p. 65–66" (12 mm); yield, 77 g. or 40%. The yield is poor but the product is very pure and shows no darkening on standing.

Action of Metallic Sodium on Bromo-ethylidene Glycol. Preparation **of Hydroxy-ethyl** Vinyl Ether.—Seventy-five g. of bromo-ethylidene glycol dissolved in three volumes of anhydrous ether was placed in a 500cc. flask equipped with a motor stirrer, mercury seal and reflux condenser protected against atmospheric moisture and carbon dioxide. Twenty g. of clean metallic sodium was added in small pieces as rapidly as convenient. A brisk reaction took place, causing the ether to boil, but after a time this subsided and gentle heat was applied. Heating and stirring were continued for seven hours. It is well to have vigorous and efficient stirring in order to expose fresh surfaces of the sodium. The ether contained a heavy suspension of the sodium salt of hydroxy-ethyl vinyl ether, together with sodium bromide and some unchanged sodium. The latter was removed by flushing through a wire gauze with ether. The ether sludge so obtained was treated with an amount of water just sufficient to dissolve the solids, the first of this being added cautiously on the chance that bits of sodium might be present. The water layer was separated and extracted several times with ether. The ether extract was washed once with a minimum amount of water and dried over potassium carbonate. After removal of the ether, employing a column, the product was distilled under reduced pressure. Apparently the only product of the reaction was hydroxy

---

[9] This product was isolated earlier (ref. 4) but by the above modifications the yield has been doubled.

[10] Stepanow, Ber., 48, 1718 (1925).

ethyl vinyl ether, b. p. 44–45' (10 mm.); 140° (760 mm.); yield 22 g., or 56.4% of the theoretical.

Anal, Subs., 0.2105: CO_2, 0.4176; H_2O, 0.1729. Calcd. for $C_4H_8O_2$: C, 54.54; H, 9.09. Found: C, 54.15, H, 9.00.

The product is a slightly viscous, colorless oil having a faint ethereal odor and n_D^{17} = 1.4564. It is soluble in water, alcohol, ether and benzene but insoluble in ligroin. It is strongly unsaturated against bromine in carbon tetrachloride, and against potassium permanganate, and also shows the reactions characteristic of the hydroxyl group. This vinyl derivative is stable when distilled from a slightly alkaline solution but is very sensitive to acids, dilute acids causing hydrolysis and traces of concentrated acids bringing about intramolecular rearrangement.

Benzoate of Hydroxy-ethyl Vinyl Ether.—Ten grams of the vinyl derivative (freshly prepared) was benzoylated in the usual manner with 10 cc. of benzoyl chloride and 20 cc. of dry pyridine. Pouring the reaction product into water, extracting with ether, washing the ether solution with cold dilute sodium hydroxide followed by water, drying over potassium carbonate and fractionating gave the benzoate of hydroxy-ethyl vinyl ether, b. p. 133° (9 mm.)

Anal. Subs., 0.2219: CO_2, 0.5406; H_2O, 0.1108. Calcd. for $C_{11}H_{12}O_3$: C, 68.75; H, 6.25. Found: C, 68.75; H, 6.56.

The product is a viscous oil, reacting as an unsaturated derivative, but in contrast to the free alcohol above shows no activity in contact with a trace of concentrated acid.

Intramolecular Rearrangement of Hydroxy-ethyl Vinyl Ether into Ethylidene Glycol.—As already described, this reaction takes place under the agency of a trace of concentrated acid. If the vinyl derivative is freshly prepared and pure, the rearrangement is so violent that it can be carried out safely only in test-tube quantities. The following modification was found practicable for the conversion of larger amounts of the unsaturated ether.

Two cc. of hydroxy-ethyl vinyl ether was placed in a flask large enough to hold the final volume of the product to be converted. A fraction of a drop of 40% sulfuric acid was added with cooling. After the rapid reaction had taken place, fresh vinyl derivative was slowly added and, since it was converted progressively, the danger of too violent a reaction was obviated. Cooling was necessary to prevent loss of ethylidene glycol.

The product so formed had all the physical and chemical properties of ethylidene glycol, b. p. 81–82' (760 mm.); n_D^{17} = 1.4035, as compared with n_D^{17} = 1.4565 for the vinyl derivative before rearrangement; n_D^{17} of ethylidene glycol prepared from acetylene and glycol, 1.4034.

Anal. Subs., 0.1404: CO_2, 0.3391; H_2O, 0.1404. Calcd. for $C_4H_8O_2$: C, 54.54; H, 9.09. Found: C, 54.09; H, 9.12.

In a quantitative experiment 4.3 g. of hydroxy-ethyl vinyl ether yielded 3.5 g. of ethylidene glycol, b. p. 81–83° (760 mm.), approximating a 90% recovery.

To confirm further the identity of the ethylidene glycol obtained above, it was quantitatively hydrolyzed to acetaldehyde and glycol; 2.552 g. of the product together with 2 g. of 5% phosphoric acid was placed in a test-tube attached to a small reflux condenser maintained at 40–50°. Gases from the condenser were led through a strongly cooled trap. Boiling the mixture in the tube for one hour yielded 1.535 g. of acetaldehyde in the trap, which corresponds to a recovery of 94% of the theoretical amount to be obtained by the hydrolysis of ethylidene glycol.

Acknowledgment is made of the receipt by one of us (L. M. P.) of a grant from the National Research Council of Canada, during the tenure of which this work was performed.

Summary

1. The synthesis of hydroxy-ethyl vinyl ether is described.

2. It is shown that this vinyl derivative in contact with a trace of concentrated acid undergoes instantaneous rearrangement into ethylidene glycol.

3. The latter change is offered as strong support for a mechanism proposed for the acetal reaction postulating a "vinyl" derivative as an intermediate product.

4. This mechanism is elaborated so as to include similar reactions such as those occurring in glucoside and polysaccharide formation.

MONTREAL, CANADA

VINYL DERIVATIVES: THEIR RELATIONSHIP TO SUGARS AND POLYSACCHARIDES[1]

BY HAROLD S. HILL[2]

RECEIVED MAY 28, 1928 PUBLISHED OCTOBER 6, 1928

In a preceding[3] paper dealing with the mechanism of acetal formations, the synthesis of hydroxy-ethyl vinyl ether and its rearrangement into ethylidene glycol are described. The extreme ease and the instantaneous character of the latter change led to the suggestion that unsaturated derivatives of the vinyl type may be the intermediates through which many other reactions of hydroxy compounds take place. From the application of this idea to the transformation of the sugars and polysaccharides, it was concluded that an unsaturated sugar[4] such as (IV) which may be considered as a vinyl derivative occupies a position of importance in a logical scheme picturing the mechanism of such reactions as occur in glucoside and polysaccharide formation.

The present paper describes the synthesis of additional vinyl derivatives, their transformations, and shows that the relationship indicated above is in fact a close one.

It seemed desirable first of all to show that the rearrangement of hydroxy-ethyl vinyl ether into ethylidene glycol

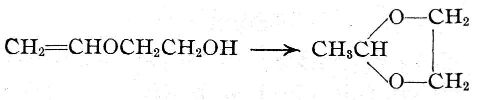
---

[1] This paper represents one of a series of publications carried out under the joint auspices of the Canadian Pulp and Paper Association, the Pulp and Paper Division of the Forest Products Laboratories of Canada and the Department of Industrial and Cellulose Chemistry, McGill University. The author wishes to express his appreciation of the facilities placed at his disposal by the three coöperating agencies.

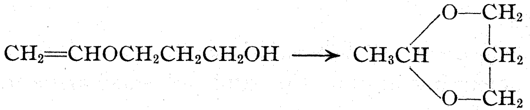
[2] Research Fellow, Canadian Pulp and Paper Association.

[3] Hill and Pidgeon, THIS JOURNAL, 50, 2718 (1928).

[4] This unsaturated sugar is somewhat similar to Fischer's glucal, Ber., 47, 196 (1914) and also to the enolic form of glucose postulated by Wohl, Ber., 33, 3095 (1900), as an intermediate in the glucose-mannose-fructose interconversion.

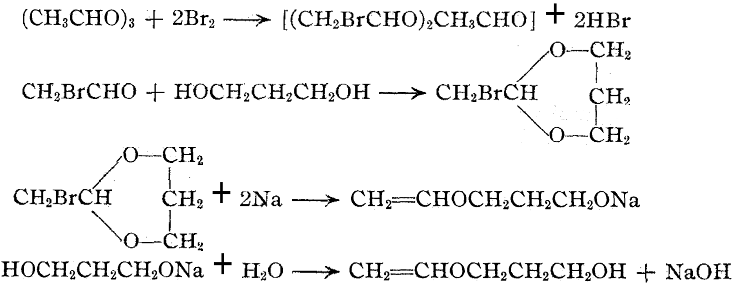


represents a general tendency toward cyclization in derivatives of this type. For this purpose the synthesis of hydroxypropyl vinyl ether (I) was undertaken, since this compound on rearrangement should give as readily the six membered cyclic acetal (II)



I II

Hydroxypropyl vinyl ether (I) was synthesized, starting with paracetaldehyde. This was brominated at a low temperature and the product condensed in *situ* with trimethylene glycol, giving in good yield bromoethylidene trimethylene glycol. The action of sodium on this halogen acetal gave (I) in 85% yield through its sodium salt, the changes being represented as follows



$$(CH_3CHO)_3 + 2Br_2 \longrightarrow [(CH_2BrCHO)_2CH_3CHO] + 2HBr$$

$$CH_2{=}CHOCH_2CH_2CH_2ONa + H_2O \longrightarrow CH_2{=}CHOCH_2CH_2CH_2OH + NaOH$$

Hydroxypropyl vinyl ether resembles closely its lower homolog previously described.[3] It undergoes the same violent, quantitative rearrangement into (II) when brought into contact with a trace of 50% sulfuric acid or dry hydrogen chloride.

It is probable, therefore, that such instantaneous cyclizations represent a general type reaction and may be looked for in all hydroxy-alkyl vinyl ethers where the hydroxyl group is in the β- or γ-position.[5]

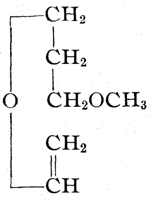
The next step was to show that a vinyl derivative will undergo reactions analogous to that of glucoside formation. For this purpose it was necessary to block off the free hydroxyl group of (I) by methylation, giving the methyl ether (III), the latter being conveniently prepared in good yield

---

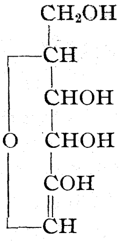
[5] This is presumably an example of the still more general tendency toward cyclization exhibited by many classes of compounds having a hydroxyl in the 3- or 4-position to an unsaturated group, as evidenced by the formation of lactones, cyclic acid anhydration, oxidic forms of sugars and cyclic oxides. The first three involve the addition of a hydroxyl to a C=O, while in the last it is to a C=C group formed by an initial dehydration.

by the action of sodium on bromo-ethylidene trimethylene glycol, as indicated above, and the subsequent in *situ* reaction of the sodium salt of (I) with methyl iodide.

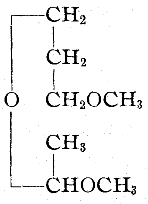
Comparison of this new ether with the postulated anhydro glucose (TV) shows the following relationships



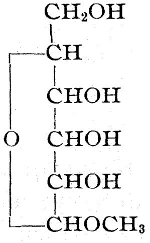
III



IV



V



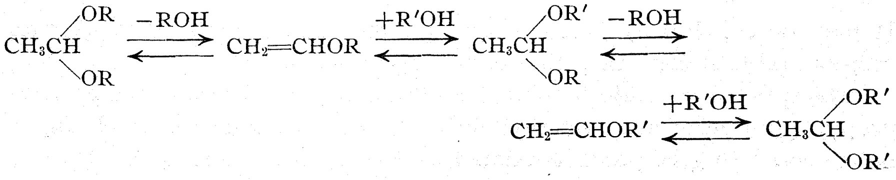
VI

If (IV) is the intermediate in the formation of a-methyl glucoside (VI), then (III) under the same conditions should give the corresponding mixed acetal or "vinylide" (V).

It was found that (III) on being mixed with an equimolecular amount of methyl alcohol and brought in contact with a trace of dry hydrogen chloride, undergoes an instantaneous reaction, the saturation in the molecule disappearing completely. Examination of the products disclosed that an interesting secondary reaction had taken place, for not only was the "vinylide" (V) found, but also a considerable amount of dimethyl acetal, $CH_3CH(OCH_3)_2$. Using an excess of methyl alcohol in the experiment, the latter acetal was formed almost exclusively.

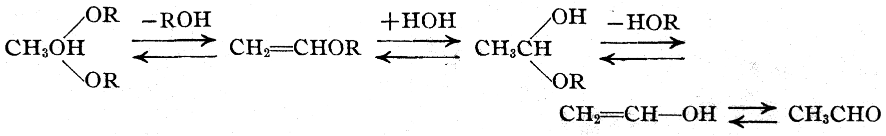
It is considered that these results strongly support the general theory of vinyl derivatives as intermediates, for they indicate the labile character of the alcohol residue in acetals and point toward the existence of an equilibrium, however slight, between the saturated acetal on the one hand and a vinyl derivative on the other.

If other alcohols are present, there may be secondary additions to the vinyl derivative and the equilibrium is continually displaced until the most stable system is attained. It appears that, in general, the lower alcohols tend to displace those higher in a series. This phenomenon is similar to that of *alcoholysis* and the analogous well-known displacements in the acetal series. Presumably the mechanism is in all cases the same, passing as indicated through the intermediate vinyl stage.



$$CH_3CH\begin{smallmatrix}OR\\OR\end{smallmatrix} \xrightleftharpoons{-ROH} CH_2{=}CHOR \xrightleftharpoons{+R'OH} CH_3CH\begin{smallmatrix}OR'\\OR\end{smallmatrix} \xrightleftharpoons{-ROH} CH_2{=}CHOR' \xrightleftharpoons{+R'OH} CH_3CH\begin{smallmatrix}OR'\\OR'\end{smallmatrix}$$

Hydrolysis, then, may be an identical reaction. Water instead of a lower alcohol adds onto the intermediate vinyl ether, shifting the equilibrium continually to the right. Analogous secondary equilibria are then established between the half acetal thus formed and vinyl alcohol and acetaldehyde.



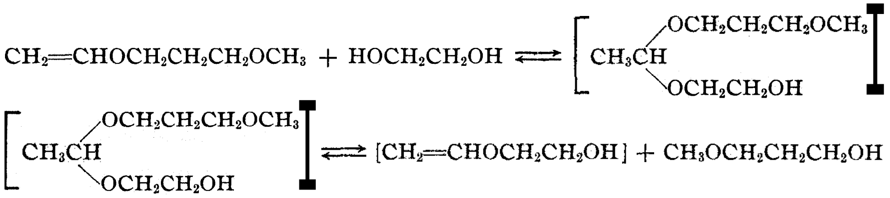
$$CH_3OH\begin{matrix}OR\\OR\end{matrix} \underset{}{\overset{-ROH}{\rightleftharpoons}} CH_2{=}CHOR \overset{+HOH}{\rightleftharpoons} CH_3CH\begin{matrix}OH\\OR\end{matrix} \overset{-HOR}{\rightleftharpoons}$$

$$CH_2{=}CH{-}OH \rightleftharpoons CH_3CHO$$

Hydrolysis of a glucoside or polysaccharide map proceed along the same lines, namely, through the intermediate unsaturated sugar of the type (IV) which, by adding on water, displaces the partial equilibrium and yields a saturated sugar in its cyclic oxide form. The latter may be considered as a cyclic half acetal. That the reaction rests at this stage and does not proceed far toward the free carbonyl derivative, as in the case with acetals, is due to the general tendency for cyclization to take place in preference to intermolecular addition. This is well brought out in the following experiments.

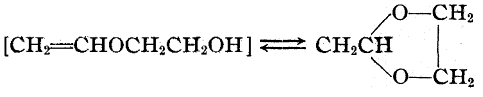
When equimolecular amounts of hydroxypropyl vinyl ether (I) and methyl alcohol are brought in contact with a trace of acid, the main product is ethylidene trimethylene glycol (II) rather than dimethyl acetal or the "vinylide" (V). Here, as in the case of sugars, cyclization is favored.

The reaction of ethylene glycol with methoxypropyl vinyl ether (III) lends further evidence. The products are ethylidene glycol, and monomethyl trimethylene glycol, presumably formed through an intermediate vinyl derivative as follows



$$CH_2{=}CHOCH_2CH_2CH_2OCH_3 + HOCH_2CH_2OH \rightleftharpoons \left[CH_3CH\begin{matrix}OCH_2CH_2CH_2OCH_3\\OCH_2CH_2OH\end{matrix}\right]$$

$$\left[CH_3CH\begin{matrix}OCH_2CH_2CH_2OCH_3\\OCH_2CH_2OH\end{matrix}\right] \rightleftharpoons [CH_2{=}CHOCH_2CH_2OH] + CH_3OCH_2CH_2CH_2OH$$



It may be concluded, therefore, that the resulting cyclic form represents a more stable system than that of the mixed acetal.

Attempts were made to obtain addition reactions between methoxypropyl vinyl ether and a-methyl glucoside, and also glucose, which might be expected to give products related to disaccharides, such as (VII).

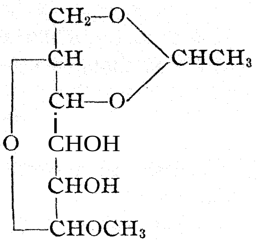
VIII



IX

A great difficulty lay in the mutual insolubility of the vinyl derivative and the sugar. Using a-methyl glucoside, however, a partial reaction took place, the final product being again not the mixed acetal (VII) but rather ethylidene a-methyl glucoside (IX).

As in the preceding scheme, the first stage is logically the formation of (VII), followed by the establishment of an equilibrium with (VIII) and the final rearrangement of this vinyl intermediate into the cyclic acetal (IX). Here also the cylic structure is indicated as being the most stable system.

The extremely rapid and quantitative character of the above reactions (whether they be inter- or intramolecular) of the vinyl derivatives may be taken as evidence that the latter are true intermediates. It also explains their lack of appearance under the conditions occurring in such changes as acetal, glucoside and polysaccharide formation.

Experimental Part

Preparation **of Bromo-ethylidene** Trimethylene Glycol.—One hundred and thirty-two g. of paracetaldehyde was brominated at −12° as previously described with 320 *g.* of bromine. After stirring the brominated mixture at −10° for eight hours, 240 g. of trimethylene glycol was slowly added, keeping the temperature below −10°. Then the temperature was allowed to rise to 0° and the mixture stirred overnight, and later for four hours at 20°. Extraction with ether was facilitated by the addition of ice water. The ether solution was neutralized with potassium carbonate, washed with 20% sodium hydroxide, water and dried over potassium carbonate. Two fractionations yielded 200 g. (55% reckoned on the bromine used) of bromo-ethylidene trimethylene glycol; b. p. 74–75° (10 mm.).

Preparation **of Hydroxy-propyl** Vinyl Ether.—Fifty-four g. of bromo-ethylidene trimethylene glycol was dissolved in 150 cc. of absolute ether in a three-necked flask equipped with *a* reflux condenser and an efficient mechanical stirrer protected from the atmosphere. Fourteen g. of freshly cut sodium was added, cooling the flask enough to keep the reaction from becoming too violent. After stirring overnight, the sludge of accumulated salts was washed with ether through a wire gauze to filter out a small amount of unchanged sodium. Enough water was added to dissolve the salts, the mixture was extracted three times with ether, and the latter solution dried over potassium carbonate. Fractionation yielded 25 g. (85% of the theoretical) of hydroxypropyl vinyl ether; b. p. 64–65' (10 mm.).

Anal. Subs., 0.2003: CO_2, 0.4305; H_2O, 0.1736. Calcd. for $C_5H_{10}O_2$: C, 58.82; H, 9.80. Found: C, 58.61; H, 9.63.

Hydroxypropyl vinyl ether is a colorless oil, strongly unsaturated against bromine in carbon tetrachloride solution, and yielding a monobenzoate with benzoyl chloride in dry pyridine solution. When treated with a few bubbles of dry hydrogen chloride, a violent reaction took place, the unsaturation completely disappearing. Neutralizing with potassium carbonate and distilling gave an almost quantitative yield of ethylidene trimethylene glycol; b, p. 108–110°.

The same transformation catalyzed with 50% sulfuric acid took place with explosive violence.

Reaction of Hydroxypropyl Ether with Methyl Alcohol.—Five and one-tenth g. hydroxypropyl vinyl ether and 1.6 g. of methyl alcohol were treated with a few bubbles of dry hydrogen chloride. After the sharp reaction was over, the products were neutralized with potassium carbonate, filtered and distilled, using a small bead column; 3.5 g. of ethylidene trimethylene glycol was obtained (b. p. 105–110°) as the main product. Using three times the amount of methyl alcohol, the main product was dimethyl acetal (b. p. 63–65°).

Preparation of Methoxypropyl Vinyl Ether.—Ninety g. of bromo-ethylidene trimethylene glycol in 250 cc. of absolute ether was treated with 23 g. of sodium as described above. After stirring overnight, most of the ether was distilled from the reaction flask (care being taken to exclude atmospheric moisture), 80 g. of methyl iodide was added and the mixture refluxed with stirring for sixteen hours. Enough water to dissolve the salts was added cautiously, the mixture extracted twice with ether and the latter solution washed with water and dried over potassium carbonate. Fractionation yielded 40 g. (69%) of methoxypropyl vinyl ether; b. p. 68–78° (152 mm.). Refractionation gave 32 g. of a pure product; b. p. 75–76° (137 mm.).

Anal. Subs., 0.1821: CO_2, 0.4140; H_2O, 0.1687. Calcd. for $C_6H_{12}O_2$: C, 62.07; H, 10.35. Found: C, 62.01; H, 10.28.

Reaction of Methoxypropyl Vinyl Ether with Methyl Alcohol.—Five and five-tenths g. of methoxypropyl vinyl ether was mixed with 1.5 g. of methyl alcohol, cooled and treated with a trace of 40% sulfuric acid. A vigorous reaction took place which was complete in a few seconds. The products were neutralized with potassium carbonate, washed with concd. calcium chloride to remove traces of CH_3OH and $CH_3OCH_2CH_2$, CH_2OH and dried over calcium chloride. Fractionation yielded 1 g. of dimethyl acetal (b. p. 63-65"), 2 g. of intermediate mixture and 3 g. of the mixed acetal $CH_3CH(OCH_3)$-$OCH_2CH_2CH_2OCH_3$ (b. p. 153–155°).

Anal. Subs., 0.2000: CO_2, 0.4142; H_2O, 0.1945. Calcd. for $C_7H_{16}O_3$: C, 56.76; H, 10.81. Found: C, 56.49; H, 10.81.

Reaction of Methoxypropyl Vinyl Ether with Ethylene Glycol. Five and eight-tenths g. of methoxypropyl vinyl ether was mixed with 3.1 g. of ethylene glycol and treated with a few bubbles of dry hydrogen chloride. On shaking a vigorous reaction took place, the unsaturation against bromine in carbon tetrachloride disappearing immediately. The product was neutralized with potassium carbonate and fractionated. The two main products were ethylidene glycol (b. p. 80–83°) and monomethyl trimethylene glycol, b. p. 86–92' (15 mm.). The latter product was further identified by its benzoate prepared in dry pyridine solution.

Anal. (benzoate). Subs., 0.2100: CO_2, 0.5264; H_2O, 0.1269. Calcd. for $C_{11}H_{14}O_3$: C, 68.04; H, 7.22. Found: C, 68.40; H, 6.80.

Reaction of Methoxypropyl Vinyl Ether with a-Methyl Glucoside.—Four g. of methoxypropyl vinyl ether was incorporated with 7.5 g. of finely powdered α-methyl glucoside and the mixture treated with a few bubbles of dry hydrogen chloride. Considerable heat was evolved although much of the glucoside did not go into solution.

After allowing to stand for four hours with occasional shaking, the paste was extracted with ether and the latter solution neutralized with solid potassium carbonate, filtered and evaporated in a vacuum. The residue was a small quantity of colorless sirup which crystallized after remaining in a vacuum for several weeks. After crystals were once obtained the sirups were readily crystallized by "seeding." Recrystallization from a mixture of ether and ligroin gave pure ethylidene α-methyl glucose, m. p. 77°.

Summary

1. The synthesis of hydroxypropyl vinyl ether and its methylated derivative is described.

2. The former compound, in contact with a trace of concentrated acid, is shown to rearrange quantitatively into the cyclic acetal, ethylidene trimethylene glycol.

3. Further evidence is brought forward regarding the mechanism of acetal, glucoside and polysaccharide formation, as well as the mechanism of the hydrolysis of this class of compounds.

4. This evidence supports the hypothesis of vinyl derivatives being the intermediates through which transformations of this nature take place.

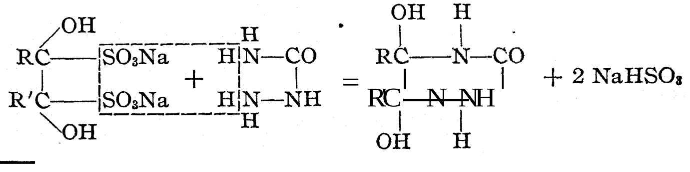
DIHYDROXY- AND DICHLORO-KETO-HEXAHYDROTRIAZINES

BY JOHN B. EKELEY AND ADRIAN A. O'KELLY

RECEIVED JUNE 6, 1928 PUBLISHED OCTOBER 6, 1928

Glyoxal and semicarbazide hydrochloride yield a mono-[1] and a disemicarbazone.[2] Similarly the aliphatic 1,2-diketones yield disemicarbazones,[3] but not the mono-derivative. Aromatic diketones also yield semicarbazones in alkaline solution,[4] but in acid solution the monosemicarbazones condense to triazine derivatives.[3]

If, on the other hand, semicarbazide hydrochloride and the sodium bisulfite addition products of glyoxal, methyl glyoxal or of aliphatic 1, 2-diketones are brought together in molecular proportions in hot water solution, there is a quantitative precipitation of a dihydroxy-keto-hexahydro-α-triazine, the compound being formed by a reaction accompanied by the splitting off of two moles of sodium bisulfite.



---

[1] O. Diels, *Ber.*, **35**, 347 (1902).

[2] Harries and Temme, *Ber.*, **40**, 171 (1907).

[3] Posner, *Ber*, **34**, 3977 (1901).

[4] Thiele and Stange, *Ann.*, **283**, 6, 27 (1894); Biltz and Arnd, *Ber.*, 35, 346 (1902).

The triazine derivatives thus obtained are insoluble in organic solvents except hot glacial acetic acid, in which they are slightly soluble and from which in very dilute solutions they may be obtained as minute colorless needles. They do not melt, but begin to decompose at definite temperatures. They are decomposed on boiling with strong acids, but in the cold yield salts. They are stable against hot alkalies. The two hydroxyl groups are replaced by chlorine on treatment with phosphorus trichloride, except in the case of the higher members which are decomposed by this reagent.

Experimental

I. Sodium Bisulfite Addition Products of Aliphatic **1,2-Diketones.**—We find no statement in the literature concerning these. When 1 mole of aliphatic 1,2-diketone is treated with 2 moles of sodium bisulfite in water solution, the diketone goes into solution and the yellow color disappears. By evaporating the solution, the crystalline addition product is obtained. The diketones were prepared from the corresponding monoketones by hydrolysis of the oximes prepared by means of nitrous acid.

TABLE I

SODIUM BISULFITE ADDITION PRODUCTS

Ketone	Decompn. temp., °C.	S, calcd., %	S, found, %
Diacetyl	145–155	21.77	21.21

Experiments carried out with isobutyrylacetyl did not yield the expected dihydroxytriazine derivative. A soluble compound was formed whose constitution we have not yet determined.

Summary

1. Semicarbazide hydrochloride reacts with the sodium bisulfite addition products of glyoxal, methylglyoxal and 1,2-aliphatic diketones with the formation of dihydroxy-keto-hexahydro-a-triazines, compounds insoluble in the usual organic solvents except acetic acid, in which they are slightly soluble. They do not melt, but begin to decompose at definite temperatures; soluble in acids; stable against alkalies.

2. The above compounds yield with phosphorus trichloride dichloro-keto-hexahydrotriazines which resemble the original substances in their properties.

3. The sodium bisulfite addition products of a number of 1,2-diketones have been prepared.

THE REDUCTION OF AROMATIC NITRO COMPOUNDS WITH SODIUM ALCOHOLATES

BY C. M. SUTER[1] AND F. B. DAINS

RECEIVED JUNE 18, 1928 PUBLISHED OCTOBER 6, 1928

Nearly 100 years ago (1834) Mitscherlich[2] used a solution of potassium hydroxide in ethyl alcohol as a reducing agent and obtained with nitrobenzene, azoxybenzene and the potassium salt of an organic acid. Since that time investigations in this field have been confined mainly to the action of various aromatic nitro compounds upon solutions of sodium in

---

[1] From a dissertation presented by C. M. Suter to the Faculty of the Graduate School of the University of Kansas in partial fulfilment of the requirement for the degree of Doctor of Philosophy.

[2] Mitscherlich, *Ann.*, 12, 311 (1834).

methyl or ethyl alcohol or sodium or potassium hydroxide dissolved in water or the same alcohols.[3] In general azoxybenzene or its derivatives were isolated, together with acids such as carbonic, oxalic, etc., and occasionally the formation of primary amines was noted, while with halogen nitrobenzenes some of the halogen might be displaced, yielding phenols or phenol ethers.

As a result of some observations on the action of sodium butylate on bromonitrobenzene, it was decided to investigate especially the reduction of nitro aromatic compounds with the higher sodium alcoholates in other than alcohol solutions. Benzene was chosen as solvent because it would diminish the ionizing effect of the excess of alcohol and would without question speed up the reaction, as was shown by Brühl[4] in his study of activated sodium methylate in xylene, where he obtained a quantitative yield of azoxybenzene.

Experimental

The general procedure was as follows. Sodium (0.1 mole) was added to the alcohol (2 4 moles) dissolved in benzene (100–450 cc.). The mixture was then refluxed for several hours until the metal had been changed to the alcoholate. To the cooled solution was added the nitro compound (0.05 mole) dissolved in a little benzene if a solid, in small portions so that the reducing agent was always in excess. The reaction usually began in the cold but for completion the mixture was heated on a water-bath for two hours. It was then distilled with steam, which removed the benzene solvent **A,** and other readily volatile substances such as excess alcohol and traces of aldehyde and ketones.

The water distillate, B, was found to contain the amine, unchanged nitro product and benzaldehyde when benzyl alcohol was used. The residue, C, in the flask consisted of non-volatile products and sodium salts.

The different portions were worked up as follows. The benzene solution, **A,** was extracted with water to remove traces of aldehyde or ketone that might be formed and then with dilute sulfuric acid, which dissolved any amine present. The water distillate, B, was acidified with sulfuric acid and separated from any unchanged nitro product. The acid solutions were then made up to a definite volume and the total amine determined by titration with a bromate–bromide solution, using the method of Francis and Hill.[5] It was found that the small amounts of alcohol present in the solution had but little effect on the accuracy of the titration in the cold but did not interfere if the solutions were warm.

The non-volatile reduction products in the flask, C, (mainly azoxybenzenes) which separated from the water solution as solids or oils, were isolated, washed with water, dried and weighed and their identities determined. The water solution in C contained the sodium salts of aliphatic or amino acids, occasionally small amounts of phenolic compounds and sodium halides from halogen nitrobenzenes. In some cases the volatile acids were determined qualitatively in the distillate after acidifying with sulfuric or

were used as oxidizing agents, both for ease in the separation of the reduction products and to compare the effect of halogen in the ortho, meta and para positions.

Discussion

The results point out distinctive differences between the action of methyl and ethyl alcohols and those from propyl on, while series VI–XXIII brings out clearly the special activity of the higher aliphatic alcohols in that nearly 40% of the reduction products appear as amines and not as azoxy derivatives. In XV, where butyl alcohol alone was used as solvent, the decreased amount of amine (15%) illustrated the definite effect of the benzene solvent. The amines are evidently formed directly and not through intermediate azoxybenzenes, since sodium butylate had no reducing effect on *p*,*p*′-dichloro-azoxybenzene under the same conditions. The reductions with benzyl alcohol (XXIV–XXXII) are noteworthy in that there is practically no amine formation but instead high yields of azoxybenzene and of benzoic acid or the intermediate benzaldehyde, which has been isolated for the first time. This absence of amine may be due to the stability of the benzoic acid, which remains unchanged while the aliphatic acids are oxidized further to acids with less carbon content and even to formic acid and are hence more effective reducing agents. Aliphatic aldehydes and ketones, the first oxidation products, speedily disappear. Only in VII was a trace of acetone and in XXII evidence of a ketone obtained and acetic acid absolutely proved.

o-Halogen Nitrobenzenes with Sodium Alcoholates

These reactions are grouped by themselves in Table II since they offer some interesting differences as compared with the *p*- and m-halogen isomers. While the experimental results have shown the usual formation of amines,[6] it has been found that the azoxybenzenes were replaced almost entirely by a-amino acids, o-halogen $C_6H_4NHCH(R)COOH$, when *n*-propyl or alcohols of the type RCH_2-CH_2OH were used.

Synthesis of Phenylamino Acids

α-*o*-Chloro-anilinopropionic Acid, $ClC_6H_4NHCH(CH_3)COOH$ (XXXVII–XLI).—Sodium (6.9 g.) was dissolved in benzene (250 cc.) and n-propyl alcohol (80 cc.). To this solution was added o-chloronitrobenzene (16 g.) and the mixture refluxed for two hours.

The reaction product contained 40% of o-chloro-aniline but no dichloro-azoxybenzene. From the alkaline solution was isolated on acidifying 12.5 g. of an acid melting at 150° after crystallizing from hot water, in which it is soluble to the extent of 0.44 g. per 100 cc. at the boiling point; at 30°, 0.094 g. per 100 cc.

Anal. Calcd. for $C_9H_{10}ClNO_2$: N, **7.06; Cl, 17.73;** mol. wt., **199.5.** Pound: **N, 6.67, 6.86; Cl, 17.6; mol. wt., 230** in acetic acid.

Its identity was further proved by comparison with the acid synthesized as follows. A mixture of o-chloro-aniline **(30** cc.), 2-bromopropionicacid (18 cc.) and water **(60** cc.) was heated over a small flame for thirty minutes until the solution became homogeneous. It was then made alkaline, distilled with steam to remove excess aniline and the amino acid was precipitated with dilute sulfuric acid. It crystallized from hot water in white needles, m. p. 150°.

Anal. Calcd. for $C_9H_{10}ClNO_2$: N, **7.00.** Found: **6.99, 6.97.**

The acid was soluble in alkalies, sodium carbonate, dilute mineral acids and the usual organic solvents, though not in benzene near its freezing point. A drop of copper sulfate added to a water solution of the acid gave a green coloration characteristic of this class of compounds When heated above 165°, it lost carbon dioxide with the formation of monoethyl-o-chlorophenylamine, which was identified by conversion into its phenylurea, m. p. 144°.

N-Ethyl-o-chloro-aniline, *o*-$C_2H_5NHC_6H_4Cl$.—This was prepared from o-chloro-aniline and diethyl sulfate. The oil boiled at 219° (corr.) at **726** mm ; sp. g., 25°/4°, **1.104;** 35°/4°, **1.0911.** The hydrochloride melted at 138–139°.

Anal. Calcd. for $C_8H_{10}ClN$: N, **9.03.** Found: 8.9, 9.1.

a-Ethyl-a-o-chlorophenyl-6-phenylurea made from the amine and phenyl isocyanate crystallized from alcohol in white needles which melted at **144".**

Anal. Calcd. for $C_{15}H_{15}ClN_2O$: N, **10.20.** Found: **10.21, 10.37.**

α-o-Chloro-anilinobutyric Acid, $ClC_6H_4NHC(C_2H_5)COOH$ (XLIV–XLV).—Sodium-n-butylate and o-chloronitrobenzene gave the amine and the amino acid, which was very soluble in organic solvents but less so in water than the lower homolog. It was best purified by crystallization from gasoline; the white rosets melted at 95°.

Anal. Calcd. for $C_{10}H_{12}ClNO_2$: N, **6.55.** Found: **6.30, 6.20.**

Its identity was confirmed by comparison with the same acid prepared from o-chloro-aniline and 2-bromobutyric acid.

Discussion

The results tabulated show that only alcohols with the grouping CH_2-CH_2OH (XXXVI–XLVI, XLIX, I,) thus far have yielded the amino acids. With ethyl alcohol (XXXVI) where it might be expected, the acetic aldehyde has resinified too quickly to condense with the nitrosobenzene. Isobutyl (XLVIII) and cinnamyl (LIII) alcohols with a single hydrogen attached to the second carbon gave none, while benzyl alcohol (LI–LII) showed the same behavior with all three isomers.

LIII	.1	$C_6H_5CH{=}CH$	300	.05 *o*-Chloro	..	Impure	$C_6H_5CH{=}CHCOOH$

While there is no experimental evidence for the real cause of the special reactivity of the *o*-halogen derivatives, it may be associated with the increased negative nature of the nitroso nitrogen due to the neighboring halogen atom and the increased ability of the nitroso nitrogen group to add an aldehyde complex and then rearrange as follows

$$o\text{-}XC_6H_4NO_2 + RCH_2CH_2OH = o\text{-}XC_6H_4NO + RCH_2CHO + NaOH = RCH_2CHOH\,(ONa)$$

$$o\text{-}XC_6H_4NO + RCH_2CHOH(ONa) = o\text{-}XC_6H_4N(OH)CRHCHOH(ONa) \;\; \text{(rearrange)}\; o\text{-}XC_6H_4NHCH(R)COONa + H_2O$$

Where X is chlorine or bromine, the amino acid formation goes smoothly; with the less negative iodine (XLII), the yield is much diminished, while an o-methoxy group (XXXIV) gave only the amine and tar.

Summary

1. A study has been made of the action of sodium alcoholates on (mainly halogen) nitro aromatic compounds in benzene solution.
2. With the exception of *o*-halogen nitro derivatives, propyl, butyl and *iso*-amyl alcohols gave a yield of from 50–90% reduction products, consisting of amine and azoxybenzenes.
3. o-Halogen nitrobenzenes condensed with the methylene grouping of the alcohols RCH_2CH_2OH with the formation of amino acids, o-halogen $C_6H_4NHCH(R)COOH$.

4. Benzyl alcohol reduced the nitro compound to azoxybenzene and was fully oxidized to benzaldehyde and benzoic acid.

5. The aliphatic alcohols were oxidized to acids of less carbon content, among them formic.

NITROGEN TRICHLORIDE AND UNSATURATED HYDROCARBONS. II

BY GEORGE H. COLEMAN, G. M. MULLINS AND ELIZABETH PICKERING

RECEIVED JUNE 20, 1928 PUBLISHED OCTOBER 6, 1928

The reaction of nitrogen trichloride with the unsaturated hydrocarbons,[1] 1-butene, 2-butene and trimethylethylene has been reported in a previous communication, as has also its reaction with the unsaturated ketones,[2] benzalacetophenone and benzalacetone.

The reaction has now been studied with ethene, propene, methylpropene, 2-pentene and cyclohexene. There is a wide difference in the reaction rates of these hydrocarbons. Ethene reacts most slowly and methylpropene most rapidly. The degree of difference is indicated by the fact that at 20–25° two weeks or longer is required for the completion of the reaction with ethene, while with methylpropene the reaction, even at -45 to $-50°$ is complete within two to three hours. The reaction rates of the other hydrocarbons fall between these two extremes.

The products of the reaction with ethene are nitrogen, ammonium chloride, ethylene chloride and 2-chloro-1-dichloro-amino-ethane. This compound was not isolated but was converted by hydrochloric acid to 1-amino-2-chloro-ethane. On further reduction with sodium amalgam ethylamine was obtained.

With propene, which reacts more rapidly than ethene but more slowly than the others, the products are similar to those obtained with ethene. Of the two possible addition products, $CH_3CHNCl_2CH_2Cl$ and $CH_3CHClCH_2NCl_2$, only the first was definitely shown to be formed. Attempts to prove the presence of the other isomer were not successful.

With methylpropene, although the products were much the same, the reaction differed in some respects from the others. In nearly all of the reactions thus far studied of nitrogen trichloride with unsaturated hydrocarbons, all or at least the greater part of the stable addition product remains in solution in the carbon tetrachloride as the dichloro-amino compound and is obtained as the hydrochloride of the corresponding amine by treatment with hydrochloric acid. In this case, however, most of the

[2] (a) Coleman and Craig, *ibid.*, 49, 2593 (1927); (b) 50, 1816 (1928).

amine was precipitated as the hydrochloride along with the ammonium chloride during the reaction. A similar precipitation of the amine hydrochloride occurs with benzalacetone.[2b] This may be due to a greater reactivity toward hydrochloric acid of the dichloro-amino group in these compounds. Again only one addition product $(CH_3)_2CNCl_2CH_2Cl$ was found. The formation of a moderate yield of the amine in this reaction, although the dichloro-amino group is attached to a tertiary carbon atom, may be due to the very low temperature at which the reaction was carried out. Experience with similar compounds in reactions at higher temperatures has indicated that little or none of the amine is usually formed. In general the lower the temperature at which the reaction is carried out the better the yield of the amine.

The reactions with 2-pentene and cyclohexene are quite similar to those already described. Stable addition products are obtained in each case.

Experimental Part

The unsaturated hydrocarbons used were prepared by well-known methods. Ethene was obtained from ethyl alcohol and sulfuric acid. Propene was prepared from isopropyl iodide and alcoholic potassium hydroxide. Ethene and propene were collected and measured over water. Methylpropene was prepared by adding isobutyl iodide slowly to warm alcoholic potassium hydroxide. The gas was passed through a 30cm. water-jacketed fractionating column and subsequently through a concentrated solution of calcium chloride. The amount obtained was determined by titration with bromine in carbon tetrachloride solution. 2-Pentene was prepared from diethyl carbinol and sulfuric acid by the method of Norris and Joubert.[3] Cyclohexene was prepared from cyclohexanol by the method given in "Organic Syntheses."[4] The hydrocarbons were all dried with fused calcium chloride and dissolved in cold carbon tetrachloride.

Nitrogen trichloride was prepared and analyzed as described in earlier

The method of carrying out the reaction was essentially the same as that previously used.[5] The highest yields of addition products were obtained when at least two moles of the hydrocarbon for each mole of nitrogen trichloride were used. With methylpropene, when the reaction was carried out at a low temperature, a little chloroform was added in order to keep the reaction mixture liquid. In every case except with methylpropene the dichloro-amino chloro compound was changed to a chloro-amine by dry hydrogen chloride. With methylpropene, as already mentioned, the chloro-amine hydrochloride was obtained during the initial

[5] Ref. 1, p. 3086.

addition reaction. A small amount of chloro-amine hydrochloride was obtained in each instance by final treatment with aqueous hydrochloric acid. Benzoyl derivatives of the chloro-amines were prepared, and usually the Schotten-Baumann method was used. However, in the case of the chloro-amine from methylpropene, the hydrochloride was suspended in benzene, a little concentrated potassium hydroxide solution added and the mixture shaken until all the hydrochloride had reacted. The benzene solution of the amine was separated and dried with solid potassium hydroxide. To this after filtering was added a little less than the calculated amount of benzoyl chloride and the mixture was allowed to stand for one or two hours. It was then filtered and the benzene was evaporated nearly to dryness on the water-bath. The residue solidified on cooling. It was crystallized from petroleum ether (b. p. 40–60°). Table I summarizes the results.

TABLE I

YIELDS OF CHLORO AMINES AND ANALYSES OF THEIR BENZOYL DERIVATIVES

Hydrocarbon	Prep. of amine hydrochloride Temp., °C.	Yield, %	M. p., °C.	Formula of benzoyl derivative	Nitrogen, % Calcd.	Found	Found	Chlorine, % Calcd.	Found	Found
Ethene	20 to 25	13.7	104–105	$C_9H_{10}ONCl$	7.63	7.82	7.70	...	...	...
Propene	−10	19.5	74–75	$C_{10}H_{12}ONCl$	7.09	6 93	7.01	17.97	18 27	18.04
Pentene	0 to 10	10–21	106–107	$C_{12}H_{16}ON_2Cl$[a]	10.35	10.33	10.31	13.10	13.16	13.20
Cyclohexene	−19	23	162–163	$C_{13}H_{16}ONCl$	5.89	5.82	5.91	14.95	15.10	15.11
Methylpropene	−50	12 2	83–84	$C_{11}H_{14}ONCl$	6.62	6.69	6.74	...	...	...

[a] *p*-Nitrobenzoyl derivative. The corresponding benzoyl derivative is an oil.

The chloro-amines obtained from ethene and propene were reduced with sodium amalgam in acid solution to the corresponding amines, ethylamine and isopropylamine. The benzoyl derivatives of these were prepared and identified by mixed melting points with the known compounds. No depression was observed in either case. Attempts to reduce the chloro-amines obtained from methylpropene and 2-pentene were not entirely successful. This was also true of the benzoyl derivative obtained from methylpropene. However, when the benzoyl derivative was tested with alcoholic silver nitrate for the presence of chlorine attached to a tertiary carbon atom, no precipitate was obtained until the solution was warmed. A control test with a known tertiary chloride formed a precipitate immediately. This test indicated that the compound was benzoyl-2-amino-1-chloro-2-methylpropane, since the isomer would contain chlorine attached to a tertiary carbon atom.

Summary

Nitrogen trichloride reacts with ethene, propene, methylpropene, 2-pentene and cyclohexene.

Nitrogen, ammonium chloride, the dichloride of the hydrocarbon and a C-chloro-N-dichloro-amine are formed with each.

O,N,N-TRIALKYLHYDROXYLAMINES

BY LAUDER W. JONES AND RANDOLPH T. MAJOR

RECEIVED JUNE 21, 1928 PUBLISHED OCTOBER 6, 1928

A number of trialkyl substituted hydroxylamines of the amine oxide type, R_3NO, have been described, but information concerning the isomeric compounds of the form R_2NOR is very limited. With the exception of Lossen's[1] O,N,N-triethylhydroxylamine, the description of which was so meager as to make the evidence for its existence quite doubtful, and the substituted hydroxylamino alcohols, $R(RO)NCH_2CH_2OH$, described by Jones and Burns[2] and by Jones and Major,[3] no O,N,N-trialkylhydroxylamines have been prepared.

Dunstan and Goulding[4] isolated trimethylamine oxide, $(CH_3)_3NO$, from the products obtained by the action of methyl iodide upon hydroxylamine. To account for the amine oxide, they suggested that O,N,N-trimethylhydroxylamine, $(CH_3)_2NOCH_3$, or its salt, was probably an intermediate product and that, by rearrangement, it passed to the amine oxide.[5]

$$(CH_3)_2NOCH_3 \longrightarrow (CH_3)_3N{=}O$$

Since O,N,N-trimethylhydroxylamine had not been prepared, it was not possible to reach a decision concerning the correctness of this assumption. However, certain other O,N,N-trisubstituted hydroxylamines were found to be comparatively stable compounds[1,2,3,6] which showed no tendency to rearrange to amine oxides. This made the explanation of the reaction proposed by Dunstan and Goulding rather unlikely. It is interesting to note, also, that Meisenheimer and his co-workers have observed that certain amine oxides, when heated in alkaline solution, suffer the reverse change and pass to O,N,N-trisubstituted hydroxylamines.[6b,c]

In the course of these investigations, O,N,N-trimethylhydroxylamine was obtained by the action of methyl iodide upon O,N-dimethylhydroxylamine in ether according to the equation

$$CH_3I + 2CH_3ONH(CH_3) \longrightarrow CH_3ONH_2(CH_3)I + CH_3ON(CH_3)_2$$

The ether solution, separated from the iodide, was treated with phenyl isocyanate to eliminate any O,N-dimethylhydroxylamine as α-phenyl-

[3] Jones and Major, *ibid.*, 49, 1532 (1927).

[4] Dunstan and Goulding, J. *Chem. Soc.*, 75, 794 (1899).

[5] Dunstan and Goulding, *ibid.*, 75, 1004 (1899).

[6] (a) Behrend and Leuchs, Ann., 257, 225, 237 (1890); (b) Meisenheimer, *Ber.*, 52, 1667 (1919); (c) Meisenheimer, Greeske and Willmersdorf, *Ber.*, 55, 513 (1922); (d) ref. 3, pp. 1535, 1536.

β,β′-methylmethoxyurea. Ether and the trimethyl compound were then distilled from the urea and the O,N,N-trimethylhydroxylamine hydrochloride was precipitated from the ether by hydrogen chloride gas. The free base, liberated from the salt in the usual manner, was a liquid boiling at 30°. It did not reduce ammoniacal silver nitrate. It showed no tendency to rearrange to trimethylamine oxide. Obviously it cannot be regarded as the intermediate in the preparation of trimethylamine oxide as Lossen supposed. Undoubtedly methyl iodide reacts with hydroxylamine in such a fashion that methyl groups become attached to the nitrogen atom until the compound $(CH_3)_3NOHI$ is formed, which is responsible for the amine oxide.

When O,N,N-trimethylhydroxylamine was heated with concentrated hydrochloric acid at 190°, methylamine and formaldehyde were produced. Behrend and Leuchs[7] found that O,N,N-tribenzylhydroxylamine was decomposed by concentrated hydrochloric acid to give dibenzylhydroxylamine and benzyl chloride according to the equation

$$(C_6H_5CH_2)_2NOCH_2C_6H_5 + HCl \longrightarrow (C_6H_5CH_2)_2NOH + ClCH_2C_6H_5$$

If O,N,N-trimethylhydroxylamine decomposed in a similar manner, we should expect dimethylhydroxylamine and methyl chloride as products of the reaction. It is well known that N,N-dialkylhydroxylamines are quite readily decomposed to give aldehydes and alkylamines.[8] Therefore, if one disregards salt formation, the action of hydrochloric acid on O,N,N-trimethylhydroxylamine may be represented schematically as follows

$$\begin{aligned}&(CH_3)_2NOCH_3 + HCl \longrightarrow (CH_3)_2NOH + CH_3Cl\\&(CH_3)_2NOH \longrightarrow CH_3N{=}CH_2 + H_2O\\&CH_3N{=}CH_2 + H_2O \longrightarrow CH_2O + CH_3NH_2\end{aligned}$$

The possibility that the production of formaldehyde depended upon the initial elimination of the methoxy group as formaldehyde according to the equation

$$(CH_3)_2NOCH_3 \longrightarrow (CH_3)_2NH + CH_2O$$

followed by decomposition of dimethylamine by the acid to yield methylamine, was excluded because of the fact that at the temperature of the experiment, namely, 190°, dimethylamine was not decomposed by concentrated hydrochloric acid.

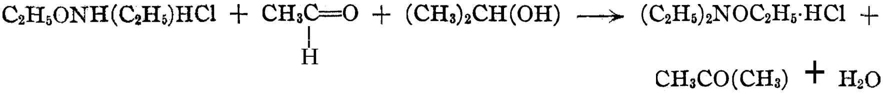
By similar reaction, O,N-diethyl-N-methylhydroxylamine was formed from methyl iodide and O,N-diethylhydroxylamine. Ethyl iodide, however, reacted with O,N-diethylhydroxylamine very slowly; even when the reaction was allowed to continue three times as long, scarcely any addition was observed.

---

[7] Behrend and Leuchs, *Ann.*, 257, 231 (1890).

[8] (a) Walder, *Ber.*, 219, 1629, 3287 (1886); (b) Behrend and Leuchs, *Ann.*, 257, 233 (1890); (c) Dunstan and Goulding, J. Chem. *Soc.*, 75, 793 (1899); (d) Bewad, J. *prakt. Chem.*, 63, 193 (1901).

An unsuccessful attempt was made to prepare O,N,N-triethylhydroxylamine by the action of acetaldehyde on O,N-diethylhydroxylammonium chloride in the presence of isopropyl alcohol, according to the equation



$$C_2H_5ONH(C_2H_5)HCl + CH_3\underset{H}{\underset{|}{C}}{=}O + (CH_3)_2CH(OH) \longrightarrow (C_2H_5)_2NOC_2H_5\cdot HCl + CH_3CO(CH_3) + H_2O$$

Ethyl piperidine has been made in a similar manner by the action of acetaldehyde on piperidine hydrochloride in the presence of isopropyl alcohol.[9] Since acetone was observed among the products of the reaction, it was thought possible that isopropyl alcohol reduced O,N-diethylhydroxylammonium chloride. This was found to be the case; a mixture of O,N-diethylhydroxylammonium chloride, heated with isopropyl alcohol at 150°, gave acetone, ethylammonium chloride and probably ethyl alcohol according to the equation

$$C_2H_5ONH(C_2H_5)HCl + (CH_3)_2CH(OH) \longrightarrow C_2H_5NH_2\cdot HCl + CH_3CO(CH_3) + C_2H_5OH$$

When trimethylamine oxide is treated with methyl iodide, trimethylmethoxyammonium iodide is formed according to the equation[10]

$$(CH_3)_3N{=}O + CH_3I \longrightarrow [(CH_3)_3NOCH_3]I$$

The question arose whether the same compound would be formed by the action of methyl iodide on O,N,N-trimethylhydroxylamine, as follows

$$(CH_3)_2NOCH_3 + CH_3I \longrightarrow [(CH_3)_3NOCH_3]I$$

This was found to be the case; the compound formed in this way corresponded in every respect to the substance described by Dunstan and Goulding and by Meisenheimer.

Experimental Part

1. O,N,N-Trimethylhydroxylamine, $(CH_3)_2NOCH_3$

Preparation of O,N,N-Trimethylhydroxylammonium Chloride.—Two-tenths mole of O,N-dimethylhydroxylamine, prepared by Major and Fleck's modification of Jones' method,[11] was added to a solution of 0.1 mole of methyl iodide in dry ether. A white solid soon began to form. After the mixture had stood in a closed vessel for four days, the white precipitate was removed by filtration. It melted at 134° and weighed 13 g. It was dissolved in alcohol and shaken with sufficient silver oxide to combine with all of the iodide ion present. The free base was then distilled at room temperature under reduced pressure and collected in dilute hydrochloric acid. The small oily residue left in the distilling flask was probably trimethylmethoxyammonium hydroxide. The hydrochloric acid solution, evaporated to dryness, gave a white, crystalline solid which, after one crystallization from absolute alcohol, melted at 115–116°. A mixture of this compound with pure O,N-dimethylhydroxylammonium chloride, m. p. 115–116°, also melted at 115–116°.

---

[9] D. R. P. 291,222; Friedlander, 12, 803 (1914–16).

[10] (a) Dunstan and Goulding, J. *Chem. Soc.*, 75,797 (1899); (b) Meisenheimer, *Ann.*, 397,288 (1913).

[11] (a) Jones, *Am.* Chem. J., 20, 44 (1898); (b) Major and Fleck, THIS JOURNAL, 50,1480 (1928).

A little *dry* potassium carbonate, to combine with any hydrogen iodide, and 0.17 of a mole of phenyl isocyanate were added to the cooled ethereal filtrate from the above mentioned solid (m. p. 134°). The isocyanate removed any O,N-dimethylhydroxylamine by combining with it to give a urea derivative. The mixture was allowed to stand in a closed container at room temperature for fifteen hours. Ether and free O,N,N-trimethylhydroxylamine were then distilled into a receiver surrounded by an ice-bath. Dry hydrogen chloride passed into the ether solution caused a white precipitate which was recrystallized from absolute alcohol; m. p. 123°; yield, 46%.

Anal. Subs., 0.2691: AgCl, 0.3416. Calcd. for $C_3H_{10}ONCl$: Cl, 31.81. Found: 31.66.

Chloroplatinate.—To 0.2 g. of O,N,N-trimethylhydroxylammonium chloride dissolved in absolute alcohol a solution of 0.5 g. of chloroplatinic acid in absolute alcohol was added. Orange-colored crystals precipitated. They were recrystallized from hot absolute alcohol; m. p. 159°, with decomposition.

Anal. Subs., 0.2356: Pt, 0.0819. Calcd. for $C_6H_{20}O_2N_2PtCl_6$: Pt, 34.85. Found: 34.79.

Isolation of the Free Base.—To prepare O,N,N-trimethylhydroxylamine, the hydrochloride was treated with an excess of a concentrated solution of potassium hydroxide. This solution was distilled and the vapors were passed over solid pieces of potassium hydroxide heated to 95° before they were condensed. Pure O,N,N-trimethylhydroxylamine distilled at 30°. The hydrochloride, regenerated from base by passing dry hydrogen chloride into an ether solution of it, melted at 123° and corresponded in every way with the hydrochloride from which the free base had been made. This excluded the possibility of rearrangement. Free O,N,N-trimethylhydroxylamine possessed a fishy odor somewhat like that of other alkyl substituted hydroxylamines. It did not reduce ammoniacal silver nitrate.

Decomposition of O,N,N-Trimethylhydroxylamine by Treatment with Hydrochloric Acid.—A solution of 0.7 g. of O,N,N-trimethylhydroxylamine in 5 cc. of concentrated hydrochloric acid was heated in a sealed tube at 190° for eight hours. Considerable gas, undoubtedly methyl chloride, escaped when the tube was opened. The contents of the tube was dark in color. About half of it was distilled. The distillate had a pronounced odor of formaldehyde and gave a distinct color test for this substance with a solution of guaiacol in concentrated sulfuric acid.[12] The portion that remained in the distilling flask was evaporated to dryness on a water-bath. A rather dark colored solid was obtained, which, after recrystallization twice from absolute ethyl alcohol, was colorless and melted at 231°. A mixture of this compound with methylammonium chloride, m. p. 231°, also melted at 231°.

Action of Hydrochloric Acid on Dimethylamine.—A solution of 1 g. of dimethylammonium chloride, m. p. 171°, in 5 cc. of concentrated hydrochloric acid was heated at 190° for nine hours. The tube was cooled and opened and its contents evaporated to dryness on a water-bath. Unchanged dimethylammonium chloride, melting at 171°, was recovered.

2. O,N-Diethyl-N-methylhydroxylamine, $C_2H_5ON(C_2H_5)CH_3$

One-tenth mole of O,N-diethylhydroxylamine, prepared by the method of Major and Fleck,[11b] was added to a solution of 0.05 mole of methyl iodide in dry ether. The mixture was allowed to stand in a closed container at room temperature for four days. A heavy, pink oil gradually formed. It was separated from the ether solution by decantation. After washing it thoroughly with dry ether, it was made alkaline with

---

[12] "Deutsches Arzneibuch," R. v. Decker's Verlag, Berlin, 1926, p. LIV.

potassium hydroxide and the free base recovered in the usual manner. Four g. of the free base, b. p. 78–84°, was recovered. It had the characteristic odor of O,N-diethylhydroxylamine. The major fraction, b. p. 83°, was added to a solution of phenyl isocyanate in benzene. Evaporation of the benzene, after the mixture had stood for a day, left a white solid which melted at 63°, after it had been recrystallized once from ligroin. Pure α-phenyl-β,β'-ethylethoxyurea melts at 63°.[13]

The ether solution, from which the pink oil was separated, was shaken with a little mercury in order to remove a trace of dissolved iodine. A little potassium carbonate and 0.9 of a mole of phenyl isocyanate were then added to remove any O,N-diethylhydroxylamine by the formation of a substituted urea. The mixture was allowed to stand in a closed container at room temperature for two days. Ether and free O,N-diethyl-N-methylhydroxylamine were then distilled and collected in a receiver surrounded by an ice-bath. Dry hydrogen chloride was passed into the ether solution. A heavy oil precipitated. The ether was decanted but since the oil was somewhat soluble in ether, probably due to a partial splitting into hydrogen chloride and O,N-diethyl-N-methylhydroxylamine, it was not washed with pure ether but with a little ether which had been saturated with hydrogen chloride. The oil failed to solidify.

Free O,N-diethyl-N-methylhydroxylamine was obtained from this hydrochloride in the manner described above in the preparation of O,N,N-trimethylhydroxylamine from its hydrochloride. It boiled at 79°. It had an odor somewhat like that of the other alkyl substituted hydroxylamines but slightly more ethereal; yield, 20%. Dry hydrogen chloride precipitated an oily hydrochloride from an ether solution of a portion of the free base.

Chloroplatinate.—A solution of 0.25 g. of O,N-diethyl-N-methylhydroxylamine in absolute alcohol was saturated with dry hydrogen chloride. The calculated amount of a solution of chloroplatinic acid in absolute alcohol was added. Orange needles soon precipitated. The amount of these was increased by adding dry ether. They were recrystallized from hot 95% alcohol; m. p. 158°. The compound was very soluble in water, readily soluble in hot 95% alcohol, but soluble only with difficulty in hot or cold absolute alcohol and insoluble in ether.

Anal. Subs., 0.2055: Pt, 0.0651. Calcd. for $C_{10}H_{28}O_2N_2PtCl_6$: Pt, 31.68. Found: 31.68.

3. Action of Isopropyl Alcohol on O,N-Diethylhydroxylammonium Chloride

To a solution of 0.56 g. of O,N-diethylhydroxylammonium chloride in 1 cc. of water was added 1 cc. of acetone-free isopropyl alcohol. This mixture was heated at 150° for two hours. When the tube was cooled and opened, a brownish solution was found. A portion of this solution was distilled and the distillate tested for acetone with vanillin according to the method of Kolthoff.[14] It gave a very pronounced test for acetone.

The rest of the solution was evaporated to dryness on the water-bath. The dark, solid residue was recrystallized several times by dissolving it in absolute alcohol and reprecipitating it by the addition of dry ether; m. p. 98°. A mixture of this hydrochloride with ethylammonium chloride (m. p. 98°) also melted at 98°.

4. Trimethylmethoxyammonium Iodide, $[(CH_3)_3NOCH_3]I$

To 1 g. of O,N,N-trimethylhydroxylamine was added an equivalent molecular portion of methyl iodide. The mixture became turbid at once and in four hours had

changed entirely to a solid, white, crystalline mass. This was recrystallized from dry methanol. It did not have a definite melting point but, as described by Meisenheimer for the trimethylmethoxyammonium iodide prepared from trimethylamine oxide and methyl iodide, gradually darkened and decomposed at about 162°.[10b] It formed narrow, plate-like crystals which were readily soluble in water, less so in alcohol and insoluble in ether.

Anal. Subs., **0.2271:** AgI, **0.2451.** Calcd. for $C_4H_{12}ONI$: I, 58.48. Found: **58.34.**

Decomposition of Trimethylmethoxyammonium Hydroxide by Heat.—When a solution of trimethylmethoxyammonium hydroxide, obtained from the iodide made by the action of trimethylamine oxide on methyl iodide, was heated, formaldehyde was formed.[15] In order to find out whether or not the same change would take place with the trimethylmethoxyammonium hydroxide obtained from O,N,N-trimethylhydroxylamine and methyl iodide, **1** g. of trimethylmethoxyammonium iodide was made alkaline with a concentrated solution of sodium hydroxide. The volatile portions of this solution were distilled into an aqueous solution of *p*-nitrophenylhydrazine hydrochloride. An orange-colored precipitate formed which was recrystallized from dilute alcohol; m. p. **181°**. Formaldehyde p-nitrophenylhydrazone melts at 181–182°.[16] The odor of formaldehyde was also very marked when trimethylmethoxyammonium iodide was warmed with sodium hydroxide.

Summary

1. O,N,N-trimethylhydroxylamine and O,N-diethyl-N-methylhydroxylamine have been prepared by the action of methyl iodide on O,N-dimethylhydroxylamine and O,N-diethylhydroxylamine, respectively.

2. It has been shown that O,N,N-trimethylhydroxylamine is a comparatively stable compound which shows no tendency to rearrange to trimethylamine oxide. The probable course of the action of methyl iodide on hydroxylamine has been outlined in harmony with this fact.

3. The decomposition of O,N,N-trimethylhydroxylamine when heated with hydrochloric acid has been studied and the probable course of the reaction discussed.

4. The action of isopropyl alcohol on O,N-diethylhydroxylammonium chloride has been investigated.

5. It has been found that the trimethylmethoxyammonium iodide obtained by the action of methyl iodide on O,N,N-trimethylhydroxylamine is the same as that obtained by the action of methyl iodide on trimethylamine oxide.

MONONITRO- AND DINITROTHIOPHENES

BY V. S. BABASINIAN

RECEIVED JUNE 22, 1928 PUBLISHED OCTOBER 6, 1928

I. Mononitrothiophene

The introduction of a nitro group into the thiophene nucleus has been a problem fraught with difficulties. Victor Meyer and his co-workers[1] made "countless futile attempts" to nitrate this compound by the usual method. They finally succeeded in accomplishing this[2] by drawing a vigorous stream of air charged with thiophene through red fuming nitric acid. The product was a mixture of mononitro- and dinitrothiophenes and an oily residue. The two nitro compounds could only be extracted and separated by repeated fractional distillation and the yield was admittedly unsatisfactory. The nitration of ethylthiophene by this method failed to produce the mononitro derivative;[3] diethylthiophene yielded a product of unknown composition;[4] while the nitration of thioxene resulted in the formation of a resin.[5] Despite these limitations, for thirty years this remained the only known method for the nitration of thiophene and its homologs.

Following the study of diacetyl-ortho-nitric acid,[6] benzoyl nitrate,[7] and acetyl nitrate,[8] as nitrating agents, Steinkopf and Kirchoff[9] proposed an improved method for the nitration of thiophene. The compound was dissolved in acetic anhydride and treated with a solution of fuming nitric acid in the same solvent, the temperature during nitration being maintained between 0 and 5°. Upon treating the product with ice water, an unstable dark oil and a brown precipitate were formed, from which mononitrothiophene was obtained by distillation with steam. Although it must be admitted that this is a decided improvement over the earlier method, the success of the experiment depends upon painstaking manipulation at a low nitration temperature, and the oily product has been found to undergo rapid decomposition.

A Modified Method of Nitration

The method of nitration proposed in this paper has been given a thorough trial. The process is carried out, almost exclusively, at the room tem-

perature. The reaction yields a product which is stable under all conditions and the weight of the purified substance is from 80 to 85% of that required by theory. Moreover, the method has been repeatedly employed, with equal success, for the nitration of a derivative of thiophene.

Although solutions containing diacetyl-ortho-nitric acid, or acetyl nitrate, have often been employed with marked success for the nitration of aromatic hydrocarbons or their derivatives,[10] attempts to nitrate thiophene in this Laboratory with these reagents have clearly shown that in order to insure a satisfactory yield it is necessary to observe certain rigid conditions. Pictet and Genequand[11] and, later, Pictet and Khotinsky[12] had made the observation that these reagents may acetylate, oxidize or nitrate, the course of the reaction depending upon circumstances.

With thiophene there is no indication that acetylation occurs when acetic acid or anhydride solutions of these nitrating agents are employed. That oxidation takes place, with the incident rupture of the thiophene ring, cannot be doubted. It has also been demonstrated that in the formation of mononitrothiophene with these solutions, temperature is an important factor. At lower temperatures the reaction, if it takes place at all, is almost exclusively one of nitration; while at elevated temperatures oxidation sets in almost invariably, the course of the reaction being indicated by the evolution of heat and the liberation of nitrogen peroxide. Moreover, at higher temperatures the liberated nitrogen peroxide attacks the thiophene vapor in the nitrating flask, converting it into a tarry product, which has been shown to contain traces of dinitrothiophene by the application of the Meyer-Stadler test.[13] Schaarschmidt's studies[14] show that the nitration of thiophene with nitrogen peroxide yields products which are not easy to purify,

No less than twenty-five nitrations have been carried out in this Laboratory with solutions of nitric acid and thiophene in acetic acid or acetic anhydride. The method that has reduced the side reactions to a minimum is given in outline.

Procedure

(1) Eighty-four g. of thiophene is dissolved in 340 cc. of acetic anhydride and (2) eighty g. of nitric acid (sp. gr. 1.52) is dissolved in 600 cc. of glacial acetic acid.

[14] Schaarschmidt and so-workers, *Ber.*, **58B**, *499* (1925)

Each solution is divided into two equal parts. One-half of solution **(2)** is introduced into a large three-necked, round flask, provided with a thermometer, a motor stirrer and a dropping funnel. The flask is cooled to 10°. With moderate stirring one-half of the thiophene solution is introduced, drop by drop, and at such a rate as to prevent the heating of the reaction mixture above the room temperature. A rapid rise of temperature will occur during the addition of the first fraction of the thiophene solution. The temperature is controlled by dipping the nitrating flask into a bath of cold tap water. The use of ice water is not necessary, as cooling with ice will retard the reaction. On the other hand, care should be taken to avoid superheating the reaction mixture. After the addition of the first half of thiophene, the temperature of the reaction mixture is reduced to 10° and the remainder of nitric acid is rapidly introduced into the flask. Nitration is continued by the gradual addition of thiophene. Throughout the nitration the solution should show a permanent light brown color. The appearance of a pink or dark red color indicates oxidation.[15] The product is allowed to remain at the room temperature for two hours. It is then treated with an equal volume of ice water with rapid shaking. Mononitrothiophene will begin to separate out in faint yellow crystals. More crystals will form if the mixture is allowed to remain in the ice chest for at least twenty-four hours. It is filtered cold through a Büchner funnel, washed thoroughly with ice water, pressed and dried in a brown desiccator,[16] charged with sulfuric acid and granules of caustic soda.

The filtrate and the washings contain in solution a quantity of mononitrothiophene. This is recovered by distillation with steam. The acid distillate will consist of white crystals and a solution of the compound. The solid is removed by filtration and washed. The filtrate is extracted with ether, neutralized with a weak solution of sodium carbonate, dried with calcium chloride and subjected to distillation.

If the nitration was carried out in accordance with this outline, the product will be crystalline and faint yellow in color. The color is due to traces of dinitrothiophene and other impurities. Mononitrothiophene has been crystallized by earlier workers from ether, alcohol, benzene and other solvents. As a rule these solvents fail to yield a snow-white product. It has been found in this work that petroleum ether (b. p. 20–40°) possesses decided advantages in that by prolonged boiling it extracts mononitrothiophene but does not readily dissolve the impurities. With petroleum ether snow-white crystals of the compound have been obtained in needles 5 to 8 inches in length.

The method of nitration outlined in this paper has been employed repeatedly by the author. In every instance the yield of the purified product was found to be over 80% of the theoretical quantity.

Discussion

Experiments conducted under varying conditions of concentration and temperature lead to the following generalizations.

1. Glacial acetic acid alone does not induce nitration to any extent at the ordinary temperature. At higher temperatures partial oxidation takes place, a tar is produced and a quantity of unattacked thiophene is recovered.

2. In moderate quantities acetic anhydride alone will induce nitration when the reaction is carried out at 0°. Even at this low temperature ni-

---

[15] The tarry product formed as a result of oxidation dissolves in the reaction mixture, imparting to it a pink or a dark red color.

[16] Earlier investigators have noted that the compound is extremely sensitive toward light, ref. 2, p. 2649.

tration is accompanied by oxidation with the formation of an unstable by-product.

3. Under the most favorable conditions the yield is satisfactory and the product free from contamination when thiophene is added to nitric acid. The reverse process does not complete the reaction; if the reaction mixture be heated to complete nitration, the unchanged thiophene is oxidized, heat is evolved and nitrogen peroxide liberated.

II. Dinitrothiophene

The entry of a negative substituent into the thiophene nucleus protects the compound from the oxidizing action of nitric acid, permitting nitration by the ordinary method. By the direct addition of the negatively substituted derivative to fuming nitric acid at low temperatures, nitro compounds have been obtained from b-thiophenic acid,[17] acetothienone,[18] ethyl acetothienone,[19] methyl acetothienone,[20] and from a number of polysubstituted derivatives.[21]

That mononitrothiophene has not been heretofore employed for the large-scale production of the dinitro compound has undoubtedly been due to the difficulty of preparing the former. The only method described in the literature for the preparation of dinitrothiophene is that of Meyer and Stadler.[22] It should be added that although the yield by this process was highly unsatisfactory, the compound had been subjected to a thorough investigation.[23]

The Preparation of Dinitrothiophene

The nitrating mixture proposed for the conversion of thiophene into the mononitro derivative does not react with the latter to produce dinitrothiophene. **A** reaction carried out with this mixture resulted in the recovery of the nitrothiophene employed. On the other hand, mononitrothiophene is readily nitrated with a mixture of nitric and sulfuric acids to form dinitrothiophene. Although derivatives of thiophene are known to react with sulfuric acid with the greatest ease, sulfonic acids have not been detected in this process of nitration.

Procedure

Thirty-five g. of nitric acid (sp. gr. 1.4) was dissolved in 55 g. of sulfuric acid (sp. gr. 1.82) and the ice-cooled solution was treated with 20 g. of mononitrothiophene in

gram portions. The first 5 g. of the solid formed an almost colorless solution. Additional quantities produced cloudiness, imparting to the liquid a faint yellow color. When the reaction mixture was brought to room temperature, it separated into two transparent layers—a reddish-yellow upper layer and a faint yellow lower layer. It was heated in a water-bath with continued shaking, the temperature being gradually increased in the course of half an hour from **30** to **85°**. The reaction product, consisting of an upper yellow layer and a lower light brown layer, was cooled in an ice-bath for one hour. The white crystals of dinitrothiophene were filtered with suction, digested in ice water and dried. Upon treatment with ice, the filtrate formed an additional quantity of the compound in fine needles. The product was crystallized from ordinary alcohol; yield, over 80% of the theoretical quantity; melting point, 52°.

Isomeric Dinitrothiophenes

In their studies of dinitrothiophene, Meyer and his co-workers[24] had found that the compound melting at **52°** yields upon distillation with steam an isomer melting at 78°. After searching investigation they concluded that the two isomers were identical in structure. They made the further assertion that by repeated fractional distillation with steam ordinary dinitrothiophene (m. p. 52°) is completely transformed into the isomer melting at 78°.[25, 23a,b]

It should be stated that these investigators had based the latter assertion on experiments carried out with only small quantities of the lower melting modification.

An extended study of the behavior of ordinary dinitrothiophene fails to show that the compound melting at 52° can be completely transformed into the isomer melting at 78°.

1. When dinitrothiophene is subjected to prolonged distillation with steam, a dark residue remains in the distillation flask, which was presumably taken by earlier workers as a decomposition product. When an alcoholic solution of this residue is purified with animal charcoal, it yields dinitrothiophene possessing a sharp melting point of 54°. The product is not very volatile with steam and could not be converted into the higher melting modification after repeated distillation with steam.

2. In a study of the vapor pressure curve for dinitrothiophene,[26] a trace of the compound was found to condense in the cooler regions of the isoteniscope at temperatures above 140°. This fraction melted at **76–78",** while the bulk of the compound in the apparatus gave, after crystallization from alcohol, a melting point of 52–54°. If ordinary dinitrothiophene was transformed in the isoteniscope into its isomer at temperatures above 140°, it was natural to assume that prolonged heating would induce fur-

---

[24] Ref. **2,** p. **2649.**

[25] Ref. **1,** p. **98.**

[26] Results to be published.

ther transformation, converting the lower melting compound into the other modification. The compound melting at 52–54' was therefore transferred into a long combustion tube, closed at the lower end. The tube was submerged in a bath of toluidine and heated at 180°. In a few hours a solid melting at 72–78° condensed in the cooler regions of the tube. Continued heating, for almost one week, failed to produce additional quantities of the higher melting isomer. The residue in the tube when freed from traces of tarry impurities showed a sharp melting point of 54".

3. Specimens of the two isomers were spread in thin layers in two quartz test-tubes and exposed for one hour, at a distance of ten inches, to the action of ultraviolet irradiation, a Cooper-Hewitt Quartz Uviarc being used for the experiment. The ordinary modification had melted completely at the end of the hour and the isomer had changed into a semi-solid. The two tubes were exposed for another hour at a distance of fifteen inches. A slight decomposition had taken place in each tube. The materials were dissolved in alcohol, treated with animal charcoal and crystallized. No change in melting point was observed in either compound.

Evidently ordinary dinitrothiophene contains a weighable quantity of the isomer melting at 78°, but there is no conclusive evidence of transition from one isomer into the other.

Summary

Solutions containing acetyl nitrate and di-acetyl-ortho-nitric acid will nitrate thiophene and may simultaneously oxidize it, the course of the reaction depending upon concentration and temperature.

When conditions are under proper control, nitration will take place almost exclusively, even at the room temperature, with a satisfactory yield of mononitrothiophene.

With a mixture of nitric and sulfuric acids mononitrothiophene is readily converted into dinitrothiophene.

Studies of the behavior of dinitrothiophene do not confirm the assertion that the ordinarily prepared compound is transformed into a higher melting isomer.

NITROGEN TRICHLORIDE AND UNSATURATED HYDROCARBONS. III. NITROGEN TRICHLORIDE AND DIPHENYLKETENE

BY GEORGE H. COLEMAN AND ARTHUR W. CAMPBELL[1]

RECEIVED JUNE 28, 1928 PUBLISHED OCTOBER 6, 1928

Many aliphatic unsaturated hydrocarbons[2] of the olefin series react with nitrogen trichloride to form, among other products, C-chloro-N-dichloro-amines. This is also true for some of the unsaturated ketones.[3]

In the present work this reaction was studied with derivatives of ethene in which one or more of the hydrogen atoms of this compound had been replaced by phenyl groups. Diphenylketene was also used since the ketenes undergo addition reactions very readily with ammonia and the amines. It was also thought that the evolution of a large amount of nitrogen which characterizes most addition reactions of nitrogen trichloride might not occur with a highly reactive compound like diphenylketene.

Phenylethene and 1,2-diphenylethene react fairly rapidly with nitrogen trichloride in carbon tetrachloride solution to form nitrogen, the dichloride of the hydrocarbon, a small amount of ammonium chloride and a C-chloro-N-dichloro-amine. These compounds are easily reduced with hydrochloric acid to the corresponding C-chloro-amines, both of which have been previously prepared by other methods.[4] With phenylethene two products are possible. Only one, however, 1-amino-2-chloro-1-phenylethene, was isolated. The reaction rates as well as the products do not differ very greatly from those of the corresponding methyl derivatives, propene and 2-butene.

1,1-Diphenylethene and 1,1-diphenyl-1-propene have reaction rates which are of the same general order as the first two hydrocarbons of this series. Neither of them, however, forms a stable addition product with nitrogen trichloride under the experimental conditions used. Triphenylethene reacts quite slowly, and in this respect differs very decidedly from the corresponding trimethyl derivative, the reaction rate of which is perhaps as rapid as any which has thus far been studied. No amine was isolated. Apparently tetraphenylethene does not react until the mixture is warmed slightly. The slow evolution of nitrogen which then occurs

---

[1] This paper is an abstract of the thesis submitted by Arthur W. Campbell in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the State University of Iowa.

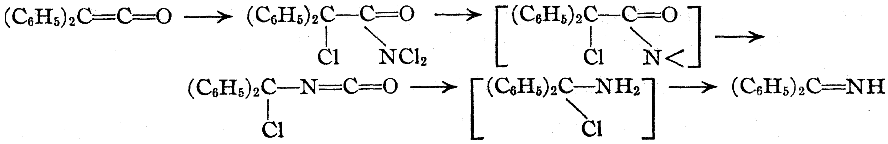
may be due to reaction with the phenyl groups. Nitrogen trichloride is known to react with benzene and its derivatives.[5] No amine was obtained.

Diphenylketene reacts rapidly with nitrogen trichloride. Practically no nitrogen is evolved and the characteristic odor of nitrogen trichloride disappears if an excess of the ketene is used. On the basis of the addition reactions of nitrogen trichloride with the unsaturated hydrocarbons and the unsaturated ketones, and the well-known reactions of the ketenes, it seems probable that the addition product formed is diphenylchloroaceto-N-dichloro-amide. When the reaction mixture is warmed for a short time with a solution of sodium hydroxide and the non-aqueous layer separated, dried and hydrogen chloride passed into it, benzophenone-imide hydrochloride is precipitated. The reaction possibly involves the following steps



$$(C_6H_5)_2C{=}C{=}O \longrightarrow (C_6H_5)_2\underset{\displaystyle Cl}{\underset{|}{C}}{-}\overset{\displaystyle C{=}O}{}\!\!\searrow NCl_2 \longrightarrow \left[(C_6H_5)_2\underset{\displaystyle Cl}{\underset{|}{C}}{-}C{=}O \searrow N{<}\right] \longrightarrow$$

$$(C_6H_5)_2\underset{\displaystyle Cl}{\underset{|}{C}}{-}N{=}C{=}O \longrightarrow \left[(C_6H_5)_2C{-}NH_2 \searrow Cl\right] \longrightarrow (C_6H_5)_2C{=}NH$$

Experimental Part

The Reaction with Phenylethene (Styrene)

1-Amino-2-chloro-1-phenylethane.—The nitrogen trichloride was prepared and analyzed as described in earlier papers.[3b] The phenylethene was dissolved in carbon tetrachloride. The apparatus was protected from the light and arranged for collecting and measuring the nitrogen evolved. The nitrogen trichloride solution was added slowly through a separatory funnel in the course of one to two hours. During the addition the reaction flask was cooled to −10° or lower and gently shaken. The reaction was fairly rapid and was complete soon after the last of the trichloride had been added. The precipitate of ammonium chloride formed during the reaction was filtered off and dry hydrogen chloride passed into the carbon tetrachloride solution. The amine hydrochloride which precipitated was filtered, dried and weighed.

The amounts used in a typical run were as follows: 71 mg. moles of nitrogen trichloride in 250 g. of carbon tetrachloride, 200 mg. moles of phenylethene in 400 g. of carbon tetrachloride. In this run there were formed 46.4 mg. atm. of nitrogen, 3.2 mg. moles of ammonium chloride and 19.6 mg. moles of the amine, which is 27.6% of the theoretical yield calculated from the nitrogen trichloride.

Benzoyl-1-amino-2-chloro-1-phenylethane.—The benzoyl derivative was prepared from the amine hydrochloride by the Schotten-Baumann method. The product after recrystallization from petroleum ether melted at 133–134° (uncorr.).

Anal. Subs., 0.1553: 5.53 cc. of 0.1076 *N* HCl. Calcd. for $C_{15}H_{14}ONCl$: N, 5.59. Found: 5.36. Subs. 0.1980: 7.70 cc. of 0.0996 *N* $AgNO_3$. Calcd. for $C_{15}H_{14}ONCl$: Cl, 13.66. Found: 13.72.

This compound has been prepared by Gabriel and Colman,[4a] who record a melting point of 137°. The isomeric compound, benzoyl-2-amino-

---

1-chloro-1-phenylethane, prepared by Wolfheim[6] has a melting point of 124".

The Reaction with 1,2-Diphenylethene (Stilbene)

1-Amino-2-chloro-1,2-diphenylethane.—The 1,2-diphenylethene was prepared from benzylmagnesium chloride and benzaldehyde by the method described by Hell.[7] The reaction with nitrogen trichloride was carried out at −14°. The procedure was similar to that with phenylethene. The time of addition was one hour. Nitrogen was evolved for a short time after all of the trichloride had been added. A heavy precipitate of the dichloride of the hydrocarbon and a little ammonium chloride formed during the reaction. This was filtered off and the ammonium chloride separated by solution in water in which the dichloride is insoluble. The amine hydrochloride was obtained as before by treatment with hydrogen chloride. In one run there were obtained from 91.8 mg. moles of nitrogen trichloride, 16.8 mg. moles of the amine, 70.5 mg. atm. of nitrogen and 2.8 mg. moles of ammonium chloride.

Benzoyl-1-amino-2-chloro-1,2-diphenylethane.—The benzoyl derivative was prepared from the hydrochloride of the amine by the Schotten-Baumann method. After recrystallization from alcohol it melted at 192–193° (uncorr.). The compound has been prepared by Darapsky and Spannagel,[4b] who report a melting point of 195°.

The Reaction with 1,1-Diphenylethene

1,1-Diphenylethene was prepared by the method of Allen and Converse.[8] The reaction with nitrogen trichloride was carried out as described for phenylethene. No amine hydrochloride was obtained. In one run there was obtained from 90 mg. moles of nitrogen trichloride, 85 mg. moles of nitrogen and 4.6 mg. moles of ammonium chloride. The reaction rate was much the same as that of 1,2-diphenylethene.

The Reaction with 1,1-Diphenyl-1-propene

The hydrocarbon was prepared from benzophenone and ethylmagnesium iodide by the method of Klages.[9] The reaction was carried out as described for phenylethene. The reaction rate did not differ noticeably from that of the two hydrocarbons just described. Practically all of the nitrogen of the nitrogen trichloride was given off as a gas. No amine was formed.

The Reaction with Triphenylethene

The hydrocarbon was prepared from benzophenone and benzylmagnesium chloride by the method of Hell and Wiegandt.[10] The reaction rate of this compound was much slower than the others thus far described. Ten hours or longer were required for the completion of the reaction. Again practically all of the nitrogen appeared as gas. No amine was formed.

[10] Hell and Wiegandt, *Ber.*, 37, 1431 (1904).

The Reaction with Tetraphenylethene

The hydrocarbon was prepared from diphenylmethane and dichlorodiphenylmethane by the method of Norris, Thomas and Brown.[11]

At −10° there was apparently no reaction with nitrogen trichloride. When the mixture was warmed to 30°, a slow evolution of nitrogen began and continued for thirty-five to forty hours. A little ammonium chloride formed during the reaction but no amine was obtained.

Diphenylketene **and Nitrogen Trichloride.**—A solution of diphenylketene was prepared from diphenylchloro-acetyl chloride and zinc by the method described by Staudinger.[12]

In carrying out the reaction with nitrogen trichloride, the apparatus was arranged for collecting any gas which might be liberated. The nitrogen trichloride solution was added to the ketene solution through a separatory funnel in the course of an hour. A slight excess of the ketene was always used. During the addition the ketene solution was kept at −10° and gently shaken. Little or no gas was evolved. The solution was allowed to remain at this temperature for some time after the trichloride had been added. A residue which proved to be largely zinc chloride formed at the bottom of the flask. The solution was poured off and warmed for thirty to forty minutes at about 40° with 6 *N* sodium hydroxide solution. The non-aqueous layer was separated, dried and hydrogen chloride passed into it. A heavy precipitate of benzophenone-imide hydrochloride was formed. This was filtered off. About an equal quantity of benzophenone was obtained from the filtrate by evaporation.

The best yield of benzophenone-imide hydrochloride obtained was 35% calculated from the nitrogen trichloride. A part of this was purified by dissolving in water, adding a slight excess of cold sodium hydroxide solution and extracting with carbon tetrachloride, drying and reprecipitating with hydrogen chloride. This was analyzed for nitrogen by the Kjeldahl method.

Anal. Subs. 0.2037, 0.2006: 7.88, 7.78 cc. of 0.1205 N HCl. Calcd for $C_{13}H_{12}NCl$: N, 6.44. Found: 6.55.6.56.

A portion of the hydrochloride was heated for a short time with water. The oily product was extracted with ether and the ether evaporated. Benzophenone crystallized on cooling. It was identified by the preparation of the phenylhydrazone.

Summary

1. Nitrogen trichloride reacts with phenylethene and 1,2-diphenylethene to form among other products, C-chloro-N-dichloro-amines. With 1,1-diphenylethene, 1,1-diphenyl-1-propene, triphenylethene and tetraphenylethene no amines are formed under the experimental conditions used.

2. Nitrogen trichloride reacts with diphenylketene. The addition product when warmed with sodium hydroxide solution forms benzophenone imide.

THE PREPARATION OF ETHYL PHENYLMALONATE AND OF 5-PHENYL-BETA-HYDROXYETHYLBARBITURIC ACID[1]

BY WILLIAM L. NELSON AND LEONARD H. CRETCHER

RECEIVED JULY 7, 1928 PUBLISHED OCTOBER 6, 1928

In continuation of the study of the effect of the introduction of a hydroxyl group on the toxicity and therapeutic action of medicinal substances, which has been under way for some time in this Laboratory,[2] it was desired to prepare a number of barbituric acids substituted in the 5-position with phenyl and hydroxyalkyl groups.

In spite of the valuable hypnotic properties of 5-ethylphenylbarbituric acid ("Luminal") but few aryl substituted barbituric acids have been prepared. This is probably largely due to the fact that barbituric acids of this type are difficult to synthesize.

The method which has been generally applied to the synthesis of 5-phenylbarbituric acids has been as follows. Esters of phenylacetic acid have been condensed with esters of oxalic acid to produce an ester of phenyloxalylacetic acid and the latter compound decomposed by heat with loss of carbon monoxide and formation of an ester of phenylmalonic acid.[3] The latter compounds, on condensation with urea, give the desired product.

For the synthesis of Luminal a further method of preparation of the intermediate methyl ethylphenylmalonate has recently been described by Rising and Zee.[4] The procedure recommended involves the following steps: ethylation of phenylacetonitrile; condensation of the sodium salt of phenylbutyronitrile with methyl chloroformate to form methyl ethylphenylcyano-acetate; treatment of the latter substance with a methyl alcohol solution of hydrogen chloride to form the desired ester.

Inasmuch as it is our purpose to prepare a number of derivatives of phenylbarbituric acid, it appeared to us highly desirable to have a method as satisfactory as possible for the preparation of ethyl phenylmalonate, an intermediate useful for the preparation of all of them. For this reason considerable time was devoted to a study of the synthesis of this compound.

---

[1] This investigation was conducted in cooperation with the National Research Council Sub-committee on Hypnotics, 1926.

[3] (a) W. Wislicenus, Ber., 27,1091 (1894); (b) Rising and Stieglitz, THIS JOURNAL, 40,723 (1918).

[4] Rising and Zee, THIS JOURNAL, 49, 541 (1927). Another paper by these authors has just appeared [THIS JOURNAL, 50, 1208 (1928)] wherein they describe an improvement of their method which produces an over-all yield of 43.1% of methyl ethylphenylmalonate from phenylacetonitrile.

It was first attempted to prepare ethyl phenylmalonate by condensation of ethyl phenylacetate with ethyl carbonate. The directness of the method is the important advantage which this process would have over that in common use. The condensation was attempted, under varying conditions, in alcohol, ether and benzene, and with both sodium and sodamide. Condensation was effected only with sodium and only in ether and benzene. At best (in benzene) it was not possible to obtain a yield greater than 20%, due to the condensation of ethyl phenylacetate with itself. This is in accord with the observations of Volhard[5] and of Scheibler and Mahboub.[6]

Our attention was then directed to phenylacetonitrile as a suitable intermediate for our purpose. The sodium salt, prepared with sodium in ether, was condensed with ethyl chloroformate. The yield of ethyl phenylcyano-acetate was only 50%.

We next studied the condensation of phenylacetonitrile with ethyl carbonate. The method of Hessler[7]—sodium as condensing agent, in ether—was repeated with results closely checking those of Hessler, who obtained a yield of 55% of ethyl phenylcyano-acetate. Sodium ethylate in alcohol gave 55% and sodamide in benzene gave 30%. By far the best results were obtained with sodamide in ether, according to the method of Bodroux[8] for the condensation of benzyl cyanide with esters. For maximum yield (70%) it is necessary to follow closely the conditions given in the Experimental Part of this paper.

Inasmuch as phenylmalonic esters are not alkylated in good yield, it was thought that it might be an advantage to alkylate phenylacetonitrile before attempting the condensation to introduce the second carboxyl group, In no case, however, did we succeed in condensing a substituted benzyl cyanide with ethyl carbonate.

The conversion of phenylcyano-acetate to ethyl phenylmalonate was effected most advantageously with hydrogen chloride and alcohol according to the method of Wislicenus.[9] It is essential that the alcoholic solution of the nitrile be thoroughly saturated with hydrogen chloride, as analysis showed in one case where saturation was not complete, a nitrogen content indicating 10% of unchanged nitrile, which is practically impossible to separate from the ester owing to the fact that their boiling points are only about three degrees apart.

The ethylation of ethyl phenylmalonate was accomplished most advantageously in alcohol solution with ethyl iodide or bromide or by heating the dry sodium salt of the ester with ethyl bromide in a sealed tube at

110° without a solvent. Ethylation in alcoholic solution is attended by decomposition of the ethyl phenylmalonate and production of ethyl phenylacetate.[10] It was observed that in case an excess of sodium is used decomposition may be practically complete.

Since our primary interest was not in the discovery of an improved process for making Luminal, we have not occupied ourselves to any extent with the preparation of this substance. A few experiments were conducted on condensing ethyl phenylethylmalonate with urea. The yields averaged between 30–40% and were of the same order as reported by Rising and Stieglitz from the condensation of the methyl ester with urea.[3b]

For the preparation of 5-β-hydroxyethylphenylbarbituric acid according to the method devised in this Laboratory for preparing β-hydroxyethyl compounds,[2c,11] it was necessary to prepare ethyl phenyl-β-vinyloxyethylmalonate as an intermediate. Its synthesis from ethyl phenylmalonate and β-chloro-ethylvinyl ether offered some difficulty in contrast to the ease with which ethyl vinyloxyethylmalonate is prepared from ethyl malonate.[12]

Attempts to condense the sodium salt of the ester with the chloro compound in alcohol, ether, benzene, toluene and xylene were unsuccessful. It was only upon heating the components in a sealed tube in absence of a solvent that we were able to obtain the desired product in appreciable amount.

Experimental Part

Ethyl Phenylcyano-acetate.—Three hundred grams of anhydrous ether and 42 g. of pulverized sodamide were placed in a dry two-liter three-necked, round-bottomed flask. A mercury sealed stirrer passed through the middle neck and a dropping funnel and tall reflux condenser were fitted to the side necks. During constant stirring, 117 g. of freshly distilled phenylacetonitrile was added drop by drop. A vigorous reaction ensued with evolution of ammonia. After all of the nitrile had been added, the reaction mixture was boiled in a water-bath for one-half hour. After cooling to room temperature, 150 g. of freshly distilled ethyl carbonate was added drop by drop. Replacement of the ether lost by evaporation is frequently necessary. After all of the carbonate had been added, the flask was warmed another half hour; then it was cooled in an ice-bath and treated with dilute hydrochloric acid until the aqueous layer was acid to litmus. The product was filtered and the ethereal layer separated and dried over calcium chloride.

After removal of the ether and fractionally distilling *in vacuo*, 133 g. of the desired ester was obtained, boiling (7 mm.) at 140–148° (nearly all at 145°). This is a yield of 70.3%.

A portion was further purified by redistillation. It was a colorless liquid and boiled at 165° at 19 mm.; $d_4^{20} = 1.091$.

Ethyl Phenylmalonate.—A rapid stream of dry hydrogen chloride was passed into a solution of 45 g. of ethyl phenylcyano-acetate, 65 g. of 95% alcohol and 2 g. of water. The flask was connected with a condenser and the hydrogen chloride added to saturation

[10] Wislicenus, *Ber.*, 28, 815 (1895).

[11] Cretcher, Koch and Pittenger, THIS JOURNAL, 47, 1173 (1925).

[12] Ref. 11, p. 1176.

of the hot solution. The reaction mixture was then cooled in an ice-bath and the cold solution saturated with hydrogen chloride. The flask was allowed to stand overnight at room temperature and on the following morning was heated one hour on a steam-bath. After cooling, sufficient water was added to dissolve the precipitated ammonium chloride; the ester was extracted with ether, washed with water and dried over calcium chloride. After removal of the ether the residual liquid was distilled. A yield of 44 g. (78.3%) of ethyl phenylmalonate was obtained at 163–166° at a pressure of 18 mm.

A portion was further purified. It was a colorless liquid and boiled at 168° (19 mm.); $d_4^{20} = 1.095$. Wislicenus[13] reported the boiling point to be 170–172° at 14 mm. He did not determine the density.

Ethyl **Phenylethylmalonate**.—This ester was produced most satisfactorily by the reaction of ethyl iodide or bromide with the sodium salt of ethyl phenylmalonate in boiling absolute alcohol. With ethyl iodide the yield was 61.1%. This ester boils at 170° (19 mm.); $d_4^{20} = 1.071$. The boiling point given in U. S. Patent 1,036,624 is 166° at 12 mm.

5-Phenylethylbarbituric Acid **(Luminal)**.—Luminal was prepared as follows: 0.69 g. of sodium was dissolved in 11 g. of absolute alcohol in a glass tube and 0.9 g. of powdered urea added to the solution; 2.64 g. of ethyl phenylethylmalonate was then added. The tube was sealed and heated in an oil-bath at 115° for three hours. The tube was then cooled, opened and the contents filtered. Alcohol was removed from the filtrate by distillation *in vacuo*. The residue was dissolved in water and the unaltered ester removed by extraction with ether. The aqueous layer was acidified with a slight excess of dilute hydrochloric acid. A pure white crystalline substance was precipitated. After filtering and drying, the crude product melted at 171°. Upon recrystallization from water the melting point was 173–174°. The yield was 35% of the theoretical.

Ethyl **Phenylvinyloxyethylmalonate**.—After many unsuccessful attempts to prepare this ester in good yield, the following procedure was adopted: 2.3 g. of sodium was pulverized in boiling xylene. The containing tube was cooled, the xylene decanted and the sodium washed quickly with several portions of anhydrous ether. Forty g. of dry ether was added and then 23.6 g. of ethyl phenylmalonate in small portions. There was a very vigorous reaction. A calcium chloride tube was attached to the condenser and the reaction mixture allowed to stand overnight. The ether was then removed by boiling, finally under vacuum. Thirty g. of β-chloro-ethylvinyl ether was added, the tube sealed and heated at 140–145° for fourteen hours. After cooling the tube was opened, water added to dissolve the salt and the ester extracted with ether. After removal of the ether, 15.5 g. of product was obtained, boiling mostly at 189–190° at 10 mm. This is a yield of 52%.

The compound was further purified by redistillation for analytical purposes. Ethyl phenylvinyloxyethylmalonate boils at 196–197°, 17 mm. $d_4^{20} = 1.098$. It decomposes on standing in sunlight, the odor of acetaldehyde being quite strong after several weeks.

Anal. Calcd. for $C_{17}H_{22}O_5$: C, 66.63; H, 7.24. Found: C, 66.43; H, 7.42.

5-(Phenyl-β-hydroxyethyl)-barbituric Acid **(Hydroxy-Luminal)**.—The condensation of ethyl phenylvinyloxyethylmalonate and urea to form 5-phenylvinyloxyethylbarbituric acid was accomplished under exactly the conditions described for the preparation of Luminal. The vinyloxy compound was not isolated in pure form but converted directly into the hydroxy-Luminal by hydrolysis with acid.[2c] For purification the substance was crystallized from water. The yield of pure hydroxy-Luminal, melting at 200°, was only about 10% of the theoretical.

Anal. Calcd. for $C_{12}H_{12}O_4N_2$: N, **11.30.** Found: N, **11.21.**

5-(Phenyl-β-hydroxyethyl)-2-thiobarbituric Acid.—This compound was prepared by condensation of ethyl phenylvinyloxyethylmalonate with thiourea. The procedure was the same as that given directly above, m. p. 167°. The yield was 15%.

Anal. Calcd. for $C_{12}H_{12}O_3N_2S$: N, **10.6.** Found: N, **10.9.**

Phenylvinyloxyethylacetonitrile $C_6H_5CH(CH_2CH_2OCH{=}CH_2)CN$.—This nitrile was prepared by reaction of phenylacetonitrile and β-chloro-ethylvinyl ether, according to the general method devised by Bodroux and Taboury.[14] The yield was 50%. The pure compound boils at 147° (8 mm.); $d_4^{20} = 1.029$.

Anal. Calcd. for $C_{12}H_{13}ON$: N, **7.48.** Found: **N, 7.33.**

Summary

1. A convenient method for the preparation of ethyl phenylmalonate has been described.
2. A new barbituric acid closely related to Luminal, 5-phenyl-β-hydroxyethyl-2,4,6-trioxypyrimidine, has been synthesized.

PITTSBURGH, PENNSYLVANIA

THE REACTION BETWEEN THE BINARY SYSTEM, MAGNESIUM + MAGNESIUM IODIDE, AND AROMATIC ACIDS AND ACID DERIVATIVES

BY M. GOMBERG AND W. E. BACHMANN

RECEIVED JULY 9, 1928 PUBLISHED OCTOBER 6, 1928

The interaction of magnesium + magnesium iodide and aromatic ketones results in addition of MgI to the C=O group.[1] A similar reaction occurs with 1,2-diketones,[2] with thio-ketones[3] and apparently with quinones.[4] The MgI, the probable formation of which has been postulated, may thus be regarded as functioning like a monovalent element, as sodium. This comparison holds in reactions that are to be discussed in this communication on acids and in communications to follow, on various classes of compounds containing double and triple bonds.

Reaction of Acids with Magnesium + Magnesium Iodide.—This reaction takes place in two steps: (a) displacement of the acid hydrogen by MgI and (b) reduction of the resulting salt.

The displacement of hydrogen is best explained by the fact that there is an equilibrium reaction between MgI_2 and the organic acid. Only a small amount of HI results by virtue of this reaction; nevertheless, in the

---

[4] Fieser, THIS JOURNAL, **50**, 464 (1928).

presence of metallic magnesium, which reacts with the HI, the reaction proceeds quantitatively according to the following formulation

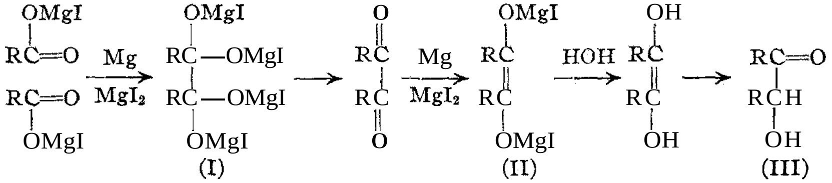
$$2RCOOH + Mg + MgI_2 \longrightarrow 2\ RCOOMgI + H_2 \tag{1}$$

In the course of the reaction the iodomagnesium salt[5] suffers a partial decomposition into the magnesium salt and magnesium iodide, an equilibrium apparently being established between the components of the system

$$2RCOOMgI \rightleftharpoons (RCOO)_2Mg + MgI_2 \tag{2}$$

Since magnesium iodide is thus being regenerated, it follows that a small amount of halide may suffice for a large amount of acid.

With the evolution of hydrogen from the acid at an end, reduction of the salt ensues. Since the hydrogen escapes as such, it is obvious that the reduction is not occasioned by the hydrogen but by the binary system. The reduction proceeds, presumably, along the following course



(3)

Addition of water to the reduction mixture hydrolyzes the iodomagnesium compound of the stilbene-diol (11), and the corresponding benzoin (III) is produced. The yields of benzoins obtained varied, however, with the conditions of experiment and with the nature of the individual acid, and ranged from **30** to 75%. We have reason to assume that the glycolate (II) is practically the sole product of the reduction, and that the low yields of benzoin are due to some subsequent decomposition of the glycolate. Occasionally more than just a small amount of the corresponding benzil is produced, an indication that in such cases some of the product (I) has escaped further reduction to product (II).

Reaction of Esters.—Alkyl esters of aromatic acids are saponified by magnesium iodide in ether solution[6]

$$RCOOCH_2R' + MgI_2 \rightleftharpoons RCOOMgI + ICH_2R' \tag{4}$$

We found that this reaction proceeds in a solution refluxed on the steam-bath. Consequently, in the reaction of the ester with our binary system, saponification takes place first, and this is followed by reduction of the resulting iodomagnesium salt to the precursor (II) of benzoin. At the

---

[5] Whether the iodomagnesium salt has the constitution assigned to it or whether it be of the type $(RCOO)_2MgMgI_2$ [Ivanov, *Compt.* rend, 185, *505* (1927)], does not affect our discussion. However, like Grignard and others [Grignard, *Compt. rend.*, 185, *507* (1927); Meisenheimer, *Ber.*, 61, 708 (1928); Meisenheimer and Schlichenmaier, *Ber.*, 61, 720 (1928)], we are of the opinion that the monomolecular formula best represents the structure of the salt.

[6] Zal'kind, J. *Russ. Phys.-Chem. Soc.*, 46, 692 (1914).

same time the alkyl halide, which has resulted from saponification, reacts with the magnesium and there may thus be formed a hydrocarbon, $R'CH_2$-CH_2R', and also the Grignard reagent, $R'CH_2MgI$; the latter may in its turn react with unsaponified ester and with the salt. It may be mentioned that benzoin has been observed also as one of the products of the action of sodium on esters.

Aryl esters, as phenyl benzoate, are split in a manner different from that in the case of alkyl esters

$$\text{RCOOAr} + \text{MgI}_2 \rightleftharpoons \text{RCOI} + \text{IMgOAr}\ (\text{Ar} = \text{Aryl}) \qquad (5)$$

Since no iodomagnesium salt has been formed, no benzoin results on subsequent treatment with the binary system. The acyl iodide, we find, does not yield the stilbene glycolate on reduction, nor does it give rise to benzil when treated with metallic magnesium.[7]

Reaction of Peroxides.—Acyl peroxides react vigorously with magnesium iodide alone

$$\text{RCOO—OOCR} + 2\text{MgI}_2 = 2\text{RCOOMgI} + \text{I}_2 \qquad (6)$$

Likewise, bromine is set free from magnesium bromide. In the presence of magnesium, the halogen is converted into magnesium halide and the organic salt is then reduced to the stilbene-diol compound.

Experimental

Displacement of Hydrogen from the Acids.—Metallic magnesium reacts very slowly with the organic acids dissolved in anhydrous ether or benzene, or in a mixture of both, in the concentrations employed in our experiments (about 5%). Even on prolonged boiling with solutions of acids of twice that concentration only a small quantity of hydrogen is evolved. If, however, to the mixture a small amount of iodine or of magnesium iodide (3 to 10%) is added, the reaction sets in at once—vigorously at the start but soon subsiding. The metal before long becomes coated with the insoluble magnesium salt and the reaction stops entirely. On the other hand, if magnesium iodide is present in amount sufficient to furnish the halomagnesium salt (Equation 1), then the reaction goes to completion in a short time. After many preliminary experiments the following method was adopted as the most suitable for determining the quantity of hydrogen evolved.

A solution of 0.01 mole of magnesium iodide was prepared in 60 cc. of a mixture of ether and benzene (1:2) and a weighed amount of magnesium powder (usually 0.6 g.) was added. The reaction flask was attached by means of a ground-glass connection to a small condenser, from the top of which a capillary tube led to a gas buret filled with water. Between the condenser and buret was a calcium chloride tube. The acid (0.02 mole), in the form of pellets, was supported on a glass basket,[8] which was set above the level of the liquid and so arranged that when the solution was boiling the condensate dripped down upon the acid and brought it down into the solution only gradually. A steady stream of hydrogen was evolved into the buret and the reaction was at an end in fifteen to twenty minutes. In the following table are given representative values obtained with several acids.

p-Toluic	**102**	**81**	Diphenylacetic	**94**	97
α-Naphthoic	**100**	**86**	Stearic	**90**	**87**
β-Naphthoic	**104**	**93**			

[a] We have repeated this experiment several times, using most carefully purified acid, and have always obtained the high yield of hydrogen. We wonder whether this may not be due to replaceability of the hydrogen in the alkyl group, similar to what Kohler, Stone and Fuson, THIS JOURNAL, 49, **3181** (1927), have found to be the case with many compounds toward the Grignard reagent.

The formation of hydrogen in our reaction depends primarily upon liberation of hydrogen iodide, which then reacts with the metallic magnesium $RCOOH + MgI_2 \rightleftharpoons RCOOMgI + HI$; $Mg + 2HI \longrightarrow MgI_2 + H_2$. The presence of the equilibrium was demonstrated by the following experiment. **A** mixture of benzoic acid and magnesium iodide, without metallic magnesium present, was refluxed for twenty-four hours; under these conditions the HI, which otherwise would have reacted with magnesium, was now continually being removed through its reaction with the ethyl ether, tending to form ethyl iodide.[9] From **12.2** g. of acid and **32** g. of MgI_2, **12.3** g. of ethyl iodide was obtained. Even in the presence of metallic magnesium this reaction took place to some extent. This reaction, and loss of some HI carried away by escaping hydrogen, accounts for the low yields of hydrogen obtained (Table I).

That hydrogen iodide, under the conditions of our experiments, does react with magnesium in the presence of ether with evolution of hydrogen was definitely established.[10] Dry hydrogen iodide was passed into benzene and it was found that this solution did not react with magnesium. However, addition of an equal volume of ether to this mixture induced *immediate* reaction with extremely lively evolution of hydrogen The quantity of gas corresponded to 96% of the magnesium that had been dissolved. We found also that hydrogen bromide and magnesium react in a mixture of ether and benzene with evolution of hydrogen. Though HCl alone in ether-benzene did not react, the addition of $MgBr_2$ brought about a reaction. On several occasions we analyzed the seemingly homogeneous crystalline deposit that had separated and found it to be not far from the composition $BrMgCl$, or $MgCl_2 \cdot MgBr_2$.

If the reaction mixtures from the organic acids are hydrolyzed soon after all of the hydrogen has been evolved, practically all of the acid can be recovered unchanged from the aqueous solution of its salts. In the case of benzoic acid traces of hexahydrobenzoic acid were unmistakably recognized. Prior to hydrolysis the iodomagnesium salts separated from the solution usually as insoluble, oily etherate compounds; in rare cases crystallization set in. We isolated and analyzed these solid products and found that they consist of mixtures of the halomagnesium and the normal magnesium salts of the acids. In one instance, with benzoic acid, the crystalline compound was almost entirely the pure salt $RCOOMgI$.

Magnesium bromide was found to give insoluble addition products with organic acids, $2RCOOH \cdot MgBr_2 \cdot 2C_4H_{10}O$. As a rule the corresponding magnesium iodide

compounds were soluble under similar conditions. With toluic acid, however, a crystalline compound of the composition $2RCOOH \cdot MgI_2 \cdot 2C_4H_{10}O$ was formed.

Reduction of Acids

The amount of magnesium iodide employed for reduction usually corresponded to that required by the formulation (3). Frequently much less was used in virtue of the ability of the iodomagnesium glycolate to lose MgI_2.[11]

Reduction of Benzoic Acid.—A mixture of magnesium + magnesium iodide was prepared from 95 g. (0.75 atom) of iodine and 20 g. of magnesium powder in 100 cc. of ether and 200 cc. of benzene. To this colorless mixture 30.5 g. (0.25 mole) of benzoic acid was added in portions. When the lively evolution of gas had ceased, the mixture, protected from air by means of a mercury trap, was heated on the steam-bath. After five days of heating the dark, reddish-brown solution was filtered from the undissolved magnesium and treated with water. Dilute acid was added to dissolve the copious precipitate of magnesium hydroxide that had been produced. The organic solution was extracted with dilute sodium carbonate solution, which removed unchanged benzoic acid. Evaporation of the solvents left a solid contaminated with some oily by-products, and these were removed by digestion of the crude product with ether. The residue consisted of practically pure benzoin, and weighed 12.0 g., which represents a yield of 30%. From the ether extract a small amount of benzoin and benzil were isolated. In another experiment the yield of benzoin was 43%. One reason for the reaction being incomplete appears to be the precipitation of an insoluble material upon the magnesium, probably an etherate of $(MgI)_2O$. The reaction was also carried out at room temperature. A mixture prepared exactly as above, after having been shaken for eighteen days, yielded on hydrolysis 34% of benzoin and 4% of benzil. The remainder was mostly unchanged benzoic acid, with hardly any oily by-products such as occur when the reaction has been carried out by the aid of heat.

Prior to hydrolysis the reduction product is the iodomagnesium salt of stilbene-diol. Its reactions were compared with those of the same glycolate but made directly from benzil, and were found to be identical: treated with iodine, it gave benzil: with benzoyl chloride, the stilbene-diol dibenzoate, m. p. 156°, was formed.

For further verification of our inference that benzoin comes from the reduction of the salt $C_6H_5COOMgI$, we have prepared that salt by two standard methods: $RCOOH + CH_3MgI \longrightarrow RCOOMgI \longleftarrow CO_2 + IMgR$. In each case the reaction mixture was heated with metallic magnesium and the final results were 46% and 20% yields of benzoin, respectively. In some instances one may find it desirable, from the preparative point of view, to make a benzoin from the aryl halide without isolation of the intermediately formed acid. We have done so with benzoin and α-naphthoin from phenyl bromide and naphthyl bromide, respectively.

Reduction of *p*-Toluic Acid.—Taken for experiment: 13.6 g. (0.1 mole) of p-toluie acid, 38 g. (0.3 atom) of iodine and 10 g. of magnesium powder in 150 cc. of benzene–ether (2:1). In a short time the evolution of gas was at an end and the mixture was gently refluxed on the steam-bath for three days. The dark, reddish-brown solution was filtered and decomposed with water. A large amount of toluic acid was extracted from the solution by sodium carbonate. The reduction product was found to consist for the most part of dimethyl benzil rather than the benzoin. Consequently the entire crude product was oxidized to the benzil by heating it for several hours with 8 g. of copper sulfate, 8 g. of pyridine and 4 g. of water. After purification the *p,p'*-dimethyl benzil

---

[11] Gomberg and Bachmann, THIS JOURNAL, 49, 2588 (1927).

weighed 3.59 g. (30% yield). The substance melted at 102–104°, and it was found to be identical in all respects with the dimethyl benzil obtained from *p*-tolualdehyde through the benzoin condensation.

Reduction of **α-Naphthoic** Acid.—To the binary system prepared from 15 g. (0.1 atom) of iodine and 10 g. of magnesium powder in 120 cc. of 1:1 ether–benzene, 17.2 g. (0.1 mole) of α-naphthoic acid was added in portions of several grams at a time. After hydrogen had ceased coming off, the mixture was heated. In a few minutes the solution became green in color, then greenish-brown and finally dark reddish-brown. After seven hours the heating was discontinued and the mixture was hydrolyzed. The naphthoic acid that was recovered by extraction with sodium carbonate was contaminated with a gummy product which was found to be very soluble in cold benzene and could thus be removed, leaving 3.05 g. of naphthoic acid. Evaporation of the ether–benzene solution left a residue consisting of a mixture of naphthoin, naphthil and some oil. For a determination of the extent of reduction which the acid had suffered, the crude product was oxidized by means of copper sulfate and pyridine to naphthil. The oxidation product was recrystallized from benzene and obtained in the form of pale yellow needles; m. p. 189–190°; weight, 4.85 g., which is equal to 31% of that possible. Our a-naphthil was found to be identical with the product obtained by oxidation of a-naphthoin which had been prepared from the naphthaldehyde. Although the conditions of reduction of the acid were varied over a wide range, the yield of α-naphthoin or naphthil invariably ran between 30 and 35%.

Reduction of **β-Naphthoic** Acid.—Taken for reaction: 17 g. of iodine, 12 g. of magnesium, 200 cc. of ether–benzene, 17.2 g. of β-naphthoic acid. A few minutes after evolution of hydrogen had ceased, the mixture became light green, then dark green and finally dark reddish-brown in color. After eleven hours the solution was filtered and decomposed with water. The amount of unchanged naphthoic acid was 8% and the reduced product consisted of naphthoin mixed with a considerable quantity of naphthil. The mixture was oxidized by means of copper sulfate and there was thus obtained 11 g. of pure recrystallized β-naphthil, which represents a yield of 70%. Several smaller runs gave yields as high as 75%. From hot benzene the β-naphthil crystallizes in cream-colored needles; m. p. 157–158".

Anal. Calcd. for $C_{22}H_{14}O_2$: C, 85.18; H, 4.55%. Found: C, 84.90; H, 4.84. Mol. wt. Calcd.: 310. Found: 323.

The amount of metallic magnesium dissolved in the come of the reduction process and the magnesium hydroxide produced on hydrolysis of the reduction mixture were determined and they were found to correspond to that required by formulation (3).

Reduction of ***p*-Phenylbenzoic** Acid.—A mixture of 4.0 g. of p-phenylbenzoic acid, 4.0 g. of magnesium iodide and 5 g. of magnesium powder in 60 cc. of benzene–ether (2:1) was heated for five days. In the course of the reaction the solution became green and then reddish-brown in color. After hydrolysis a small amount of unchanged acid was recovered and from the reduction product, after treatment with copper sulfate, 1.7 g. (46%) of *p,p'*-diphenyl benzil was obtained. It was recrystallized from a mixture of alcohol and benzene and was obtained in the form of yellow needles, m. p. 139–140°. It was identical with *p,p'*-diphenyl benzil which had been synthesized through the benzoin condensation from *p*-phenylbenzaldehyde.

Reaction of Esters with Mg + MgI_2

Saponification of Benzyl Benzoate by Magnesium Iodide.—Fifty-three grams (0.5 mole) of benzyl benzoate was added to a solution of 70 g. of magnesium iodide in 300 cc. of ether–benzene (1:2), and the resulting solution was heated on the steam-bath for one week. The red solution was then poured into water. In the aqueous solution was found 30.32 g. (99%) of benzoic acid in the form of water-soluble salts. The ether–benzene solution was dried over anhydrous sodium sulfate and then concentrated to a small volume. On being cooled the solution deposited a large amount of benzyl iodide. By recrystallization from alcohol, 20 g. of pure benzyl iodide was obtained.

Reduction of Benzyl Benzoate.—Taken for experiment: 25.6 g. (0.2 atom) of iodine, 10 g. of magnesium and 21.2 g. (0.1 mole) of the ester, in 120 cc. of the mixed solvents. After a day the greenish color initially formed changed to brown and later to reddish-brown. After being heated for a week the solution was filtered and hydrolyzed. From the ether–benzene solution was obtained a mixture of bibenzyl and benzoin, and they were separated from each other by dissolving the former in petroleum ether. After purification the bibenzyl weighed 6.2 g (70%) and the benzoin amounted to 4.8 g. (45%).

Methyl Benzoate.—Thirty-four grams of this ester was heated with the proper amount of magnesium + magnesium iodide, and yielded 2.2 g. of benzoin. Here the yield of benzoin is necessarily small because the methyl iodide that is produced on saponification forms readily with the magnesium a Grignard reagent, which in turn is able to react with the ester or salt.

Phenyl Benzoate.—No benzoin was obtained on heating 10 g. of phenyl benzoate with the reducing mixture. The main products were phenol, 4.2 g. (90%) and a resinous mass which was found to be soluble in the usual organic solvents, but no crystalline products were obtained for identification. We find that benzoyl iodide treated with the binary system gives resins of a similar nature.

Reaction between Benzoyl Peroxide and Mg + MgI$_2$.—A solution of 4.88 g. (0.2 mole) of benzoyl peroxide in 50 cc. of benzene was slowly added to a solution of magnesium iodide in ether–benzene. The very first drop of the peroxide solution liberated iodine, and as more solution was added the mixture became dark red and a heavy oil of the etherate of iodomagnesium benzoate separated. After twenty hours the mixture was poured into water. From the aqueous solution, on acidification, 4.90 g. (100%) of benzoic acid was obtained. Titration by standard thiosulfate solution showed the presence of 5.0 g. (99%) of iodine. In the same manner benzoyl peroxide liberated bromine from magnesium bromide.

For reduction, 30.3 g. of benzoyl peroxide was cautiously added to a mixture of magnesium and magnesium iodide prepared from 65 g. of iodine and 10 g. of magnesium in 300 cc. of ether–benzene. Each addition of peroxide was accompanied by hissing and crackling noises, and by liberation of iodine. Most of this iodine reacted at once with the magnesium. The grayish mixture was heated for four days. Hydrolysis then gave 12 g. of benzoin, which represents a yield of 45%.

Summary

Organic acids in solution in ether and benzene react vigorously with the binary system Mg + MgI$_2$, hydrogen is evolved and the acid is converted completely into the salt RCOOMgI. This salt then undergoes reduction and, at least in the case of aromatic acids, the reduction product is R(IMgO)C=C(OMgI)R, which when hydrolyzed gives rise to the corresponding benzoin in yields of 30 to 75%. The reducing effect of the binary system is ascribed to the intermediate formation of the compound MgI.

Alkyl esters of aromatic esters and acyl peroxides are reduced by the binary system in a similar manner. Aryl esters are affected differently.

The reduction of acids or of esters by this binary system offers a con-

venient method for obtaining benzoins. This method should prove particularly useful in those instances when the aldehyde requisite for the usual benzoin condensation is not readily accessible.

THE RELATIVE RATES OF BROMINATION OF THE OLEFINS[1]

BY HAROLD S. DAVIS[2]

RECEIVED JULY 10, 1928 PUBLISHED OCTOBER 6, 1928

This paper deals mainly with experimental work on the rates of reaction of the lower olefins with bromine, particularly in carbon tetrachloride solution.

1. The Dark Reaction of Ethylene with Bromine in Dry Carbon Tetrachloride Solution Is Very Slow.—Contrary to general belief,[3] it was found that ethylene brominates in carbon tetrachloride at a rate measurable with time and that if the solutions are dried and kept away from bright light, the reaction requires hours and even days for completion.

2. The Rate of the Dark Reaction of Ethylene with Bromine in Carbon Tetrachloride Varies Greatly with the Quantity of Moisture in the Solution.—Solutions of bromine in carbon tetrachloride were dried in the following ways: (*a*) by refluxing for four hours with phosphorus pentoxide and distilling into a dry receiver protected from moisture in the air by phosphorus pentoxide. In some cases the solution was first shaken for several days with phosphorus pentoxide before refluxing and distilling. (b) By shaking for different periods of time with phosphorus pentoxide and settling Evaporation tests on the clear supernatant liquid showed that it contained less than one part of phosphorus pentoxide in one hundred thousand by weight.

When dry ethylene was added to these solutions the reaction went quite

[1] This paper contains results obtained in an investigation on the "Relative Rates of Reaction of the Olefins," listed as Project No. 19 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the cooperation of The Central Petroleum Committee of the National Research Council.

[2] Director and Research Associate, Project No. 19.

[3] Thus Plotnikov, "Lehrbuch der Photochemie," 1920, pp. 245–255, states that ethylene and bromine unite to form the dibromide at ordinary temperatures instantaneously and completely and the reaction only slackens to one measurable with time at −100°. Working at this temperature in petroleum ether solution, he found the reaction to be of the second order. On the other hand, Stewart and Edlund, THIS JOURNAL, 45, 1014 (1923), found ethylene and bromine to be practically unreactive in the gaseous state.

slowly in the absence of light. Numerous experiments showed the reactions to be of the second order and in solutions 0.05 M for both bromine and ethylene, the lowest value obtained for the reaction coefficient,[4] K, at 25° was 0.006.

An indication of the quantitative relationships between the rate and the water content was obtained in the following experiment which showed the rate of reaction of ethylene with bromine in dry carbon tetrachloride to increase over five times on the addition of 5% by volume of carbon tetrachloride saturated with water.

TABLE I

EXPERIMENT SHOWING THE EFFECT OF WATER ON THE RATE OF DARK BROMINATION OF ETHYLENE IN DRY CARBON TETRACHLORIDE

Conditions: The bromine–carbon tetrachloride solution was distilled from phosphorus pentoxide, and ethylene dried by the pentoxide was added thereto. The course of the reaction was followed by the withdrawal of samples and titration for their bromine content. At the end of the fourth hour, 5% by volume of carbon tetrachloride saturated with water was added. (Water content of resulting solution 0.0005 *M*).[a] Temperature, 25°. *a* (ethylene) = *b* (bromine) = 0.057 M.

t, hours	0	1	2	3	4	5
% reacted	0	5	8	10	12	20
K		0.0167	0.0095	0.0063	0.0065	0.035

[a] C. W. Clifford, *J. Ind. Eng. Chem.*, 13, 632 (1921), gives the following values for the solubility of water in carbon tetrachloride expressed as grams per 100 g. of solution: at 24.0°, 0.010; at 28.5°, 0.013.

Preliminary experiments on the rates in solutions saturated with water at 25° gave much higher values for *K*(0.4 to 4.0).

It might have been expected, from analogy with the effect of water on the photochemical reaction of hydrogen and chlorine,[5] that changes in the water content would affect the rate only when the merest traces were present. This does not, however, appear to be the case. Careful quantitative measurements on the problem will be of considerable value.

It seemed unlikely that water was the only substance which would change the rate of this reaction and tests were made on the effects of two others known to be present in the solutions, namely, oxygen and hydrogen bromide.

The effect of oxygen on the reaction did not appear to be great. That it had no accelerating influence was shown by the fact that the rate could be made very slow in solutions which had been in intimate contact with air. Nor was any increase in the rate noticed when in one experiment a volume of air equal to that of the dissolved ethylene was forced into the reaction tube. That oxygen does not hinder the reaction is indicated by the fact that the rate was still slow in dry solutions from which most of

[4] $K = 1/[t(a - b)] \ln[(a - x)/(b - x)]\, b/a$, where t = time in minutes, a = initial molar concn. of ethylene, b = initial molar concn. of bromine, and x = molar quantity of each combined in time *t*.

[5] Coehn and Jung, *Z. physik. Chem.*, 110, 719 (1924).

the air had been expelled by boiling for a few moments under reduced pressure. The following experiment shows that hydrogen bromide does not affect the rate.

TABLE II

EXPERIMENT SHOWING THAT HYDROGEN BROMIDE HAS LITTLE OR NO EFFECT ON THE RATE OF BROMINATION OF ETHYLENE IN CARBON TETRACHLORIDE

a (ethylene), 0.071 M; b (bromine), 0.056 M Dry HBr forced into tube equiv. if dissolved to 0.0517 M soln.

Bromine reacted, %	K	Bromine reacted, %	K
28	0.43	64	0.55
42	0.33	74	0.44

The small increase in K can probably be attributed to traces of moisture added with the hydrogen bromide and not to the latter.[6]

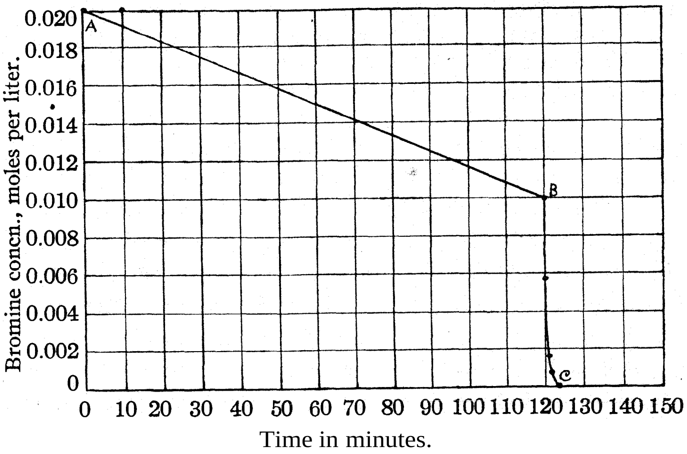

Fig. 1.—Curve showing the effect of sunlight on the rate of bromine addition to ethylene in carbon tetrachloride solution at room temperature. Ethylene concn., 0.06 M; bromine, 0.02 M. Curve A to B—rate of reaction in a 50cc. Nessler tube with light mainly excluded by a brass jacket, $K = 0.07$. Curve B to C—rate of reaction when the tube was removed from its jacket and exposed to bright sunlight, $K = 44$.

3. Bright Light Enormously Increases the Rate of Bromination of Ethylene in Carbon Tetrachloride.—This is illustrated by Fig. 1, which shows the effect of bright sunlight in speeding up the reaction. However, the rates were found to be little affected by illumination sufficient to permit color comparison measurements on the solutions in Nessler tubes, as described later.

---

[6] However, Williams and James, J. *Chem. Soc.*, 1928 343, have shown that hydrogen bromide is a very effective catalyst in the addition reaction between ethylenic acids and bromine, Water and hydrogen chloride produce similar effects but not of the same degree.

4. The Rate of the Dark Bromination of Ethylene in Dry Carbon Tetrachloride Increases Progressively as the Temperature is Lowered from 25 to 0°.—In the following experiments the rates at 25 and 0° were found on the same mixture at different stages of the reaction by simply changing the temperature. This procedure was necessary because as already pointed out the rates in separate experiments with dry solutions vary greatly even at the same temperature due to differences in the residual moisture content.

TABLE III

THE RELATIVE SPEEDS OF THE DARK BROMINATIONS OF ETHYLENE IN DRY CARBON TETRACHLORIDE AT 25 AND 0°

No.	Method of drying Br_2-CCl_4 soln.	Method of measurement	*K* 25°	0°	Ratios of K 25°	0°
1	Distn. from P_2O_5	Titration	0.008	0.4	1	50
2	Distn. from P_2O_5	Color comparison	.4	8	1	20
3	Shaking with P_2O_5	Color comparison	.013	1.4	1	110
4	Shaking with P_2O_5	Color comparison	.012	1.5	1	130

The reaction actually proceeds faster at 0° than at 25°. Measurements at intermediate temperatures have shown that there is no sudden change in the rate. It increases progressively as the temperature is lowered.

These are really very striking experiments. A solution of ethylene and bromine in dry carbon tetrachloride loses its color very slowly in the dark or even in ordinary daylight; but if placed in ice, or better in ice and salt, the color fades away rapidly even though the solution is kept absolutely in the dark. Reheating to 25° does not regenerate the color On the other hand, if the solution is heated up to 25° before decolorization is complete, then the rate falls off to what it was originally at that temperature, but can be speeded up again by lowering the temperature, etc.

That the decreasing of the color really measures the course of the reaction is shown by the following facts. 1. Similar results were obtained when the course of reaction was followed by titration of the bromine (Expt. I, Table III). 2. The color of a bromine–carbon tetrachloride solution changes little, if any, on cooling from 25 to 0°. 3. The quantity of bromine used up was found to be equimolecular to the ethylene, the latter being determined by the volume of ethylene added and the former by the volume of the bromine-carbon tetrachloride solution and its fall in concentration as determined by titration.

The bromine unites to the double bond in the ethylene and there is little substitution as measured by the hydrogen bromide evolved. Thus the products from Expt. 1, Table III (including the gases) were washed with about an equal volume of water which was then filtered and the bromide ion precipitated by silver nitrate). Nephelometric comparisons with similar clouds produced in known solutions of potassium bromide showed that less than 1% of the bromine which had entered into the reaction was to be found as hydrogen bromide.

5. It Is Suggested that the Dark Bromination of Ethylene in Carbon Tetrachloride Proceeds Mainly through a Bromine Hydrate and that the Concentration of this Hydrate Increases as the Temperature Is Lowered from 25 to 0°.—The fact that the dark bromination of ethylene in dry carbon tetrachloride goes very slowly indicates the bromine molecule as such to be relatively inactive toward this olefin. Since traces of water speed up the reaction, it seems reasonable to assume that this is accomplished through a union between the bromine and the water, for ethylene shows little tendency to add the latter, while hydrates of bromine are known to exist. Further, the union of bromine with water, which we may picture thus , so weakens the bond between the bromine atoms that in dilute aqueous solution the complex separates largely into hydrobromic and hypobromous acids.

In support of the hypothesis that the concentration of the hydrate increases as the temperature is lowered, the following facts may be cited. *(a)* The critical temperature of decomposition for the hydrate of bromine in open vessels is 6.8°.[7] (b) I found that the color of an 0.057 N aqueous bromine solution decreased about 40% on cooling from 25 to 3°. On reheating to 25" the color returned to its original value. (c) The "Budde Effect" in bromine vapor is probably due to a photo-active bromine hydrate of composition Br_2H_2O[8] and this effect increases as the temperature is lowered, indicating that the equilibrium $Br_2 + H_2O$ Br_2H_2O shifts to the right.[9]

This phenomenal increase in the rate of bromination of ethylene in dry carbon tetrachloride with decrease in temperature is of considerable interest.[10] It shows how minute traces of intermediate compounds may affect the temperature coefficient of a reaction. It is conceivable that in other cases they might cause an abnormal increase in the reaction rate with rise of temperature.

[9] Lewis and Rideal, *ibid.*, **1926**, 596.

[10] Bodenstein, "Photochemical Reactions in Liquids and Gases," The Faraday Society, **1925**, p. **533**, with great perspicacity has thus expressed himself regarding the "purely chemical dark reactions" which very often follow primary photochemical changes—"It need not appear strange that the velocity should decrease with a rise of temperature for the velocity of a reaction which 'uselessly' consumes the intermediate products **may** easily increase far more rapidly with the temperature than that of the reaction leading to the desired ultimate product."

The reactions I have described are, however, not initiated by visible light, since they take place in complete darkness.

6. The **Olefins Brominate** (Dark Reaction) at Very Different Rates in **Dry** Carbon Tetrachloride.—It has been shown that rates of dark bromination of ethylene in carbon tetrachloride can vary (one hundredfold, at least) with changes in the minute moisture content of the solution. It was further found that the rates of bromination of propene and several higher olefins are also greatly dependent upon the dryness of the solutions. Quantitative data on the relation between the rates and the moisture content for the separate olefines have not yet been obtained.[11]

Qualitatively it was found that, just as for ethylene, the bromination of propene goes considerably faster at 0° than at 25". On the other hand, temperature changes seem to have little effect on the rates of bromination of trimethylethene or di-isobutene in dry carbon tetrachloride. Note the following values for di-isobutene: at 25°, K = 23; at 3°, K = 21.

To be consistent with the hypothesis given above for ethylene, it must be considered that the main reaction here is not through a hydrate of bromine but either with the bromine itself or with an intermediate compound between the bromine and the solvent, or between the bromine and some impurity. The di-isobutene was only moderately pure and air was always present. Further, in the bromination of both trimethylethene and di-isobutene, large quantities of hydrogen bromide are given off. Although such foreign substances do not appreciably affect the rate of bromination of ethylene, they may influence that of a higher olefin.

Accordingly, it is not possible to give figures which will represent the relative rates of bromination of the olefins in carbon tetrachloride because the ratios change with the temperature and probably, as my results indicate, with the moisture content. Nevertheless, the data show tremendous differences in the rates at which the olefins are brominated. Thus on intensive drying the bromination of ethylene required days, that of propene, hours, but that of trimethylethene could not be extended beyond a few minutes. The lowest values obtained so far for the different olefins are as follows.

7. **Light** Increases the Rates of Bromination of the **Olefins** but Decreases the Relative Differences between Them.—In the following experiments the rates of dark bromination of the olefins in dry carbon

---

[11] Reliable data on this subject may help to clear up the discordances found by other investigators of the rates of bromination of unsaturated compounds in carbon tetrachloride and other solvents. Thus Sudborough and Thomas, *J. Chem. Soc.*, 97, 715, 2450 (1910), found great variations (even 12-fold) in the reaction coefficient for the bromination of olefinic acids in this solvent, although their materials were purified with great care. They state that, "The only reason for this that we can offer is that a trace of some impurity has a considerable effect on the velocity of the reaction," and they also showed that the rate of bromination of crotonic acid is dependent on the dryness of the carbon tetrachloride. See also Herz and Mylius, *Ber.*, 39, 3817 (1906); Hofmann and Kirmreuther, Ber., 42, 4481 (1909).

tetrachloride were first found by the color comparison method and then before the reaction was complete the vessel A, Fig. 2, was exposed to radiation from a 200-watt, 120-volt, clear "Higrade" tungsten lamp suspended end on with the filament 20 cm. from the reaction tube. The reaction rate was again followed by color comparison.

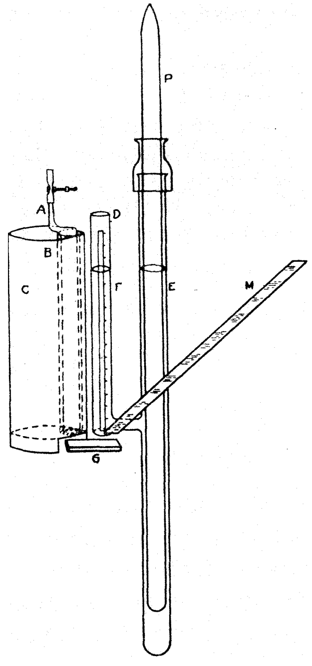

Fig. 2.—Diagram of apparatus used in the color comparison method. A—Reaction chamber' a 50-cc. tube with clear glass ends. B—Brass tube open at both ends and soldered through bottom of bath C. D—Nessler tube containing color standard. F—Scale lettered backwards. M—Mirror for reading scale from above. E—Auxiliary tube with plunger P for rapidly raising or lowering the liquid level in D. G—White surface to reflect light through reaction tube.

The following explanation is suggested for the striking fact that light greatly decreases the relative differences in the bromination rates of the olefins. Assume that an olefin molecule and a molecule of the brominating agent must together have a minimum of activity before interaction can take place. A highly active molecule of either can react with a relatively inactive one of the other. When now a large number of brominating molecules are highly activated by the absorption of light quanta, interaction is extended to olefin molecules which escaped in the dark because of the lowness of their activity. Further, since degrees of activity must be distributed among molecules somewhat like speeds according to the kinetic theory of matter, it is evident that the proportional number of additional molecules thus caught over unit time in the reaction net will be greatest for the olefin having the smallest number reacting in the dark. Thus in Table V, ethylene gave the least increase but the greatest proportional increase (200) for K under the influence of light.

From similar reasoning, water or other catalysts which increase the activity of the brominating agent should decrease the relative differences in the rates of reaction; and if an agent is found which increases the rates and also the relative differences in the rates of reaction of the olefins, we may feel sure that it is operating in some way through the olefin molecules and not through the other reactants.

8. Studies on the Reactions of Olefins with Halogens May Clear Up Many of the Questions Unanswered by Researches on the Photochemical Reactions of Halogens with Hydrogen.—There are many analogies between the reactions of halogens with hydrogen and with olefins. The following peculiarities of the latter type offer addi-

TABLE IV

LOWEST VALUES OBTAINED AT 25° FOR THE DARK BROMINATION RATES OF VARIOUS OLEFINS IN CARBON TETRACHLORIDE DRIED BY PHOSPHORUS PENTOXIDE. THE RELATIVE VALUES ARE ONLY QUALITATIVE

Olefin	K	Olefin	K
Ethylene	0.006[a]	2 Butene Isobutene	60.0
Propene	0.2	Trimethylethene	250.0
1-Butene	2.0	Di-isobutene	20.0

[a] The fact that the ethylene brominates at the slowest rate does not agree with the statement of Plotnikov, "Lehrbuch der Photochemie," 1920, 245, that ethylene reacts with bromine, the fastest of all the olefinic compounds. Suida and Wesley, Z. anal. *Chem.*, 64, 147 (1924), state that ethylene reacts the slowest of the olefins to bromine water but do not give the basis for this conclusion.

TABLE V

A COMPARISON OF THE LIGHT AND DARK BROMINATIONS OF OLEFINS IN DRY CARBON TETRACHLORIDE

Olefin	K, Dark reaction		K, Total light reaction	
	Values	Ratios	Values	Ratios
Ethylene	0.01	1	2	1
Propene	0.2	20	2.5	1.3
Di-isobutene	20.0	2000	40.0	20.0

tional opportunities for learning about the mechanisms involved.[12] *(a)* The reactions are not only photosensitive but proceed in the dark. *(b)* The nature of the unsaturated hydrocarbons can be modified by the radicals attached thereto and it is therefore much easier with olefins than with hydrogen to find what influence the substance being halogenated has on the reaction. (c) The effect of the solvent can be studied. Preliminary experiments showed that the rate of bromination of ethylene is much higher in acetic acid than in carbon tetrachloride, the lowest value obtained for K in the former solvent being 15 compared to 0.006 in the latter when both had been distilled from phosphorus pentoxide.

9. The Methods Used for Following the Course of the Brominations Were (A) Color Comparison with a Standard Bromine Solution, (B) Titration of the Bromine. Care Must Be Taken in the Preservation of the Dried Bromine–Carbon Tetrachloride Solutions.—A. In the color comparison method, the bromine concentration was measured by the height of a standard bromine solution necessary to give the same color intensity. The following measurements will show the degree of accuracy in these measurements.

Actual height of solution..................	100	67.4	60.6	29.6	26.2
Height estimated from color comparison....	100	66.8	54.8	29.9	23.7

The method has the disadvantage that some light must always be sent through the solution during the measurements but the low illumination

---

[12] Plotnikov, ref. 3, has stressed the importance of research in this field.

required seems to have little effect on the reaction. It has the great advantages that no samples need be withdrawn from the sealed up reaction vessel and that as many measurements as desired can be made quickly.

Except for preliminary experiments, the reactions were carried out in closed tubes of the type shown in A, Fig. 2, which permitted clear vision through the glass surfaces at the top and bottom. Fifty cc. of the solution of bromine in carbon tetrachloride was placed in the tube through the side neck and then the olefin was added. If a liquid, it was measured from a pipet. If a gas, it was drawn into the partially evacuated chamber from a mercury buret.

There was a vapor space of about 15 cc. in the reaction tubes, but from solubility experiments[13] it was calculated that 93% of the ethylene and 99% of the propene were dissolved by the carbon tetrachloride. Accordingly, no correction was made for the undissolved part.

B. Titration.—In order to follow by titration the course of the bromination of an olefin in carbon tetrachloride, measured samples were removed at definite intervals and shaken with a little water saturated with potassium iodide. The precipitated iodine was then titrated. The bromine reacts with the iodide before the water can appreciably speed up the bromination of the olefin. The titration should be carried out at once as the brominated olefin products can slowly liberate iodine from potassium iodide.[14]

Some of the difficulties encountered in making these measurements account for the discrepancies shown in the results. At 25° carbon tetrachloride dissolves about 0.012% of water by weight, corresponding to a 0.01 *M* solution. Yet, apparently, it is the variations in this minute content which cause the differences in the dark bromination of ethylene in this solvent at 25°.

It is hard to dry carbon tetrachloride thoroughly but when once dry it does not readily take up moisture again. If a drop of water is added without shaking to a solution of equimolecular quantities of bromine and ethylene in dry carbon tetrachloride, the color may persist for a long time, although in solutions saturated with water it will disappear in a few minutes.

Naturally, moisture diffuses but slowly into dry carbon tetrachloride and when its solutions of bromine and ethylene are shaken with water, the greater part of the reaction takes place in the water phase. If potassium iodide is present in the latter, then apparently the bromine as it diffuses from the carbon tetrachloride into the water reacts much faster with the

[13] Carbon tetrachloride was saturated with the gaseous olefin by bubbling and the concentration of the solution determined by bromine titration. The following values were found for the solubility, X, expressed as the concn. of the dissolved olefin divided by the concentration of the gaseous olefin at equilibrium: ethylene at 25°, $X = 4.3$; ethylene at 0°, $X = 5.1$; propene at 25°, $X = 32$ (approx.).

[14] See Sudborough and Thomas, *J. Chem. Soc.*, 97, 717 (1910).

iodide than with the olefin. These facts are illustrated by the following measurements.

	Method of treatment of the bromine–carbon tetrachloride solution (10 cc. samples)	Concn. of bromine as shown by titration of the iodine
1.	Original solution shaken with potassium iodide solution	0.0558 M
	Solutions containing ethylene	
2.	After two minutes the sample was poured into potassium iodide solution and shaken	.0538 *M*
3.	Sample was poured into water, shaken and allowed to stand for ten minutes. Then potassium iodide solution was added	.0165 M
4.	One drop of water was added and the sample allowed to stand for ten minutes. Then it was poured into potassium iodide solution and shaken.	.0433 M

It is now evident that concordant results for the bromination of olefins in carbon tetrachloride cannot be expected unless the solutions have very accurately the same moisture content, and a large number of my results have had to be rejected on this account. Great care must be taken to preserve the dried solutions from atmospheric moisture. All samples removed must be replaced by dried air since there may be enough water vapor in air at 25° to form a solution over 10% saturated in an equal volume of carbon tetrachloride. As already shown, this may increase the bromination rate many times. Finally, bromine-carbon tetrachloride solutions decompose cork and rubber connections and must be preserved in all glass containers.

Materials.—Commercial refined ethylene was used. It dissolved at a slow, steady rate in 86% sulfuric acid (about 0.13% per pass into an Orsat pipet). This showed the absence of propene and higher olefins which are readily absorbed by this acid. Before use it was passed through two bubblers of concentrated sulfuric acid.

Propene was prepared by dehydrating C. P. isopropanol. The alcohol was kept well cooled and well stirred while an equal weight of phosphorus pentoxide was slowly added. On heating the product, propene was smoothly evolved. It was washed with dilute alkali and with water.

Isobutene was made by heating tertiary butanol (m. p. 15° and miscible without any cloud in water) with about one-third its weight of hydrated oxalic acid. The reaction proceeded smoothly at 87–100°, giving an almost quantitative yield of olefin.

1-Butene was prepared by warming normal butyl iodide (Eastman Kodak Co.) with saturated alcoholic potash containing about three times the quantity of hydroxide theoretically necessary. The product was washed well with water, liquefied and distilled. Coffin and Maass[15] have shown that this method yields a very pure product. It is, however, rather expensive.

Impure 1-butene was made by dehydrating normal butanol, b. p. 117.4–117.9°, at 340–360° over an active alumina catalyst which had never been heated above 400°; 80% of the alcohol passed was dehydrated and over 90% of this appeared as olefins. It has been reported that this method yields a mixture of 1-butene and 2-butene in

---

[15] Coffin and Maass, THIS JOURNAL, 50, 1429 (1928).

the approximate proportions of 70 to 30.[16] I found that about 5% of the alcohol appeared as normal butyl ether.

When this olefin mixture was dried by rapid passage through phosphorus pentoxide and brominated in dry carbon tetrachloride, its bromination curve showed a very sharp break. About 35% (presumably 2-butene) reacted very rapidly and the remaining 65% slowly. This would indicate that the mixture contained about 35% of 2-butene and 65% of 1-butene.

The mixture was washed with 50% sulfuric acid and with 10% caustic potash, liquefied and distilled from sodium. A column was used provided with an evacuated and silvered jacket and with a still-head cooled by chilled air to −12°. The fraction boiling at −5.5 to −4.8°, which was 70% of the total, was collected and stored in a steel cylinder. Its dry bromination curve indicated that it contained 13% of 2-butene and 87% of 1-butene.

The main interest of these experiments lies in the possibilities they show of making pure I-butene by acid treatment and fractionation of the butene mixture obtained by dehydrating normal butanol over alumina.

2-Butene was prepared by dehydrating 2-butanol manufactured from petroleum gases. Harries[17] states that dehydration with phosphorus pentoxide gives a very pure product but obtained a yield of only 64%. It was found that excellent yields, over 90%, of olefin could be reached by heating the alcohol with about 1.5 times its volume of 86% phosphoric acid at 95 to 120°. The product was liquefied and distilled from calcium chloride in the column already described. The fraction boiling from 1.5–1.7° was collected. Its bromination curve showed that 84% brominated rapidly (2-butene) and the remaining 16% slowly.

A mixture of the product with 50% by volume of propene gave a bromination curve in dry carbon tetrachloride which indicated that approximately 50% of the material, evidently propene, had brominated at a much slower rate than the residue.

These preliminary results with mixtures of the butenes and propene show clearly the possibility of measuring the relative rates of bromination for two olefins under identical conditions by tests on known mixtures of the pure substances.

The trimethylethene obtained through the kindness of Dr. R. Reuter had been made by dehydrating tertiary amyl alcohol with 46% sulfuric acid; b. p. 38.4–38.5°.

The di-isobutene was prepared by distilling tertiary butanol with 50% sulfuric acid and fractionating the product; b. p. 101–103°.

The bromine before use was distilled from potassium bromide.

Carbon tetrachloride guaranteed to be free from sulfur compounds was used to make up the bromine solutions, which were then dried as already described.

Summary

1. The dark reaction of ethylene with bromine in dry carbon tetrachloride solution is very slow.

2. The rate of the dark reaction of ethylene with bromine in carbon tetrachloride varies greatly with the quantity of moisture in the solution.

3. Bright light enormously increases the rate of bromination of ethylene in carbon tetrachloride.

4. The rate of the dark bromination of ethylene in dry carbon tetrachloride increases progressively as the temperature is lowered from 25 to 0°.

[16] Lépingle, Bull. *soc. china.*, [4] 39, 741, 864 (1926); Bull. *Amer. Petroleum Institute*, **8,** No. 54, 8 (1927).

[17] Harries, *Ann.*, **383,** 181 (1911).

5. It is suggested that the dark bromination of ethylene in carbon tetrachloride proceeds mainly through a bromine hydrate and that the concentration of this hydrate increases as the temperature is lowered from 25 to 0°.

6. The olefins brominate at very different rates in carbon tetrachloride.

7. Light increases the rates of bromination of the olefins but decreases the relative differences between them.

8. Studies in the reactions of olefins with halogens may clear up many of the questions unanswered by researches on the photochemical reactions of halogens with hydrogen.

9. The methods used for following the courses of the bromination were (A) color comparison with a standard bromine solution, (B) titration of the bromine.

THE RELATIVE RATES OF ABSORPTION OF THE GASEOUS BUTENES INTO SULFURIC ACID[1]

BY HAROLD S. DAVIS[2]

RECEIVED JULY 10, 1928 PUBLISHED OCTOBER 6, 1928

In 1909 Michael and Brunel[3] published data on the proportions of the butenes which were absorbed by sulfuric acid in Hempel pipets after definite periods of shaking. From inspection of the results they gave certain approximate figures for the relative rates of absorption of the three isomers.

Calculations from the data of Michael and Brunel show that in each experiment the rate of solution of the butene was approximately proportional to the quantity undissolved. The following table gives the values of K calculated for the separate experiments where $K = 1/t \ln 1/(1-x)$, t = minutes the pipet was shaken, and x = fraction of olefin dissolved at time t.

The following conclusions can be drawn regarding the rates of solution of olefin gases when shaken with sulfuric acid in Hempel pipets.

1. A pure butene was absorbed at a rate approximately proportioned to the gas undissolved (see Experiments 1, 2, 5, 6 and 7. The high initial rate of solution in 5 may perhaps be attributed to traces of *iso*butene).

0	..	..
20	0.18	10
40	.33	10
60	.44	9.7
80	.55	10
	Av. =	10

7. Pure 1-butene, 76% sulfuric acid, 29–30°

t	X	$K \times 10^{-3}$
0	..	..
20	0.09	4.8
40	.17	4.7
60	.27	5.3
80	.35	5.4
	Av. =	5.0

[a] Recalculated, taking the proportion soluble in strong sulfuric acid as 100%.

[b] The 2-butene dissolved so much more slowly than the isobutene that it was counted merely as a diluent of the latter.

It is true that the values for K are only approximately constant in any one experiment. Nevertheless, the averages of these values become quite significant for the different gases.

It should be emphasized that Michael and Brunel did not carry out these experiments with a view to calculating absorption coefficients and it is a tribute to the accuracy of the data that this can be done with results so satisfactory as those given above.

2. When diluted with non-reacting gas, isobutene was absorbed at a rate proportional to the isobutene undissolved. The magnitude of the rate was, however, cut down in approximate proportion to the dilution (see Expts. 3 and 4).

This accords with the results from certain experiments of mine on the rates of absorption of olefins by sulfuric acid in rotating tubes at constant volume. The rate of solution was very closely proportional to the partial pressure of the olefin even when admixed with varying quantities of air.

The rates of absorption of the butenes into sulfuric acid may therefore be fairly well compared by their absorption coefficients, K, Table II, from which effects of changes in the gaseous volume, partial pressure of the olefin and time of shaking have been largely eliminated.

TABLE II

ABSORPTION COEPFICIENTS K FOR THE THREE BUTENES INTO SULFURIC ACID IN HEMPEL PIPETS

No.	Olefin	Concn. of H_2SO_4, %	Temp.. °C.	Absorption coefficient, K[a]
1	Isobutene (pure)	58.6	21–22	47×10^{-3}
2	Isobutene (pure)	58.6	28–29	105×10^{-3}
3	Isobutene (57.5%)	58.6	21–22	46×10^{-3}
4	Isobutene (51.8%)	58.6	28–29	75×10^{-3}
5	2-Butene (pure)	58.6	28–29	0.54×10^{-3}
6	2-Butene (pure)	76	29–30	10.0×10^{-3}
7	1-Butene (pure)	76	29–30	5.0×10^{-3}

[a] Calculated for the pure gas at atmospheric pressure.

TABLE III

RELATIVE RATES OF ABSORPTION OF THE BUTENES

From Table II			Relative rates of absorption into sulfuric acid[a]	
$\frac{K_2(\text{2-butene})}{K_1(\text{1-butene})}$	at 29–30°	2	1-butene	1
$\frac{K_3(\textit{iso}\text{butene})}{K_2(\text{2-butene})}$	at 28–29°	140–195	2-butene	2
			isobutene	280–390

[a] This last comparison will not hold broadly if the relative rates depend upon the concentration of the acid or the temperature. The effects of these two conditions on the absorption of olefins into sulfuric acid are now being investigated experimentally.

Summary

Calculations on the relative rates of absorption of the three butenes into sulfuric acid have been made from the experimental data of Michael and Brunel.

CERTAIN NEW OXIDATION REACTIONS OF ALDEHYDES

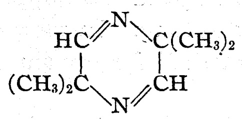
BY JAMES B. CONANT AND JOHN G. ASTON

RECEIVED JULY 12, 1928 PUBLISHED OCTOBER 6, 1928

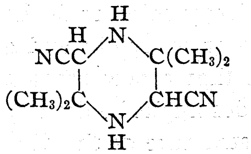
As a continuation of the quantitative study of the irreversible oxidation of organic compounds,[1] we have investigated the oxidation of aldehydes by reversible oxidizing reagents of known potential. In this work we employed the following oxidizing agents in dilute solution at SO°: potassium ferricyanide, potassium tungsticyanide, potassium molybdicyanide, potassium dichromate and ceric sulfate. The last two were used in molar sulfuric acid solution and the others in alkaline buffer solutions. The quantitative results showed that the reduction of these reagents by aliphatic aldehydes proceeded rapidly at certain acidities and that the results could be formulated in terms of "apparent oxidation potentials" as in previous papers from this Laboratory. An examination of the products of the reaction showed surprising complications, however. Instead of the expected oxidation to the corresponding acid, other reactions were apparently predominant in both the alkaline and the acid solutions. We have established that these reactions are the result of an oxidation in the a-position, which we have been able to study in some detail in the case of isobutyraldehyde. The difficulty of isolating products from dilute solutions containing inorganic reagents has prevented our obtaining equally satisfactory evidence with the other aldehydes. Therefore, this paper is concerned primarily with the behavior of isobutyraldehyde. The results of our quantitative study will be reported later.

The Formation of Dihydropyrazine and Piperazine Derivatives by the Action of Ferricyanide

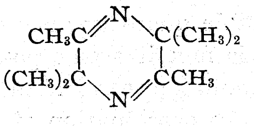
Isobutyraldehyde is oxidized by potassium ferricyanide at 80°, if the solution is made slightly alkaline by the slow addition of potassium hydroxide. In dilute solution (about 0.14 *M* with respect to aldehyde) the chief product is 2,2,5,5-tetramethyldihydropyrazine (I); the yield is about 27%. No *iso*butyric acid is produced. In more concentrated solutions (about 0.28 *M*) 2,2,5,5-tetramethyl-3,6-dicyanopiperazine (II) is also formed. The combined yield of the piperazine and dihydropyrazine derivatives amounted to about 60% of the aldehyde employed, but the iso-



I



II



III

---

[1] Conant and Pratt, THIS JOURNAL, 48, 3178, 3220 (1926).

lation of the dihydropyrazine from the more concentrated runs is unsatisfactory since it is contaminated with some oily material.

In this strange reaction the nitrogen atoms of the heterocyclic compounds have been gained at the expense of the ferricyanide ion, since ferric hydroxide and formic acid are also formed. The maximum yield of the two compounds from 0.14 mole of aldehyde corresponds to a gain of 0.126 g. atom of nitrogen. This would be made available by the complete decomposition of 0.021 mole of ferricyanide (about 10% of the equivalent amount of the oxidizing agent). The amount of ferric hydroxide actually obtained corresponded to the decomposition of 0.0130 mole of ferricyanide or 65% of this amount. The major part of the ferricyanide ion was reduced to ferrocyanide, which was isolated from the reaction mixture as crystalline potassium ferrocyanide. An electrometric titration of the reaction mixture also showed that at least 65% of the oxidizing agent was reduced to ferrocyanide.

Further insight into the mechanism of the reaction was obtained by studying the action of potassium ferricyanide in alkaline solution at 80° on methyl isopropyl ketone. The product of the oxidation in this case is the known hexamethyldihydropyrazine (III);[2] the yield was about 25%. The constitution of the tetramethyldihydropyrazine (I) follows from the analysis, molecular weight and the transformation by reduction into a piperazine derivative which yielded a di-nitroso compound. The action of hydrocyanic acid on the dihydropyrazine yielded the dicyanopiperazine (II), whose structure was thus established.

The fact that methyl isopropyl ketone yields a dihydropyrazine when oxidized with alkaline ferricyanide throws much light on the mechanism of the reaction with isobutyraldehyde. The α-oxidation of the ketone is the normal course of the oxidation and it seems quite certain that the α-amino ketone, $CH_3COCNH_2(CH_3)_2$, is an intermediate product. This substance is known to undergo condensation to hexamethyldihydropyrazine in alkaline solution.[2] As a by-product of this condensation another volatile basic material (probably a pyrrole derivative) is formed. We have also found a small amount of other volatile basic material in our reaction mixture. Further evidence of the existence of an intermediate product is afforded by the fact that the formation of hexamethyldihydropyrazine proceeds slowly after oxidation is complete. Thus, a reaction mixture from which no more dihydropyrazine could be distilled yielded an appreciable quantity after standing overnight and again distilling. In view of this fact it seems possible that a new preparative method for certain α-amino ketones and aldehydes might be developed.

An examination of the structure of the dihydropyrazine resulting from *iso*butyraldehyde as well as the analogy with the reaction of methyl *iso*-

---

[2] Gabriel, **Ber., 44, 65 (1911).**

propyl ketone shows that the fundamental mechanism is the oxidation of the a-carbon atom. It is the possibility of this reaction and not the presence of the aldehydic group which is responsible for the peculiar course of the reaction between isobutyraldehyde and ferricyanide. The mechanism by which the nitrogen is introduced into the organic molecule is obscure. It might involve the formation of the a-hydroxy aldehyde (or ketone) but this possibility appears to be eliminated by the fact that α-hydroxy-isobutyraldehyde yields no dihydropyrazine when heated with a mixture of ferri- and ferrocyanides in alkaline solution. Since the work reported below demonstrates that the a-oxidation of aldehydes in dilute solution is a regular reaction of these substances, we believe that the first step in the process is an oxidation (dehydrogenation) involving the elimination of the a-hydrogen atom. The first product is probably a highly reactive substance which combines with the complex cyanide forming the a-amino aldehyde (or ketone).

The dicyanopiperazine (11) is probably formed by the interaction of the dihydropyrazine and the hydrocyanic acid set free by the decomposition of a portion of the complex ion.

The oxidation of acetaldehyde by alkaline potassium ferricyanide at 80° yields no acetic acid, no volatile basic products and only a trace of ferric hydroxide. The reduction of the ferricyanide to ferrocyanide was evident both from the electrometric measurements and by the isolation of large amounts of potassium ferrocyanide. After concentration and precipitation of the inorganic salt by alcohol, a gummy material was left. It corresponded, however, to only 10% of the aldehyde employed. No satisfactory evidence as to its nature has yet been obtained and beyond the significant fact that no acetic acid is formed in the reaction, we are not able to make any statements in regard to the course of the reaction between fenicyanidc and acetaldehyde. The reaction of ferricyanide with other aliphatic aldehydes has not yet been investigated.

The a-Oxidation of Aldehydes in Acid Solution

In order to determine whether or not a-oxidation of aldehydes is a general reaction, we examined the action of a number of oxidizing agents in acid solution. Again, our most satisfactory results were obtained with isobutyraldehyde, though the facts given below prove beyond doubt that a-oxidation also takes place to some extent under certain conditions with *n*-butyraldehyde and acetaldehyde.

Potassium dichromate oxidizes a dilute solution of *iso*butyraldehyde in molar sulfuric acid at 80°, with the formation of acetone, carbon dioxide and *iso*butyric acid. In a solution 0.14 M with respect to both aldehyde and reagent the yield of acetone was **37%.** In more concentrated solutions (0.28 *M* to 0.56 *M*) less carbon dioxide (29 to 35%) and more *iso*butyric acid was obtained. The formation of acetone and carbon dioxide must be the result of the oxidation of isobutyraldehyde in the a-position. Isobutyric acid under the same conditions is not oxidized by dichromate but both a-hydroxy-isobutyric aldehyde and acid yield acetone.

The oxidation of *n*-butyraldehyde by dichromate in molar sulfuric acid at 80° yields considerable amounts of carbon dioxide. This must be the result of oxidation of the carbon chain, presumably in the a-position. The reaction was studied by determining both the evolution of carbon dioxide and the number of equivalents of oxidizing agent required for complete oxidation. In a 0.07 M solution the amount of a-oxidation was 25% as determined by the carbon dioxide; 3.6 hydrogen equivalents of dichromate were consumed per mole of aldehyde. The number of equivalents increased to 4.1 in a 0.035 M solution and 4.4 in a 0.018 M solution. The oxidation to *n*-butyric acid corresponds to two equivalents, to carbon dioxide and propionic acid to eight equivalents. Thus, on the basis of the amount of oxidizing agent used up, the process of moxidation comprised about 40% in the very dilute solutions. The amount of carbon dioxide did not increase above 25% but this is undoubtedly due to the difficulty of driving off and determining very small amounts of carbon dioxide in the more dilute solutions.

Ceric sulfate in molar sulfuric acid at 80° is rapidly reduced by *iso*butyraldehyde and in this case it was possible to obtain evidence of the formation of a-hydroxy-isobutyraldehyde in addition to acetone. Unfortunately the isolation of the hydroxy aldehyde from very dilute solutions is difficult and it was not possible to obtain the pure substance or a definite derivative. However, we developed a procedure for estimating the amount of this aldehyde in a dilute water solution which also contained acetone and isobutyraldehyde. The details of the procedure are given in the experimental portion of this paper. The method was carefully tested with known solutions of the three compounds. It depends on the different degree of volatility with steam of the three and on a rather specific reaction of the hydroxy aldehyde. This compound does not give the usual iodoform test but does give iodoform if the solution is warmed with an excess of sodium hydroxide.

Only about 20% of isobutyric acid was formed in the ceric sulfate oxidations. In addition to the a-hydroxy aldehyde, the acetone and the acid, one other product was shown to be present in small amounts. This was a crystalline solid melting at 166–169' and volatile with steam. Only about 0.01 g. per gram of aldehyde was obtained. The elucidation of its structure awaits further work.

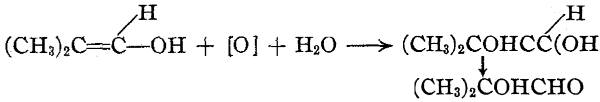
A few experiments were performed with potassium permanganate. A 0.5 *M* solution of this reagent was very slowly dropped into a 0.1 M solution of isobutyraldehyde in molar sulfuric acid at 80–90°. Distillation of the reaction mixture yielded a distillate which contained acetone and gave the characteristic tests for a-hydroxy-isobutyraldehyde. The amount of isobutyric acid was estimated by the Du Claux method; it amounted to only 40% of the theoretical quantity. Isobutyric acid itself is not attacked by permanganate under the same conditions.

Acetaldehyde is oxidized in the a-position, yielding carbon dioxide, if potassium permanganate in molar sulfuric acid in *very* dilute solution is employed. The temperature was 80–90°. One hundred cc. each of *0.25 M* solution of the reagent and *0.25 M* solution of the aldehyde were slowly dropped into *200* cc. of molar sulfuric acid which was rapidly stirred. If no excess of permanganate is allowed to accumulate, the amount of carbon dioxide evolved may correspond to as much as 20% a-oxidation. The yield of acetic acid (determined by the Du Claux method) drops accordingly. If the aldehyde and permanganate are mixed at once, the formation of acetic acid is practically quantitative.[3]

Cobaltic sulfate in 8 N sulfuric acid at 0° oxidizes isobutyraldehyde. The presence of both acetone and hydroxy aldehyde was shown by tests performed with the distillate; isobutyric acid is also formed; no estimation of the relative amounts of products was found possible. Palladium black and chloranil (tetrachloroquinone) slowly oxidize isobutyraldehyde and the presence of a-hydroxy aldehyde in the product was shown by tests performed on the distillate.

Mechanism of the Reaction

The most obvious explanation of our somewhat unexpected results would be that the enolic form of the aldehyde was oxidized by the addition of two hydroxyl groups.



$$\begin{array}{rcl} (CH_3)_2C{=}\overset{H}{C}{-}OH + [O] + H_2O & \longrightarrow & (CH_3)_2COHC\overset{H}{C}(OH)_2 \\ & & \downarrow \\ & & (CH_3)_2COHCHO \end{array}$$

Such an explanation seems to us improbable, however, for several reasons. In the first place, it gives no clue to the striking effect of dilution which so materially increases the amount of a-oxidation with acid oxidizing agents. In the second place, such reagents as ceric sulfate, cobaltic sulfate, palladium and chloranil and ferricyanide do not usually add oxygen to an ethylene linkage as demanded by this mechanism. A third argument against the above mechanism is the fact that the amount of enol present in a strongly acid solution must be very small and yet our results show that a-oxidation proceeds in molar sulfuric acid. The oxidation of the enolic form of acetaldehyde has been carefully studied by Evans and Adkins.[3,4] Using a solution 0.1 M in respect to both potassium permanganate and acetaldehyde, they found that at 25" or at 75° only acetic acid was formed if no alkali were added. With increasing amounts of potassium hydroxide the yield of acetic acid diminished and carbon dioxide and oxalic acid were formed. Obviously these investigators were studying the real oxidation of the enolic form of acetaldehyde. Such an

oxidation is an α-oxidation but would appear to be different from the α-oxidation we have studied by using very dilute solutions of permanganate and aldehyde in sulfuric acid.

If the oxidation of the enolic form according to the equation written above is eliminated, it is necessary to construct some other hypothesis. Since the quantitative results are important in this connection, we will postpone a further consideration of the mechanism until the next paper.

We are indebted to Mr. Carl O. Tongberg for his assistance during part of the experimental work.

Experimental Part

2,2,5,5-Tetramethyldihydropyrazine, .—One hundred and fifteen grams of potassium ferricyanide (0.35 mole) was dissolved in one liter of water in a flask fitted with a mechanical stirrer, a reflux condenser and dropping funnel. The flask and contents were heated in a bath at 80° and 10.0 g. of redistilled *iso*butyraldehyde (0.14 mole) were run in; 320 cc. of 1.0 N sodium hvdroxide was then dropped in over forty-five minutes with stirring. After all of the sodium hydroxide had been introduced, the mixture was allowed to stand for fifteen minutes at 80°, filtered from a red sediment of iron oxide (which weighed 1.11 g. after ignition) and then distilled slowly under ordinary pressure until 1000 cc. of distillate had been collected. The 1000 cc. of distillate was then distilled through a long spiral column until the refractive index of the distillate fell to that of water. The distillate was then continuously extracted for six hours, using 50 to 100 cc. of ether. After drying the ether was distilled from the extract until no more ether passed over. On cooling the residue crystallized. Most of the remaining ether was removed by applying suction to the flask for two or three minutes after cooling. The crystals after drying between filter paper melted at 76–81°. The yield was 2.62 g. (27.5% of the theoretical). The compound was purified by sublimation in vacuum and by drying over dehydrite. It melted at 83–84' and distilled at 160° without decomposition. It is very soluble in water, forming a weakly basic solution which turns methyl orange but not phenolphthalein. A dilute solution gives a yellow precipitate with bromine water and a white precipitate on adding an equal volume of saturated mercuric chloride solution. The application of the bromine test to a fresh reaction mixture showed that the dihydropyrazine was present immediately after the oxidation was complete.

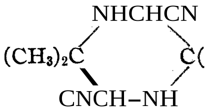
No detectable amount of dihydropyrazine was formed when α-hydroxy-*iso*butyraldehyde was substituted for isobutyraldehyde.

Anal. Calcd. for $C_8H_{14}N_2$: C, 69.6; H, 10.1; N, 20.3. Found: C, 69.5; 69.2; H, 10.4, 10.2; N (Kjeldahl), 20.2. *Equiv.* Weight by titration with standard HCl (methyl orange end-point), calcd., 69.0. Found: 68.2. *Mol. wt.* in benzene (freezing point): Sample, 0.1240; benzene, 17.37 g.; At = 0.257°, 0.263°. Calcd. for $C_8H_{14}N_2$: 138. Found: 141, 136.

Dinitroso-2,2,5,5-tetramethylpiperazine, .—The tetramethyldihydropyrazine was reduced to the corresponding piperazine by means of sodium and alcohol. The piperazine was distilled with steam from the diluted reaction mixture and the distillate treated with hydrochloric acid and potassium nitrite. The dinitroso compound separated as a white crystalline precipitate; 3 g. of the dihydropyrazine yielded 1.8 g. of crude product, m. p. 208–210°. It was recrystallized from 5% acetic acid and melted at the same point.

Anal. Calcd. for $C_8H_{16}N_4O_2$: C, 48.0; H, 8.11; N, 28.0. Found: C, 47.9; H, 5.1; N, 28.1.

2,2,5,5-Tetramethyl-3,6-dicyanopiperazine,



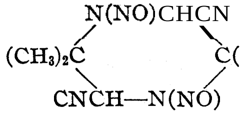
$$(CH_3)_2C\begin{matrix}NHCHCN\\ \\ CNCH{-}NH\end{matrix}C(CH_3)_2$$

—One hundred and eighty-five grams of potassium ferricyanide (0.56 mole) dissolved in 400 cc. of water, 10 g. of isobutyraldehyde (0.14 mole) and a solution of 14.3 g. of sodium hydroxide in 100 cc. of water were employed and the procedure was identical with that described in the preparation of the dihydropyrazine; the sodium hydroxide was added during thirty minutes, and the reaction mixture was then stirred for one hour longer at 80–85°. A small amount of oil formed on the surface of the reaction mixture. This on cooling solidified to crystals. The whole reaction mixture was continuously extracted for ten hours with 50-100 cc. of ether. The ether extract was mixed with a considerable quantity of white solid which was filtered off and dried between filter paper, m. p. 189–192°; yield, 2.0 g. The product after being twice recrystallized from benzene melted at 193–194.5°. The reaction mixture, after the ether extraction, was filtered from the fine red precipitate of ferric hydroxide, which when dried and ignited weighed 1.04 g. (0.0065 mole of Fe_2O_3, corresponding to 0.0130 mole of ferricyanide). The ether extract, after filtering off the solid already mentioned, was dried and distilled and the residue fractionated; the bulk of the product boiled at 170°; yield, 2.3 g. This fraction crystallized, but the crystals of the tetramethyldihydropyrazine were mixed with some thick oily materials.

Anal. Calcd. for $C_{10}H_{16}N_4$: C, 62.4; H, 8.4; N, 29.2. Found: C, 62.5; H, 8.6; N, 29.5. Mol. wt. Calcd. for $C_{10}H_{16}N_4$: 192. Found: (1) in acetone boiling-point method: 0.3360 g. (second increment) 14.2 g. of acetone; At, 0.211°, mol. wt., 187. (2) By the micro method in camphor: 206, 225.

The compound was also prepared by heating a 1% aqueous solution of 2,2,5,5-tetramethyldihydropyrazine at 100°, passing in hydrocyanic acid gas and allowing the mixture to stand for one hour at 70–90°. The dicyano compound separated as a white solid, the yield was 1.4 g. (theoretical). The identity of the material with that formed by the interaction of femcyanide and isobutyraldehyde was established by a mixed melting point.

Dinitroso-2,2,5,5-tetramethyl-3,6-dicyanopiperazine,



$$(CH_3)_2C\begin{matrix}N(NO)CHCN\\ \\ CNCH{-}N(NO)\end{matrix}C(CH_3)_2$$

—A solution of 1.0 g. of recrystallized 2,2,5,5-tetramethyl-3,6-dicyanopiperazine in 50 cc. of glacial acetic acid was treated with 1.2 g. (12% excess of theoretical for dinitroso derivative) of n-butyl nitrite at room temperature. After standing overnight the crystals which had separated were filtered off, washed with acetic acid and dried between filter paper, m. p. (with violet decomposition), 178° (placed in baths below this temperature and slowly heated, the decomposition point is always 178°, if placed in baths somewhat above 178°, some time elapses before the decomposition takes place), yield, 1.04 g., 80% of the theoretical. Recrystallization from benzene did not raise the melting point.

Anal. Calcd. for $C_{10}H_{14}N_6O_2$: C, 48.0; H, 5.64; N, 33.6. Found: C, 48.0; H, 5.9; N, 35.3.

Investigation of Acidic Products Formed by the Interaction of Ferricyanide and Isobutyraldehyde

(a) Experiments with Buffer Solutions.—3.29 g. of potassium ferricyanide and 4.22 g. of potassium ferrocyanide were dissolved in one liter of the borate buffer which was made by adding a solution of 326 cc. of 0.2 *M* sodium hydroxide to 1000 cc. of 0.2 *M* boric acid 0.2 M in potassium chloride. The mixture was heated to 80° and 0.724 grams (0.01 M) of freshly distilled isobutyraldehyde in 50 cc. of water was added with vigorous mechanical stirring. The oxidation proceeds fairly rapidly in this buffer at 80° as was shown by the change of potential of a platinum electrode in a number of similar experiments. The mixture was stirred for twenty minutes at 80° and then a further 3.29 g. of potassium ferricyanide was added and the mixture stirred for five hours at 80°. At the end of this time the mixture was cooled and 10 cc. of 35% sodium hydroxide added to neutralize all of the boric acid; the solution was evaporated under reduced pressure to a small volume, acidified with sulfuric acid, then continuously extracted for six hours with ether. The ether solutions thus obtained contained boric acid and had an odor of hydrocyanic acid. The ether was distilled off and the residue dissolved in water. An aliquot portion of the aqueous solution thus obtained was titrated with standard sodium hydroxide, using a quinhydrone electrode. The electrometric end-point showed that the amount of acid present corresponded to only 0.0030 mole in the original reaction mixture (compared with 0.010 mole of aldehyde employed). The potential of the mid-point corresponded to a K_A of 1.42×10^{-4} for the acid (K_A for formic acid $= 2.14 \times 10^{-4}$; for isobutyric acid, 1.48×10^{-5}). Parallel experiments in which isobutyric acid was added to the buffer solution showed that our procedure extracted at least 95% of the material from a 0.01 M solution. It was also established that a titration using the quinhydrone electrode was satisfactory in the presence of boric acid and small amounts of hydrocyanic acid and that the value of K_A for the acid present could be determined with an accuracy of 3040%.

The fact that the acid which was extracted was formic acid was further established by evaporating the solution and testing the salt for reducing properties. It reduced mercuric oxide and silver nitrate on heating. As a further confirmation that isobutyric acid was not obtained, the oxidation of isobutyraldehyde by ferricyanide was carried out as above, using a phosphate buffer of $P_H = 10.4$, 0.2 M in phosphate ion, in which the oxidation proceeds more rapidly. The ether extraction of the solution after concentration and acidification yielded only about 30% of the theoretical quantity of acid. This acid on conversion into sodium salt gave no crystalline *p*-toluide when heated with hydrochloric acid and *p*-toluidine; a blank with isobutyric acid showed this to be a sensitive test for this acid.

(b) Oxidation Using Minimum Quantities of Sodium Hydroxide.—One hundred and thirteen grams (0.343 mole) of potassium ferricyanide was dissolved in one liter of water in a 2-liter, round-bottomed flask fitted with a condenser, a stirrer, two bright platinum wire electrodes, a buret dropping funnel and a saturated potassium chloride bridge leading to a calomel electrode. The whole was heated to 80° by immersion in a bath at 80°. The electromotive force of the system was read on a potentiometer. 10.3 g. (0.143 mole) of isobutyraldehyde dissolved in 150 cc. of water was added from the dropping funnel. 1 *N* sodium hydroxide was added from the buret until the potential had fallen to a value which then remained constant, indicating that the reaction was complete; a total of 313 cc. of sodium hydroxide was added. The solution was removed from the bath and after cooling was found to be neutral to phenolphthalein and basic to methyl orange. Titration of a sample showed that 100 cc. of 1 N acid would be required to neutralize the entire batch to the methyl orange end-point; therefore 0.313 mole of sodium hydroxide was neutralized in the course of the reaction, calculated from the phenolphthalein end-point and 0.213 calculated from the methyl orange end-point. These amounts correspond to 2.19 and 1.5 moles per mole of aldehyde, respectively. On the basis of the reaction $2K_2Fe(CN)_6 + 2KOH \longrightarrow 2K_4Fe(CN)_6 + H_2O + 0$, it is seen that if one molecule of the aldehyde takes up one atom of oxygen to yield a neutral substance, two equivalents of hydroxyl ion are used up. The formic acid which was found to be produced to the extent of about 0.3 mole per mole of aldehyde by the decomposition of ferricyanide would be half taken care of by the potassium ions of the potassium ferricyanide; 0.15 mole of free acid would thus be produced and about 0.3 mole of the weakly basic dihydropyrazine. The dihydropyrazine is sufficiently basic to turn methyl orange but not phenolphthalein; the discrepancy between these two end-points is thus accounted for as well as the slight excess over two moles of alkali required for the complete neutralization to phenolphthalein.

Determination of the Amount of Potassium Ferrocyanide Formed by the Reduction of Potassium **Ferricyanide** at **80°** by *Iso***butyraldehyde.**—A solution of 5 cc. of 0.05 M potassium ferricyanide in 60 cc. of 0.2 N potassium sulfate was heated in a thermostat at 80° in a cell equipped with two bright platinum electrodes, a mechanical stirrer and a saturated potassium chloride bridge connecting it with a saturated calomel electrode. One cc. of a 0.125 M solution of isobutyraldehyde was run in, followed by the slow addition of 5 cc. of 0.517 *N* sodium hydroxide over five minutes. Rapid reduction took place, the potential falling from 0.256 volt to -0.022 volt after all the alkali had been added. A blank was run at 80° using potassium *ferrocyanide* instead of ferricyanide without adding isobutyraldehyde, but 5 cc. of 0.056 N sodium hydroxide was added. The excess alkali in both experiments was neutralized by the addition of the calculated amount of sulfuric acid and 7 cc. of 2 N acetic acid was added to each cell after cooling to room temperature. The amount of ferrocyanide was determined by electrometric titration with 0.01 N potassium dichromate,[5] the experiment with the pure ferrocyanide serving to standardize the procedure. In two experiments 14.9 and 15.8 cc. of 0.01 N dichromate were required as compared to 25 cc. calculated from the ferricyanide used and 22.5 cc. by standardization using ferrocyanide in the blank run. The yield of ferrocyanide was thus 63–70% of the theoretical.

Oxidation of Methyl Isopropyl Ketone with Potassium **Ferricyanide.**—A solution of 115 g. of potassium ferricyanide in one liter of water in a flask fitted with *a* reflux condenser, mechanical stirrer and dropping funnel was heated in a bath at 80°, 11.4 g. of methyl isopropyl ketone added and 320 cc. of 1.0 N sodium hydroxide dropped in slowly over twenty-five minutes with vigorous mechanical stirring. The reaction mixture was allowed to stand for about thirty minutes at 80° after the alkali had been added and then slowly distilled until one liter had passed over. The clear distillate was redistilled slowly through a long spiral column. A crystalline solid separated in the receiver; it weighed 2.9 g. and melted at 85–87". On again distilling the solution from which the the solid separated, more solid was obtained in the new distillate. The residue from the original reaction mixture also yielded a further quantity when after four days' standing 200 cc. was distilled from it. In this case the solid separated from the distillate without redistillation, which indicates that the four days' interval had caused the formation of the compound from some intermediate (presumably the a-amino ketone). In all 6.0 g. of hexamethyldihydropyrazine hexahydrate, m. p. 85–87°, was obtained, 33% of the theoretical amount. The identity of the compound[2] was established by the melting point of the hydrate (87–89° after steam distillation; Gabriel gives 88–89°) and anhydrous material (m. p. 65–63"; Gabriel gives 69–69.5°) and by analysis.

The Oxidation of Acetaldehyde by Potassium Ferricyanide at 80° in Alkaline Solution.—A solution of 180 g. (0.546 mole) of potassium ferricyanide in one liter of water in the same apparatus that was used in oxidizing iso-butyraldehyde under these same conditions was heated to 80° and a solution of 10.75 g. (0.245 mole) of acetaldehyde in 100 cc. of water was added. 1 N sodium hydroxide was then added slowly until the potential of two bright platinum electrodes in the solution against a

---

[5] The point of inflection in the e.m.f.-cc. curve at the end-point during the titration of potassium ferrocyanide in acid solution with potassium dichromate at these concentrations is not as sharp as one would expect. The titration curves show certain abnormalities and deviate from the theoretical logarithmic curve, but experiments showed that the comparative results are quite accurate.

saturated calomel half-cell had fallen to a steady value, indicating that the reaction was complete; 598 cc. of 1 *N* sodium hydroxide was required. The solution after cooling was alkaline; 74 cc. of 1 N sulfuric acid was required to neutralize this solution. Thus 524 cc. of 1 N sodium hydroxide had been used up, which corresponds to 2.14 equivalents of alkali per mole and demonstrates that practically no acidic substance was produced during the oxidation of acetaldehyde. That reduction of the ferricyanide had taken place was shown by the fall in potential of the system from 0.345 volt to −0.0301 volt. Only a trace of iron oxide was precipitated.

A run exactly the same as the one above was evaporated in vacuum in a bath at 50–55° to a volume of 300 cc., the distillate being collected in an ice-cooled receiver. An equal volume of alcohol was added to the residue. The salts thus precipitated were filtered off. This material was apparently mostly potassium ferrocyanide, giving a blue precipitate with ferric chloride. The mother liquor from the alcohol precipitated was evaporated in a vacuum below 40° to a volume of 80 cc. and 150 cc. of alcohol was added to precipitate the rest of the salts. Very little material was thrown out by this procedure. The solution after filtering was evaporated almost to dryness in a vacuum. A thick sirup was left behind; weight, 2 g. Analysis by the Kjeldahl method showed that this material contained 5.6% of nitrogen. The distillates were examined for possible oxidation products of acetaldehyde but nothing was found.

The Products of Oxidation of Isobutyraldehyde by Potassium Dichromate in Dilute Acid Solution at 80°.—A solution of 27.2 g. (0.555 equivalent) of potassium dichromate and 30 cc. (1.08 equivalents) of concentrated sulfuric acid was placed in a 2-liter flask fitted with a reflux condenser, dropping funnel and mechanical stirrer. The flask and contents were heated in a bath at 80°. With vigorous stirring, 10.0 g. (0.139 mole) of *iso*-butyraldehyde was rapidly run in. The mixture was kept at 80° for three hours. The solution was then cooled. Its volume was 1040 cc. Titration of a sample with 0.05 M ferrous ammonium sulfate in acid solution, using potassium ferricyanide as outside indicator, showed that this solution was 0.072 N in dichromate. On refluxing a sample and again titrating, it was found that no more dichromate was used up. Thus 1 mole of *iso*butyraldehyde had used up 3.43 equivalents of potassium dichromate. From the solution 865 cc. was distilled at ordinary pressures. The first fractions had a distinct odor of acetone. By titration 0.0573 mole of isobutyric acid was found in the distillate. The distillate was neutralized and distilled slowly, using a long column. Three grams of material distilled over at 56.5° and the thermometer then rose rapidly to 99°. The first fraction on redistillation yielded 2 g. of a liquid, b.p. 56.5–60°, which was identified as acetone by the formation of dibenzalacetone.

The solution from which the acetone was distilled was concentrated to

20 cc., acidified with 15 cc. of 6 N sulfuric acid and extracted with ether. After drying with potassium sulfate the ether was distilled from the extract through a long column and the liquid residue fractionated: Fraction 1, 90–151°, water + *iso*butyric acid, 1.5 g.; Fraction 2, 151–153°, *iso*butyric acid, 2.02 g.

A similar experiment in which a-hydroxy-isobutyric acid was substituted for the *iso*butyraldehyde also yielded acetone.

Quantitative Study of the **α-Oxidation** of Isobutyraldehyde and *n*-**Butyraldehyde** in Different Concentrations. (a) Apparatus.—A 500-cc. round-bottomed, three-necked flask was fitted with a mechanical stirrer with a mercury seal, a reflux condenser connected to two U-tubes containing sulfuric acid and glass beads and provided with a tube going to the bottom of the flask, which served as a nitrogen inlet. A dropping funnel fitted with a pressure equalizer, in the form of a by-pass connected to the nitrogen stream, was fitted directly into this inlet tube. Nitrogen could be let through the by-pass so that it swept out the funnel and passed through the solution in the flask. The nitrogen was purified by passing through two towers of soda lime.

(b) Procedure.—A solution of potassium dichromate and sulfuric acid in 250 cc. of water was made in the flask and refluxed for one-half hour, keeping a current of nitrogen passing through the flask. The flask was then placed in a bath held at 80° and a weighed potash bulb similar to that used in combustions was connected to the other end of the two U-tubes containing sulfuric acid and glass beads. With rapid mechanical stirring the *iso*butyraldehyde either as pure liquid or solution was introduced and the reaction allowed to run at 80°. The solution was then refluxed for one-half to one hour to drive out all of the carbon dioxide. A slow current of carbon dioxide-free nitrogen was passed through the flask during the entire process. The bulbs were then disconnected and weighed with the usual precautions. The reaction mixture was then washed from the flask into a 500-cc. graduated cylinder, thoroughly mixed by blowing air through and its volume read to 2 cc. A buret was then filled with the solution and a titration made against a standard ferrous ammonium sulfate solution which was approximately 0.1 N, using dilute potassium ferricyanide as outside indicator. The volume in which the titration was carried out varied from 100–300 cc.; five cc. of concentrated hydrochloric acid per 100 cc. was always added. In the more concentrated solutions a portion of the reaction mixture was diluted before titration, so that the concentration of dichromate was about 0.1 N.

In all cases the completeness of the reaction was tested by subsequently refluxing the solution for two hours and titrating again. If there was no appreciable amount of dichromate used up the reaction was assumed to be complete.

The results are summarized in Table I; the per cent. a-oxidation is calculated directly from the amount of carbon dioxide and also from the number of equivalents of dichromate used up per mole, assuming for *iso*butyraldehyde the reaction

$$(CH_3)_2CHCHO + 30 \longrightarrow (CH_3)_2CO + CO_2 + H_2O$$

and for n-butyraldehycle

$$CH_3CH_2CH_2CHO + 40 \longrightarrow CH_3CH_2COOH + CO_2 + H_2O$$

TABLE I

THE AMOUNT OF α-OXIDATION IN THE REACTION OF BUTYRIC ALDEHYDES WITH POTASSIUM DICHROMATE AT 80° AT VARIOUS TEMPERATURES~

[a] The sulfuric acid and potassium dichromate were dissolved in 250 cc. of water except when a star indicates that the aldehyde was added as a solution in 25 cc. of water. In these cases 225 cc. of water was used. In Experiment B1, the remainder of the reaction mixture was distilled in steam till no more acid came over. The distillate was diluted to 500 cc. Titration showed it to be 0.1702 N in acid. Allowing for the reaction mixture used in titration of dichromate, from this result we calculate that 0.666 moles of acid are yielded per mole of aldehyde.

Action of Potassium Dichromate on n-Butyric Acid and Isobutyric Acid in Acid Solution at **80°** in the Presence of Chromic Sulfate.—To a solution of 100 cc. of water, **3** cc. of concentrated sulfuric acid, 2.73 g. of potassium dichromate, and 9.27 g. of chrome alum (potassium chromium sulfate) was added 1.22 g. of isobutyric acid in one experiment and 1.22 g. of n-butyric acid in another. The mixtures were refluxed for four hours and the solution titrated for dichromate with ferrous ammonium sulfate as has been already described for the aldehyde oxidations. It was found that in both cases no detectable amount of potassium dichromate had been reduced.

The Oxidation of Isobutyraldehyde by Ceric Sulfate at 80°.—A mixture of 300 cc. of 0.6 M sulfuric acid and 3.0 g. (0.042 mole) of *iso*butyraldehyde was heated to SO° in a flask equipped with a stirrer, dropping funnel, reflux condenser and nitrogen-inlet tube. A total of 300 cc. of 0.156 N ceric sulfate solution (containing 10 cc. of sulfuric acid) mas dropped in slowly during two hours; the reduction of the ceric salt was evident by the decolorization. The reaction mixture was neutralized with 60 g. of sodium bicarbonate and slowly distilled through a long spiral column. Fractions of 3 to 10 cc. each were collected and tested with (a) Schiff's reagent (decolorized fuchsine), (b) Tollens reagent, (c) by adding a few drops of a saturated solution of p-nitrophenylhydrazine hydrochloride, (d) by adding a few drops of iodine solution followed by enough 10% sodium hydroxide to decolorize, (e) by boiling for thirty seconds with 3 drops of 10% sodium hydroxide and then applying test d. Distillation of a number of dilute solutions of acetone, isobutyraldehyde, and α-hydroxy-isobutyraldehyde (prepared by hydrolysis of α-bromo-*iso*butyraldehyde) showed that it was possible to identify these compounds in the presence of each other by means of this fractionation and these tests. The distillation of 37 cc. from 500 cc. of a 1 per cent, isobutyraldehyde solution is sufficient to remove so much aldehyde that subsequent fractions give no test with Schiff's reagent, whereas with the hydroxy aldehyde, the aldehyde continues to come over and give this test from even a 0.2% solution after 100 cc. have been distilled. The iodoform test (d) is specific for acetone and the same test after heating with sodium hydroxide (e) is specific for the hydroxy aldehyde in the absence of acetone. The acetone comes over completely in the first tenth; test (e) is then specific. The formation of an amorphous yellow precipitate with *p*-nitrophenylhydrazine (test c) and the Tollens test (test b) also persisted much longer when a solution of the hydroxy aldehyde was distilled. These several confirmatory tests were always available and exactly the same procedure was used in testing a reaction mixture that was used in the blank runs.

It was found that after one-tenth of the reaction mixture had been distilled tests a, b, c and e were still given strongly by the distillate. This proves the presence of hydroxy-isobutyraldehyde. By comparing the tests with those given by corresponding distillates from a solution of known concentration of hydroxy aldehyde, it was estimated that the reaction mixture contained 0.5 g. of a-hydroxy-isobutyraldehyde. The first fractions of the distillate gave the iodoform test in the cold, proving the presence of acetone.

The amount of isobutyric acid formed was estimated by acidifying with sulfuric acid the residue from the distillation just described and again distilling. The first 4 cc. was 0.025 N in acid as determined by titration; after 400 cc. had been collected the distillate was running only 0.0025 N in acid. The total acid distilled over up to this point was 0.00329 mole or only 14% of the aldehyde employed. In another similar experiment an estimate of the isobutyric acid was made by the method of Duclaux.[6] According to this author the ratio of acidity in the first three 10cc. portions is 1:0.83:0.64 and 25% of the acid distils in the first 10 cc. The corresponding numbers found on distilling the acidified reaction mix-

ture were 1: 0.82: 0.60. Assuming that 25% of the acid was distilled in the first 10 cc., the total *iso*butyric acid in the reaction mixture was found to be only 22% of the theoretical based on the aldehyde employed.

Oxidation of Isobutyraldehyde with Permanganate in Dilute Sulfuric Acid.—The experiments were carried out by dropping a dilute solution of the permanganate into a well-stirred solution of the aldehyde in molar sulfuric acid. In a typical experiment 0.025 mole of aldehyde in 200 cc. of molar sulfuric acid was treated with 0.008 mole of potassium permanganate in 100 cc. of water at 25°. On distilling through a fractionating column the fractions of the distillate gave strong positive tests for acetone and α-hydroxy-isobutyraldehyde. The method of testing was the same as that described above. The same result was obtained at 80°.

Oxidation of Acetaldehyde with Potassium Permanganate in Acid Solution.—The amount of carbon dioxide formed in the oxidation of acetaldehyde was determined in the same manner as that described above in the experiments with isobutyraldehyde and dichromate. The method was tested by the liberation of carbon dioxide from bicarbonate; the recovery of carbon dioxide was 80%. The temperature was 85–95°. Both the aldehyde and the permanganate in dilute solutions were slowly dropped into 200 cc. of molar sulfuric acid which was stirred. The maximum yield of carbon dioxide was obtained by operating in such a way that no excess of permanganate was ever present as determined by the color. One hundred cc. of 0.25 *M* permanganate and 100 cc. of 0.25 M acetaldehyde solution were employed. The extent of α-oxidation as measured by the carbon dioxide evolution varied from 3.2 to 22%. The amount of acetic acid formed was estimated by distilling over one-tenth and titrating the distillate. A blank run with 0.020 mole of acetic acid and the same volume of sulfuric acid and water showed that 6.2% of the acid distilled in the first tenth. Using this factor, the amount of acetic acid was found in a series of runs to vary from 0.022 mole to 0.017. The highest amount corresponded to the lowest yield of carbon dioxide and vice versa.

Oxidations of Isobutyraldehyde with Other Reagents.—Isobutyraldehyde (0.025 mole) in 670 cc. of 8 N sulfuric acid containing 0.055 mole of cobaltic sulfate (prepared by electrolytic oxidation) was allowed to stand at 0° for one hour and overnight at room temperature. The reduction of the cobaltic salt was evident at 0° by the color change. The material was distilled in the usual way and the fractions of the distillate were tested. Strong tests for acetone and α-hydroxy-isobutyraldehyde were obtained. The first tenth of the distillate was titrated and the total *iso*butyric acid calculated from a factor obtained in a blank run using the same sulfuric acid and pure isobutyric acid. The yield of isobutyric acid was estimated as 25% but there was some unchanged aldehyde so that not much significance can be attached to this figure.

A suspension of 0.020 mole of chloranil and 0.5 g. of palladium black in 400 cc. of water was heated to boiling in nitrogen and 0.011 mole of *iso*-butyraldehyde in 100 cc. of water slowly added. The reaction took one hour. After cooling and filtering, the solution was distilled in the usual way. The distillate gave a strong test for a-hydroxy-isobutyraldehyde but contained no acetone.

Summary

1. The oxidation of isobutyraldehyde by ferricyanide in alkaline solution at 80° yields 2,2,5,5-tetramethyldihydropyrazine and 2,2,5,5-tetramethyl-3,6-dicyanopiperazine and no isobutyric acid. From methyl *iso*-propyl ketone under the same conditions hexamethyldihydropyrazine is formed. The reaction involves the oxidation of the a-carbon atom and the gain of nitrogen from a fraction of the complex cyanide.

2. The oxidation of isobutyraldehyde with ceric sulfate at 80° in acid solution yields acetone and a-hydroxy-isobutyraldehyde as well as *iso*-butyric acid. The same products are formed in acid solution by potassium permanganate and cobaltic sulfate. Chloranil and palladium yield a-hydroxy-isobutyraldehyde.

3. Potassium dichromate in acid solution at 80° oxidizes *iso*butyraldehyde in the *α*-position, yielding acetone to the extent of 40% in very dilute solutions. The process of a-oxidation is favored by dilution. *n*-Butyraldehyde is also oxidized in the a-position, as shown by the formation of carbon dioxide.

4. Potassium permanganate oxidizes acetaldehyde in acid solution at 80°, yielding carbon dioxide as well as acetic acid if precautions are taken to keep the reactants in *very* dilute solution with an excess of aldehyde.

THE ABSORPTION SPECTRA OF SOME PHTHALEINS AND SULFONEPHTHALEINS OF PHENOL AND ORTHO-CRESOL[1]

BY R. C. GIBBS AND C. V. SHAPIRO[2]

RECEIVED JULY 17, 1928 PUBLISHED OCTOBER 6, 1928

In continuation of our previous investigations[3] on the absorption spectra of compounds of the triphenylmethane series, data are now presented for some phthalein and sulfonephthalein derivatives of phenol and o-cresol.

---

[1] The investigations upon which this article is based were supported by grants from the Heckscher Research Foundation for the Advancement of Research, established by August Heckscher at Cornell University.

All of the compounds used in the course of the present research were prepared at this Laboratory under the direction of the late Professor W. R. Orndorff and were of analytical purity.

Some preliminary work here on the ultraviolet absorption of these compounds[4] in various solvents and a few reports on their absorption in the visual region in acid and alkaline solutions[5] have been published.

Phenoltetrachlorophthalein, o-cresolphthalein and *o*-cresoltetrachlorophthalein are typical lactoid phthaleins, which yield colorless solutions in neutral solvents. Their absorption spectra in absolute ethanol solution, together with that of phenolphthalein[6] in the same solvent, Fig. 1, are characterized by a pair of bands in the region of frequency numbers, 3500 to 3700. Similar bands have been found for a large number of benzenoid compounds of the triphenylmethane series,[7] of which many are lactones of the phthalein class, but some are carbinols of triphenylmethane derivatives. It is therefore believed that these bands are characteristic not of a single typical atom or group of atoms but rather of the molecule as a whole, when all three benzene nuclei are in their normal, benzenoid state.

It is extremely unlikely that the methane carbon atom in triphenylmethane derivatives, even when unsaturated as represented by the quinoid state of the molecule, can be the seat of absorption in the wave length range from the visible region down to the ultraviolet at about 2300 Å., as recently suggested by Vogt.[8] The aliphatic hydrocarbons exhibit absorption only in the extreme ultraviolet below 1900 Å. while the simple, unsaturated hydrocarbons have bands in the region of 2200 to 1900 Å.[9] On the other hand, as is well known, benzene shows strong, banded absorption in the middle ultraviolet from 2700 to 2300 Å. and the effect of changing from the benzenoid to the quinoid state with the production of visible color, that is, the production of absorption in the visual region, is well illustrated by comparison of the absorption spectra of hydroquinone and benzoquinone.[10] In a system consisting of several benzene nuclei and a methane, or other simple type of hydrocarbon carbon atom, the absorption will therefore be due entirely to the combined effects of the benzene nuclei. This hypothesis of the negligible part played by the central carbon atom in determining the absorption is neatly confirmed by unpublished results obtained at this Laboratory on the absorption spectrum of a triphenyl derivative of germanium,[11] which was found to be of a type very similar to that of triphenylmethane.

The tetrachlorophthaleins each have two more bands in addition to the pair cited above, one to the side of longer, the other to the side of shorter wave lengths. Comparing phenol- and o-cresolphthalein, it is seen that the bands for the latter are shifted toward longer wave lengths and the same relation holds between their tetrachloro derivatives. The effect of chlorine substitution in the phthalic acid residue, however, in spite of a large increase of molecular weight, is to shift the bands toward shorter wave lengths, as is evident if the bands in common for phenol- and phenoltetrachlorophthalein and for o-cresol- and *o*-cresoltetrachlorophthalein as given in Table I are compared.

substances whose constitution has been the subject of some debate.[12] Orndorff and Sherwood[12b] have suggested that, because phenolsulfonephthalein is a sulfonic acid derivative of benzaurin, a strongly basic compound, it probably forms an inner salt. In aqueous solution, however, they postulated the addition of a molecule of water, bringing about the formation of a quinoid hydrate. If this theory were correct, it is to be expected that both phenolsulfonephthalein and **o-cresolsulfonephthalein** would exhibit different types of absorption in aqueous and absolute ethanol solution, since in the latter solvent hydrate formation could not occur. It has previously been shown that a sharp differentiation between the quinoid and quinoid hydrate forms, as found in fresh and faded solutions, respectively, of fuchsone, benzaurin and aurin,[13] can be readily obtained by means of their absorption spectra. In the present instance the spectroscopic evidence completely confirms the existence of the quinoid form, or inner salt, in alcoholic, and the quinoid hydrate in aqueous solution. Figs. 2 and 3, respectively, show the absorption curves for phenolsulfonephthalein and o-cresolsulfonephthalein in both solvents. Curve A in each case is for the aqueous solution; the curves are entirely similar, with the bands for o-cresolsulfonephthalein shifted slightly toward longer wave lengths. For the absolute ethanol solutions Curves B of Figs. 2 and 3 are obtained and they are of a radically different type from the "A" curves. The

assignment of the inner salt configuration to these sulfonephthaleins in ethanol solution is based on the similarity of their absorption curves to those obtained for the sulfuric acid solutions, Pigs. 4 and 5. In the latter case salt formation occurs through the neutralization of the basic, quinoid oxygen by the sulfuric acid and it is reasonable to assume that the formation of an inner salt in neutral alcoholic solution by the sulfonic acid radical gives rise to a similar distribution of intramolecular forces, which uniquely determine the nature of the absorption spectrum. It is necessary to work in absolutely dry ethanol and with perfectly dry samples of the sulfonephthaleins in order to obtain this absorption characteristic of the inner salt, as the formation of the hydrate readily takes place in the presence of traces of water. The effect of minute traces of moisture, which cannot after all be completely avoided, is apparent in both of the "B" curves, for a weak band is found in the region of frequency number 2300 which is evidently related to the strong band occurring at the same approximate position for the aqueous solutions. If more water is present, as in a 95% ethanol solution, hydrate formation is complete and the solution has the bright yellow color of an aqueous solution instead of the salmon color in absolute ethanol. This accounts for the type of curve obtained by Howe and Gibson[4] for their "alcoholic" solution of phenolsulfonephthalein, which evidently contained a fair amount of water, since the absorption recorded by them resembles that here presented for an aqueous solution.

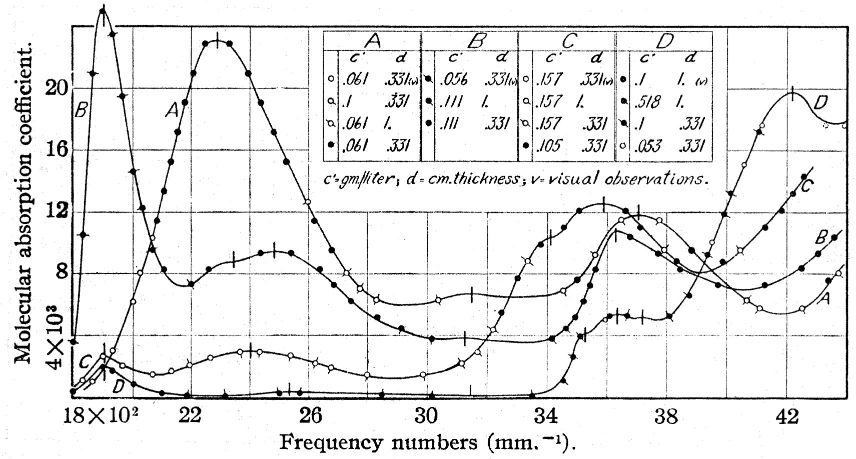

Fig. 3.—o-Cresolsulfonephthalein—neutral solutions: *A*, aqueous; *B*, absolute ethanol—fresh solution; *C*, solution B—after standing for one year; D, diethyl ether—absolute ethanol solution.

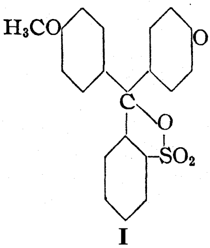
The formation of a hydrate in aqueous solution is not observed with all sulfonephthaleins. Hydroquinolsulfonephthalein[14] exhibits the same ab-

---

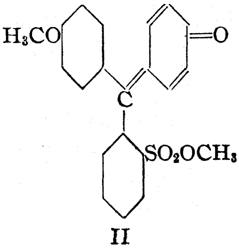
[14] Shapiro, This Journal, 50, 1772 (1928).

sorption in both aqueous and ethanol solution and this is of the acid type, as found for example in concentrated sulfuric acid. The introduction of more hydroxyl groups stabilizes the inner salt configuration, probably by enhancing the acid properties of the sulfonic acid radical. This effect on the acid properties of the phthaleins and sulfonephthaleins due to an increase of the number of hydroxyl groups appears to be quite general and will be discussed in a subsequent paper.

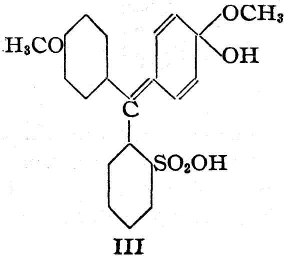
When the alcoholic solutions of phenolsulfonephthalein and *o*-cresolsulfonephthalein are allowed to stand in a dark room for a year in tightly stoppered pyrex bottles, the color decreases considerably in intensity and the solutions no longer give the characteristic color changes of the sulfonephthaleins in acid and alkaline solution. Curve C, Fig. 2, shows the absorption of such a faded solution of phenolsulfonephthalein. The band in the visual region at 1966 has not changed in position but it has only one-twelfth of its original intensity. In the ultraviolet region, however, the character of the bands has been completely modified. This is evidently due to the conversion of the phenolsulfonephthalein into its diethyl ether,[15] for by determining the absorption of the pure diethyl ether in ethanol solution, Curve D is obtained and it runs quite parallel to Curve C. Moreover, the absorption of the diethyl ether solution does not remain constant but slowly approaches that of the faded solution of the sulfonephthalein. There is thus indication that the diethyl ether, which can be obtained in the form of almost colorless crystals[15] and is considered as a lactoid derivative, I, sets up equilibrium in solution with a colored modification, which may be an ether–ester, II, or possibly a mixed quinoid hydrate, III.



I



II



III

The existence of the lactoid form in the equilibrium mixture is confirmed by the presence of the characteristic pair of bands at 3540 and 3639, which have previously been associated with the benzenoid condition of the molecule.[7]

o-Cresolsulfonephthalein likewise fades to a considerable extent in ethanol solution, as shown in Curve C, Fig. 3, with the peak of the band at 1905 decreasing to one-tenth of its original intensity after one year. In the ultraviolet region, however, the absorption increases and new bands

---

[15] Orndorff and Shapiro, THIS JOURNAL, 46, 2858 (1924).

develop which are not related either to those of the fresh solution, or to those of a freshly prepared solution of the diethyl ether of *o*-cresolsulfonephthalein, Curve D. In fact, at a still later stage (not shown on Fig. 3), the bands at 3411 and 3588 of Curve C had again increased 50% in intensity, with some indication that they were shifting closer together. The absorption of the pure diethyl ether of *o*-cresolsulfonephthalein, Curve D, is similar to that for the ether of phenolsulfonephthalein, except for the presence of a band in the extreme ultraviolet at 4218. It is probable that there is a corresponding band in phenolsulfonephthalein diethyl ether, but further in the ultraviolet and hence beyond the range of our spectrograph, since in general the bands for phenolsulfonephthalein are located to the side of higher frequency numbers with reference to the corresponding bands of o-cresolsulfonephthalein. The fading of the alcoholic solution of o-cresolsulfonephthalein cannot, therefore, be ascribed to ether formation in view of the relation between Curves C and D, but further observations will be continued on both of these solutions, in particular to follow any changes that may develop in that of the diethyl ether. The positions of the bands in the faded ethanol solutions of the sulfonephthaleins and in the ethanol solutions of their diethyl ethers are presented in Table II.

TABLE II

Phenolsulfonephthalein and o-cresolsulfonephthalein readily dissolve in concentrated sulfuric acid to form orange colored solutions, in which the sulfonephthalein is presumably present as the sulfate. If hydrochloric acid is added to an aqueous solution of the sulfonephthalein, which is originally present therein as the quinoid hydrate, as we have indicated above, water is split off with the formation of the basic quinoid form, which then reacts to form a hydrochloride. The extent to which this srries of reactions proceeds depends, however, on the amount of acid present, and by determining the absorption spectrum at different concentrations of acid it is possible to follow the course of the salt formation. When the solution contains 10,000 molecules of hydrochloric acid to one of the sulfonephthalein, the same absorption bands are found as in the sulfuric acid solutions, but at intermediate concentrations of acid some of the "neutral" bands, that is, those characteristic of the quinoid hydrate form, persist. Phenolphthalein and o-cresolphthalein in concentrated sulfuric acid likewise form salts of a quinoid structure which should have the same molecular configuration as those of the sulfonephthaleins and should, therefore, give rise to the same type of absorption spectra. In the case of phenolphthalein, however, it has already been pointed out[6] that the occurrence of sulfonation is a complicating factor in its effect on the absorption spectrum and a similar result has now been found for o-cresolsulfonephthalein, as is evident from an inspection of their absorption curves.

Figure 4 shows the absorption curves for the phenol derivatives. Curve A for phenolsulfonephthalein in concentrated sulfuric acid and Curve B for the same compound in aqueous solution with the addition of 10,000 molecules of hydrogen chloride are fairly parallel, with the bands in the sulfuric acid solution shifted uniformly toward longer wave lengths. Curve C is a reproduction of our previously published curve for phenolphthalein in sulfuric acid,[6] with the addition of a band in the extreme ultraviolet at 4280, which has since been found. It is similar to Curves A and B up to frequency number 3230, beyond which the three broad bands are in sharp contrast with the single prominent band of phenolsulfonephthalein at 3771.

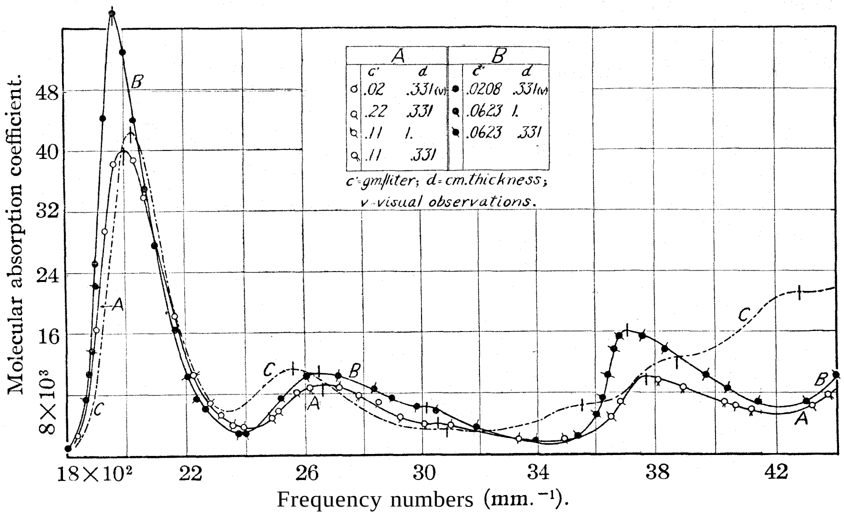

Fig. 4.—Acid solutions: *A*, phenolsulfonephthalein—concd. sulfuric acid; B, phenolsulfonephthalein—1 mole: 10,000 moles of hydrochloric acid; *C*, phenolphthalein—concd. sulfuric acid.

Figure 5 gives a similar set of curves for the o-cresol compounds. Curve A for *o*-cresolphthalein in sulfuric acid corresponds in all respects with the curve for phenolphthalein in the same solvent, Fig. 4. Evidence for progressive sulfonation was also obtained, in that the intensity of the absorption in the visual region was observed to diminish slowly in the course of several days. Curve B for o-cresolsulfonephthalein in concentrated sulfuric acid exhibits some peculiarities beyond 3400, in that instead of having a single, well-defined band, as with phenolsulfonephthalein, a shallow double band is produced. In aqueous hydrochloric acid, Curve C, the absorption is normal, with the bands having the same relative positions and intensities as for phenolsulfonephthalein in acid solution and for both sulfonephthaleins in absolute ethanol solution. The data for the positions of the band heads in these several neutral and acid solutions are summarized in Table III.

In alkaline solution, phenolsulfonephthalein and o-cresolsulfonephthalein exhibit their characteristic bluish-red color, due to the formation of the quinoid, di-basic salt. There are, however, two conditions under which this color is subject to modification. In the first place, at very low concentrations of alkali, corresponding to two molecules of the base to one of the sulfonephthalein and at low concentrations of the sulfonephthalein, hydrolysis occurs to a marked extent owing to the weak nature of the acid.

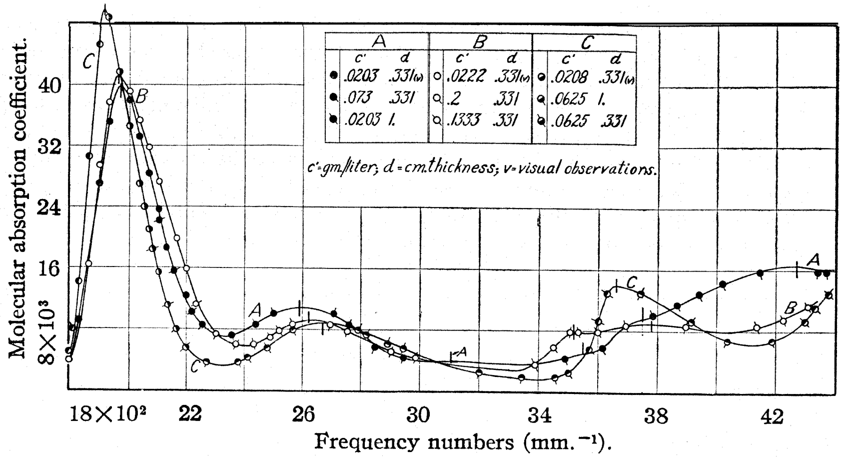

Fig. 5.—Acid solutions: A, o-cresolphthalein—concd. sulfuric acid; B, *o*-cresolsulfonephthalein—concd. sulfuric acid; *C*, *o*-cresolsulfonephthalein—1 mole : 10,000 moles of hydrochloric acid.

This is brought out in Fig. 6, Curves A and A', for the absorption of an aqueous solution of phenolsulfonephthalein containing the theoretical amount of alkali for producing the dipotassium salt. Curve **A** was for a solution containing 0.0609 g. of phenolsulfonephthalein to the liter and it will be noted that for the thinnest cell available, 0.331

cm., it was not possible to obtain the peak of the band in the visual region at 1782 indicated on the curve by a broken line. Upon diluting to a concentration of 0.0203 g. to the liter, the solution changed from its bluish-red color to an orange and the absorption in the visual and near ultraviolet regions, Curve **A'**, showed a large decrease in the intensity of the band at 1782 and a simultaneous increase of that at 2300, which is the first band in the neutral aqueous solution, Fig. 1, Curve A. At a ratio of 100 molecules of potassium hydroxide to one of phenolsulfonephthalein, Curve B, *the* full alkaline color developed and was then stable at all practical dilutions. It is now apparent on examining Curve A for the higher concentration of the sulfonephthalein in solution with two molecules of alkali that even undex these conditions hydrolysis is effective, for traces of two of the neutral bands still persist at 2250 and 3642.

The same phenomenon occurs with o-cresolsulfonephthalein in an aqueous solution containing two equivalents of potassium hydroxide, Fig. 6, Curve **A,** except **that** the *o*-cresol compound appears to be somewhat more susceptible to hydrolysis, for at a concentration of 0.061 g. to the liter the absorption curve has the same contour as that for phenolsulfonephthalein at a concentration of 0.0203 g. to the liter. It was found on examining a solution containing 0.1 g. of o-cresolsulfonephthalein to the liter, that the intensity of the first two bands was reversed, that at 1745 becoming much stronger than the one at 2287. With 100 molecules of potassium hydroxide present, the absorption becomes stable at all practical dilutions and Curve B is obtained, which is entirely comparable with that of phenolsulfonephthalein obtained under similar conditions. In each case there are three bands, with those for *o*-cresolsulfonephthalein shifted uniformly toward longer wave lengths.

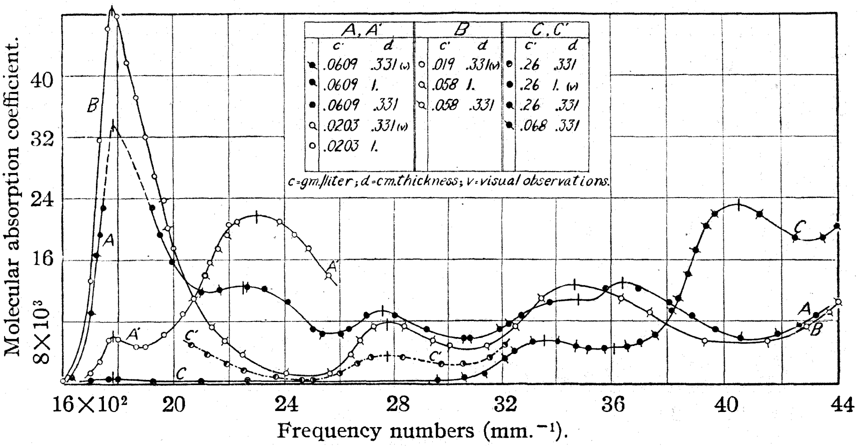

Fig 6.—Phenolsulfonephthalein in aqueous alkaline solutions: A, A′, 1 mole:2 moles of potassium hydroxide; B, 1 mole:100 moles of potassium hydroxide; *C*, C′, 33% potassium hydroxide—two days after preparation of solution.

As both phenolsulfonephthalein and o-cresolsulfonephthalein are commonly used as indicators for the absolute determinations of *P*H values, it is evident that when working with alkaline solutions of low concentration, if only slightly buffered or unbuffered, it is essential to carry out comparisons with the standard solutions under very nearly identical conditions of concentration of the alkaline medium and of the indicator. The use of the partially neutralized indicator, as recommended by **Clark,**[16] is evidently an improvement in the light of the above data, but the caution

[16] Clark, "The Determination of Hydrogen Tons," Williams and Wilkins Co., Baltimore, 1922, p 80

still applies for very low alkali concentrations. It is, furthermore, not safe, in view of the hydrolysis of the dibasic salts of the indicators, to assume as **Brode**[17] has done in the development of his spectrophotometric method for the determination of hydrogen-ion concentration, that Beer's law always holds over a range of concentrations.

The second of the two conditions under which the alkaline color of these sulfonephthaleins is modified is in the presence of high concentrations of alkali. In aqueous solutions containing 33% potassium hydroxide, the deep red color of phenolsulfonephthalein rapidly fades to a pale pink in two days, while o-cresolsulfonephthalein requires six months to reach the same stage. This fading, which is common to all phthaleins in strongly alkaline solutions, is due to the formation of the colorless tripotassium salt of the carbinolcarboxylic acid. With phenolsulfonephthalein an attempt was made to record the absorption of its solution in 33% potassium hydroxide immediately after its preparation but, owing to the rapidity of the fading, consistent data could not be obtained. Curve C', Fig. 6, represents a portion of the data thus obtained and brings out the band at 2774, which is missing in Curve C for the same solution, two days later. In the ultraviolet region, Curve C shows three bands, whereas in the solution containing 100 molecules of alkali to one of phenolsulfonephthalein there is only one in the same region.

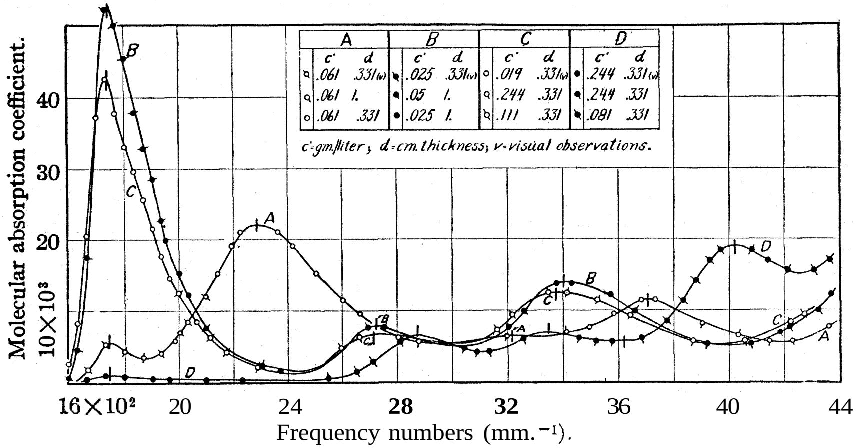

Fig. 7.—o-Cresolsulfonephthalein in aqueous alkaline solutions: *A*, 1 mole:**2** moles of potassium hydroxide; B, 1 mole:100 moles of potassium hydroxide; *C*, 33% potassium hydroxide—fresh solution; *D*, solution C—after standing for six months.

As the fading was so much slower in the case of o-cresolsulfonephthalein in 33% potassium hydroxide, it was possible to obtain the absorption of the fresh solution, Curve C, Fig. 7, and it will be noted that except for a

---

[17] **Brode**, THIS JOURNAL, 46, 587 (1924).

slight decrease in intensity, which is probably due to an incipient fading, the bands are very close to those for an aqueous solution of *o*-cresolsulfonephthalein containing 100 molecules of potassium hydroxide, Curve B. At the end of six months, however, when the solution had changed to a pale pink, the absorption, Curve D, had likewise changed completely in character, yielding a curve very like that of phenolsulfonephthalein after two days, except that there remains a well defined band at 2874, for which there is no counterpart in the faded solution of the latter substance. The relatively greater stability of o-cresolsulfonephthalein in strongly alkaline solution, as indicated by the above data, renders it more desirable than phenolsulfonephthalein as an indicator under such conditions. The relation between the bands in the various alkaline solutions of these two sulfonephthaleins is well brought out in Table IV.

Summary

1. The absorption spectra of phenoltetrachloro-, o-cresol-, and *o*-cresoltetrachlorophthaleins are discussed in their relation to that of phenolphthalein. Evidence is presented to support the view that the absorption of triphenylmethane compounds is due primarily to the joint effect of the three phenyl nuclei and not to the central methane carbon atom.

2. A consideration of the absorption spectra of phenolsulfonephthalein and o-cresolsulfonephthalein in neutral aqueous and ethanol, and in sulfuric acid solutions, leads to the conclusion that they possess the inner salt structure in ethanol solution but the quinoid hydrate in aqueous solution.

3. The absorption spectra of these sulfonephthaleins in weakly alkaline solutions bring out the progress of hydrolysis of the dibasic salts at low concentrations. The implications of this fact with respect to their use as indicators are pointed out.

4. In concentrated alkaline solutions, both phenolsulfonephthalein and o-cresolsulfonephthalein are converted largely into the colorless tribasic salts of the carbinolcarboxylic acid, although the reaction proceeds very much more rapidly with the former.

DI-NORMAL-BUTYL ETHER AS A SOLVENT FOR THE GRIGNARD REAGENT

BY C. S. MARVEL, A. T. BLOMQUIST AND L. E. VAUGHN

RECEIVED JULY 19, 1928 PUBLISHED OCTOBER 6, 1928

The need for a solvent with a higher boiling point than that of diethyl ether for the preparation and use of the Grignard reagent has long been felt. The low boiling point of diethyl ether with the consequent loss of it in handling and danger of the formation of explosive mixtures of its vapor and air has limited the use of the Grignard reagent in commercial work to very rare cases. Numerous papers describing the use of higher aliphatic ethers, various phenyl ethers and high boiling hydrocarbons have appeared in the literature.[1]

It seemed likely that a suitable substitute for diethyl ether would be di-n-butyl ether, which has occasionally been used as a solvent in the Grignard reaction. This ether may be prepared in a pure condition easily and cheaply fron n-butyl alcohol and its boiling point is high enough so that it can be conveniently handled without excessive loss due to evaporation. Furthermore, distillation alone gives an ether free from moisture and butyl alcohol, thus avoiding the difficulties met in the purification of ordinary ethyl ether. While it has been suggested as a solvent in this reaction, there is very little information in the literature concerning the yields of the Grignard reagents from different halogen compounds or of the yields of products that may be obtained from Grignard reagents in this solvent. Gilman and McCracken[1] report a yield of 55.9% of phenylmagnesium bromide from bromobenzene and magnesium in di-n-butyl ether.

The present investigation has shown that the yields of the Grignard reagent from several typical halogen compounds when di-n-butyl ether is the solvent are nearly equal to those obtained in diethyl ether. It has also been shown that in a typical reaction of the Grignard reagent, such as that with carbon dioxide, as good a yield of product can be obtained in di-n-butyl ether as when diethyl ether is used. For a reaction such as that between the Grignard reagent and ethylene oxide, where an elevated temperature is needed to complete the reaction, di-n-butyl ether is more

---

[1] A review of this topic is given in a recent paper by Gilman and McCracken, *Rec. trav. chim.*, **46**, 463 (1927).

convenient to use than is the usual mixture of ether and benzene. For the preparation of primary alcohols from the Grignard reagent and formaldehyde di-n-butyl ether has a decided advantage over diethyl ether since in the higher boiling solvent a temperature can be reached which will bring about depolymerization of paraformaldehyde in the reaction mixture. This obviates the necessity of depolymerizing the paraformaldehyde as a separate operation. One disadvantage that should be mentioned is that di-n-butyl ether cannot be used conveniently as a solvent in reactions used for the preparation of neutral substances which boil too close to its own boiling point (141°). The di-n-butyl ether may be recovered from these reaction mixtures with very little loss and after distillation is again ready for use.

Experimental Part

1. Preparation of Grignard Reagents in Di-n-butyl Ether.—In determining the yields of various Grignard reagents in di-n-butyl ether a standard procedure essentially the same as that devised by Gilman and his students[S] was used. A 200-cc., three-necked flask was fitted with a mechanical stirrer, separatory funnel, reflux condenser and thermometer. In the flask was placed about 40 cc. of di-n-butyl ether, 1.5 g. of magnesium turnings and a crystal of iodine. The theoretical amount of halogen compound dissolved in enough di-n-butyl ether to make a total volume of 30 cc. was placed in the separatcry funnel. A small amount of the solution of the halogen compound was added and the reaction flask was heated until the reaction started. This temperature varied somewhat with the different halogen compounds. When the reaction was once started, stirring was begun and the remainder of the solution of the halogen compound was added at a rate which allowed the reaction to proceed smoothly. After addition of the last of the solution of the halogen compound stirring was continued until the mixture had cooled to room temperature. The reaction mixture was then rapidly transferred to a volumetric flask and the reaction vessel rinsed with more solvent. The level of the liquid in the volumetric flask was brought up to the mark by the addition of more solvent and aliquot parts were titrated with standard acid.

The di-n-butyl ether used in these experiments was prepared from n-butyl alcohol and sulfuric acid. It was washed with sodium hydroxide solution and distilled twice. The fraction boiling at 140–142° was collected. The halogen compounds and magnesium were of the ordinary grade used for the preparation of the Grignard reagent.

The results of the experiments are listed in the following table.

TABLE I

YIELDS OR GRIGNARD REAGENT FROM VARIOUS HALOGEN COMPOUNDS AND MAGNESIUM IN DI-n-BUTPL ETHER

Halogen compound	Yield, %	Halogen compound	Yield, %
Ethyl bromide	91–93	Zsobutyl bromide	82–86
n-Propyl bromide	89–90	n-Heptyl bromide	73–81
Zsopropyl bromide	79–80	Cyclohexyl bromide	80–83
n-Butyl bromide	86–87	Bromobenzene	70–77
sec.-Butyl bromide	68–72	α-Bromonaphthalene	63–71
		β-Phenylethyl bromide	68–71

---

[2] Gilman, Wilkinson, Fishel and Meyers, THIS JOURNAL, **45**, 150 (1623); Gilman and Meyers, *ibid.*, **45**, 159 (1923); Gilman and McCracken, *ibid.*, **45**, 2462 (1923).

The yields recorded in the table are the upper and lower yields (to the nearest whole number) of a number of runs..

2. Reactions of the Grignard Reagent in Di-n-butyl Ether. dl-Methylethylacetic Acid.—The standard procedure for the preparation of an acid from the Grignard reagent was followed[3] except that di-n-butyl ether was substituted for diethyl ether. The yield of dl-methylethylacetic acid (b. p. 173–175") from 274 g. of *sec.*-butyl bromide was 135 g. (66% of the theoretical amount). In diethyl ether the yield has been found to be 135–136 g.

n-Nonyl Alcohol.—The general procedure for the preparation of n-hexyl alcohol from n-butyl bromide[4] was followed with the exception that di-n-butyl ether was used as a solvent in place of the usual solvents, ether followed by benzene. The Grignard reagent was prepared from 179 g. of n-heptyl bromide in about 300 cc. of di-*n*-butyl ether. This solution was cooled to 0° and with stirring an excess of ethylene oxide was added. The temperature was maintained at 0° for one hour after the addition of the ethylene oxide and then allowed to rise to 40° and maintained at that point for one hour. Finally the mixture was heated on the steam-bath for two hours and then decomposed and the product was isolated according to the procedure used for n-hexyl alcohol. The yield of n-nonyl alcohol boiling at 95–100° (12 mm.) was 95 g. (65% of the theoretical amount).

Cyclohexyl **Carbinol.**—The proportions of the reagents used were those desc ibed for this preparation by Adams and **Noller.**[5] The general procedure was the same except that the Grignard reagent was prepared in di-n-butyl ether. The solution was heated to 100–110° and 100 g. of dry paraformaldehyde was added in small portions to the well stirred solution over a period of about two hours. The product was isolated as described for the preparation in diethyl ether. The yield of cyclohexyl carbinol (b. p. 88–93' (18 mm.)) from 163 g. of cyclohexyl bromide was 70 g. (60% of the theoretical amount). In diethyl ether the yield has been found to be 61–65% of the theoretical amount.

Summary

1. Di-n-butyl ether may be used in place of diethyl ether as a solvent for the preparation of the Grignard reagent without materially reducing the yield.
2. The three typical reactions of the Grignard reagent which were studied have been found to give as good yields in di-n-butyl ether as when diethyl ether is used as a solvent. In two of these reactions the procedure is simplified by the use of the higher boiling solvent.

THE REACTIVITY OF THE METHYLATED SUGARS. III. THE ACTION OF DILUTE ALKALI ON TETRAMETHYL-*d*-MANNOSE

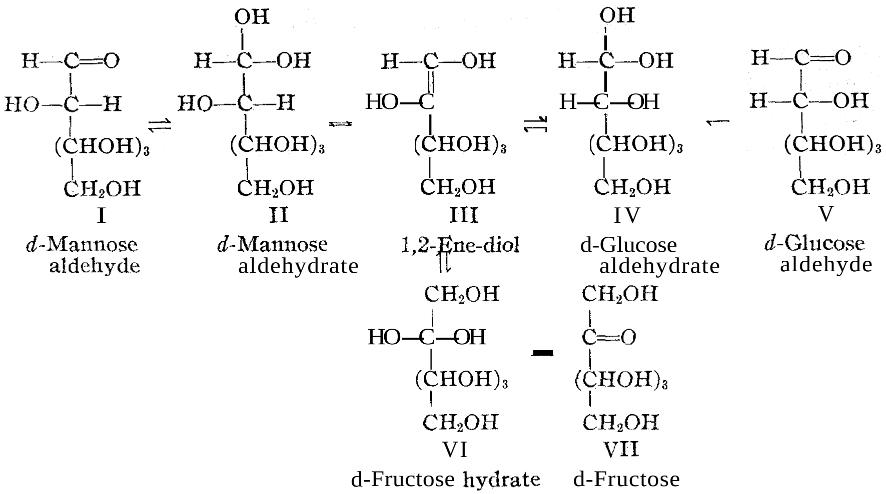
By Richard D. Greene[1] with W. Lee Leu-is

Received July 26, 1928 Published October 6, 1928

Attention has already been directed[2] to the fact that the methylated sugars offer excellent opportunities for testing experimentally the validity of certain of the theories developed to explain the reactivity of the simple sugars.

The interconversion of sugars by alkalies, first studied by Lobry de Bruyn,[3] and explained by him and also by Fischer[4] and by Wohl,[5] was exhaustively studied by Nef[6] and his students. Nef's study of the action of alkalies and alkaline oxidizing agents on the sugars led him to interpret the reactions on the basis of the formation of intermediate ene-diols. Thus the obtaining of isomeric hexoses from d-glucose in alkaline solution and of acids of from one to five carbon atoms by alkaline oxidation was readily explained by assuming progressive enolization. It is this theory of enolization and, more especially, the actual mechanism of enol formation when methylated mannose is treated with alkali, that is our chief concern here. Nef[6,7] explained enol formation by assuming that a given sugar can selectively add and lose water in such a way as to produce ene-diols, and from them various isomeric sugars.

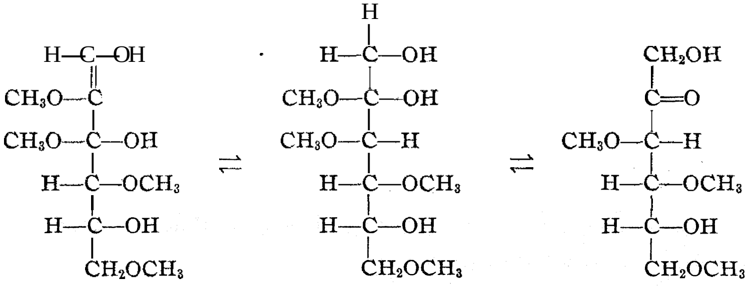
On the basis of Nef's explanation the interconversion of *d*-mannose into d-glucose and d-fructose may be illustrated as follows



---

[1] Abstracted from a dissertation submitted by Richard D. Creene to the Graduate

By assuming that enolization continues down the carbon chain, Nef accounted for the formation of other products, as d-glutose and d-pseudofructose. If Nef's theory of enol formation is entirely correct, we can make certain predictions as to the behavior of the methylated sugars with alkali. Thus 2,3,4,6-tetramethyl-*d*-mannose should add water to form its aldehydrate, which would then lose water to form the 1,2-monomethyl ene-diol. This, in turn, by selective loss and addition of water, might form 2,3,4,6-tetramethyl-*d*-glucose. It might, however, equally well form an unstable hemi-acetal (IX), which would undoubtedly lose methyl alcohol to form 3,4,6-trimethyl-*d*-fructose.



VIII IX X

This trimethylfructose (X) would then be subject to a repetition of the same process of enolization and demethylation, and in the presence of oxidizing agents should yield fragments of from one to five carbon atoms (in the chain) just as in the case of the unmethylated sugars.

Actually the facts are not consistent with such behavior. The resistance of the methylated sugars to mineral acids and to fermentation is well known. It has been shown that they are much less reactive with Fehling's solution[8] than are the unmethylated sugars. The oxidation of tetramethyl-d-glucose with alkaline hydrogen peroxide[2"] yielded predominantly formic and carbonic acids with a methylated five carbon acid, whereas Nef's difficulty in obtaining any five carbon acid from unmethylated glucose is historic. It was further shown that tetramethyl-*d*-glucose[2b] under the action of dilute alkali yields a mixture of methylated glucose and mannose with a certain amount of the ene-diol common to them.

School of Northwestern University, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

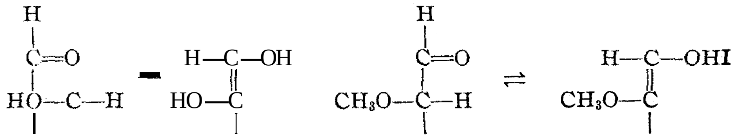
The conclusion from these facts must be that enolization is definitely blocked at carbon 2 when the labile hydrogen of the sugar is replaced by the non-polar methyl group. Nef's theory as it stands does not account for the behavior of the methylated sugars and so must not be an entirely correct explanation of the reactivity of the simple sugars. By a simple modification, however, it can be made to fit all the facts. If the concept of enolization by addition and loss of water be modified in favor of a simple keto-enol tautomerism, we can harmonize the behavior of the substituted and unsubstituted sugars perfectly.



$$\begin{array}{c}H\\|\\C{=}O\\|\\HO{-}C{-}H\\|\end{array} \quad - \quad \begin{array}{c}H{-}C{-}OH\\\|\\HO{-}C\\|\end{array} \qquad \begin{array}{c}H\\|\\C{=}O\\|\\CH_3O{-}C{-}H\\|\end{array} \rightleftarrows \begin{array}{c}H{-}C{-}OHI\\\|\\CH_3O{-}C\\|\end{array}$$

We can now understand their difference in reactivity for we would not suspect that, under our conditions, methyl should go from oxygen to carbon. It seems highly reasonable then, that tetramethyl-d-mannose with alkali should produce a system containing only tetramethylated glucose and mannose.

In the further verification of this principle it was first necessary to find conditions under which mannose would produce a system containing considerable amounts of glucose and fructose, with minimum secondary effects. Having then applied identical conditions to the methylated sugar, we should be in a position to generalize correctly from the results.

A solution molar in mannose and 0.035 *N* in calcium hydroxide held at 35° for 200 hours fulfilled the above requirements. Tetramethyl-*d*-mannose, which had been obtained crystalline for the first time, was subjected to similar conditions. In the analytical investigation of the action of alkali on tetramethylmannose it was found that the specific rotation increased from +2.4° to an equilibrium value of $42". This is precisely the value obtained from a synthetic mixture of equal quantities of tetramethylmannose and tetramethylglucose. Determination of total methylated aldoses by iodine titration gave the surprising result of apparently increased aldose content. This is ascribed to the presence of a certain amount of the ene-diol, common to the two sugars, which seems to possess unusual stability. This view is confirmed by the fact that treatment with acid restores the original iodine value. Investigation of the alkaline solution of mannose did not show the presence of an unmethylated ene-diol of any stability.

The separation of the two tetramethyl sugars from the reaction mixture was accomplished by their conversion to the anilides, which were separated on the basis of their solubility in aniline, tetramethylglucose anilide being much the more insoluble.

This investigation, in showing that tetramethyl-d-mannose with alkali gives no methylated ketose and an undiminished amount of methylated aldose, affords direct evidence that the process of enolization involves the movement of hydrogen atoms rather than selective hydration and dehydration. In addition, the general enol explanation of sugar reactivity finds further support. While this work does not involve, and therefore does not answer, the question of the absolute ring structures of the two tetramethyl sugars dealt with, yet their interconvertibility indicates that they possess the *same* ring structure.

Experimental Part

The Preparation of Crystalline Tetramethylmannose.—α-Methylmannoside was prepared from vegetable ivory nuts by the method of Hudson;[9] the yield was about 50%

---

[9] Hudson, "Organic Syntheses," John Wiley and Sons, Inc., New York, 7, 64 (1927).

of the weight of vegetable ivory used. From the mannoside so obtained **the** completely methylated mannoside was prepared by the method of Haworth.[10] The tetramethyl-a-methylmannoside was a limpid, colorless liquid; b. p. 116° at 2 mm. It later solidified to a mass of prisms, m. p. 39–40°. The specific rotation in water was *[a],* = \$43.5" (c = 5). The mannoside was hydrolyzed with hydrochloric acid and the tctramethylmannose was isolated according to the method of Irvine.[11] Vacuum distillation had been employed by previous workers in the purification of tetramethylmannose, but with quantities not exceeding 30 to 40 g., perhaps. An attempt at vacuum distillation (2–5 mm.) of 258 g. of tetramethylmannose resulted in complete decomposition, with the formation of some tetramethylglucose and a large amount of partially demethylated products. A similar attempt at distillation of 633 g. promised the same result and the method of purification by distillation was abandoned.

Extraction with petroleum ether (b. p. 40–50°) was tried on a freshly prepared sample of tetramethylmannose as a means of removing the small amount of unhydrolyzed mannoside present. Equal volumes of the petroleum ether and tetramethylmannose were heated at about 55° in order to produce gentle refluxing, while the mixture was stirred vigorously. After one hour the mixture was allowed to demulsify and cool and the solvent layer was decanted. This treatment was repeated. The residual sirup (90% of the original) was almost entirely freed from solvent *in vacuo*. After several days standing the sirup crystallized completely. The large lot of undistilled material above (633 g.) crystallized largely after seeding. It was now possible to purify the sugar by recrystallization, as with tetramethylglucose. This operation was carried out in a continuous siphon extractor. In this way 270 g. of pure crystalline tetramethylmannose was obtained. The yield was not calculated because of the previous treatment of the material. Methoxyl was determined by the modified Zeisel method.[12]

Anal. Subs., 0.1492, 0.1209: AgI, 0.5862, 0.4762. Calcd. for $C_6H_8O_2(OCH_3)_4$:OCH_3, 52.5. Found: 51.9, 52.1.

The constants of the sugar were as follows

	Recrystallization $[\alpha]_D^{20}$ (c = 5 in all cases)			
	H_2O	CH_3OH	$CHCl_3$	M. p.
First	+2.4°	+27.6°	+23.0°	50–51°
Second	+2.4°	+27.6°	+23.0°	50.5–51.5°

The preparation of the tetramethylglucose and tetramethylfructose referred to in the course of this work is described by M. L. Wolfrom.[2b]

Preparation of **Tetramethylmannonic Lactone** from Crystalline **Tetramethylmannose**.—Ten *g.* of crystalline tetramethylmannose was oxidized with bromine according to the method of Purdie and Irvine [13] The crude lactone was purified by the sodium salt method of Haworth.[14] The pure lactone was a colorless sirup, which showed no tendency to crvstallize. Mol. wt. by titration, 235. Calcd. for $C_{10}H_{18}O_6$: 234. OCH_3, calcd., 53.0. Found, 52.2. A solution of the lactone in water (c = 2.97) changed in specific rotation *[a],* from +136.4° to +62.8° in six days. This agrees with the data of Upson and Whitnah[15] and confirms the conclusion of Haworth[14] that

the tetramethylmannonic lactone prepared from "normal" tetramethylmannose is an "unstable" one.

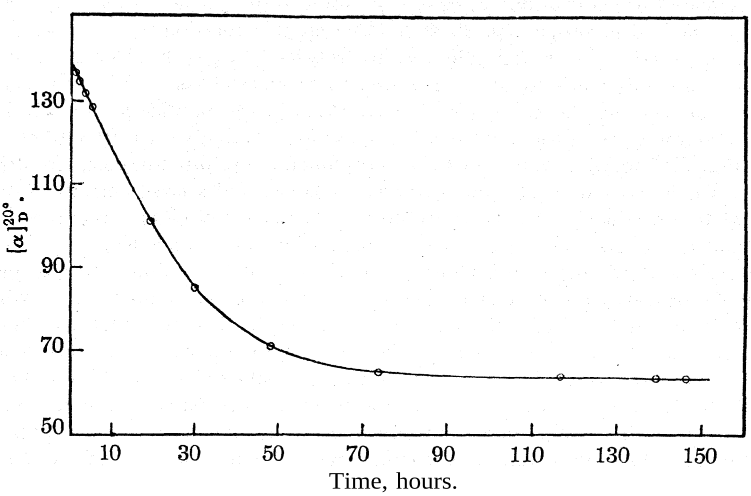

Fig. 2.—Change in specific rotation of tetramethylmannonic lactone in water (c = 2.969).

The Action of Dilute Alkali on Mannose.—It was proposed to find the optimum conditions for the interconversion of mannose and then to apply these to tetramethylmannose. A solution molar in mannose and 0.342 N in calcium hydroxide was allowed to stand at 35° for 200 hours. During this period the specific rotation changed from +14.3° to +0.6° (constant) and the solution had become neutral to phenolphthalein.

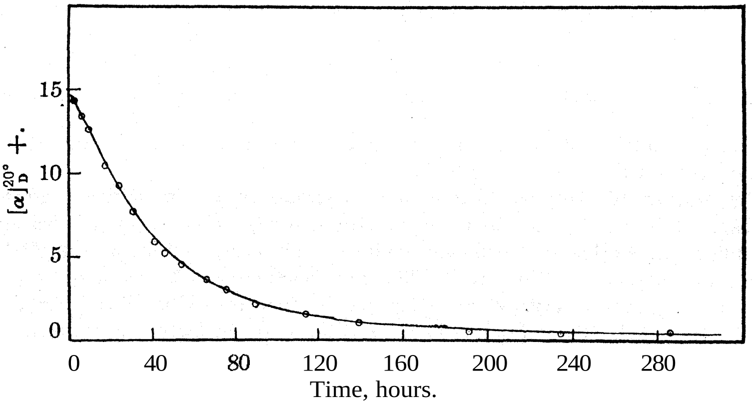

Fig. 3.—Change in specific rotation of mannose and alkali.

The amounts of glucose, mannose and fructose were determined periodically and finally. The percentages of the three sugars were calculated from the determination of reducing sugar by the Munsen-Walker method, aldoses by iodine titration[16] and mannose as

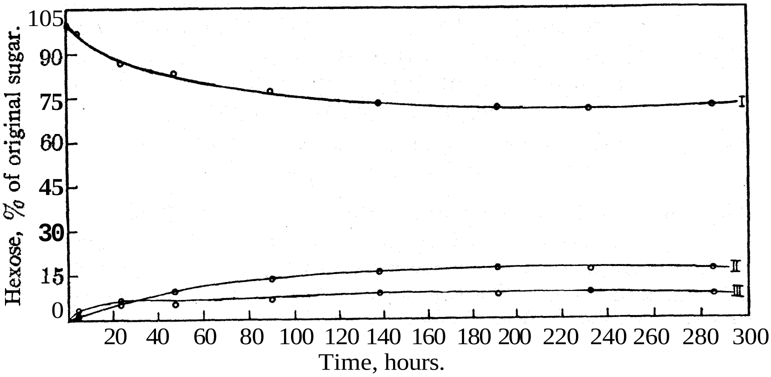
---

[16] Cajori, *J. Biol. Chem.*, 54, 617 (1922).

the phenylhydrazone.[17] The applicability of these methods had been tested on known solutions of the three sugars. The final percentages so determined were: mannose 71.7, glucose 8.9, fructose 16.9, non-sugar bodies, probably saccharinic acids (by diff.) 2.5. The polarimetric reading calculated from these percentages and the accepted specific rotations of the three sugars was −0.6° as against the observed value +0.6°. This is nearly as close agreement as the analytical determinations warrant.

In view of the evidence of the apparent stability of the methylated ene-diol, the reaction solution of the *unmethylated* sugar was tested. Iodine titration and Fehling's solution gave identical values with and without acidification, indicating no more than a transient existence of the simple ene-diol.

Preliminary Study of the Action of Alkali on Tetramethylmannose.—The action of 0.034 *N* calcium hydroxide on mannose had produced a considerable degree of interconversion and it seemed probable that the same conditions would be applicable to tetramethylmannose. Solutions of tetramethylmannose were made up molar in the sugar and with alkalinity of 0.03 N barium hydroxide, 0.035 *N* calcium hydroxide, 0.04 N barium hydroxide and 0.056 N barium hydroxide. Little or no specificity in the two alkalies was observed. These solutions were held at 35° and polarimetric observations were made at intervals. The specific rotation4 increased from the initial value of +2.4°, respectively, to +38.9°, +41.5°, +41.8° and +41.8° in about 200 hours. The alkalinity gradually decreased until the solutions were almost neutral. It is clear that a true equilibrium is involved since further increase of alkali beyond a certain point does not increase the specific rotation. The result has further interest, in view of the statement appearing frequently in sugar texts that rotation drops in alkaline solution.



I, mannose; II, fructose; III, glucose.

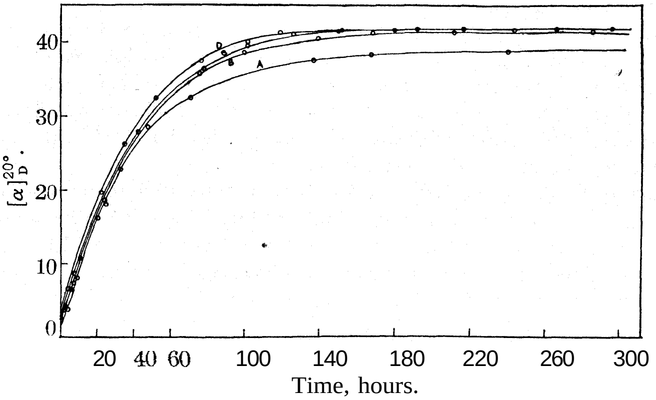
Fig. 4.—Formation of glucose and fructose from mannose and alkali.

The nature of this change was investigated by the method of iodine titration. This method was used in the determination of methylated aldoses in a known mixture of tetramethylmannose, tetramethylglucose and tetramethylfructose and found to be perfectly applicable.[2b] Determinations of the iodine values of the equilibrated solutions yielded results from 117 to 152% of the original, varying with the strength of alkali. This was taken as indicating the presence of a certain amount of the stable monomethyl ene-diol, which was capable of reacting with more iodine than the sugar. Treatment of the equilibrated solutions with acid caused a return to the original value

---

[17] Sherrard and Blanco, *J. Ind. Eng. Chem.*, *15*, 612 (1923).

of 100% tetramethyl aldohexose, indicating the absence of tetramethylfructose. The specific rotation of +42° was not appreciably altered by such treatment. Reference to the specific rotations of tetramethylmannose (+2.4°) and tetramethylglucose (+82°), shows that a mixture of equal quantities of the two sugars would have a specific rotation of +42°. Treatment of a mixture of equal quantities of the two sugars with 0.035 N alkali gave a constant specific rotation of +42°. The presumption of the presence of equal amounts of the two sugars in the equilibrated mixture is confirmed by the actual isolation of their anilides.



A, 0.03 N $Ba(OH)_2$; *B*, **0.035** N $Ca(OH)_2$; *C*, 0.04 N $Ba(OH)_2$; D, 0.056 N $Ba(OH)_2$.

Fig. 5.—Action of different strengths of alkali on tetramethylmannose.

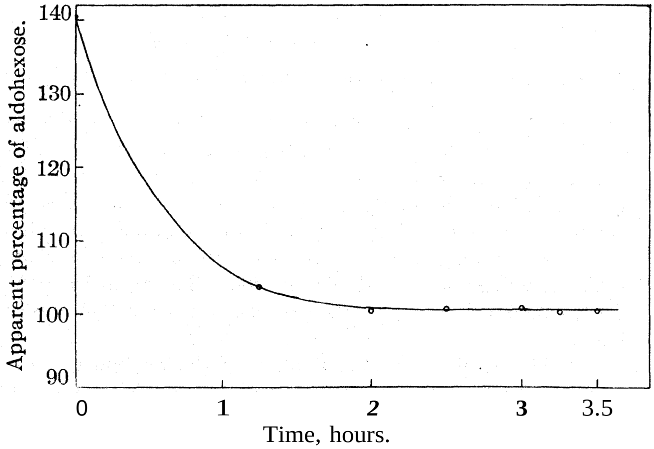


Fig. 6.—Rate of de-enolization of tetramethylmannose.

Optimum Conditions for **De-enolization.**—The complete reconversion of the enediol to sugar required a surprisingly strong acid treatment. Three N hydrochloric acid at 35° reduced the iodine from 152 to 100% apparent aldohexose in four hours. Since sulfuric acid could be removed more readily (as barium sulfate) it was substituted.

A portion of a reaction solution from 0.035 N calcium hydroxide was made 3 N in sulfuric acid and $M/2$ in sugar and held at 35° with the following results.

Interval, hours	(Original)	0	1.25	2	2.5	3	3.25	3.5
I, value, % app. aldohex.	140.4	103.7	100.4	100.8	100.7	100.1	100.3	

Further work showed that weaker acid at a higher temperature would render de-enolization complete. A solution 0.02 N in sulfuric acid and $M/5$ in sugar was heated at 95°. In fifteen minutes the iodine value dropped from 140.4 to 100.5% apparent aldohexose. In actual practice it was thought better to employ a temperature of 50° and a longer time.

Quantitative Recovery of the Sirup.—This phase of the work presented difficulties as serious as they were unexpected. Originally it was taken for granted that the sugar could be recovered quantitatively from the equilibrated solution without any special difficulty. While their known greater stability gave them an apparent advantage over the simple sugars, nevertheless the methylated sugars seem to possess a degree of volatility which necessitated the utmost care in their isolation from aqueous solution. After de-enolization of the equilibrated solution with sulfuric acid, the acid was removed by the addition of 0.1 N barium hydroxide drop by drop, until just faintly acid, and barium carbonate for the remainder of the acid. After removal of the barium sulfate by filtration, the water was evaporated at 25 mm. and 45–50°. The residual sirup was taken up in alcohol and finally in ether, any precipitate being removed before evaporating the solvent in *vacuo*. In this way but an 80–85% recovery of sirup was possible. The use of alcohol and ether was then discarded as unnecessary and the water was removed at 35° instead of at 45–50°. After these modifications a yield of 93.5% of sirup was obtained.

Methods of Separation and Identification.—Tetramethylglucose was established qualitatively as a product of the interconversion of tetramethylmannose, as follows. The equilibrated sirup from the experiment with 0.056 N alkali was seeded with tetramethylglucose. Crystallization occurred and the crystals were freed from sirup and recrystallized from petroleum ether. The following constants were obtained: $[\alpha]_D^{20}$ in water ($c = 1.14$) + 83.7°; m. p. 89–90°; identical with those of pure tetramethylglucose. Both equilibrated sirups and synthetic mixtures of equal amounts of the two sugars actually exhibited spontaneous crystallization of tetramethylglucose, in nearly equal amounts (10–15%) of the tetramethylglucose present. In this way substantial confirmation of the presence of equal amounts of the two sugars in the equilibrated solution was afforded. Attempts were made to separate the sugars as such quantitatively by crystallization and by the use of solvents, without success. Of their known compounds the anilides[18] appeared promising, being nicely crystalline and quantitative in formation. The two anilides were prepared

---

[18] Irvine, J. Chem. *Soc.*, 93, 95 (1908); 97, 1449 (1910).

by heating for three hours at 100° a mixture of 8 moles of aniline with a 30% solution of the sugar in absolute alcohol. After recrystallization from absolute alcohol both anilides were obtained in a high degree of purity, with the following constants.

$[\alpha]_D^{20°}$ in Ethyl Alcohol with 0.001% Hydrochloric Acid (c = 5)

Anilide	Initial	Final	M. p.
Tetramethylglucose	+230°	+59°	138°
Tetramethylmannose	Variable	−8.5"	Variable

These anilides exhibit mutarotation with definite and reproducible equilibrium values, just as the sugars do. The tetramethylglucose anilide has a constant melting point, indicative of one solid form.

The original workers[18] had recorded such a wide variation in the case of hydrolysis of the two anilides that it seemed to promise a method of separation. This variability in case of hydrolysis was not confirmed, but the relative insolubility of the tetramethylglucose anilide in aniline was successfully utilized.

A trial separation was made on the anilides prepared from a mixture of equal amounts of the two sugars. Seven g. each of tetramethylmannose and tetramethylglucose was dissolved in 42 cc. of alcohol (absolute) and 42 cc. (8 moles) of redistilled aniline was added. The mixture was heated at 100° for three and one-half hours. After standing for eighteen hours the mass of crystals which had formed was filtered off. After removal of the alcohol a crop of crystals came out of the aniline and was filtered off. The aniline was completely removed from the remaining solution by distillation in *vacuo* and the mixed anilides were separated on the basis of fractional solubility in aniline. The more insoluble portions, high in tetramethylglucose anilide, were recrystallized from absolute alcohol. A melting point of 137–139° was taken as the criterion of purity. As the tetramethylmannose anilide content of the remainder was increased, crops were removed by crystallizing from alcohol. The purity of the tetramethylmannose anilide was later ascertained by determination of the specific rotation and that of the tetramethylglucose anilide also was confirmed in this way. Out of a calculated weight of 18.45 g. of mixed anilides, 7.59 g. of pure tetramethylglucose anilide and 8.02 g. of pure tetramethylmannose anilide were isolated. In addition to this a crystalline residue of 1.5 g. of mixed anilides remained, making 17.11 g. of crystalline anilides (92.8% calcd.) remaining at the end of the separation. In addition 0.8 g. of very dark, tarry matter remained. The enormous number of leachings with aniline and its subsequent removal induce progressive tar formation.

Tetramethylmannose with 0.0325 N Barium Hydroxide.—Tetramethylmannose (35.424 g.) was dissolved in an amount of 0.0407 *N* barium hydroxide sufficient to make a volume of 150 cc. This solution, 1 M in sugar, 0.0325 *N* in alkali (sp. gr, 1.043;

22.65% sugar) was kept at 35°. The specific rotation at 182 hours was +41.3°, indicating 49.5% tetramethylglucose and 50.5% tetramethylmannose. The iodine value was 125% of the original and the color of the solution was slightly yellow. The solution, now 139 8 cc. containing 33 02 g. of sugar, was combined with 185 cc. of 0.1 *N* sulfuric acid and 374 cc. of water. This solution, $M/5$ in sugar and 0.02 N in acid, was kept at 50° for four hours in order to de-enolize it. The iodine value was then 103.5%, indicating almost complete conversion of the enol.

The de-enolized solution, 701.8 g. containing 32.81 g. of sugar, was neutralized by the dropwise addition of 130 cc of 0.1 N barium hydroxide at 40°. The slight acidity left was removed by the addition of 0.4 g. of barium carbonate. After removal of the barium sulfate the iodine value of the solution was found to be 103.4%.

The amber colored solution, 1090 g. containing 32.66 g. of sugar, was evaporated *in vacuo* at 25 mm. and 35°. The evaporation was carried out in a one-liter Claisen flask with a removable glass column. The receiver was kept ice-cold. The flask was weighed every two hours after the removal of nearly all the water, and was found to reach constant weight after twenty hours of distillation. The residual brown sirup weighed 30.85 g., a yield of 94 5%. This, however, contained a slight dark-brown residue, which was separated in the subsequent removal of the sirup preparatory to making the anilides. By decanting the alcohol solution of the sirup, 0.32 g. of the dark residue remained, leaving 30.53 g., net, of sirup, or 93.5%. This residue was not investigated beyond ascertaining that it was soluble in water, insoluble in alcohol, was mainly organic and gave a test for barium. The iodine value of the sirup was 107.3%, a slight increase over the value previously obtained on the solution. The specific rotation was \$40.4". The iodine value of the aqueous distillate indicated the presence of 0.39 g. of sugar. Reckoning this in the yield, the total weight accounted for is 95.7% of the original.

After the removal of 3.83 g. of sirup as a specimen, the remaining 26.70 g. was dissolved in 82 cc. of absolute alcohol and 82 cc. of water white aniline was added. The mixture was heated in a glycerol bath at 100° for 3.2 hours, using an air condenser. After standing for two days, the solution had failed to yield any crystals. One-tenth of the solution (2.67 g. of sugar) was evaporated in *vacuo* and efforts were made to obtain crystals from it. A small amount of crystalline material was obtained, but it appeared that the formation oi the anilides had been quite incomplete, perhaps because of the presence of moisture from the original sirup. The test portion was kept separate and the main lot (2403 g. of sugar) was freed from alcohol and partly from aniline, in order to eliminate any possible water. The solution was then restored to the original concentrations of aniline and alcohol and heated at 100° for two hours. Now, after cooling, a reasonable crystallization occurred.

The reaction mixture at this stage was very black and from previous experience it seemed highly desirable to remove the crystalline mixed anilides from the dark material before attempting their separation. By progressive concentration of the alcohol solution 26.18 g. (83%, calcd.) of crystalline anilides was obtained. At this point it was necessary to precipitate some of the tar by dissolving the residue in alcohol–ether and adding petroleum ether (40-50°). Crystallization following this step raised the total to 90%. Some more tar was removed from the residue at this point by steam distillation. The light-colored, water-soluble portion (3 g.) was heated with 9 cc. of absolute alcohol and 9 cc. of aniline at 100° for three hours. By crystallization as before, in a desiccator held at 5°, the total weight of crystalline anilides was raised to 29.74 g., or 93.9% of the calculated weight (31.67 g.).

The mixed anilides were repeatedly leached with aniline, the undissolved portions being recrystallized from absolute alcohol (generally 1:5) to obtain pure tetramethylglucose anilide, m. p. 137–139°. As the remaining material increased in tetramethylmannose anilide content, it was also crystallized out. In the later work a superior method was developed. This consisted in dissolving the mixed anilides in 3 parts of aniline and allowing almost pure tetramethylglucose anilide to crystallize.

In this way 12.50 g. of tetramethylglucose anilide of m. p. 137–139° was obtained in 11 portions. A composite melting point with pure tetramethylglucose anilide showed no depression. The specific rotation (CH_3OH, $c = 2.36$) decreased from +228.7° to +58.9° on the addition of 0.001% of dry hydrogen chloride. A slightly greater amount of tetramethylmannose anilide. 12.79 g., was obtained in 6 lots, a composite of which yielded a specific rotation (CH_3OH, 0.0001%, hydrogen chloride, $c = 4.93$) of −8.5°, in agreement with the accepted value. A crystalline residue of 0.37 g. gave a specific rotation of +31.9° in the same solvent, indicating that this unseparated portion contained 60% of tetramethylglucose anilide and 40% of tetramethylmannose anilide. A tarry residue of 2.08 g. raises the total residual weight to 27.74 g., a loss of 2.00 g. in manipulation. The enormous number of transfers and lengthy treatment with aniline make this appear not unreasonable.

Reviewing the significant steps of the process, 32.66 g. of tetramethylmannose after treatment with alkali yielded 30.53 g. of recovered sirup, or 93.5%. Of this 30.53 g. of sirup, 24.03 g. (net) was converted to the anilides. Out of a possible 31.67 g. of anilides, 29.74 g. of crystalline material, or 93.9%, was obtained. From these mixed anilides 25.29 g. of the pure anilides was separated, a yield of 85%.

The nature of the processes and the yields obtained, along with the analytical data, justify the conclusion that the action of dilute alkali on tetramethylmannose, followed by suitable acid treatment, produces a mixture of equal amounts of tetramethylmannose and tetramethylglucose. From this we can only conclude that the interconversion of sugars is an enolic process involving migratory hydrogen atoms.

The authors wish to make grateful acknowledgments to Dr. F. C. Whitmore for valuable contributions to the theory and procedure of this problem.

Summary

1. The action of dilute alkali on mannose was investigated and conditions were found for conversion to glucose and fructose with minimum saccharinic acid formation. The composition of the solution at equilibrium was determined.

2. Tetramethylmannose was obtained in crystalline form for the first time.

3. On treating 100 g. of tetramethylmannose with dilute alkali, 93.5 g. of sugar was recovered. This yielded a weight of crystalline anilides equivalent to 87.8 g. of sugar. The weight of pure anilides separated from this was equivalent to 74.7 g. of sugar, of which 36.9 g. was tetramethylglucose and 37.8 g. was tetramethylmannose.

4. No methylated ketose was formed.

5. Evidence is presented for the presence of the monomethyl ene-diol common to tetramethylmannose and tetramethylglucose.

6. The ring structures of the normal forms of tetramethylmannose and tetramethylglucose are indicated to be identical.

7. The prediction of the ene-diol theory as applied to the action of dilute alkali upon tetramethylmannose has been confirmed.

REACTIONS OF ALPHA, BETA-UNSATURATED DINITRILES

BY BEN B. CORSON AND ROGER W. STOUGHTON

RECEIVED AUGUST 7, 1928 PUBLISHED OCTOBER 6, 1928

Malononitrile, by virtue of its methylene group, readily condenses with carbonyl compounds to yield α,β-unsaturated dinitriles.[1] In several instances we obtained two products, the usual α,β-unsaturated dinitrile (I) and a dimer (II) whose structure we are still investigating.

$$C_6H_5CHO + CH_2(CN)_2 \longrightarrow \underset{\text{I}}{C_6H_5CH{=}C(CN)_2} \quad \text{also} \quad \underset{\text{II}}{C_{20}H_{12}N_4}$$

This paper deals with condensation products corresponding to I.

There is a close resemblance between the reactions of α,β-unsaturated dinitriles and those of α,β-unsaturated aldehydes and ketones, the resemblance being due to the presence in both classes of substances of a reactive conjugated system, $C{=}C(C{\equiv}N)_2$ and $C{=}C{-}C{=}O$, respectively.

We have studied this resemblance in four reactions which are typical of α,β-unsaturated aldehydes and ketones, namely, the reaction with sodium bisulfite, oxidation by permanganate, reversal of reaction of formation (aldol or ketol condensation) by means of sodium hydroxide and the addition of the elements of hydrocyanic acid.

Benzalmalononitrile (I) and similar substances dissolve in sodium bisulfite solution—slowly in the cold, rapidly when warmed. The product thus formed (III) resembles the sulfonates (IV)[2] obtained from the reaction

between α,β-unsaturated aldehydes and ketones and sodium bisulfite in that it is not reversed into the original components by means of acid or base. Lapworth and McRae[3] assumed a similar structure (V) for the product formed in the reaction between benzalcyano-acetic ester and sodium bisulfite.

$$[C_6H_5CH(SO_3Na)CH(CN)_2] \quad \text{III} \qquad C_6H_5CH(SO_3Na)CH_2COC_6H_5 \quad \text{IV}$$

$$[C_6H_5CH(SO_3Na)CH(CN)CO_2C_2H_5] \quad \text{V}$$

We were unable to isolate the sodium salt (III) in pure condition; Lapworth and McRae did not isolate V. However, by titration of the excess sodium bisulfite with iodine solution we found that one molecule of dinitrile reacted with one molecule of sodium bisulfite.

These a,@-unsaturated dinitriles are readily oxidized by potassium permanganate In acetone solution. Thus, benzalmalononitrile (I) yields benzoic acid; m-nitrobenzalmalononitrile, m-nitrobenzoic acid; o-methoxy benzalmalononitrile, o-methoxybenzoic acid.

It has long been known that acid, and especially alkali, reverses the reaction of formation of α,β-unsaturated compounds such as mesityl oxide. Likewise, the reaction of formation of these dinitriles is readily reversed. Benzalmalononitrile (I) shaken for ten minutes at room temperature with $N/5$ sodium hydroxide, produces benzaldehyde in good yield.

These α,β-unsaturated dinitriles add the elements of hydrocyanic acid. Hydrocyanic acid has been added to other α,β-unsaturated compounds by means of alkali cyanides[3,4] but the metallic derivatives of the addition products have not been isolated heretofore. Their appearance in this case is probably due to favorable solubility relations.

The general procedure was to treat the dinitrile with potassium cyanide solution, warm the mixture for a few minutes and acidify with hydrochloric acid. When the mixture was acidified, trinitrile was obtained. On the other hand, if the reaction mixture was allowed to stand without acidification, a potassium derivative was deposited. For example, starting with *p*-methoxybenzalmalononitrile (VI) we obtained a 95% yield of trinitrile (VII) if we acidified the solution after the reaction with potassium cyanide had taken place. However, if the reaction mixture was allowed to stand without acidification, a 90% yield of a potassium deriva-

[4] (a) Pinner, *Ber.*, 14, 1072 (1881); (b) Lapworth, *J. Chem. Soc.*, **85**, 1214 (1904); (c) **83**, 995 (1903); (d) 89, 945, 1869 (1906); (e) Clarke and Lapworth, *ibid.*, 89, 1869 (1906); (f) Knoevenagel, *Ber.*, 37, 4065 (1904); (g) Anschütz, *Ber.*, 26, 827 (1893); (h) Wigginbotham and Lapworth, *ibid.*, **121**, 49 (1922); (i) Baker and Lapworth, *ibid.*, 127, 560 (1925); (j) Lapworth and Baker, "Organic Syntheses," John Wiley and Sons, Inc., New York, 8, 89 (1928).

tive was obtained whose nitrogen and potassium content agreed with the percentage composition of compound VIII

$$\begin{tikzcd} & \underset{\text{VII}}{p\text{-}CH_3OC_6H_4CH(CN)CH(CN)_2} \\ \underset{\text{VI}}{p\text{-}CH_3OC_6H_4CH{=}C(CN)_2} + KCN + HOH \arrow[ur] \arrow[dr] & \\ & \underset{\text{VIII}}{C_{12}H_8ON_3K} \end{tikzcd}$$

These trinitriles function as weak acids, dissolving in bases to form salts. The trinitrile (VII) obtained by the addition of the elements of hydrocyanic acid to *p*-methoxybenzalmalononitrile (VI) dissolves easily, even in such weakly alkaline solutions as potassium cyanide or dilute ammonium hydroxide solution. Recovery of trinitrile was practically quantitative from the potassium and from the ammonium salts. The yield from the silver salt was 73% of the theoretical amount.

$$p\text{-}CH_3OC_6H_4CH(CN)CH(CN)_2 \underset{HCl}{\overset{NH_4OH}{\rightleftarrows}} C_{12}H_8ON_3^- + NH_4^+$$

A white silver salt precipitates when dilute silver nitrate solution is added to a dilute solution of either the potassium or the ammonium salt. We analyzed several potassium and silver salts but the percentage of metal was usually high (around 5% high). The high values for silver and potassium may be due to the presence of some di-salt, for example, p-$CH_3OC_6H_4CAg(CN)CAg(CN)_2$.

The potassium derivative alkylates to give a carbon–carbon linkage. The potassium salt (IX) corresponding to α-phenyl-α,β,β-tricyano-ethane (XV) reacts with methyl iodide to form a methyl derivative (X) whose structure was established by conversion into the corresponding succinic acid (XI).

$$\underset{\text{IX}}{C_{11}H_6N_3K} \longrightarrow \underset{\text{X}}{C_6H_5CHCNCCH_3(CN)_2} \longrightarrow \underset{\text{XI}}{C_6H_5CH(CO_2H)CH(CH_3)CO_2H}$$

The melting point of this acid (XI) agreed with that given in the literature but since only a small amount of the product was obtained it seemed wise to synthesize a larger amount for purification and comparison. This was accomplished by means of the following series of transformations.

$$\begin{tikzcd} \underset{\text{XII}}{C_6H_5CH{=}C(CN)CO_2CH_3} \arrow[r] & \underset{\text{XIII}}{C_6H_5CHCNCH(CN)CO_2CH_3} \arrow[dl] & \\ \underset{\text{XIV}}{C_6H_5CHCNCCH_3(CN)CO_2CH_3} \arrow[r] & \underset{\text{XI}}{C_6H_5CH(CO_2H)CH(CH_3)CO_2H} \end{tikzcd}$$

There is nothing certain about the constitution of these salts. We see no evidence to justify any conclusion as to their structure, whether they be carbides or nitrides, that is, $C_6H_5CH(CN)CK(CN)_2$ or $C_6H_5CH(CN)$-$C{=}C{=}NK(CN)$, respectively.

The structure of the trinitriles was established by relating it to that of succinic acid. The structure of the α,β-unsaturated dinitriles follows from their method of formation and also from their relationship to the trinitriles.

$$RCHO + CH_2(CN)_2 \longrightarrow RCH{=}C(CN)_2 \longrightarrow RCHCNCH(CN)_2 \longrightarrow RCH(CO_2H)CH_2CO_2H$$

Incidentally, this is a very convenient set of reactions for use in proof of structure of many substances with the following constitutions, $RCH{=}C(CN)CO_2R$ and $RCH{=}C(CN)_2$. The nitrile groups in such substances are very resistant to hydrolysis.[5]

In order to hydrolyze a nitrile group so situated, hydrogen must first be introduced into the molecule in a position alpha to the nitrile group. This can be accomplished by reduction, which leads to complications because the product is apt to be a mixture of cyano and amino compounds.[5b]

$$RCH{=}C(CN)CO_2R \longrightarrow RCH_2CH(CN)CO_2R + RCH_2CH(CH_2NH_2)CO_2R$$

The better method for the introduction of alpha hydrogen is that employed in the present instance, namely, the addition of the elements of hydrocyanic acid to the α,β-unsaturated nitrile.

Experimental Part

I. Dinitriles

Preparation.—Equivalent quantities of aldehyde and malononitrile were dissolved in a suitable solvent and a few drops of piperidine added with shaking. The solution warmed up somewhat and became more or less reddish. Within fifteen minutes the mixture was solid with crystalline condensation product. It is advisable to carry out the reaction in an open beaker in order to facilitate removal of the solid. These condensations can be run without solvent but the products are apt to be dark colored. Solvent is desirable.

In the case of furfural the condensation must be run in a high dilution of water and in the presence of a weak catalyst (a pinch of sodium acetate). When the usual procedure was followed, the product was a sticky red gum with which we could do nothing. However, it is only in the condensation of furfural that special precautions are necessary.

For catalyst we usually used piperidine. However, other alkaline reagents also bring about condensation, for example, sodium methylate, sodamide, sodium acetate, ammonium carbonate, diethylamine and aniline. Reaction proceeded slowly in the presence of small amounts of formic and acetic acids. We have run several condensations between benzaldehyde and malononitrile without addition of any catalyst. Without catalyst the reaction required a day or so, whereas with piperidine the reaction was done in fifteen minutes. However, it is not to be concluded from this experiment that the condensation really takes place without the aid of a catalyst. Our materials were not sufficiently pure to preclude the presence of a trace of some basic or acidic impurity which might act as catalyst.

The condensation procedure can be best illustrated by the two following sets of directions, one for the preparation of piperonalmalononitrile (XIX), the other for furfuralmalononitrile (XXIII).

---

[5] (a) Heller and Wunderlich, *Ber.*, **47**, 1617 (1914); (b) Kohler and Corson, THIS JOURNAL, **45**, 1975 (1923); (c) Rosenmund and Boehm, *Ann.*, **437**, 125 (1924).

Condensation of Piperonal with Malononitrile.—To a solution of 30 g. of piperonal (0.2 mole) and 15 g. of malononitrile (0.24 mole) in 130 cc. of n-butyl alcohol was added with stirring, 8 drops or so of piperidine. The solution became somewhat reddish and warmed up a little. Within five minutes the mixture was solid. After cooling to room temperature the product was jammed up, filtered by suction, washed with water containing a small amount of acetic acid and finally air dried. The yield was 38 g. or 96% of the theoretical amount. A small yield (±1 g.) slowly crystallized from the mother liquor. The product is lemon yellow; it has no irritant action upon the nose or eyes. The analytical sample was crystallized 3 times from acetic acid and dried at 100" in a vacuum over quicklime. It melts at 199–200°.[6]

Condensation of Furfural with Malononitrile.—Forty-eight g. of furfural (0.5 mole) and 33 g. of malononitrile (0.5 mole) was added to 250 cc. of water contained in a wide-mouthed Erlenmeyer flask equipped with a mechanical stirrer. The stirrer was started and a pinch of sodium acetate added to catalyze the condensation reaction. A flocculent yellow solid soon appeared. There was perhaps a slight rise in the temperature of the reaction mixture. At the end of half an hour the mixture was filtered by suction. After air drying the product weighed 70 g., which corresponds to 80% of the theoretical amount. The mother liquor slowly deposited 2 g. more of the product. The analytical sample was crystallized 4 times from carbon tetrachloride and finally air dried. Furfuralmalononitrile **(XXIII)** is straw yellow and melts at 72.5--73".

Physiological Properties.—Certain of these dinitriles have the effect of sneeze and tear gases. They are harmless when wet but to handle the dry powder is diastrous. When crystallizing *m*-nitrobenzalmalononitrile, for instance, the alcohol solution should not be boiled very much since the alcohol vapor has a peppery sting. In sneezing caused by *m*-nitrobenzalmalononitrile (XVIII) the mucous discharge from the nose becomes bright yellow on exposure to air. In sneezing caused by *o*-chlorobenzalmalononitrile (XX) the face smarts, especially if damp. The smarting is intensified-by washing. Most of the discomfort can be avoided if a gas mask is worn whenever dry solid is to be handled. However, the majority of the dinitriles reported in this paper have no irritant effect, as furfuralmalononitrile (XXIII) and *p*-methoxybenzalmalononitrile (VI).

Solubilities of Dinitriles.—As a general rule these substances are very soluble in acetic acid, acetone, benzene, chloroform and methyl acetate; less soluble in the higher alcohols, carbon tetrachloride and ether; sparingly soluble in carbon bisulfide, petroleum ether and water. The crystallizing properties of these dinitriles are excellent—they crystallize readily from a variety of solvents.

Solubility in Sodium Bisulfite Solution.—All these a,β-unsaturated dinitriles are soluble in sodium bisulfite solution with the exception of cyclohexylidene malononitrile (XXI). One and one-half grams of finely ground benzalmalononitrile (I) was suspended in 100 cc. of saturated sodium bisulfite solution and the mixture mechanically shaken at room

[6] All melting points reported in this paper are corrected for exposed thread and were read from a thermometer which had been calibrated against one which had been examined by the U. S. Bureau of Standards.

[a] Kjeldahl analysis with mercury catalyst.

temperature. At the end of twenty-four hours the substance had gone into solution. The same substance dissolved immediately when the mixture was warmed to 70° or so.

It would seem that the salts of sulfonic acids are formed since the dinitriles are not regenerated on addition of excess acid or base. In spite of several attempts we were unable to isolate any of these sodium salts. However, by determining the amount of bisulfite used we were able to show that one molecule of sodium bisulfite reacted with one molecule of dinitrile. Two examples follow.

To a warm solution (±65°) of 1.657 g. of sodium bisulfite in about 50 cc. of water was added 1.443 g. of benzalmalononitrile. The mixture was shaken for fifteen minutes or so until all the dinitrile had dissolved. The solution was then cooled to room temperature and diluted to 100 cc. A portion of this solution was titrated against a solution of iodine, 1 cc. of which was equivalent to 0.00506 g. of sodium bisulfite. The excess of bisulfite was found to be 0.567 g. since 17.63 cc. of the solution required 19.88 cc. of iodine solution. Therefore, 1.443 g. of benzalmalononitrile used up 1.091 g. of sodium bisulfite, which is in the molecular ratio of 1.00 to 1.12.

Using the same analytical procedure, 2.014 g. of furfuralmalononitrile was treated with 1.976 g. of sodium bisulfite. After dilution to 100 cc., 27.66 cc. required 19.99 cc. of iodine solution. Therefore, 2.014 g. of furfuralmalononitrile had used up 1.610 g. of sodium bisulfite, which is in the molecular ratio of 1.00 to 1.09.

Oxidation with Permanganate.—α,β-Unsaturated dinitriles are readily oxidized in acetone solution by means of potassium permanganate. These substances break at the ethylene double linkage. We isolated benzoic and substituted benzoic acids. Our method is illustrated by the following procedure.

One gram of m-nitrobenzalmalononitrile (XVIII) was dissolved in 200 cc. of acetone. To this solution was added with shaking a hot aqueous solution of *2* g. of potassium permanganate (25% excess) in 100 cc. of water. Manganese dioxide appeared as soon as the solutions were mixed. The mixture was warmed on a steam-bath for fifteen minutes and then filtered; perrnanganate color had disappeared. The filtrate was freed from acetone by heating on a steam-bath. Norite was added and the solution filtered. The solution was cooled and then extracted with ether in order to remove non-acidic organic material and next heated over a flame and evaporated to a volume of 50 cc. This *50* cc. of solution was poured with stirring into 50 cc. of concentrated hydrochloric acid. The m-nitrobenzoic acid was extracted with ether and the ether extract dried with anhydrous sodium sulfate. After evaporation of the ether the organic acid was crystallized from 50 cc. of 1% hydrochloric acid. Crystallization yielded 0.32 g. of pure m-nitrobenzoic acid; ether extraction of the mother liquor gave an additional yield of 0.13 g. The total yield was 0.45 g. or 50% of the theoretical amount. The product melted at 140° and was identifidd by comparison with an authentic sample of m-nitrobenzoic acid prepared by the method of Kamm and Segur.[7]

Using the same procedure we obtained a *60%* yield of benzoic acid by the oxidation of benzalmalononitrile (I). The product was identified by means of a mixed melting point comparison. Starting with 0.9 g. of *o*-methoxybenzalmalononitrile (XVI) and 1.6 g. of potassium permanganate, we obtained 0.43 g. of impure o-methoxybenzoic acid (60% yield). Crystallization from water yielded pure o-methoxybenzoic acid melting at 100.5–101°. The melting point of *o*-methoxybenzoic acid is recorded in the literature as 98.5, 98.5–99 and 99°.[8] We had no authentic sample on hand for a mixed melting point comparison.

Reversal by Means of Sodium Hydroxide.—Benzalmalononitrile decomposes readily in the presence of sodium hydroxide. A good yield of benzaldehyde is obtained after shaking for ten minutes at room temperature in contact with *N*/5 aqueous sodium hydroxide.

In order to obtain an idea as to the extent of this reversal, we carried out the following procedure. To a dilute solution of sodium hydroxide contained in a 250cc. distilling flask connected to a water condenser was added a known amount of dinitrile. The alkaline mixture was boiled and about 50 cc. of distillate collected. The odor of ammonia was apparent after distillation had proceeded for a few minutes. The benzaldehyde in the distillate was precipitated by means of an acidic aqueous solution of phenylhydrazine hydrochloride. The precipitate was collected in a fretted glass

---

[7] Kamm and Segur, "Organic Syntheses," John Wiley and Sons, Inc., New York, 3, 73 (1923).

[8] (a) Graebe, ***Ann.,*** 139, 139 (1865); (b) Bromwell, *Am.* ***Chem.*** **J , 19,** 577 (1897); (c) Lander, J. *Chem. Soc.,* 77, 745 (1900).

Gooch, dried and weighed. The product thus obtained was shown to be benzaldehyde phenylhydrazone by means of a mixed melting point comparison with an authentic sample. We obtained 1.48 g. of benzaldehyde phenylhydrazone from 1.93 g. of benzalmalononitrile; this corresponds to 60% of the theoretical amount. We ran a blank with pure benzaldehyde against our phenylhydrazine reagent in order to test the analytical procedure. Starting with 0.6194 g. of benzaldehyde we obtained 0.8847 g. of benzaldehyde phenylhydrazone, 77.3% of the theoretical amount. This indicates that the yield of phenylhydrazone in the reversal experiment was 60/77.3 × 100% or 77.6%.

In like manner we obtained 2.80 g. of p-methoxybenzaldehyde phenylhydrazone from 3.58 g. of *p*-methoxybenzalmalononitrile. This corresponds to 45% of the theoretical amount. The identity of the product was established by means of a mixed melting point comparison with an authentic sample.

II. Trinitriles

We obtained trinitriles from four of the unsaturated dinitriles, namely, benzal- (I), *p*-methoxybenzal- (VI), o-methoxybenzal- (XVI) and dioxymethylene benzalmalononitrile (XIX). The crude trinitriles from *p*- and o-methoxybenzalmalononitrile were fairly pure and the yields almost quantitative. The crude yield from piperonalmalononitrile was the smallest and the least pure. The general procedure follows.[9]

Addition of Hydrocyanic Acid to *p*-Methoxybenzalmalononitrile.—To 13.5 g. (0.74 mole) of finely ground **p-methoxybenzalmalononitrile** (VI) wet with 15 cc. of ethyl alcohol was added a hot, filtered solution of 9.5 g. (1.5 moles) of potassium cyanide in 15 cc. of water. The mixture was stirred and heated for two to three minutes on a steam-bath. The dinitrile dissolved. The red solution was then diluted with an equal volume of water. If the reaction had proceeded to completion the solution remained clear on dilution. Sometimes, however, a flocculent, tan-colored precipitate appeared. This substance seemed to be neither the original dinitrile nor the trinitrile sought. This precipitate should be removed by filtration before proceeding. Usually, however, the solution remained clear. A large excess of concentrated hydrochloric acid was stirred into the clear solution. A milkiness appeared, then a rather dark, heavy oil which quickly solidified and granulated (stirring should be continued for a few minutes after precipitation). The mixture was filtered by suction and the solid air dried. The crude product weighed 15.5 g.; one crystallization cut the yield down to 14.5 g. or 95% of the theoretical amount. The analytical sample was recrystallized several times from tertiary amyl alcohol with one or two treatments with Norite and finally dried in a vacuum at 80° over concentrated sulfuric acid. The pure substance is light cream colored and melts at 122–122.5°.

Solubility, Color and Physiological Action of **Trinitriles.**—The solubilities of the trinitriles are similar to those of the dinitriles, usually very soluble in acetic acid, acetone, benzene, chloroform and methyl acetate; less soluble in alcohols, carbon tetrachloride and ether; sparingly soluble in carbon bisulfide, petroleum ether and water. The trinitriles are lighter colored than the dinitriles. It may be that further purification would totally decolorize them. None of the trinitriles have the irritant physiological action of the dinitriles.

---

[9] This is practically the procedure outlined by Lapworth and Baker (ref. 4j) for the addition of hydrocyanic acid to ethyl benzalcyano-acetate.

Potassium Derivative as Intermediate.—When the reaction with potassium cyanide was carried out according to the preceding directions, the trinitrile was obtained directly without the intermediate appearance of a potassium salt. However, when the following modified procedure was employed a potassium derivative could be isolated.

Benzalmalononitrile (I) and potassium cyanide were mixed as in the preparation of trinitrile. The mixture was stirred and warmed for two to three minutes. The solution was then quickly filtered by suction. Large pink crystals of the potassium derivative (IX) crystallized from the filtrate. We were unable to purify this potassium salt by recrystallization. We could, however, remove the greater part of the pink color by grinding in a mortar with dry ether or n-butyl acetate. The salt darkens and shrivels around 180°; it partially melts around 190°. It is very soluble in water; rather soluble in acetone and acetic acid (the acetic acid solution soon deposits trinitrile); less soluble in the alcohols; insoluble in benzene, ether, n-butyl acetate and carbon bisulfide. It crystallizes poorly from n-butyl alcohol. The analytical sample was washed with ether and dried in a vacuum at 100°.

Anal. Calcd. for $C_{11}H_6N_3K$: N, 19.2; K, 17.8. Found: N, 19.0; K, 17.6.

Starting from *p*-methoxybenzalmalononitrile (VI), the corresponding potassium derivative was obtained in 88% yield. The high figures for potassium suggest that a second active hydrogen has undergone partial salt formation.

Anal. Calcd. for $C_{12}H_8ON_3K$: N, 16.9; K, 15.7. Found: N, 16.7; K, 17.5, 17.6.

These potassium salts decompose slowly in water solution. A water solution was made by dissolving 1.6 g. of the potassium derivative of α-phenyl-α,β,β-tricyanoethane in 12 cc. of water. There resulted a clear, red solution, alkaline to litmus. In three hours considerable brown sediment had settled out. We were unable to identify this solid. It reminds one of the flocculent precipitate which occasionally appears on diluting the reaction mixture in the preparation of the trinitriles. This water solution was allowed to stand for two months and became thick with dark solid. A strong odor of ammonia developed and perhaps there was an odor of hydrocyanic acid.

Neutralization of Trinitriles.—The trinitriles, as acids, dissolve in bases—even in such weakly alkaline solutions as potassium cyanide solution and dilute ammonium hydroxide. Solution takes place readily.

Acidification of Salts.—Trinitrile is obtained pure and in quantitative yield on acidification of the corresponding potassium or ammonium salt. Three grams of the potassium derivative of α-phenyl-α,β,β-tricyano-ethane ($C_{11}H_6N_3K$, IX) was dissolved in 50 cc. of water and the red solution was acidified with a slight excess of acetic acid. Trinitrile (XV) was precipitated immediately. The yield of pure, dry trinitrile was 2.55 g., the theoretical amount being 2.50 g.

In another instance, 1.31 g. of α-(*p*-methoxyphenyl)-α,β,β-tricyano-ethane (VII) was dissolved in a mixture consisting of 10 cc. of concentrated ammonia water and 50 cc. of water. The resulting solution of ammonium salt was slightly yellow. Trinitrile was precipitated by addition of 20 cc. of concentrated hydrochloric acid. The yield of dry trinitrile was 1.29 g., which corresponds to 98.5% of the theoretical amount.[10]

Silver Salt.—To a dilute solution of the ammonium salt of *p*-$CH_3OC_6H_4CHCNCH(CN)_2$ was added, in the dark, with stirring, a dilute solution of silver nitrate. The silver salt immediately appeared. The salt is pure white at first but soon darkens, especially if exposed to the light. The solid was washed, first with methyl alcohol, finally with ether. It was dried, in the dark, over sulfuric acid in a vacuum desiccator. Choking fumes were given off during ignition of the silver salt.

Anal. Calcd. for $C_{12}H_8ON_3Ag$: Ag, 33.9. Found: Ag, 39.9.

Another sample of the silver derivative of *p*-$CH_3OC_6H_4CHCNCH(CN)_2$ was made by adding silver nitrate solution to a solution of the potassium salt.

Anal. Calcd. for $C_{12}H_8ON_3Ag$: Ag, 33.9. Found: Ag, 38.0.

Both of these analyses are high and they also disagree between themselves to the extent of 2%.

The silver salt behaves like the potassium and ammonium salts in that it regenerates the corresponding trinitrile upon acidification. The yield, however, is not quantitative. A sample of the silver salt (which had become dark upon standing) of *p*-$CH_3OC_6H_4CHCNCH(CN)_2$ was acidified with dilute nitric acid. The product was contaminated with so much silver (from previous decomposition of the salt) that the quantitative results were of no significance. We recrystallized the product and showed that trinitrile (*p*-$CH_3OC_6H_4CHCNCH(CN)_2$) was present.

Better results were obtained by acidifying the silver salt before it had a chance to darken. Trinitrile (1.105 g. of *p*-$CH_3OC_6H_4CHCNCH(CN)_2$) was dissolved in dilute ammonia water and the excess of ammonia neutralized with dilute nitric acid. To the clear solution of ammonium salt was added silver nitrate solution in excess. A white precipitate of silver salt appeared. The silver salt was immediately decomposed by the addition of dilute nitric acid. The precipitated trinitrile was filtered on a fretted glass crucible, dried and weighed. The product was pure *p*-$CH_3OC_6H_4CHCNCH(CN)_2$, 0 800 g. (73% of the theoretical amount). There was no odor of hydrocyanic acid upon acidification.

Alkylation of Potassium Derivative to Form $C_6H_5CHCNCCH_3(CN)_2$.—Eighteen grams of the potassium derivative of $C_6H_5CHCNCH(CN)_2$ was suspended in 25 cc. of methyl alcohol. The mixture was treated under a reflux with 6 cc. of methyl iodide. Within five minutes the alcohol had come to a boil. After the force of the reaction

---

[10] In a recent interesting investigation by Rising and Zee, THIS JOURNAL, 50, 1699 (1928), (see Rising and Zee, *ibid.*, 49, 541 (1927)), certain sodium derivatives (seemingly similar to the salts encountered in this work but of smaller molecular weight) were found to yield hydrocyanic acid on treatment with acid This was construed as evidence for the nitride formula, that is, $C_6H_5CH{=}C{=}NNa$ and $C_6H_5C(C_2H_5){=}C{=}NNa$.

had subsided, an additional 10 cc. of methyl iodide was added and the mixture allowed to stand for six hours. The reaction mixture was finally poured into water. In the course of a day a white solid appeared. The yield was small. The substance was crystallized several times from isobutyl alcohol; it melts at 83–84'. It is soluble in acetone, acetic acid, ether and the alcohols; less soluble in carbon tetrachloride.

Anal. Calcd for $C_{12}H_9N_3$: N, 21.5. Found: N, 21.3.

Proof of Structure of **Alkylated Nitrile, $C_6H_5CHCNCCH_3(CN)_2$.**—In order to establish the structure of the alkylated nitrile we transformed it into the corresponding succinic acid (XI). This was accomplished by refluxing for several hours with 20% hydrochloric acid. An acid was obtained which melted at 182–183° with a little bubbling. This is one of the melting points recorded in the literature for α-phenyl-β-methyl succinic acid.[11]

Methyl **α-Phenyl-α,β-dicyano** Propionate, $C_6H_5CHCNCH(CN)CO_2CH_3$.—The elements of hydrocyanic acid were added to methyl benzalcyano-acetate (XII) in the usual manner. An oil was obtained upon acidification. The mixture of oil and water was aspirated for several hours until the oil had solidified into a hard lump. The product was crystallized three times from *iso*propyl alcohol and, finally, once from methyl alcohol. It melts at 100–101°. It is very soluble in acetone, acetic acid and methyl acetate; rather soluble in benzene, ether and the alcohols; less soluble in carbon bisulfide and carbon tetrachloride; sparingly soluble in petroleum ether and water.

Anal. Calcd. for $C_{12}H_{10}O_2N_2$: N, 13.1. Found: N, 12.7.

Methyl α-Phenyl-α,β-dicyano-β-methyl Propionate, $C_6H_5CHCNC(CN)CH_3$-CO_2CH_3.—Thoroughly dried nitrile ester (XIII) prepared above was dissolved in a cold methyl alcohol solution of sodium methylate (1 equivalent of sodium methylate, based on $C_6H_5CHCNCH(CN)CO_2CH_3$). The yellowish solution was treated with an excess of methyl iodide. The mixture came to a slight boil. After standing in warm water for one hour, the reaction mixture was poured into water and extracted with ether. An oil was obtained from the ether extract. We tried to distil the product under 5 mm. pressure but it decomposed. However, the crude oil solidified upon long standing. The solid was crystallized from methyl alcohol. We did not have sufficient material to determine its solubility in the various solvents. The colorless crystals melt at 87–88'.

Anal. Calcd. for $C_{13}H_{12}O_2N_2$: N, 12.3. Found. N, 12.3.

α-Phenyl-β-methylsuccinic Acid, XI.—Methyl α-phenyl-α,β-dicyano-β-methyl propionate was refluxed for several hours with 20% hydrochloric acid. A good yield of phenylmethylsuccinic acid resulted. It was purified by several crystallizations from hot water. It melted at 182–183° with some effervescence. A mixed melting point comparison showed it to be identical with the acid obtained from $C_6H_5CHCNCCH_3(CN)_2$

Anal. Calcd. for $C_{11}H_{12}O_4$; 0.5316 g. requires 25.54 cc. of $N/5$ KOH. Found 25.69 cc. 0.1875 *g*. requires 18.01 cc. of $N/10$ KOH. Found: 17.88 cc.

The silver salt was prepared, dried in a vacuum and analyzed. It is quite stable toward light as had already been observed by Zelinsky and Buehstab.

Anal. Calcd. for $C_{11}H_{10}O_4Ag_2$: Ag, 51.15. Found: Ag, 50.96.

III. Hydrolysis of Trinitriles to Succinic Acids

The trinitriles were transformed into succinic acids by refluxing for several hours (three to ten hours, depending on the substance) with a con-

---

[11] *(a)* Zelinsky and Buchstab, *Ber.*, 24, 1876 (1891); (b) Ruhemann, *J. Chem. Soc*, 81, 1216 (1902); (c) Upson and Thompson, THIS JOURNAL, 44, 185 (1922).

siderable excess of 20% hydrochloric acid. The products were recrystallized from hot water.

Ten grams of a-phenyl-a,β,β-tricyano-ethane (XV) yielded upon hydrolysis and decarboxylation 9.6 g. of phenylsuccinic acid (90% of the theoretical amount). Its identity was established by comparison with an authentic sample prepared by the method of Bredt and Kallen.[12]

Ten grams of α-(*p*-methoxyphenyl)-α,β,β-tricyano-ethane (VII) yielded 7 g. of colorless p-methoxyphenylsuccinic acid **(67%** of the theoretical amount). It was recrystallized several times from hot water and finally dried at 100° in a vacuum over sulfuric acid. Its melting point depends upon the speed of heating. Heated slowly it melts at 204–206°; heated rapidly it melts at 207–208°. Uncertain melting point is often characteristic of dibasic acids and is doubtless due to the formation of a small amount of anhydride, the presence of which lowers the melting point. The faster the heating, the less anhydride formed and, therefore, the higher the melting point.

Anal. Calcd. for $C_{11}H_{12}O_5$: **0.4448** g. requires **19.85** cc. of $N/5$ KOH. Found: **19.83** cc.

p-Methoxyphenylsuccinicacid has been reported by Baker and Lapworth[13] as melting at 194–195° (10° below our melting point). Chrzaszezewska[14] describes it as pale yellow and melting still lower, 189–190°.

Because of this disagreement in melting points we prepared the anhydride for further comparison. The acid was refluxed for one hour with acetyl chloride. The acetyl chloride was removed by vacuum evaporation at room temperature and the residual solid crystallized from chloroform–petroleum ether mixture. The product melts at 91–92°, which agrees well with the melting point of **90.5"** observed by Baker and Lapworth.

Dimethyl *p*-Methoxyphenylsuccinate, p-$CH_3OC_6H_4CH(CO_2CH_3)CH_2CO_2CH_3$.—The dimethyl ester was obtained in 50% yield by refluxing **6.5** g. of the corresponding trinitrile (VII) with a solution of **9** cc. of concentrated sulfuric acid in **25** cc. of **98%** methyl alcohol. After boiling for five hours, the solution was poured into ice water and the mixture extracted with ether. The colorless product was recrystallized several times from methyl alcohol. It melts at **93–94'.** We were unable to obtain consistent analyses for the carbon content. **A** qualitative test showed nitrogen to be absent.

Anal. Calcd. for $C_{13}H_{16}O_5$: C, **61.9;** H, **6.0.** Found: **C, 57.8, 56; H, 5.5, 5.7.**

***o*-Methoxyphenylsuccinic** Acid, o-$CH_3OC_6H_4CH(CO_2H)CH_2CO_2H$.—Ten grams of the corresponding trinitrile (XXIV) yielded **6** g. of substituted succinic acid **(57%** of the theoretical **amount**).[15] The product, however, was a mixture. Fractional crystallization from water separated it into two fractions. The more soluble fraction melted cloudy around 122°; the melt cleared around **185"** and bubbled at about **197".** We did not investigate this fraction. The less soluble fraction was *o*-methoxyphenylsuccinic acid. It melts with slow heating at 182–184°; with rapid heating at 184–185°.

Anal. Calcd. for $C_{11}H_{12}O_5$: C, **58.9;** H, **5.4.** Found: C, **59.1;** H, **5.5.** Calcd.:

0.3743 *g*. requires 16.67 cc. of $N/5$ KOH. Found: 16.67 cc. Calcd.: 0.2106 g. requires 18.79 cc. of $N/10$ KOH. Found: 18.78.

Piperonylphenylsuccinic acid was obtained in poor yield by the alkaline hydrolysis and decarboxylation of $3,4\text{-}CH_2O_2C_6H_3CH(CN)CH(CN)_2$ (XXV). The product was very pale yellow and melted at 210–212°, which agrees with the melting point of 211° observed by Lapworth and McRae.[16]

This work was assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

1. Several new condensation products of malononitrile with aromatic aldehydes are reported.

2. These α,β-unsaturated dinitriles closely resemble α,β-unsaturated aldehydes and ketones in that they (a) dissolve in sodium bisulfite solution, (b) are oxidized by potassium permanganate, (c) are reversed into the original components by sodium hydroxide and (d) add the elements of hydrocyanic acid.

3. The trinitriles, resulting from the addition of hydrocyanic acid to the dinitriles, function as weak acids, dissolving in bases to form salts. Acidification of the potassium, ammonium and silver salts results in regeneration of trinitrile. The potassium salt alkylates with methyl iodide to give carbon–carbon alkylation.

THE ACTION OF SELENIUM MONOCHLORIDE UPON FATTY OILS

BY ELLERY H. HARVEY AND H. A. SCHUETTE

RECEIVED AUGUST 10, 1928 PUBLISHED OCTOBER 6, 1928

The discovery by Parkes[1] that rubber could be vulcanized by immersing it in sulfur monochloride, followed by his observation[1] that "articles having properties analagous to those from india-rubber or gutta percha" could be made from fatty oils by the action of this substance, eventually gave rise to its introduction into the field of analytical chemistry by Warren[2] and then by Fawsitt.3 Warren's conclusions, which were based upon the nature of the reaction product, were subsequently questioned.[4] Fawsitt's

suggestion that the accompanying thermal effect might be utilized after the manner of Maumené's sulfuric acid number of fatty oils[6] received but scant attention and attempts to revive the former proposal by improving the technique of the method and following closely guarded experimental conditions, which measurements of this type require, have served to indicate that this feature of the reaction is impractical in so far as it might be used as a diagnostic "number" of fatty oils.[6]

The relationships which obtain in the oxygen family of the chemical elements and the renewed interest which has centered within recent years around selenium and its compounds suggested to the authors the desirability of observing the action of its monochloride upon the fatty oils under conditions? which simulate those once proposed by Fawsitt,[3] except that a diluent was to be used to facilitate the formation of a homogeneous reaction mixture.

Apparatus, Materials and Procedure.—The nested beakers of Fawsitt with cotton-filled intervening space were replaced by a silvered 300-cc. Dewar flask 55 mm. in diameter and 160 mm. in height. The latter was packed in kieselguhr and covered with a flanged Bakelite cap drilled to accommodate a stirrer, thermometer and pipet, respectively.

For experimental material there were selected twenty-two fatty oils representative of nine groups in the classification of Mitchell.[8] Their purity, in the sense that they conformed in' name to that for which they were sold, was experimentally verified. Selenium monochloride, b. p. 130°, was prepared from elementary selenium by the method of Divers and Shimos[9] and the sulfur monochloride was purified from a commercial preparation by that of Pope.[10]

For the purpose of measuring the thermal effect in the contemplated reaction, 25 g. of the fatty oil in question and a like amount of pure, drv xylene were weighed into the calorimeter. There was then quickly introduced (15 sec.) 1 cc. of the reagent at the same temperature as the fatty oil solution, the stirrer was started and the maximum temperature rise and the time of reaching this point were noted. Since the loss of heat through the glass is negligible from the standpoint of the purposes for which this reaction serves, and since the only escape of heat is from the surface exposed to the outer air, radiation losses were corrected for by the formula $C = 0.5t(R_1 \pm R_2)$, in which R_1 and R_2 represent the initial and maximum temperatures, respectively, and t is the number of minutes which elapsed from the moment that the reagent was added to the time at which the maximum temperature was reached.[11]

[7] By making allowance for the heat capacity of the apparatus and the specific heats of the solvent, oil, sulfur monochloride and reaction product it should be possible to calculate the exact amount of heat evolved, but since this reaction was studied from the standpoint of its probable suitability for analytical purposes, the observed rise of temperature is fully efficient.

Fatty acid	Oleic acid	15.0	*50*	.30	14.80	0.5	29.60

Discussion

Selenium monochloride is, in the light of thermometric measurements, more energetic in its action upon the fatty oils than is the corresponding sulfur compound. Although on the one hand the action of the latter appears to be, under the conditions set forth in this communication, of a rather complicated nature—an action which is characteristic not of groups whose members bear some resemblance to each other in their physical properties or chemical natures, but rather of individuals and one which cannot be ascribed alone to the nature of the fatty acid radicals present —on the other hand the action of selenium monochloride is more far reaching. In addition to substitution and addition, which results wholly if not in part with the sulfur compound, here there must also be taken into consideration the effect of the decomposition of the selenium compound itself. The deposition of elementary selenium in many case points to this conclusion. Ditmar[12] advances the opinion that at low temperatures

---

[12] Ditmar, Kunststoffe, 4, 292 (1914).

the reaction with sulfur monochloride is one of addition and that at normal temperatures substitution accompanies this phenomenon. Lack of specificity is even more pronounced in this case. The thermal rise which was observed with approximately one-half of the oils whose behavior was studied is about the same as with the sulfur monochloride, but of greater significance is the fact that the rise per minute is appreciably greater. Palm oil is the only one which showed any suggestion of a similar behavior.

Conclusions

The thermal effect which is observed when selenium monochloride acts upon fatty oils is an additive one produced not only by substitution and addition but by the decomposition of the reagent itself. In view of this situation, the use of selenium monochloride under conditions which simulate in a measure those of sulfuric acid[5] is impractical as a test which has any diagnostic value for the fatty oils.

THE ACTION OF SILVER ON DIPHENYL-TERTIARY-BUTYLETHYNYLBROMOMETHANE

BY PAUL L. SALZBERG AND C. S. MARVEL

RECEIVED AUGUST 10, 1928 PUBLISHED OCTOBER 6, 1928

It was recently[1] shown that hexa-*tert.*-butylethynylethane reacted with liquid sodium-potassium alloy and with liquid sodium amalgams to give the corresponding alkali metal derivative of tri-*tert.*-butylethynylmethyl, thus indicating that aliphatic acetylenic groups possess the properties necessary to cause weakening of the central bond in a substituted ethane. These results would lead to the prediction that the replacement of two phenyls in hexaphenylethane by acetylenic radicals would not greatly decrease the dissociation. However, Moureu, Dufraisse and Houghton[2] have shown that the action of metals on diphenylphenylethynylchloromethane gives rise to a hydrocarbon which is much more stable than would be expected of *sym.*-tetraphenyldiphenylethynylethane. To gain further knowledge of the effect of acetylenic groups on the stability of hexa-substituted ethanes, a study of the closely related tetraphenyldi-*tert.*-butylethynylethane has been undertaken.

Diphenyl-*tert.*-butylethynylcarbinol was easily prepared from *tert.*-butylethynylmagnesium bromide and benzophenone. The bromide was prepared by the action of phosphorus tribromide on the carbinol. When an ether solution of this bromide was shaken with molecular silver in an

---

[1] Salzberg with Marvel, THIS JOURNAL, 50, 1737 (1928).

[2] Moureu, Dufraisse and Houghton, *Bull. soc. chim.*, [4] **41**, 56 (1927).

atmosphere of nitrogen, a greenish-yellow solution with a very slight red fluorescence was obtained. The fluorescence disappeared when a stream of oxygen was run into the flask over the surface of the solution and then reappeared when the supply of oxygen was cut off. This indicated that the solution contained a free radical which was being oxidized. However, when an attempt was made to determine quantitatively the amount of oxygen absorbed it was found that only a very small amount (a few tenths of a cc.) was taken up by the solution. Furthermore, evaporation of the ether left a pure, stable, colorless hydrocarbon and not a peroxide.

This hydrocarbon had the composition of $C_{38}H_{38}$, corresponding to the expected ethane. However, there is some question as to its exact structure. It melts higher (155°) than hexa-*tert.*-butylethynylethane (131°) and this is unexpected since the bromide melts lower than tri-*tert.*-butylethynylbromomethane. The ethane was not cleaved at the ethane linkage by either 40% sodium amalgam or sodium–potassium alloy, as would be expected. It does react with them to give colored solutions of the metal derivative. Carbon dioxide decolorizes this solution but no appreciable amount of water-insoluble acid could be recovered from the reaction mixture. Furthermore, this hydrocarbon was stable toward heat.

In view of the ease with which hexa-*tert.*-butylethynylethane rearranged with heat to give a higher melting hydrocarbon, it was thought that rearrangement might have occurred during the formation of the hydrocarbon $C_{38}H_{38}$ obtained in this work. In order to test this theory, the reaction between the bromide and silver was carried out in the presence of oxygen, which should prevent the rearrangement by the formation of a peroxide. When this reaction was run, oxygen was rapidly absorbed and considerable heat was evolved. When the temperature was not controlled, two or three times the theoretical amount of oxygen was absorbed. By keeping the temperature at 0° the absorption of oxygen was only about one and one-half times the theoretical amount. However, all attempts to isolate a peroxide were unsuccessful. An oily material was obtained that had the odor of benzophenone.

The absorption of oxygen in this experiment is due to some reactive intermediate, presumably diphenyl-*tert.*-butylethynylmethyl. When tri-*tert.*-butylethynylbromomethane was treated with silver in the presence of oxygen, the absorption of oxygen was negligible. This shows that the percentage of free radical normally present in a reaction mixture of this type is not enough to cause oxygen absorption.

The most logical explanation of these observations seems to be that silver reacting with diphenyl-*tert.*-butylethynylbromomethane produces a free radical diphenyl-*tert.*-butylethynylmethyl which in the presence of oxygen is oxidized to products which are of lower molecular weight. In the absence of oxygen the free radical undergoes some rearrangement to produce a stable hydrocarbon $C_{38}H_{38}$. The structure of this hydrocarbon is now under investigation.

Experimental Part

Diphenyl-*tert.*-butylethynylcarbinol.—The Grignard reagent was prepared from 38 g. of *tert.*-butylacetylene by adding it from a dropping funnel to 115 cc. of a 4.116 N ether solution of ethylmagnesium bromide over a period of ten hours. The heat of the reaction caused the ether to reflux and a very efficient condenser filled with water at 0–5° was needed to avoid loss of the acetylene. When this reaction was finished a saturated solution of 85 g. of benzophenone in dry ether was added during one hour. The reaction mixture was then stirred for six hours, allowed to stand overnight and finally refluxed for about an hour. The reaction mixture was then decomposed by pouring it onto 500 g. of cracked ice and adding 25 g. of ammonium chloride and just enough dilute hydrochloric acid to dissolve any precipitate of basic magnesium salts The ether layer was separated, dried over sodium sulfate, filtered and heated on a steam-bath to remove the solvent. The residue was dissolved in an equal volume of petroleum ether (b. p. 40–60°) and the solution was cooled to −15°. The carbinol separated as white crystals; m. p. 63–66.5°. This grade of product was used for preparing the bromide. Recrystallization gave a very pure product which melted at 66.5–67.5°.

Anal. Subs., 0.2370: CO_2, 0.7502; H_2O, 0.1625. Calcd. for $C_{19}H_{20}O$: C, 86.36; H, 7.58. Found: C, 86.32; H, 7.67.

In the first run considerable difficulty was experienced in obtaining a crystalline compound. The crude product was distilled under reduced pressure and the main portion boiled at 132–135° at 0.4–0.5 mm. The supercooled liquid had the following constants: n_D^{25}, 1.5550; sp. gr. $\frac{25}{25}$ = 1.0124. This material crystallized after standing for a few days at −15°.

Diphenyl-*tert.*-butylethynylbromomethane.—Three g. of the carbinol was dissolved in 25 cc. of petroleum ether and the solution cooled to 0°. Then 1 g. of phosphorus tribromide was added and the solution was stirred for one-half hour. To the mixture was added 100 cc. of 10% sodium bicarbonate solution and stirring was continued for ten minutes. The petroleum ether solution was separated, dried over sodium sulfate, filtered and evaporated under reduced pressure at room temperature. The residue was dissolved in 5 cc. of dry ether, 5 cc. of absolute alcohol was added and then the solution was evaporated under reduced pressure until crystals began to form. The mixture was then allowed to stand at 0° overnight in order that all of the bromide might crystallize. The bromide was collected on a filter and dried in a vacuum desiccator. The yield of crude product (m. p. 56.5–59.5°) was 3 g. (81% of the theoretical amount) Recrystallization from alcohol and ether gave a product melting at 58.5–60.5° (corr.)

Anal. (Stepanow). Subs., 0.2626, 0 2112: 17.62, 14.21 cc. of 0.0450 N $AgNO_3$ Calcd. for $C_{19}H_{19}Br$: Br, 24.43. Found: Br, 24.12, 24.22.

The Reaction between Diphenyl-*tert.*-Butylethynylbromethane and Silver

(a) In Air or Nitrogen.—A solution of 1 g. of the bromide in 15 cc. of dry ether was shaken in a mechanical shaker with 1 g. of molecular silver in a 30-cc. round-bottomed flask for about ten hours. A greenish-yellow solution with a slight red fluorescence resulted. The fluorescence disappeared when a stream of oxygen was passed over the surface of the solution but reappeared after the solution had stood in the air for a few minutes. This could be repeated three or four times before the color failed to reappear. The ether solution was concentrated until crystals began to appear. The mixture was then cooled to 0° until crystallization was complete. These crystals

(m. p. 151.5–154.5, corr.) were collected on a filter. Recrystallization from alcohol and ether gave a product which melted at 153.5–155° (corr.).

Anal. Subs., ***0.1786:*** CO_2, ***0.6011;*** H_2O, ***0.1265.*** Calcd. for $C_{38}H_{38}$: C, ***92.31;*** ***H, 7.69.*** Found: C, ***91.78;*** H, ***7.92.*** *Mol. wt.* Subs., ***0.1527;*** benzene, 13.465; ***At,*** 0.134°. Constant for benzene, ***5.32.*** Calcd. for $C_{38}H_{38}$: mol. wt., ***494.*** Found: ***434.***

One run was made to determine the absorption of oxygen. One g. of the bromide in 5 cc. of toluene was shaken with 1 g. of molecular silver for fourteen hours in a sealed tube. Then the tube was broken in an oxygen chamber connected with a eudiometer. There was no absorption of oxygen after twenty hours. The mixture was then filtered and worked up as before. After two crystallizations ***0.45*** g. (39% of the theoretical amount) of the same hydrocarbon was isolated. Analysis of the silver–silver bromide residue showed that the bromine had been removed to the extent of over 90% of the theoretical amount.

Similarly, when the hydrocarbon was prepared in an atmosphere of carbon dioxide and then transferred to an oxygen atmosphere, there was no absorption. Fresh molecular silver was added to this reaction mixture and shaking continued without effect.

(b) In Oxygen.—A solution of ***2*** g. of the bromide in ***10*** cc. of toluene was shaken with ***2*** g. of molecular silver in a 30-cc. round-bottomed flask filled with oxygen and connected to a eudiometer filled with oxygen. When shaking was started, oxygen was rapidly absorbed and the temperature of the reaction mixture rose to 40–50°. On attempting to isolate the reaction products only about ***0.1*** g. of the hydrocarbon was obtained. One similar run made in ether solution and maintained at about 25° by means of a water-bath gave some white crystals melting at 96–102°. An attempt to purify these yielded an oil with a strong odor of benzophenone.

Several runs were made in xylene solutions in a tube surrounded by water to maintain the temperature at about 25–30°. In every case the absorption of oxygen was ***2*** to ***3*** times the theoretical amount. In one run using ***0.3*** g. of the bromide, the absorption of oxygen seemed to stop after the theoretical amount ***(10.3*** cc.) for the formation of a peroxide had been taken up. However, on further shaking the absorption was renewed and finally about three times the theoretical amount of oxygen ***(34.9*** cc.) was used.

In another run using ***0.3*** g. of the bromide the oxygen absorption was measured while the reaction mixture was held at about 0° by surrounding the reaction tube with ice water. After thirty-eight minutes, ***14.8*** cc. ***(144%*** of the theoretical amount for the formation of a peroxide) of oxygen was absorbed.

Reaction of the Hydrocarbon $C_{38}H_{38}$ with Sodium Amalgam.—Two cc. of 1% sodium amalgam and ***0.25*** g. of the hydrocarbon in ***10*** cc. of absolute ether were shaken in an atmosphere of nitrogen. No color was developed. The 1% amalgam ***was*** then replaced by ***40%*** amalgam and shaking was continued. The solution turned red in less than a minute. After shaking overnight, the mixture was treated with dry carbon dioxide for an hour. The excess alloy was frozen and the reaction mixture was separated and decomposed with water and hydrochloric acid. The ether layer was extracted with 10% potassium hydroxide and the alkaline solution was filtered and then acidified with hydrochloric acid, No water-insoluble acid was obtained.

In a second run, ***0.36*** g. of the hydrocarbon in ether was shaken with ***3.5*** cc. of the 40% sodium amalgam in an atmosphere of nitrogen. A deep red color developed in seven minutes and after nine hours the color was almost black. Dry carbon dioxide was then passed into the mixture until the color had disappeared. On working up this mixture as described above, a few yellow crystals melting at 168–170° resulted. Not enough material was obtained for identification.

Reaction of the Hydrocarbon $C_{38}H_{38}$ with Liquid Sodium–Potassium Alloy.—A solution of **0.38** g. of the hydrocarbon in ether was shaken for three hours with 4 cc. of the liquid sodium–potassium alloy in an atmosphere of nitrogen. The solution turned red in one minute. Dry carbon dioxide was led into the mixture until the red color had disappeared, and then the ether solution was poured off and any suspended particles of alkali metal were decomposed with moist carbon dioxide. The ether solution was then extracted with water and the aqueous extract acidified with dilute hydrochloric acid. Only a slight turbidity resulted. Evaporation of the ether layer with dilute hydrochloric acid left only potassium and sodium chlorides

Attempts to Rearrange the Hydrocarbon $C_{38}H_{38}$.—A solution of 0.44 g of the hydrocarbon in **5** cc. of absolute alcohol was heated for one hour in a sealed tube at 100°. The solution was cooled to 15° and the original hydrocarbon (m. p. **150–151**°) was isolated. The recovered hydrocarbon weighed 0.36 g.

Summary

1. Molecular silver removes the halogen from diphenyl-*tert.*-butylethynylbromomethane, and a hydrocarbon $C_{38}H_{38}$ is obtained when the reaction is carried out in air or nitrogen. In an atmosphere of oxygen this reaction does not produce a hydrocarbon but oxygen is absorbed very rapidly by the reaction mixture.

2. The hydrocarbon, $C_{38}H_{38}$, reacts with liquid sodium–potassium alloy and with 40% sodium amalgam to produce colored alkali metal derivatives but apparently the molecule is not cleaved as would be expected if it has the structure of tetraphenyldi-*tert.*-butylethynylethane.

3. To explain these observations the suggestion is made that tetraphenyldi-*tert.*-butylethynylethane is formed by the action of silver on diphenyl-*tert.*-butylethynylbromomethane but it rapidly dissociates and rearranges to some other more stable structure. If oxygen is present in large amounts the free radicals produced by the dissociation of tetraphenyldi-*tert.*-butylethynylethane are oxidized before this rearrangement occurs.

URBANA, ILLINOIS

NEW BOOKS

An Introduction to General Chemistry. By **WILLIAM MARTIN BLANCHARD**, Ph.D., Professor of Chemistry, De Pauw University. Doubleday, Doran and Company. Inc., Garden City, New York, 1928. ix + 588 pp. 90 figs. **11** plates—nearly full page photogravures of famous chemists 10 charts. 14 X 21 cm. Price **93.00.**

In the preface the author states that in the preparation of the text he has made his constant guide those difficulties with chemistry encountered by the average college student, and that he has endeavored to present the more common facts and fundamental laws and theories of general chemistry in a clear, concise and orderly fashion. The product of his efforts adds another ranking member to the rapidly growing list of conventional texts written for first year college students of general chemistry. The author is conservative in the choice of topics, adhering to the usual content and order but he defers the study of ozone and hydrogen peroxide till the chapter on selenium and tellurium is reached. Chemical equations are introduced almost at the outset in Chapter 2—Oxygen. In chapters 1 to 15 inclusive each topic is taken up and developed in logical sequence with new inquiries growing out of topics that preceded. Most of the fundamental theories and principles are incorporated in these chapters. Beginning with chapter 16--Sulfur and Hydrogen Sulfide—the book becomes mainly descriptive. Throughout the book the practical applications--old and recent—are introduced. The student must thus become impressed with the debt our present-day complex society owes to the pioneers in chemistry.

Nowhere in the volume does the author indulge in any unusual tactics to capture the interest of the reader but he maintains a clear, simple, logical development which will help the student over many difficulties. Each chapter closes with a set of thought questions and exercises but no answers are given to problems. Neither have simple literature references been introduced to guide and stimulate the wide-awake student in supplementary reading. Some of the exercises, however, will send the student to the reference library. For example, while but scant attention is given to primary cells, nevertheless, p. 481, the student is asked to explain the operation of the zinc–zinc sulfate–copper–copper sulfate cell; and on p. 531 he is directed to look up the latest reports on chromium plating.

Radioactive changes and the structure of the atom are logically presented in the chapter with the periodic law, but much more could be done later in applying the electron concept to electrolysis, ionic reactions, oxidation and reduction, primary cells. A thorough integration of electron transfer and sharing into these topics has not been attempted. The proton is not mentioned; instead, hydrogen nucleus is used. The admixture of electrons with explanations given largely in terms of positive and negative charges, rise and fall of valence, etc., so common in this transition period to most of our texts, is bound to be rather confusing to the neophyte whose radio contacts have already made the electron a reality.

The proof reading has been well done and little mistakes are few in number. The opening of sentences with the pronoun "this" could be curtailed to advantage; charcoal is spoken of as a good conductor of electricity, p. 313; electrons in discharge tubes do not attain the velocity of light as stated on p. 179; Millikan's classical experiments established the value of the charge on the electron not its mass, p. 179; the millimicron should not be represented by the double letter, $\gamma\gamma$. The laws of Boyle and Charles, p. 30, are not stated in their usual precise form; Cl^- and $\mathrm{OH}-$ are called chloride and hydroxide ions; the Avogadro number appears to have been overlooked. The omission of the now obsolete laws of multiple and reciprocal proportions, p. 50, would be of no serious harm to the atomic theory and would remove a distressing hazard from the joyous progress of the average freshman.

The chapter on "The Colloidal State" is well written. Experimental evidence is introduced repeatedly establishing the molecular formulas of gases, e. g., oxygen, hydrogen sulfide, sulfur dioxide, ammonia, nitrous oxide. The theory of ionization in aqueous solution is presented early—chapter 14, p. 148—but subsequently ionic equations occur only here and there. Figures of apparatus have been greatly simplified and rarely show the complete set-up. The principle of Le Chatelier is stated in unusually simplified form, p. 276, but in the examples cited the old terms "strain" and "stress" make their appearance. Some instances are given of the interesting parallel between the reactions of substances with liquid ammonia and their reactions with water, p. 257.

Finally the reviewer ventures to repeat the question raised by Kendall in the preface to Smith-Kendall, "General Chemistry," "Is not the time ripe to begin to reduce the amount and variety of material offered to first year college students in chemistry?" Few indeed are the teachers who have classes which are able to cover in a satisfactory way the whole of the material contained in the standard college texts. Should not the emphasis be shifted somewhat too by omitting altogether a large bulk of the descriptive material offered in the chapters which generally follow sulfur and hydrogen sulfide, and substituting therefor more about the recent marvelous advances which modern chemistry is making?

HERMAN SCHLUNDT

First Principles of Chemistry. BY P. W. DOOTSON, M.A., Sc.D., F.I.C., University Lecturer and Demonstrator in Chemistry, Cambridge, and **A. J. BERRY, M.A.,** Fellow of Downing College, University Demonstrator in Chemistry, Cambridge University Press, Cambridge, England, 1927. vii + 339 pp. 43 figs. 13.5 X 20 cm. Price, $2.00.

This textbook is designed more particularly for the use of students who practically begin the study of chemistry at the University. It is to be studied as an adjunct to the lecture method of teaching, and should conserve the time taken up by writing notes in class and secure better attention to the demonstrations.

General principles and general methods are emphasized, and details have only been stressed where they have a special significance. But little attention is given to the Periodic Law, "while the now obsolete Laws of Multiple and Reciprocal Proportions have been omitted altogether." The Law of Definite Proportions, however, is stressed in the introductory chapter and illustrated by two sets of well chosen experiments. At the outset the student is introduced to the atomic theory, the chemical equation, Avogadro's theory, isotopes, heats of reaction.

In Chapter II, on water, hydrogen, oxygen, etc., water is studied first, and here we find introduced among other topics, the phase rule, Le Chatelier's theorem, aqueous solutions, water softening. This chapter also includes Gay-Lussac's Law of Combining Volumes, hydrolysis, equivalent weights, the laws of Boyle and Charles, reversed combustion.

The Ionic Theory is deferred to Chapter 10, p. 249, and its applications are introduced in the next chapter on "Metals and Their Compounds." The closing chapter, 12, describes methods of determining molecular and atomic weights.

The book contains many refreshing passages and several elegant lecture demonstration experiments are described. The various chapters contain none of the modern teaching devices, such as thought questions, problems, literature references, etc. A knowledge of logarithms is assumed in expressing hydrogen-ion concentration in terms of P_H values. The book serves the purpose for which it was written but it is probably not adapted for freshmen in this country who have had a year of high school chemistry.

On p. 106 the boiling point of iodine is given as lower than its melting point: the reverse is true. The reviewer questions the statement on p. 17 that the compression of water by the pressure of the atmosphere results in a lowering of the general sea level by rather more than one hundred feet.

HERMAN SCHLUNDT

La Notion d'Espece en Chimie. (The Idea of Molecular Species in Chemistry.) BY JEAN TIMMERMANS, Professor of Physical Chemistry at the University of Brussels Gauthier-Villars et Cie., 55 **Quai des Grands-Augustins, Paris, France, 1928. iii + 134 pp. 15 figs. 14 X** *22* **cm.**

This little book undertakes a discussion of the most favorable conditions for the determination of physical–chemical constants. Its three main divisions are devoted to answering three questions. 1. How is a physical–chemical system to be defined unambiguously?—the problem of molecular species in chemistry. 2. How is such *a* system to be realized?—the problem of pure substances. 3. How are the constants to be measured with precision and exactness?

The first section outlines in interesting fashion the historical evolution of the idea of molecular species and the application of the phase rule to both simple and intricate cases. Section two discusses the meaning of the term pure, methods of dehydration, the theory of fractional distillation and of fractional crystallization and the limitations of methods used for these latter operations. Part three contains a discussion of the ultimate standards in use, the theory of least squares as applied to experimental data and a list of the principal national laboratories undertaking the determination of constants. There is also a list of the principal reference tables on physical–chemical constants. The chapter on the evaluation of existing data, with benzene taken as an example, is particularly interesting.

The limitation of the text to a little over a hundred pages has of course made it necessary that the theoretical treatment be frequently dogmatic rather than explicit, and the quotation of specific data meager. Necessarily also the matter contained can hardly be new to experts, and is too condensed to suffice for novices in the field. Nevertheless it will make most interesting and most helpful reading to both classes, for nowhere has there been in a single publication such a complete codification of the conditions and the problems to be kept in mind by the experimenter during the work of measuring physical–chemical constants.

ARTHUR E. HILL

Grundzüge der Körperlehre. (The Basis of a Science of Material Objects.) BY DR. J. V. HOFMANN. Emil Pahl, Dresden, 1926. Portrait. vii + 80 pages. 15.5 × *23.5* cm. Price, $1.00 net from the son of the author, William E. Hofmann, 1849 Bronxdale Avenue, New York City.

This book contains three popular lectures delivered in 1870 by Joh. Val. Hofmann (a German private scholar who was not connected with a university) in exposition of the views which he had earlier set forth in his "Somatologie oder Lehre von der inneren Beschaffenheit der Korper," Gottingen, 1863. It contains a polemical chapter in which evidence is given that Kirchhoff adopted and put forward as his own in 1865 the views which Hofmann had set forth in his book. Also, it prints a letter, with facsimile, from Professor Carl Naumann in acknowledgment of the dedication of the hook to him.

Hofmann speculated about the density of atoms and about the spaces between them, etc. He held that the purely mechanical theory of heat as then recently developed by Mayer, Joule, Thomson and Helmholtz is inadequate to account for the phenomena of physics and chemistry—and that the particular properties of the kind of matter which is involved must be taken into the reckoning. He was apparently the first to see the necessity for a special science—Somatology—which should develop from the same causes the phenomena of chemistry, of crystallography, and of physics. To that extent he laid the early foundations for the work of van der Waals, Richards, Bragg and Bohr.

The present little book does not contain any very remarkable deductions. It has some reasoning which appears to be fallacious. But it is an important historical document for the reason that it shows the feeble beginnings of the speculations and experimentation which are giving to the science of the structure of matter the status that Hofmann (and Kirchhoff) thought that it deserved.

TENNEY L. DAVIS

Mechanische Eigenschaften flüssiger Stoffe. Volumen, Dichte, Kompressibilitat, Oberlächenspannung, Innere Reibung. (Mechanical Properties of Liquid Substances. Volume, Density, Compressibility, Surface Tension, Viscosity.) By R. Kremann, Professor at the University of Graz. Handbuch der allgemeinen Chemie, Band V. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 4, Leipzig, Germany, 1928. xii + 597 pp. 75 figs. 18 × 25.5 cm. Price, unbound, M 46.50; bound, M 49.

The scope of this work is indicated by the subject matter treated in the various chapters. The first main division, on volume relations of liquids, includes relation of volume to pressure, temperature and constitution, and volume relations of binary mixtures. In the second main division, dealing with viscosity, the topics dealt with are: general discussion and definitions, methods and apparatus, influence of temperature and pressure, turbulent flow, relation between viscosity and other properties and its dependence upon chemical constitution, the viscosity of mixtures and various applications of the measurement of viscosity. Under surface tension the topics treated are general discussion and definitions, methods of determining surface tension, the effect of temperature, pressure and other variables, the relation to chemical constitution, the surface tension of mixtures and solutions, and further applications for the measurement of surface tension.

The author's own labors in these fields have well prepared him for the monumental task which he has accomplished. Anyone at all familiar with the literature in any one of the three main fields treated is aware of the enormous amount of work involved in its presentation in book form. The scope of the book and the extent of the literature covered by it have naturally made it necessary to write a résumé rather than a highly critical presentation. While this is a disadvantage from certain points of view, it will greatly aid a research worker in these fields in surveying the large amount of work previously done. Incidentally it is likely to impress him with the unsatisfactory character of much of it, and with the great need for a concerted attack upon the problems of the liquid state, for it is surely true that our knowledge of the liquid state of matter is far less satisfactory than that of the gaseous and solid states. Over and over again one discovers that the only formulation of certain relationships is in terms of the notoriously inaccurate van der Waals equation. A perusal of this book should serve to suggest many important researches, which is perhaps the highest service such a work can perform.

It may seem captious to complain of omissions from a book which represents such a stupendous review of physico-chemical publications; but the reviewer has felt, in reviewing this as well as other continental publications, that some of the work done on this side of the Atlantic is either absent from European libraries or receives but casual attention. To mention only two examples: in reviewing the effect of pressure upon surface tension, there is no reference to the thermodynamic formula given by Lewis and Randall; and in connection with the surface tension of metals, values obtained by Siedentopf in **1897** are used rather than the values of Hogness obtained in **1921.** There are also instances where the author has been content merely to state a discrepancy or to quote contradictory opinions, although some of these matters, to the reviewer's knowledge, have been critically discussed in American publications. The reviewer does not wish, however, that these remarks should be taken too seriously, for he realizes that any work of such scope prepared by a single author would be subject to similar criticism.

JOEL H. HILDEBRAND

Reaktionskinetik gasförmiger Systeme. (The Kinetics of Chemical Change in Gaseous Systems.) BY C. N. HINSHELWOOD, Lecturer at Oxford University. Translated by Dr. ERICH PIETSCH and Dr. GERTRUD WILCKE. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 4, Leipzig C 1, Germany, 1928. xii + 246 pp. 12 figures. 16 × 23.5 cm. Price, unbound, M 15; bound, M 16.

The translators have included an extensive bibliography which was not present in the English edition. The period covered is from **1887** to **1927.** The first two hundred and fifty papers are of a general nature. More than five hundred references are then given, classified according to the reactions studied. An index to the bibliography lists some seventy-five reactions.

H. E. BENT

Photochemical Processes. BY GEORGE B. KISTIAKOWSKY, Research Associate in Chemistry, Princeton University. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York City, 1928. 270 pp. 8 figs. 15.5 × 23.5 cm. Price, $5.50.

The book is divided into six chapters with the following headings: "The Concept of Light Quanta and Photochemical Kinetics," "The Equivalence Law," "Chain Reactions," "Photosensitisation," "Catalysis and Inhibition," and "Frequency of Radiation, Temperature and the Rate of Photochemical Reactions."

The first chapter is the shortest one of the book. In it is given a brief non-mathematical discussion of some of the fundamental concepts underlying the field of photochemistry. The Grotthuss-Draper law, Fresnel's law, Lambert's law, Beers' law, light scattering and photo-kinetics are covered in rapid succession. Follow a brief discussion of light quanta and mention of the principal theories of the primary process in photochemical reactions. This chapter does not contain all of the theoretical discussion given in the book, the details being reserved for later discussion, largely in connection with specific reactions. The chapter is quite readable and clear. One might wish amplification of certain points, particularly in the relationship of modern theories of band spectra to photochemical theory.

In the second chapter the author has limited discussion to some thirty odd reactions for which the data warrant discussion of possible mechanisms. The difficulties involved in the choice of reactions are great and probably no two photochemists could be found who would choose identical lists of reactions to be discussed. The chapter is quite readable in spite of the large amount of detail it contains and the author has usually been quite frank in stating that no definite conclusions can be drawn with regard to certain reactions. In many cases several reaction mechanisms may be used to derive equations which are equally applicable to the data. The author must, however, be lauded for his impartiality and the chapter is a good summary of the reliable data in this field.

In the third chapter a large fraction of the space is devoted to discussion of reactions involving halogens, particularly chlorine, since these reactions have been more studied than other reactions having quantum efficiencies much larger than unity. In view of the fact that the mechanisms of few, if any, of these reactions have been satisfactorily elucidated from all standpoints, one might feel that this chapter is too long in relation to the size of the book. The chapter is, however, interesting to read even if a great deal of the work included may eventually prove to be meaningless.

In the chapter on "Photosensitisation" are included discussion of gas reactions, reactions in solution and such matters as the sensitization of photographic emulsions and chemiluminescence. The author has presented the various experimental facts clearly and where possible has given discussion of reaction mechanisms. One might wish the inclusion of more of the physical aspects of the problem, since the author seems to have accepted one point of view entirely in the discussion.

The chapter on catalysis and inhibition contains a discussion of ozone decomposition, hydrogen peroxide decomposition, chlorine water decomposition, reactions of cobaltic complexes and autoxidations. The chapter is well written and the work on these reactions is quite fully given. Definite conclusions are not always arrived at, but the various aspects of the subject are presented in such a way that the reader obtains a clear idea of the field.

The final chapter contains a lot of loose odds and ends, some of which might well have been included earlier in the book. The discussion of the temperature coefficient of photochemical reactions is particularly interesting.

The style of the book is, on the whole, very good. The author has obviously not intended to give complete bibliographies for each of the reactions discussed, but has confined himself to papers permitting of some interpretation. The fact that the reading is difficult at times is not due to any fault of the author, but to the nature of the subject, since so many self-contradictory and illogical statements are found in the literature. Some slight mistakes in literature references and in statements of the points of view of some authors have crept in, but these are not serious. One might wish a fuller theoretical discussion, but the book is a worth while summary of the work on a large number of reactions.

The reviewer takes pleasure in commending the book to anyone interested in the subject of photochemistry.

W. ALBERT NOYES, JR.

Der **gegenwärtige** Stand der Spannungstheorie. (The Present Status of the Strain Theory.) BY WALTER HÜCKEL. Fortschritte der Chemie, Physik und physikalischen Chemie, Band 19, Heft 4, Serie A. Gebrüder Borntraeger, W 35 Schoneberger Ufer 12a, Berlin, Germany, 1927. iv + 101 pp. 12 figs. 17 × 25.5 cm. Price, M 7.60.

In one respect the present status of the strain theory is much less satisfactory than was its status ten years ago. The facts no longer permit one to state the theory neatly and in a few words. Von Baeyer, who invented this one of the few really important theories of organic chemistry, adopted the improbable assumption that all rings are uni-planar. This made it unnecessary to contemplate the rather overwhelming possibility that the number of atoms in a cycle might be any positive integer from 2 to infinity, or that even a simple alicyclic hydrocarbon might exist in stereoisomeric forms. The fact of the existence of large rings was established by the recent but already classical work of Ruzicka, and the experimental verification of the implications of the idea of non-planar and strainless rings (Sachse-Mohr) has received important additions at the hands of Walter Hückel, who is therefore in position to discuss all of these researches authoritatively and in detail.

The last third of the book is devoted to a criticism of Ingold's hypothesis of valency angles. Von Baeyer assumed that for carbon this angle is always 109° 28' (or that the deviation from this angle was a measure of the strain involved). The use of this improbable assumption makes possible a great many more positive predictions than its denial. Ingold not only repudiated this assumption, but he pretended to be able to calculate the manner in which substituents would affect the valency angles. He thus made the theory more explicit than before. Ingold and Thorpe defend themselves against Hückel's adverse criticism in the *Journal of the Chemical Society, 1928,* 1318.

As a result of the industry which led to the repudiation of Von Baeyer's simplifying assumptions, chemists now have opened before them a quite endless expanse of stereo-chemical problems. Some of these are discussed very suggestively in the present volume. A further result is that the strain theory no longer constitutes a quite homogeneous and self-complete chapter of organic chemistry. Such a chapter would perhaps be constituted by a complete story of the stereo-chemistry of cyclic compounds. This realm is considerably wider than the compass or intention of Hückel's brief study but it is one to which a monograph might very well be devoted.

There can be no doubt that a knowledge of the stereo-chemistry of cyclic compounds will be increasingly important to the most diverse branches of modern organic chemistry—one might mention, for example, sugars and polysaccharides and petroleum.

WALLACE H. CAROTHERS

Schiess- und Sprengstoffe. (Powder and Explosives.) BY DR. PH. NAOÚM, Director of the Research Laboratory of the Dynamite Joint Stock Company, formerly Alfred Nobel and Company. Theodor Steinkopff, Dresden and Leipzig, 1927. xi + 199 pages. 12 figs. 15.5 × 22 cm. Price, unbound, RM 12.50; bound, RM 14.

This volume is No. XVI of a series of *Technische Fortschrittsberichte,* the purpose of which is to summarize recent progress in the various branches of applied science. It has chapters on the theory of explosives, on black powder, nitroglycerine, nitrocellulose and the other nitrated carbohydrates, smokeless powder, dynamite, ammonium nitrate explosives, chlorate and perchlorate explosives, safety explosives, liquid oxygen explosives (chapter written by Dr. K. F. Meyer) and on primary explosives, primers, detonators, etc. It contains a surprisingly large amount of information and mentions or discusses many things which have not heretofore been brought together in a single book—the use of centralite in smokeless powder, the manufacture without solvent of powder containing a low percentage of nitroglycerine, non-fulminate primers containing thiocyanates, explosive superoxides, and cyclotrimethylenetrinitramine, or Hexogen as the Germans call it, which has a velocity of detonation of 8400 meters per second and is the most brisant of all explosives—to mention a few instances. As might be expected in a book of this character, there are a number of omissions. Guanidine nitrate is described but nitroguanidine does not appear to be mentioned, the preparation of trinitrobenzene by the oxidation of trinitrotoluene is not described, and no light is given on the chemistry of the sulfite, or better bisulfite, method for the purification of TNT. The statement that nitro-urea has good chemical stability is evidently an error.

The book is distinctly one for the specialist and gives an excellent account of recent progress in explosives. It will be of value to those who are concerned with that field, whether in research or in the manufacture and testing of the products.

TENNEY L. DAVIS

Creatine and Creatinine. By ANDREW HUNTER, M.A., M.B., F.R.S. Can., Professor of Biochemistry in the University of Toronto. Longmans, Green and Co., 55 Fifth Avenue, New York City, 1928. vii + 281 pp. 15.5 × 24.5 cm. Price, $5.00.

Nearly a century has elapsed since the discovery and designation of creatine in 1832 by the distinguished French chemist Chevreul. The identification of creatinine by Liebig occurred fifteen years later. These are two organic compounds widely distributed in the tissues of vertebrates, of questionable occurrence in invertebrates, but apparently present in some of the higher plants. Creatine seems to be concentrated in the muscles, which contain as much as 98% of all of the substance that is present in the vertebrate body. One or both of the compounds circulate in the blood (though the details of their occurrence there are by no means established beyond debate). Creatinine is a never-failing constituent of the urine; the appearance of creatine therein varies under conditions as yet little understood. The chemical origin, the physiological function, the abnormal occurrence and the biochemical fate of these long recognized body constituents cannot yet be presented in larger outline with any considerable degree of certainty. The problems that Professor Hunter has discussed, often with meticulous detail, still lead to a story that is full of "gaps and guesses." As Hunter himself has remarked in reviewing some of the uncertainties: "The safest position for the present is probably the admission of ignorance" (page 241).

Here, then, are themes for investigation that challenge the ingenuity of the ablest biochemists. One is not called upon to deal with tars or gums, with ill-defined products of unknown composition. The substances in question are readily crystallizable compounds of well-known structure; their biological significance is obviously notable; the need of new interpretations is pressing. Progress has been hampered, as in so many other instances, by the apparent lack of suitable methods of investigation. Progress was decidedly slow until the introduction of Folin's colorimetric methods of estimation in 1904. These are indirect and by no means devoid of pitfalls and uncertainties. New procedures seem imperative. It might be conducive to advance if much that has been published about the physiology of creatine and creatinine were temporarily forgotten so that the new students of the subject would acquire independent, unbiased starting points and impressions. In any event Professor Hunter's monograph is a *vade mecum* of inestimable value.

STUDIES ON THE PERIODIC SYSTEM.
I. THE IONIC POTENTIAL AS A PERIODIC FUNCTION[1]

BY G. H. CARTLEDGE

RECEIVED APRIL 7, 1928 PUBLISHED NOVEMBER 6, 1928

In the more recent modifications of the periodic system emphasis has been placed upon the structure of the elements as the basis of classification. All forms of classification, however, suffer from the same essential difficulty, namely, that the elements have too protean a nature to be adequately classified by reference to any single atomic characteristic. For chemical use it is highly desirable that a periodic arrangement be devised which shall be based upon a more comprehensive and quantitative view of the elements and shall also provide a place for all valence forms of all elements. It is one of the serious defects of the Mendelejeff system that it has no quantitative basis, so that it is unable to indicate gradations in properties within a series or a family.

While the comparison of atomic structures gives a partial indication of variations in chemical behavior, even this is not adequate, inasmuch as the properties of *compounds* are to an important extent determined by the sizes of their ionic constituents as well as by their structures. The role of the ionic radii has been emphasized by Grimm,[2] and by v. Hevesy.[3] Grimm has also given a periodic classification in which the direction of variation in radii is represented.[4] The importance of certain electronic structures in giving different valence forms of the same element has been shown by Grimm and Sommerfeld.[5]

In order to obtain a more comprehensive representation of the properties of compounds, it is proposed in this paper to take account of the charge, structure and *size* of the ionic constituents of compounds, and to develop a form of representation in which it will be possible to include all valence forms of all of the elements. As a consequence of this broader and quanti-

tative basis of classification, the new arrangement eliminates the earlier difficulties with respect to the classification of hydrogen, the properties of the rare earths, the higher valence forms of copper, silver and gold, and the relations of the eighth-group elements. Being based upon ions rather than atoms it gives a clearer representation of the chemical relationships.

The Ionic Potential

In determining the properties of substances, increasing ionic charge and increasing ionic radius act in opposite directions; thus, the lattice energy of a binary polar crystal is chiefly determined by the Coulomb term, $Z^2e^2/(r_+ + r_-)$, in which e is the electronic charge and Z and r are, respectively, the valence and radius of the ions. In the same way, oxides are increasingly acidic the higher the charge or, for constant charge, the smaller the radius of the positive ion. This consideration suggests that the ratio of charge to radius should be an important property of ions and closely related to many characteristics of substances. If the ion in a crystal is regarded as a charged sphere of definite extension in space, this function is the *ionic potential* and will be represented by ϕ; that is, $\phi = Z/r$. Of course the ion in a crystal is not a conducting sphere in the strict sense, so that in calling this function the ionic potential we are using a somewhat hypothetical concept as a basis of classification. Ions actually have a real charge and a real extension in space, however, and these characteristics are observed to have a determining influence upon the properties of their compounds, so that the ratio of charge to radius is a real property of the ion.[6]

In this method of treatment it is not necessary to assume the free existence as ions of such substances as S^{6+} or C^{4-}. In crystals such as sodium chloride the lattice is undoubtedly ionic, while the intra-ionic bonds in sulfate ions, for instance, are generally regarded as non-polar. Since ions of the same structure have radii which are inversely proportional to the effective nuclear charge, the radius may be found for the electrical system corresponding to S^{6+}, even though this may not exist as a separate entity. It is only in this sense that S^{6+} will be called an ion. If it is a transition from polar to non-polar binding which is associated with the variation in properties in going through a periodic series, then it appears that this transition is directly related to the magnitude of the ionic potential, which therefore becomes an index of properties, even though calculated for hypothetical ions such as S^{6+}.

Ionic radii have been calculated from crystal data by Grimm and

---

[6] Another similar function might be used, namely, the electrostatic energy of the ion, $Z^2e^2/2r$. This possibility has been investigated, and a classification results similar to the one here given. The simpler function is to be preferred, however, in most cases.

Wolff[7] and, more recently, on the basis of the wave mechanics, by Pauling.[8] The data of Pauling have been used, as far as they go, in calculating the ionic potentials. For this purpose the ionic charge Z corresponding to the valence is divided by the radius in Ångström units. These arbitrary units of potential are sufficient to indicate the comparisons desired.

In order to obtain ionic potentials for all the elements it is necessary to use indirect methods in certain instances. The available data on the radii have been extended in the following manner.

(a) The ionic potential is directly related to the ionization potential for the removal of the *last* electron in the production of the ion in question. As was found by Millikan and Bowen,[9] there is a linear relation between the atomic number and the square root of the energy corresponding to the removal of the electron in a series of ions of the same structure. This is an extension of the Moseley rule for x-ray frequencies into the region of optical spectra. Correspondingly, for positive ions it is found that *the square root of the ionic potential increases in very approximately equal steps as the ionic charge increases without alteration in structure.* For this reason the square root of the potential is given in some of the graphs and tables which follow, and unknown potentials may be very closely estimated by this *method of constant increments.* The increment $\Delta\sqrt{\phi}$ becomes less as the principal quantum number of the outermost electrons in the ion increases. This method has been used in finding values for Ta^{5+}, W^{6+}, (75^{7+}) and Os^{8+}, the calculations being based on the potentials for Lu^{3+} and Hf^{4+}, as found in the way described in (c) below; for Po^{6+} and (85^{7+}) by reference to Bi^{5+}; and for the series Ra^{++} to U^{6+} by reference to Ra^{++} and Th^{4+}.

(b) Within the alkali and alkaline earth families there is a linear relation between the ionization potential and the square root of the ionic potential, from the sodium to cesium series, inclusive. From this relation and the known ionization potential of radium, the value of $\sqrt{\phi}$ for radium is found to be 1.24. This value, combined with that for thorium (1.90), gives the increment in $\sqrt{\phi}$ as **0.33** for unit change in charge in the series Ra^{++} to U^{6+}.

(c) Radii for the rare earth ions were computed by Grimm and Wolff[7] from the lattice spacing of the oxides as given by Goldschmidt.[10] These measurements show that the ionic radius decreases from lanthanum to lutecium, the jump being apparently larger from La^{3+} to Ce^{3+} than it is elsewhere in the series. In order that all of the radii used in estimating potentials may be consistent with each other, the radius of Lu^{3+} has been calculated from that of Y^{3+} as given by Pauling by taking the lengths of the unit cells in the cubic forms of Y_2O_3 and Lu_2O_3 as 10.60 Å. and 10.37 Å., respectively. This gives 0.88 Å. as the radius of Lu^{3+}, corresponding to $\sqrt{\phi} = 1.85$. Values for the other rare earths have been interpolated, following the data of Grimm and Wolff.

Since the external structures are alike in the series Cs^{+} to Ce^{4+} and Hf^{4+} to Os^{8+}, and since these ions belong to the same periodic series, it is reasonable to assume that the increment in $\sqrt{\phi}$ per group is the same in both parts of the series. The value 0.40 as obtained from Ba^{++} and Ce^{4+} is used for $\Delta\sqrt{\phi}$ in estimating the potentials from Lu^{3+} to Os^{8+}.

(d) The potential of the hydrogen ion $H^{\cdot}$ can be estimated only indirectly and approximately, owing to the unique character of the ion in all respects. As will be pointed out subsequently, the heat of hydration of the gaseous ion is related to the ionic potential. There is a linear relation for the alkali ions, and if this is used in connection with the heat of hydration of the H^+ ion, it gives a value of about 2 for $\sqrt{\phi_{H^+}}$. The ionization potential of the alkali elements also varies in the same order as the ionic potential, and extension of the curve indicates an ionic potential for H^+ corresponding to $\sqrt{\phi} = 4$ approximately. On account of the unique structure of the hydrogen ion it is hardly to be expected that any single constant can be obtained which will be a quantitative indication of all the properties of its compounds; this divergence in the values is not surprising, therefore, since they correspond to very different types of behavior. Nevertheless, as will be seen below and in the subsequent paper, a mean of the values obtained above serves to indicate properly the general relation of hydrogen compounds, such as hydrogen chloride and water.

Table I gives the square root of the ionic potentials obtained in the ways just described. The values are in arbitrary units, the charge being taken as the valence and the radius being expressed in Ångström units. A negative sign is attached to the values for the anion potentials. No attempt has been made to estimate potentials for ions which have an electron pair in the ion, such as Ge^{++}. Aside from the paucity of data for such cases, there is the further complication that tautomerism is apparently a common phenomenon in such valence forms, for example,

TABLE I

$Ge(OH)_2 \rightleftarrows HGeOOH$, sulfurous acid, and others, so that the electrical system is not well defined.

Radii are known for some of the transition ions, so that their ionic potentials may be found. During the completion of an 8-shell, as from Ca^{++} to Zn^{++}, there is a distinct contraction as the first electrons are added, so that the transition ion has a higher potential than the equivalent ion with the inert-gas structure: $\phi_{Mn^{++}} > \phi_{Ca^{++}}$. The data are inadequate to permit tracing the variation during the complete transition from Ca^{++} to Zn^{++} or from Sc^{3+} to Ga^{3+}, for example, but the trend is indicated by the following values, some of which are included in Fig. 1.

Ion	Ca^{++}	Mn^{++}	Fe^{++}	Co^{++}	Ni^{++}	Ti^{4+}	V^{4+}	Mn^{4+}	Zr^{4+}	Cb^{4+}	Mo^{4+}	Ru^{4+}

Fig. 1.—Square root of the ionic potentials.

Ionic Potentials and the Periodic System

There are obviously three characteristics of the ions that should be represented in the periodic system, namely, the electronic structure, the net charge and the ionic potential. For simplicity we shall define the *ionic* number as the number of extra-nuclear electrons in the *ion*, corresponding to the atomic *number* for atoms. For graphical representation the square root of the ionic potential is plotted against the ionic number in Fig. 1. A still clearer representation is given by a three-dimensional model, a photograph of which is shown in Fig. 2. In this the ionic number and ionic charge are the axes in the plane of the board, while the height of the rods is proportional to $\sqrt{\phi}$ (omitting the negative sign of the anion potentials).

These arrangements emphasize the predominance of certain ionic structures, as was suggested in Kossel's diagram.[11] The periods also are clearly shown in accordance with the requirements of the Bohr theory, the periods being designated by a number equal to $n + 1$, in which n is the quantum number of the outer electrons in the ion.[12] While by no means all known valence forms of the elements are shown in Fig. 1, holes have been drilled in the board in the model for all of them, and the potential of any ion may be estimated by considering the general order of variation. In Pigs. 1 and 2 several valence forms of manganese are shown in order to illustrate the principle.

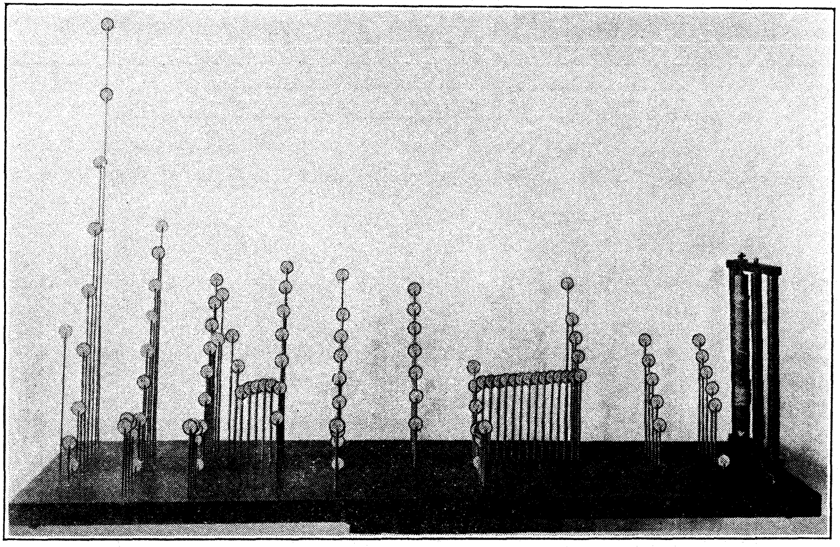

Fig. 2.—Model of the periodic system of ions. From left to right, ionic numbers; front to back, ionic charges ($^{4-}$ in front to $^{8+}$ at back); height of rods gives $\sqrt{\Phi}$.

The rapid variation in properties in the series Li^+ to N^{5+} is revealed

---

[11] Kossel, Ann. *Physik*, 49, 229 (1916).

[12] In this way positive ions that are fully oxidized belong to the ionic series of the same numerical designation as is used by Bohr for the series of elements. Partly reduced positive ions (Fe^{++}, P^{3+}) are given the same series number as the fully oxidized ions, while fully reduced anions, such as Cl^-, belong to the next higher ionic series.

by the large increment in $\sqrt{\phi}$. This makes these ions more or less unique in comparison with corresponding ions of the series below. The dual character of hydrogen in giving both an alkali-like ion H^+ and a halogen-like ion H^- is shown by its double location in the system. The numerical value of $\sqrt{\phi_{H^+}}$ shows, however, that H^+ resembles the alkali ions only in valence, its potential placing it along with Si^{4+} and Ti^{4+}, while H^- is quite like a halide ion in general relations. Correspondingly, liquid HCl and $SiCl_4$ are volatile, non-conducting substances, while $LiCl$ and LiH are high-melting substances which conduct electrolytically in the fused state.

It is obvious that the eighth-group triads are provided for in a logical manner, as is also the case with Cu^{++}, Ag^{++} and Au^{3+}. The disposition of the rare earths is particularly significant. As will be pointed out subsequently, the basic properties of an ion diminish with increasing potential. Whereas there is, in general, an increase in basic character with increasing atomic weight in comparing ions of the same valence, this order is reversed in the rare earths, so that luteciurn is even less basic than yttrium. These relations are accurately shown by the ionic potentials, and it is strikingly indicated that yttrium falls in the rare-earth elements in the neighborhood of dysprosium and holmium (which accords with its experimental behavior) while scandium is less basic (higher potential) than lutecium. The relation of the rare earths to the bivalent ions is shown in the near equality of the potentials of lanthanum and magnesium.

It will be convenient to speak of ions having very nearly equal potentials as *equipotes*.

The Periodic Families of Ions

Although it will be shown in the succeeding paper that the ionic potentials are a reliable index to the variation of numerous properties, it is necessary to remember that the ionic structure must also be taken into account in comparing the chemical and physical character of ions and their compounds. There is a close connection between the chemical relationships of the different families and series of ions and the character of their outer electronic shells, *particularly with respect to the completeness or incompleteness of these shells.* This observation has suggested a modification of the division into families as made by Mendelejeff. The successive shells are complete when they contain, respectively, 2, 8, 18, 32, and 50 (?) electrons, so that the *ionic types* to be distinguished on this basis are as shown in Table II.

In this representation A or B is used only if the simplest ion of the series has two or more electronic groups. A is used if the outer shell is either a simple 8-shell or a partial development of one, as $K^+ = 2,8,8$; $Mn^{7+} = 2,8,8$; $Mn^{++} = 2,8,13$. B is used for an outer shell of 18 or a

TABLE II

PERIODIC SERIES AND FAMILIES OF IONS

Series designation	Outer shell	Next underlying shell	**Examples**
I	*0*	..	H^+ only
11	*2*	..	H^-, N^{5+}
III *A*	8 (complete)	2 (complete)	C^{4-}, Cl^{7+}
IV *A'*	8 (incomplete)	8 (complete)	Si^{4-}, Mn^{7+}
IV *B*	18 (complete)	8 (complete)	Cu^+, Se^{6+}
V *A'*	8 (incomplete)	18 (complete)	Ge^{4-}, Ru^{8+}
V *B'*	18 (incomplete)	18 (complete)	Ag^+, I^{7+}
VI *A''*	8 (incomplete)	18 (incomplete)	Sn^{4-}, Ce^{4+}
VI *A'*	8 (incomplete)	32 (complete)	Lu^{3+}, Os^{8+}
VI *B'*	18 (incomplete)	32 (complete)	Au^+, Po^{e+}
VII *A''*	8 (incomplete)	18 (incomplete)	Ra^{++}, U^{6+}

development of one, as $As^{5+} = 2,8,18$; $As^{3+} = 2,8,18,2$. The prime marks are used to indicate the incompleteness of the two outer 8 or 18 shells; a single prime mark signifies that only the outer 8 or 18 shell is incomplete; a double prime denotes that the two outermost 8 or 18 shells are incomplete.

Inspection of Fig. 1 reveals the close relationships indicated by the brackets in the upper portion of the figure. This method of defining the periodic families brings out clearly the effects associated with the "lanthanide contraction,"[13] such as the association in nature of zirconium with hafnium, of columbium with tantalum, and so forth. The classification also serves to indicate the unique character of the ions of series I (H^+) and II ($Li^+ - N^{5+}$), as well as the double relationship of the ions of series III A, which are most like A' members in the first two groups but more like B ions in groups III to VII.

This definition of the periodic families taken in connection with Fig. 1 serves to bring out the differences among the members of a given family in the Mendelejeff arrangement. In the alkali family, for example, the relatively large divergence in properties between lithium and sodium and also between sodium and potassium is clearly shown. Potassium and rubidium have very nearly equal potentials (and properties) while the differences between rubidium and cesium are somewhat larger (less marked isomorphism, for example). Even in Group IV, in which family differences are less pronounced than in other groups, the variations in properties are significantly shown. Titanium, zirconium and hafnium are thrown together, the last two having equal potentials and very similar properties, while cerium and thorium are in another family with somewhat different potentials. The near equality of the potentials of both A and B families in Group IV corresponds to the extensive isomorphism which occurs in many of their compounds.

---

[13] Goldschmidt, Barth and Lunde, *Skrifter Norske Videnskaps.-Akad. Oslo., I, Matemat. Natur. Klasse,* **1925**, *No. 7;* v. Hevesy, *Z. anorg. allgem. Chem.,* **147**, 217 **(1925).**

The relation of the ionic potential to certain properties of compounds will be shown in subsequent papers, in which it will appear that the numerical values of the potentials may be used to indicate the order of variation of numerous effects.

Summary

1. A periodic classification of ions has been developed, with provision for all valence forms of all the elements. It is shown that no single atomic characteristic is an adequate basis for a periodic classification, and the new arrangement takes account of the charge, structure and radius of the ions. For this purpose a new function, the ionic potential, is introduced and used as a quantitative basis for the classification.

2. It is shown that the ionic potential is related to many of the characteristics of ions and their compounds, and that the new arrangement satisfactorily represents the behavior of hydrogen, the eighth group elements and the rare earths.

3. It is also shown that the properties of the ions are definitely related to the structure of their outermost electronic shells, with respect to the completeness or incompleteness of these shells. On this basis a new definition of the periodic families is given.

STUDIES ON THE PERIODIC SYSTEM. II. THE IONIC POTENTIAL AND RELATED PROPERTIES[1]

BY G. H. CARTLEDGE

RECEIVED APRIL 7, 1928 PUBLISHED NOVEMBER 6, 1928

In the preceding paper[2] it has been shown that the ratio of charge to radius is an important periodic property of the ions and may be made the basis of a quantitative classification. This function has been called the ionic potential. In the present paper the relation between the ionic potential and several related properties of substances will be developed, and it will be shown that the periodic classification presented in the preceding paper is able to indicate the order of variation of many properties which may not readily be related to the older forms of representation.

Ionic Hydration and Associated Effects

When a polar crystal is placed in water the lattice becomes disrupted under the influence of the attraction between the ions and the polarized water molecules. Following Fajans,[3] the measured heat of solution, Q,,

[1] In memory of Ira Remsen.

[2] Cartledge, THIS JOURNAL, **50, 2855** (1928).

[3] Fajans, *Ber. physik. Ges.*, ***20,*** 712 (1918); *ibid.*, 21, 549, 714 (1919).

plus the lattice energy, U, is equal to the sum of the heats of hydration of the ions. According to Born[4] the molal heat of hydration of an ion (W_h) is equal to the decrease in its electrostatic energy when the gaseous ion is placed in water; that is

$$W_h = \frac{\overline{N}Z^2e^2}{2r}\left(1 - \frac{1}{D}\right) \tag{1}$$

in which $\overline{N}$ is Avogadro's number, e the electronic charge, Z the ionic valence, r the radius of the ion and D the dielectric constant of water.

The situation is more complicated than this relation assumes in equating the decrease in electrostatic energy to the heat of hydration, since a portion of this energy goes into an increased intramolecular energy of the water molecules as a consequence of their distortion. In the case of cations an additional heat *evolution* is also undoubtedly caused by the effect of the outer electronic region of the ion in attracting the hydrogen ends of the water molecules. If the Born relationship were correct, the heat of hydration per *equivalent* should be linearly proportional to the ionic potential, ϕ, since from (1)

$$\phi = \frac{Z}{r} \propto \frac{W_h}{Z} \tag{2}$$

For the ions of the alkalies the linear relation is found to hold, although the equation is of the form

$$\frac{W_h}{Z} = a\phi + b \tag{3}$$

and the constant a does not correspond to that given by Born's equation when the crystal radii of Pauling are used for the calculation.[5] The ionic potential may be used in general, therefore, only to indicate the order of *variation* of the heats of hydration. For the alkali ions the equation $W_h = 60\phi + 30$ (kg. cal. per equivalent) represents the values of Fajans quite closely.

Since the heat of hydration of the ions of a salt is equal to the lattice energy plus the heat of solution and since, for salts with a common anion, the electrostatic energy of the cation varies inversely as the cation radius r_c, while the lattice energy varies inversely as the interionic distance $r_c + r_a$, the electrostatic energy increases more rapidly than the lattice energy as the radius is decreased. As a consequence, in a series of salts such as the alkali or alkaline earth chlorides, the heat of solution (evolution) of the anhydrous salt in sufficiently dilute solution should vary in the same order as the varying ionic potential. Table I includes data from the Landolt-Bornstein "Tabellen" which show that this conclusion is in accordance with the facts. The only exceptions to the rule are in cases in which the ions are very unlike in size, mutual repulsion of the larger ions

---

[4] Born, *Ber. physik.* Ges., 21, 679 (1919).

[5] Pauling, THIS JOURNAL, 49, 765 (1927).

then becoming a complication. With lithium fluoride the lattice energy is large and decreases very rapidly as either ion is changed in the alkali or halogen series. The decrease in the lattice energy more than compensates the decrease in the heat of hydration of the varying ions, and an increase in the heat of solution is observed (LiF to LiI or LiF to CsF). In the alkaline earth group this effect is more marked as the anion is varied. The solid arrows in Table I show the order of increasing potential and heat of solution in accordance with the rule. The broken arrows indicate increasing heat evolution with decreasing potential. The data give the heat evolution (lower figure) attending the addition of I mole of the anhydrous salt to the number of moles of water given by the upper figure."

TABLE I

HEAT OF SOLUTION (KG. CAL. PEK MOLE)

The development of acidic properties is obviously closely associated with an increase in the ionic potential. If the potential is sufficiently high, not only is the hydration greatly increased but the increase in the intramolecular energy of the bound water molecules may exceed the heat of ionization of water into hydrogen and hydroxyl ions. In such a case the change may be expressed,

$$M^{m+} + nH_2O \longrightarrow M(H_2O)_n^{m+} \longrightarrow M(H_2O)_{n-1}\,(OH)^{(m-1)+} + H^+$$

---

[6] The effect of the *relative* size of the ions in a crystal in producing "abnormal" variations in properties in a series of compounds has been quantitatively treated for certain cases since the completion of the present paper. See Pauling, THIS **JOURNAL**. SO, 1036 (1928).

This corresponds to the hydrolysis of chlorides of non-metals, such as PCl_5, or to the acid character of hydrated ions, such as the cation of hexa-aquo-chromic chloride, $Cr(H_2O)_6^{3+}$, the ionization of which according to the scheme

$$Cr(H_2O)_6^{3+} \rightleftarrows Cr(H_2O)_5OH^{++} + H^+$$

has been recently studied by Bronsted and King.[7]

As a matter of fact, according to Fig. 1 of the preceding paper, *the exclusively basic ions have values of $\sqrt{\phi}$ falling below 2.2; between 2.2 and 3.2 the ions are amphoteric, and above 3.2 all ions are acidic in character.*[8] The similarity of Be^{++}, Al^{3+} and Ti^{4+} from this point of view is strikingly suggested, corresponding to the well-known diagonal relationship of the Mendelejeff system. The relative positions of B^{3+}, Si^{4+} and P^{5+} are also apt.[9]

Another aspect of the view of hydration effects here presented is in connection with the existence of oxy-ions, such as UO_2^{++}. Compounds derived from ions of this type are stable in acid solution only if the potential of the simple cation U^{6+}, for example, exceeds the minimum value requisite for the ionization of a bound water molecule. If the potential is sufficiently high, complete hydrolysis to an acid occurs. The occurrence of ions which form such stable oxy-salts is, therefore, limited to the amphoteric region of potentials.

Ionic Potentials and Electrochemical Behavior

While the ionic potentials are obviously most closely related to the ionizing potentials of the atoms in the gaseous state, there is a qualitative connection also with the electrode potentials in electrolysis. In the alkali element family lithium has the highest ionization potential, corresponding to the order of increase in the ionic potentials. In aqueous solutions, however, lithium has also the highest electrode potential, which may be due to the existence of a smaller concentration of unhydrated ions, since the

---

[7] Bronsted and King, *Z. physik. Chem.*, *130,* 699 (1927).

[8] An apparent exception is zinc, which is in the basic region of potentials. As a matter of fact, zinc is not certainly amphoteric [Hantzsch, *Z. anorg.* Chem., *30,* 289 (1902); Britton, J. *Chem. Soc.*, *127,* 2120 (1925)], and seems to be more basic than magnesium in the extent of hydrolysis of its chloride in solution and in the readiness with which the chloride may be dehydrated by heating. Zinc and mercuric salts are, however, anomalous in other respects also (see p. 2869).

[9] The theoretical potentials of the ions of series II (B^{3+} – N^{5+}) are somewhat higher than corresponds to their observed acidic character. This is no doubt due to the fact that these ions are very small and in their hydroxyl compounds the oxygen ions are very close together. Mutual repulsion of these hydroxide ions would be equivalent to a decrease in the potential of the positive central ion and a weakening of the acidic character would result. To this cause may be ascribed the low coördination number of these ions (4) and the corresponding instability of higher hydrates (H_3NO_4 $C(OH)_4$, $R_2C(OH)_2$ compounds, etc.).

extent of the ionic hydration is, in general, greater the stronger the field of force about the ion. In comparing elements of the alkali and alkaline earth families, the ionic potential increases with the valence, corresponding to a decrease in the electrode potentials. The increase in the heat of hydration is not sufficient in these cases to counteract the increase in the ionization potential.

Even more striking results are obtained by considering the discharge potentials of the cations from fused electrolytes. Data for a number of ions are given by Neumann and Richter.[10] The discharge potential should be greater the lower the ionic potential. That this is true is strikingly shown in Fig. 1, in which univalent, bivalent and tervalent ions are included. It is obvious that lithium has a normal discharge potential in fused salts.

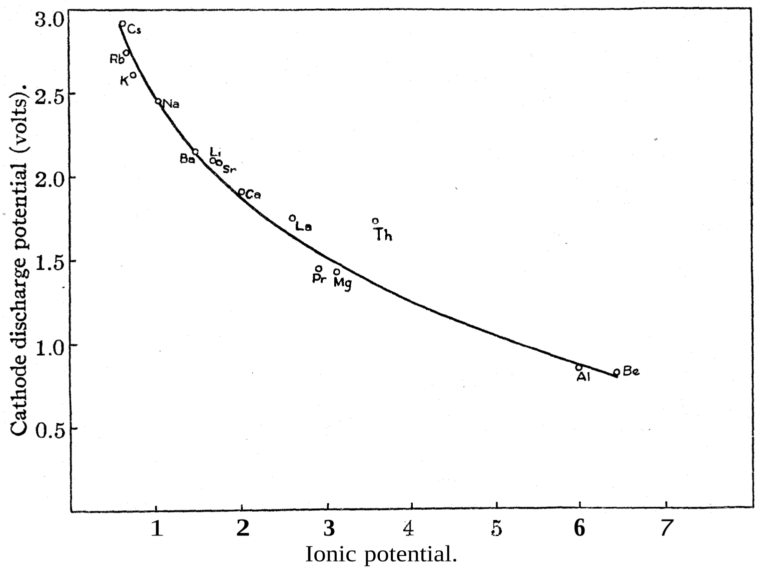

Fig. 1.—Ionic potentials and cathode potentials in the fused chlorides.

The roughly estimated ionic potential of the H^+ ion is in satisfactory agreement with the electrode potential of hydrogen. Considering only cations with inert gas structures, it will be seen from Pig. 1 of the preceding paper that all ions having lower ionic potentials than H^+ may be formed by displacement of hydrogen from acids or superheated steam. This is not the case with those having potentials greater than that of Hf, and in the ease of equipotes of H+, solution of the metal generally takes place sluggishly and oftentimes only with hydrofluoric acid, which forms a complex fluo-ion giving very low concentrations of the simple cation, as in the case of vanadium, columbium and tantalum.

---

[10] Neumann and Richter, *Z. Elektrochem.*, 31, 287,296 (1925).

Biltz and Klemm[11] have shown that there is a sharp decrease in the electrical conductance of the fused chlorides in passing from left to right in the several periodic series, and have pointed out that where the conductance becomes very low there is also an abrupt decrease in the melting point. This break in properties has been ascribed to a progressive deformation of the anion with increasing charge or decreasing radius of the cation,[12] as revealed by the decrease in the molal refraction of the anions in such a series as CaO–MgO–BeO. The deformation is regarded as finally reaching such a value that there is a transition from a polar, ionic lattice to a non-polar, molecular lattice.[13]

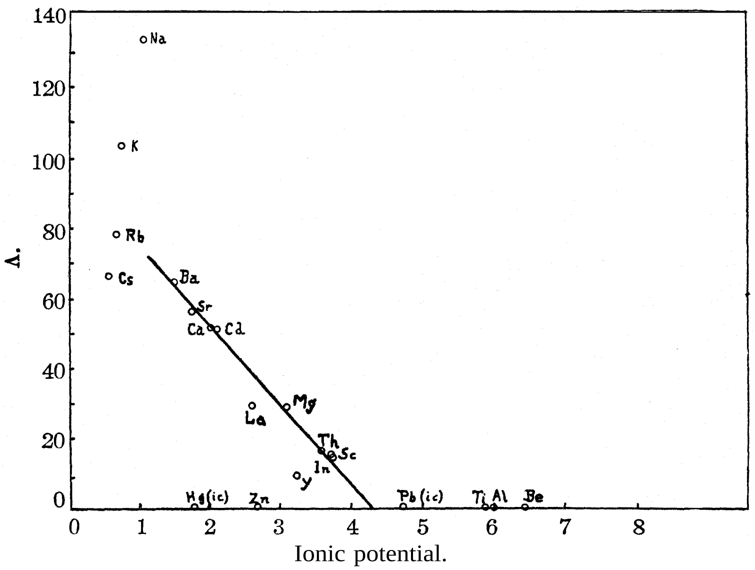

Fig. 2.—Ionic potential in relation to the equivalent conductance of fused chlorides at the melting point.

The deformation of the anion is closely related to the ionic potential of the cation, and it is found that *the zigzag line of Biltz and Klemm dividing the high melting, conducting chlorides from the volatile, non-conducting chlorides corresponds to an equipotential line* drawn at $\sqrt{\phi} = 2.2$. At lower ionic potentials the melting point of the chloride is high (generally $> 600°$); the equivalent conductance of the fused chloride increases rapidly as the cation potential becomes less than 4.2, according to the relation $\Lambda = 98 - 23\phi$ in the case of the chlorides of Mg^{++}, Ca^{++}, Sr^{++}, Ba^{++}, Cd^{++}, Th^{4+}, Sc^{3+} and In^{3+}; La^{3+} and Y^{3+} have a distinctly lower conductance

---

[11] Biltz and Klemm, *Z. physik. Chem.*, 110, *318* (1924); *Z. anorg. allgem. Chem.*, **152**, 225, 267 (1926); Klemm, *ibid.*, **152**, 235, 252, 295 (1926).

[12] Fajans and Joos, *Z. Physik*, **23**, *1* (1924).

[13] Fajans, *Naturwissenschaften*, **11**, 165 (1923).

than this relation would indicate and the conductances of the alkali chlorides increase in the reverse order (Fig. 2). As suggested by Biltz, in the case of the alkali chlorides the variation is no doubt to be ascribed to the variation in ionic mobility rather than to any incompleteness of ionization as a result of the electrostatic effects, whereas in the other cases the ionic field of force is the important factor. The low conductance and melting point of mercuric and zinc chlorides are striking exceptions to the general rule.

Considering only the quadrivalent ions, the melting points of the chlorides of both A and B families increase in the same order as the ionic potential decreases, excepting carbon and zirconium

Element	Si^{4+}	Ge^{4+}	Ti^{4+}	Sn^{4+}	Zr^{4+}	Pb^{4+}	Th^{4+}
M. p., °C.	−70	−49.5	−30	−30.2	..	−15	820
$\sqrt{\phi}$	3.13	2.74	2.43	2.30	2.24	2.18	1.90

The volatility and non-conductance of liquid hydrogen chloride are in accordance with the estimated potential of H^+, and the sharp contrast between the high melting, conducting thorium chloride and the chlorides of other quadrivalent ions is particularly striking.

Cation Potentials and the Deformation of Anions

The varying deformation of anions such as CO_3^{--} and NO_3^- is associated with numerous properties of compounds containing such ions. In a crystalline carbonate the C–O valences are presumably non-polar, the carbonate ion as a whole acting as one of the crystal units in a polar lattice. The firmness of the binding *within* the carbonate ion is less the stronger the electrostatic action of the cation. This effect has been called *a contrapolarization* by Goldschmidt;[14] for a series of salts with a common anion the effect obviously increases with increasing cation potential.

In respect to crystallo-chemical relationships, Goldschmidt has shown that an increase in temperature quite generally acts in the same direction as the substitution of a smaller cation of the same valence, that is, in the same direction as an increase in the cation potential. Thus, in the rare earth oxides the cubic modification is the high temperature form of the cerite earths, while in the yttrium earths (higher potential) it is the low temperature form.

In similar manner, the deformation of the anion may increase to the point of complete dissociation of the compound. It is found, for example, that the ionic potentials indicate the order of increasing dissociability of the carbonates and nitrates. Cations with $\sqrt{\phi} > 2$ do not form stable normal carbonates or nitrates; in cases in which $2 < \sqrt{\phi} < 2.5$, basic carbonates may be precipitated in solution which we generally soluble

---

[14] **Goldschmidt,** *Skrifter Norske Videnskaps-akad., Oslo., I, Matemat.-Natur.-Klasse, 1926, No.* **2.**

in excess of ammonium or alkali carbonate. The greater stability of nitrates as compared with carbonates at not too high temperatures may be associated with the higher potential of N^{5+} as compared with C^{4+}, the result being a greater deformability of the carbonate ion.[15] The instability of bicarbonates in the solid state may in like manner be related to the high value of $\sqrt{\phi_{H^+}}$, only the low potential alkali ions forming stable bicarbonates.

Other properties which have been associated with the deformation of ions may in like manner be related to ionic potentials, such as color[15] and the photoelectric conductance of salts.[16]

Ionic Potentials and the Hardness of Compounds

Goldschmidt[14] has pointed out that the hardness of inorganic compounds of similar composition increases as the inter-ionic distance decreases. In Table II Goldschmidt's data on the hardness of previously fused or sintered compounds are given on Moh's scale, together with the corresponding ionic potential.

TABLE II

HARDNESS AND IONIC POTENTIALS

	$\sqrt{\phi}$	2.54	1.76	1.64	1.44	1.42	1.35	1.33	121
$\sqrt{\phi}$	Ion	Be^{++}	Mg^{++}	Zn^{++}	Cd^{++}	Ca^{++}	Hg^{++}	Sr^{++}	Ba^{++}
1.19	O^{--}	9	6.5	5	...	4.5	...	3.5	3.3
1.04	S^{--}	7.5	4.5–5	4	3.2	4.0	3	ca. 3.3	ca. 3
1.00	Se^{--}	5.5	3.5	3 4	3.0	3.2	2.8	ca. 2.9	ca. 2.7
0.95	Te^{--}	3.8	..	3.0	2.8	2.9	2.6	ca. 2.8	ca. 2.6

	NaF	MgO	ScN	TiC
Hardness	3.2	6.5	7–8	8–9
$\sqrt{\phi}$ (cation)	1.02	1.76	1.92	2.43
$\sqrt{\phi}$ (anion)	0.86	1.19	1.32	1.24

It is clear that in a general way there is a parallel increase in hardness and potential.

In a recent paper[17] Noyes and Beckman have presented the results of a study of the ionization potentials for the different valence states of the elements as far as atomic number 26; these authors reach the conclusion that there is no definite relation between the ionization potential for the formation of a particular ion and the tendency of the element to assume that ionic form. While the work described in the present paper was in progress the ionization potential was considered as a possible basis of classification, but was rejected both because of the limitations in the data that are available and because it was realized that the ionic potential as

---

[15] Fajans and Scott, *Naturwissenschaften*, 11, 165 (1923), give the anion refraction per oxygen octet as 3.66 for NO_3^- and 4.08 for $^1/_2$ CO_3^{--}.

[16] Gudden and Pohl, *Z. Physik*, 16, 42 (1923).

[17] Noyes and Beckman, *Proc. Nat. Acad. Sci.*, 13, 737 (1927).

here defined is a closer index to the behavior of an ion in compounds than is the ionization potential.

The thermochemistry of chemical combination is, in general, too complex to be simply related to the periodic system.[18] In analyzing the heat of formation of polar compounds having a common anion, the ionization potential of the cation and the lattice energy of the compound have opposite signs. They vary in magnitude in the same direction when the cation radius is varied, both quantities increasing as the ionic potential increases. In general, however, the ionization potential increases more rapidly than the ionic potential, while the lattice energy increases less rapidly, being inversely proportional to $r_c + r_a$. In so far as the heat of formation of a compound is determined chiefly by the difference between these two quantities, it will be expected that in a series of compounds with one ion in common the heat of formation (per *equivalent*) will decrease with increasing potential of the varying constituent. This is true in many instances, as seen in the following data for the oxides (kg. cal. per equivalent)

$^1/_2$ MgO	$^1/_6$ Al_2O_3	$^1/_4$ SiO_2	$^1/_{10}$ P_2O_5	$^1/_6$ SO_3
72	63.4	48.7	37.0	17.2

This relationship is not uniform throughout the periodic system, however, but it will be shown in a subsequent paper that the ionic potential may be used to indicate the order of variation in thermochemical effects in the entire periodic classification.

It is proposed in subsequent publications to develop still other relationships between ionic potentials and the properties of matter.

Summary

The following generalizations may be given as a summary of the results of this paper.

1. The heat of hydration of gaseous ions increases with the ionic potential.

2. The heat of solution (evolution) of salts having a common anion increases with the ionic potential of the cation, except in the case of fluorides, with which the order is reversed.

3. Cations having $\sqrt{\phi} < 2.2$ are basic, those between 2.2 and 3.2 are amphoteric and those above 3.2 are acidic in aqueous media.

4. The discharge potentials of cations in fused electrolytes decrease regularly with increasing ionic potentials.

5. Cations having $\sqrt{\phi} > 2.2$ form volatile chlorides which are nonconductors in the liquid state. The conductance increases rapidly as $\sqrt{\phi}$ falls below 2.2, except in the case of the alkali ions, which vary in the reverse order.

6. High temperature and increase in the ionic potential of the cation

have similar effects in the polymorphic and stability relations of compounds with a common anion.

7. Binary crystals increase in hardness as the ionic potentials of their constituents increase.

THE CATALYTIC ACTIVITY OF METALLIZED SILICA GELS. V. THE OXIDATION OF ETHYLENE[1]

BY L. H. REYERSON AND L. E. SWEARINGEN

RECEIVED MAY 31, 1928 PUBLISHED NOVEMBER 6, 1928

Previous investigations of the authors[2] have shown that metallized silica gels exhibit considerable activity in certain oxidation reactions. The following investigation is an extension of this work to the oxidation of ethylene. Willstatter and Bommer[3] in their quantitative study of the conditions for the formation of formaldehyde from ethylene showed that, unless dilute, both ethylene and formaldehyde are unstable at temperatures much above 300°. They found that the use of catalysts accelerated the oxidation of ethylene but no formaldehyde was detected when catalysts were used. An osmium catalyst was found to initiate the oxidation of ethylene at about 130°, while copper proved to be effective at 250°. Blair and Wheeler[4] continued these investigations and found that, with a platinum catalyst, formaldehyde was formed at 405° when the gases were streamed through the catalyst very rapidly. As a result of these investigations, it was hoped that the use of metallized silica gels as catalysts would so lower the temperature at which reaction occurred that partial oxidation of ethylene could be effected and a mechanism for its catalytic oxidation obtained.

The experimental procedure was similar to that used by the authors in the study of the oxidation of methane.[5] Samples of the same catalysts were used as in the preceding investigations. Mixtures of ethylene, oxygen and nitrogen were passed over the catalysts at temperatures ranging from about 100 to 310° at varying rates of flow. In no case did the sum of oxygen and ethylene in the mixture exceed 50% of the gas volume. Preliminary experiments showed that the products of oxidation were carbon dioxide and water, so that the gases after passing through the catalyst were analyzed for ethylene, oxygen and carbon dioxide. In no case did tests show the presence of intermediate products of oxidation.

Experimental Results

The results of the experiments are given in Tables I to IV and Figs. 1 and 2 graphically represent typical experiments. The symbols used in the tables have the following significance.

A = the percentage of ethylene in the original mixture
A' = the percentage of ethylene found in the exit gas
A'' = the percentage of ethylene calculated to be present
O_2 = the amount of oxygen present in the original mixture
O_2' = the amount of oxygen found in the exit gas
O_2'' = the amount of oxygen calculated to be present
f = the fraction of carbon dioxide in the final mixture
F = the percentage of carbon dioxide in the final mixtures ($F = 100f$)
x = the fraction of the ethylene oxidized
X = the percentage of ethylene oxidized ($X = 100x$)
B = temperature of bath surrounding catalyst tube
C = temperature of catalyst during reaction

In the tables under the headings A', O_2' and F are given the results of the quantitative analysis of the gases after reaction. The column headed X gives the percentage of ethylene oxidized provided the reaction proceeds according to the following reaction: $C_2H_4 + 3O_2 \longrightarrow 2CO_2 + 2H_2O$. The fraction of ethylene oxidized is given by $x = 100\,f/(2A + 2Af)$, so that $100\,x = X$. From the amount of carbon dioxide formed it is also possible to calculate the amount of ethylene and oxygen which should be present with this carbon dioxide provided the oxidation of ethylene is complete. The calculated percentage of ethylene in the products of reaction is given by $A'' = A + f(A - 50)$, while for oxygen we have $O_2'' = O_2 + f(O_2 - 150)$. The values calculated for ethylene and oxygen check the experimental values very well and probably within the limits of the experimental error in the gas analysis.

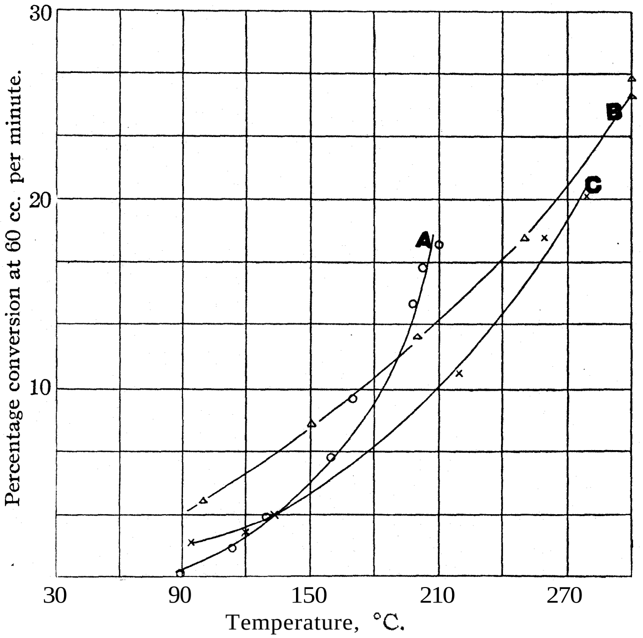

Fig. 1.—Composition of gas mixture: A = C_2H_4, 20%; O_2, 18%. B = C_2H_4, 21.3%; O_2, 16.85%. C = C_2H_4, 22.65%; O_2, 17.5%.

Discussion and Results

It is evident from these results that the catalysts used were effective in promoting the oxidation of ethylene at lower temperatures than previously reported. The copper, platinum and palladium catalysts began to be effective at about 100°. Fig. 1 shows the effect of temperature on the oxidation of ethylene for three different gas mixtures with platinized silica gel as the catalyst. The effect of increased rate of streaming on the conversion is shown graphically in Fig. 2. The silver catalyst is shown to be less effective than the other catalysts. The catalysts all speeded up the successive oxidation reactions so that no intermediate products were detected. This confirms the previous work on the oxidation of ethylene.

The experimental results here given indicate that the reaction is directly proportional to the oxygen concentration and inversely proportional to the ethylene concentration. For example, when the ratio of ethylene to oxygen is changed from 1.36 to 0.81, the amount of ethylene oxidized by the platinum catalyst at 200° increases from 19.22 to 36.10%. Thus the amount oxidized is nearly doubled. Similar results were obtained with the other catalysts. The simplest explanation for these results would seem to be that collisions of ethylene molecules with oxygen molecules which are adsorbed and activated by the effective catalyst centers resulted in reaction, whereas collisions of oxygen molecules with adsorbed ethylene molecules were ineffective. The adsorption studies of the authors[6] indicate specific adsorption of both ethylene and oxygen by these catalysts. Therefore, when the ethylene molecules are adsorbed by the active catalyst centers, then these centers, are no longer effective. The double bond of ethylene is no doubt directed toward the catalyst. When,

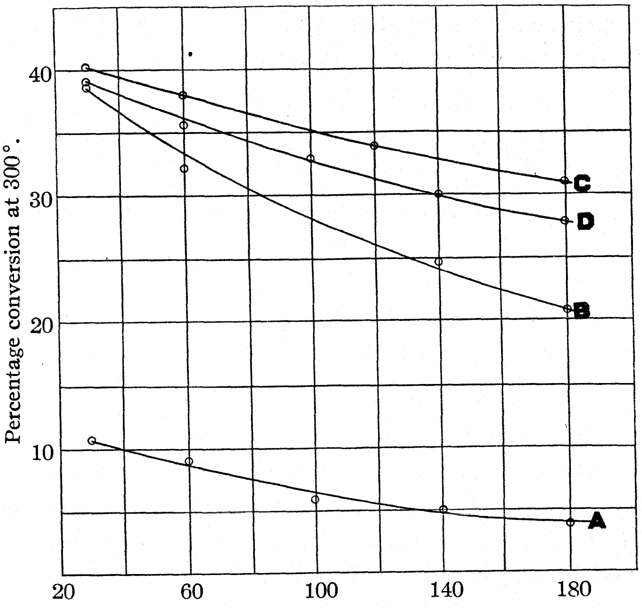

Fig. 2.—Catalysts: A, Silver; B, Copper; C, Platinum; D, Palladium.

---

[6] Reyerson and Swearingen, J. *Phys.* Chem., **31, 88** (1927).

however, an oxygen molecule reaches an active center and is adsorbed, it is activated so that it is able to react with the ethylene which reaches it. Mere adsorption is not sufficient, otherwise the silica gel itself would be an active catalyst. Because of their higher energy content the primary products of oxidation are likely to be very reactive whether they are dihydroxyethylene or formaldehyde. Furthermore, as indicated in the tables, the temperature of the catalysts is often higher than that of the bath in which they are immersed. This indicates that the temperature at which the reaction takes place may be very much higher than that indicated, so that successive collisions with oxygen molecules result in complete oxidation. Otherwise intermediate products of oxidation should be detected when the rate of streaming through the catalyst was increased.

Conclusion

1. Metallized silica gels actively promote the oxidation of ethylene, beginning to be effective at about 100".

2. The catalysts are so active that no intermediate products of oxidation are detected.

THE FLUIDITY OF MERCURY[1,2]

BY EUGENE C. BINGHAM AND THEODORE R. THOMPSON

RECEIVED JUNE 25, 1928 PUBLISHED NOVEMBER 6, 1928

Tammann and Hinnüber[3] have raised the question whether the viscosity of a liquid is trustworthy when it is measured in a tube that is not thoroughly wetted by the liquid. They claim to have found the viscosity of mercury in an amalgamated copper capillary to be 4.931 ± 78 *cp* at 13.5" instead of 1.609 *cp* for mercury in glass. Whether one accepts their explanation of the phenomenon based on "slippage," or not, the discrepancy of over 200% is quite beyond experimental error and demands investigation.

1. The hypothesis of slippage is, of course, not new. It has often been offered to account for results which at the time seemed inexplicable, but on further investigation it has always been found that some factor has been overlooked which has made this explanation unnecessary. On the other hand, the fair agreement among the results of different investigators using widely different forms of viscometers and shearing stresses constitutes what may be fairly regarded as proof that slippage is certainly not

[3] Tammann and Hinniiber, *Z. anorg. Chem.*, 167,230 (1927).

a very important factor in the flow of mercury over glass. As the subject has been discussed elsewhere,[4] repetition here is unnecessary. We propose to inquire whether there is not some other explanation for the phenomenon other than the one suggested by Tammann and Hinnuber.

2. S. Erk[5] has already suggested as an alternative explanation that the walls of metal capillaries are perhaps not as smooth as those of glass capillaries, so that the flow is not perfectly linear. Erk has shown that in the steel capillary used by Tammann and Hinniiber the velocity of flow was so high that according to the Reynold's criterion turbulence should have been expected. The weak points in this explanation are, first, that the decrease in fluidity was not marked in the steel capillary and not very marked in the copper capillary until after thorough amalgamation; and, second, that the apparent fluidity in the amalgamated copper capillary steadily decreased for several days. It is not obvious why thorough amalgamation should increase the turbulence nor why the turbulence should not reach its maximum value at once.

3. The most obvious explanation is that the copper or something derived from the copper has decreased the fluidity of the mercury. This hypothesis has been considered by Tammann and Hinnuber and rejected because copper is only soluble to 0.0032% at 15° and at this dilution the fluidity is lowered not over 0.3%. We have confirmed this, finding that the fluidity at 20° of a saturated solution of copper was 63.9 rhes,[6] as compared with 64.2 for pure mercury. The method of preparation was intentionally such that the solution would contain the impurities derived from the copper but the solution was passed through chamois skin before measurement in order to remove any suspended particles. The difference obtained is only a little more than experimental error.

4. E. von Schweidler[7] claimed to have prepared a solution of copper in mercury containing 0.5% of copper with the low fluidity of 61.7. This may have been a suspension of colloidal copper, mercury or oxide, but whatever its nature it is worth considering whether suspended material could have caused the actual reduction in apparent fluidity noted by Tammann and Hinniiber. This difficulty can be largely overcome by the cleaning out of the viscometer and the use of clean mercury, but we have proved that the fluidity is not restored to that obtained in a glass capillary, so that this explanation is inadequate.

5. Even if the copper does not dissolve to any extent in the mercury, it is possible that the mercury diffusesinto the copper and causes it to expand, thus partially filling the capillary. However, the measurements

[7] E. von Schweidler, *Wied-Sitzb.*, [2A] 104, 273 (1895).

of the diameter of the amalgamated tube made by Tammann and Hinnuber give no evidence of a decrease in diameter.

6. Copper is slightly soluble in mercury and the solution is very fluid, as already pointed out. In a saturated solution it is to be expected that the small crystals of copper would be dissolved to promote the growth of large crystals. It is therefore possible that after amalgamation there is a progressive alteration in the surface which would in time result in a pronounced change in the *effective* radius of the capillary. Since the copper taken away at one place is deposited at another, the average radius measured by Tammann and Hinnüber would not be affected, but the "constant" of the capillary should change. We have found as a matter of fact that after removing the mercury from the amalgamated capillary of a viscometer by heating in a stream of hydrogen, the constant of the viscometer as determined with pure water decreased from 4.94 to 4.79×10^{-7}, which is roughly 3.0%.

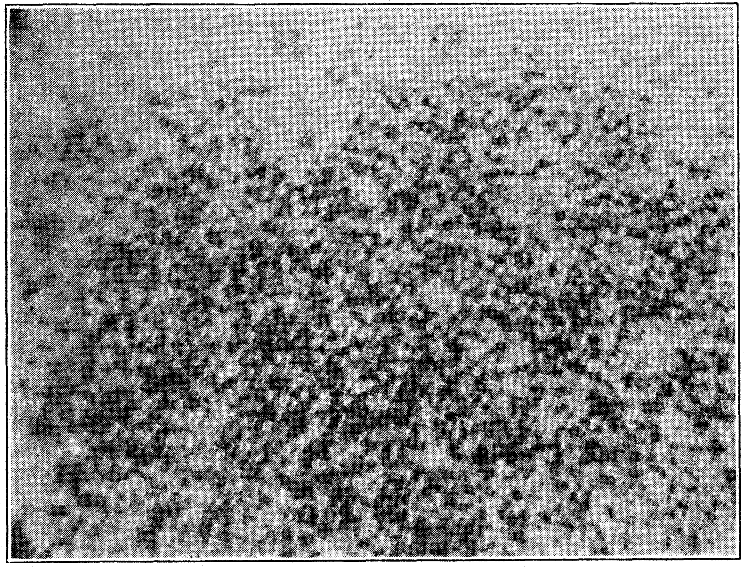

Fig. 1.—Surface after fifteen minutes.

Before amalgamation the apparent fluidity of the mercury as measured at different pressures in the copper capillary at 20° was 62.2 rhes and after twenty-four hours 62.1 rhes. We obtained in a glass capillary at 20° the fluidity of 64.3 rhes. The apparent fluidity in the copper capillary is therefore 3.3% lower than when measured in a glass capillary but it does not change rapidly with the time. Tammann and Hinnüber obtained a value 22.3% lower than the value as measured in glass. Perhaps the difference is due to partial but unequal amalgamation.

After thorough amalgamation the apparent fluidity decreased steadily but there was no evidence that it was tending toward a constant value until after ten hours it had fallen to 20% of its original value, when the experiment was discontinued. Repeating the experiment with a smaller capillary, the flow after a time ceased altogether. Tammann and Hinnüber observed that the time of flow increased for a period of five days, but on somewhat scanty evidence they assumed that the time of flow will reach a constant value. However, even if the time of flow does become constant, this fact would not prove that the fluidity of the mercury was tending toward a constant value, for it might be the capillary and not the mercury which is changing. Slippage is supposed to help the flow so that the final value of Tammann and Hinnüber should be a minimum, but our value of about 12.5 rhes is considerably lower than their value of 20.3 rhes, and it is not the minimum value.

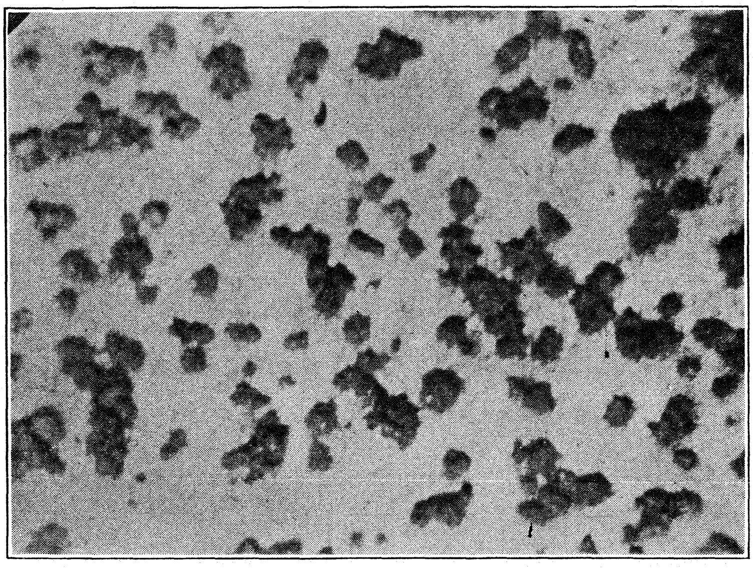

Fig. 2.—Surface after forty-two hours.

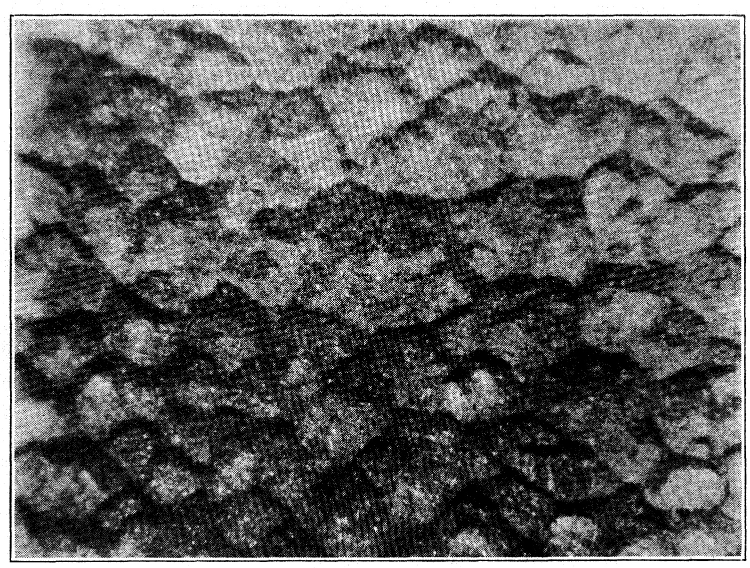
It appeared possible to prove quite conclusively that recrystallization of the copper does take place on the walls of the capillary and that it is sufficient to explain any decrease in apparent fluidity. To do this, pieces of copper were smoothly polished, amalgamated for a few seconds with mercurous nitrate and then bathed in metallic mercury for different periods of time, after which the mercury was driven off by heat in an atmosphere of hydrogen. It will be seen from Fig. 1 that the etching of the surface is quite marked after only fifteen minutes, large isolated crystals stand out prominently from the surface at the end of two days, Fig. 2, and at the end of two weeks, Fig. 3, large crystals appear to cover the entire surface. Some of the crystals were as much as 0.5 mm. above the surface, which is about twice the diameter of one of the capillaries which we used. A section made at right angles to the surface showed the irregular surface very well.

It is not necessary, however, to use any elaborate technique to show the effect, for a smooth piece of copper amalgamated for more than a few hours shows to the unaided eye a rough sandy appearance. We assume that this recrystallization has been noticed repeatedly heretofore but we are unable as yet to give any references.



Pig. 3.—Surface after two weeks.

We therefore reaffirm the earlier conclusion that there is no positive evidence of slippage of mercury in a glass tube, and we reach the new conclusion that the fluidity of mercury measured in a copper tube is unreliable, particularly when the copper is wetted by the mercury.

TABLE I

THE FLUIDITY OF MERCURY MEASURED IN A GLASS CAPILLARY

Capillary No. 1.23; $C = 1.994 \times 10^{-7}$; $C' = 0.018$; $h' = 0.15$ cm.

Temp., °C.	Time of efflux	Fluidity rhes	Av. earlier 'fluidity, Erk
0	254.5	59.4	59.3
10	244.0	62.1	61.9
20	237.0	64.3	64.8
30	228.9	66.8	66.7
40	223.4	686	69.0
50	216.9	71.0	71.1
60	211.8	72.9	73.2
70	207.3	74.9	75.1
80	203.2	76.7	77.0
90	199.3	78.5	78.9
100	196.0	80.0	80.6

The fluidity of mercury from 0 to 100° was determined as an incidental part of this investigation, using glass capillary No. 1.23. The values are a little higher at low temperatures than the mean values of earlier experimenters given by Erk,[5] and our values are somewhat lower than theirs at 40° and above. This slight change does not alter the conclusion that mercury is different from all other liquids yet studied in that its fluidity temperature curve is concave toward the temperature axis.

Summary

1. The suspicion that mercury exhibits slippage while flowing over unwet surfaces such as glass appears to be unfounded.

2. The fluidity of mercury from 0 to 100°, measured in a glass capillary viscometer with attention to recent corrections, was found to be not inconsistent with earlier determinations.

3. The rate of flow of mercury through a narrow copper capillary is irregular but decreases with time, particularly when the tube is well amalgamated. The values of the fluidity are quite untrustworthy. The effect is the indirect result of the very slight solubility of copper in mercury. Differential solubility of the crystals causes large crystals to build up on the surface of the capillary which interfere with the flow.

THE COLOR OF IODINE SOLUTIONS[1]

BY FREDERICK H. GETMAN

RECEIVED JULY 2, 1928 PUBLISHED NOVEMBER 6, 1928

The dependence of the color of solutions of free iodine upon the nature of the solvent has been the subject of numerous investigations, but notwithstanding the thoroughness of these studies the problem of the exact composition of iodine solutions yet remains to be solved completely.

As a result of their study of colors of iodine solutions, Gauthier and Charpy[2] concluded that four different colors may be distinguished, depending upon the nature of the solvent, as follows: (1) violet, as in chloroform; (2) red, as in ethylene bromide; (3) reddish-brown, as in toluene; (4) brown, as in ethyl alcohol. Although a number of solvents were found to conform to this classification, no satisfactory relation between the properties of the solvents and the colors of the solutions was discovered. Subsequent investigations by Rigollot[3] and by Krüss and Thiele[4] failed to establish any satisfactory connection between the chemical

behavior of the solvent and the color of the solutions. In 1903, Lachman,[5] after examining solutions of iodine in more than sixty carefully purified solvents, representative of twelve different types of organic compounds, was unable to distinguish more than two colors, namely, violet and brown. Furthermore, he formulated the following generalization between the color of the solution and the character of the solvent: saturated solvents give violet solutions, whereas solvents having an unsaturated character yield brown solutions. The differences in the colors of iodine solutions have been attributed by Krüss and Thiele,[4] Wiedemann and Ebert,[6] Loeb,[7] Beckmann[8] and others to differences in the molecular condition of the solute. Subsequent investigations, notably by Hildebrand and Glascock[9] Waentig,[10] Ley and Engelhardt,[11] and Dolezalek,[12] have confirmed this view and have furnished abundant experimental evidence to show that in the brown solutions the solute is more or less solvated, whereas in the violet solutions the solute consists solely of diatomic molecules of iodine. The compound, PyI_2, has actually been isolated by Waentig from a pyridine solution of iodine.

It has long been known that brown solutions of iodine tend to become violet when heated, while violet solutions become brown when sufficiently cooled. This change of color with temperature may be satisfactorily explained by assuming a displacement of the equilibrium between solvated and unsolvated iodine.

More recently, Amann[13] has put forward the view that while in some instances iodine, either free or solvated, may form true solutions, yet in other cases it forms colloidal solutions. He states that brown solutions of iodine contain ultramicroscopic particles, while violet solutions contain none.

Notwithstanding Lachman's statement that iodine solutions are either violet or brown, and that intermediate colors are never observed unless the solvents contain minute amounts of impurities, one finds repeated statements throughout the literature that solutions of iodine in certain solvents exhibit various colors such as blue-violet, red-violet, red and red-brown.

With the exception of the work of Coblentz[14] on solutions of iodine in carbon disulfide and ethyl alcohol, relatively few spectrophotometric

measurements of iodine solutions in the visible range of the spectrum have been recorded. It has seemed of interest, therefore, to undertake a series of spectrophotometric measurements of iodine solutions in typical solvents with a view to testing the validity of Lachman's statement relative to the colors of iodine solutions,

Apparatus.—The spectrophotometric measurements have been made with a Nutting photometer in conjunction with a Hilger wave length spectrometer. As a source of light a 13-watt Mazda lamp operating on the 110-volt a. c. circuit was employed. Absorption tubes of 10-cm. length were used throughout the entire series of measurements.

Materials.—Alerck's resublimed iodine served as the solute in each of the solutions. Solvents of a high degree of purity were subjected to thorough dehydration and subsequent fractionation before being used in the preparation of the solutions. The following solvents were employed: ethyl alcohol, b. p. 78.4°, 760 mm.; *iso*propyl alcohol, b. p. 80.2–81.2°, 750 mm.; acetone, b. p. 56.6°, 755 mm.; chloroform, b. p. 61.0–62.0°, 757 mm.; carbon tetrachloride, b. p. 77.0°, 763.4 mm.; carbon disulfide, b. p. 46.0–46.2°, 752 mm.; n-hexane, b. p. 68.0°, 760 mm.; benzene, b. p. 80.0–80.2°, 757 mm.; toluene, b. p. 110.2–110.8°, 758 mm.; pyridine, b. p. 114.8–115.6°, 751.6 mm.; nitrobenzene, b. p. 209.2–209.4°, 753.5 mm.; acetophenone, b. p. 202–203°, 756 mm. The aqueous solutions of potassium iodide were prepared from a high grade of salt dissolved in conductivity water.

Results.—The values of the extinction coefficients,[15] ϵ, for the different solutions, as measured at intervals of 10 mμ throughout the visible spectrum from 680 mμ to 430 mμ, are given in Table I. Inspection of the data of the table shows that, if solutions in nitrobenzene be disregarded, the solutions may be grouped in two distinct classes as follows: (1) solutions resembling that of iodine in n-hexane (violet solutions), and (2) solutions resembling that of iodine in ethyl alcohol (brown solutions). Solutions in n-hexane, benzene, toluene, carbon disulfide, carbon tetrachloride and chloroform have absorption maxima ranging between 520 mμ and 540 mp. On the other hand, solutions in ethyl alcohol, *iso*propyl alcohol, acetone, acetophenone and pyridine have absorption maxima ranging between 460 mμ and 480 mp. All of the solvents belonging to the first group are saturated in character, whereas all of those belonging to the second group are unsaturated. While not differing essentially in the spectral character of their absorption, solutions of iodine in both acetone and pyridine are found to differ markedly from the other solutions belonging to the second group in the intensity of their absorptions. With the exception of these two solutions, and that of iodine in nitrobenzene already mentioned, very little difference is found to exist between the absorptive powers of the solutions within each group. The absorption

---

[15] The extinction coefficient, ϵ, is defined by the equation $\epsilon = 1/d \log I/I_0$, where I_0 is the intensity of the light entering the solution and I is the intensity of the emergent light after having traversed d cm. of solution.

curves for solutions of iodine in n-hexane, ethyl alcohol, acetone and pyridine, as plotted from the data of Table I, are shown in Fig. 1.

The intensity of absorption is seen to be decidedly different in the two groups of solvents. The maximum intensity is found with the solvents of the first group, that is, with saturated solvents. Furthermore, the intensity of the absorption with saturated solvents is nearly identical. On the other hand, the intensity of absorption with solvents of the second group is markedly less than that with solvents of the first group. While the intensity of absorption with saturated solvents is practically constant, it varies widely amongst the different unsaturated solvents studied. These facts are clearly brought out by the data of Table II, showing the absorption maxima of the solutions examined.

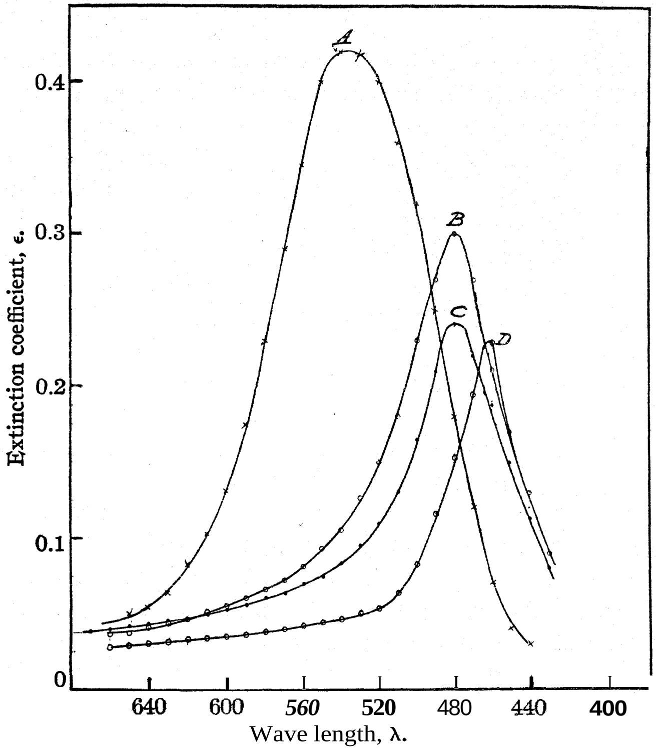

Fig. 1.—A, 0.0005 M I_2 in n-hexane; B, in ethyl alcohol; C, in pyridine; D, in acetone.

In this table λ_m denotes the wave length corresponding to the absorption maxima as determined from large scale plots of the data of Table I, while ϵ_m denotes the corresponding values of the extinction coefficients. The last column of the table gives the number of the group to which each solvent belongs.

TABLE II

ABSORPTION MAXIMA OF SOLUTIONS

Chloroform	535	.41	I	Water	470	.29	II
Nitrobenzene	50	.42					

The foregoing facts appear to substantiate Lachman's generalization that when iodine is dissolved in a saturated solvent the resulting solution is violet in color, whereas when it is dissolved in an unsaturated solvent the solution is brown in color. While in the case of saturated solvents iodine may be fairly assumed to form true solutions, its behavior with unsaturated solvents is by no means as clear. Although in the presence of an unsaturated solvent it is possible that the iodine molecule may undergo solvation, with equal probability it may be assumed to undergo association and give rise to a solution possessing a distinctly colloidal character. This latter possibility is in agreement with the view put forward by Amann[13] that brown solutions of iodine contain ultramicroscopic particles, whereas violet solutions are optically void.

It was pointed out by Ley and Engelhardt[11] that the absorption spectrum of iodine solutions changes with time, and that the differences between their results and those of Waentig[10] and of Crymble, Stewart and White[16] were to be traced to the failure of the latter observers to examine their solutions immediately after preparation. While the alteration in the character of the absorption spectrum of an iodine solution which occurs on standing is more pronounced in the ultraviolet than in the visible region of the spectrum, care has been taken throughout the present investigation to measure each solution immediately after it was prepared. The most pronounced example of the change in color with time which we have observed was furnished by solutions of iodine in isopropyl alcohol and acetone. Within a few hours after the solutions were prepared, the original brown color had faded to a light amber, and within a few days the solutions became absolutely colorless. This is undoubtedly due to a chemical reaction between the components of the solutions.

It is well known that solutions of iodine in aqueous potassium iodide darken on exposure to light. Recently the increase in the ultraviolet absorption of aqueous solutions of potassium iodide on exposure to light has been measured by Brode[17] and shown to be due to the presence of free iodine in the solutions. When a fixed weight of iodine is dissolved

---

[16] Crymble, Stewart and White, *Ber.*, 43, 1183 (1910).

[17] Brode, THIS JOURNAL, 48,1877 (1926).

in aqueous solutions of potassium iodide of increasing concentration, it has been found that the ultraviolet absorption increases with the concentration of the potassium iodide. In order to determine whether a similar increase in absorption occurs in the visible portion of the spectrum, 0.0005 *M* solutions of iodine in 0.01 *M* and 0.1 *M* potassium iodide have been measured. As will be seen from the last two columns of Table I, the more concentrated solution possesses slightly greater absorbing power.

The photochemical decomposition of iodine solutions has been studied by Stobbe and Schmidt.[18] They point out that solutions of iodine in alcohols slowly undergo transformation into solutions of periodides, such as hydrogen tri-iodide or other addition compounds. This reaction is accelerated by spongy platinum as well as by light. While the absorption spectrum of true solutions of iodine reveals but a single band in the visible portion of the spectrum, the ultraviolet absorption spectra of periodide solutions are found to resemble each other and to he characterized by two bands having wave lengths of 357 mμ and 290 mμ. Stobbe and Schmidt state that during the change of an iodine solution into a solution containing periodides, solutions of mixtures are formed which exhibit three absorption bands. In the solutions of iodine whose absorption spectra have hitherto been described by earlier observers, Stobbe and Schmidt have estimated that from 5 to 100% of the iodine present had undergone transformation into periodides. Furthermore, Stobbe and Schmidt found upon irradiating solutions of iodine in chloroform or benzene for twenty-four hours with a quartz mercury lamp, that the solutions became yellow on diluting with the respective solvents instead of acquiring the reddish color which unilluminated solutions of iodine assume when similarly diluted.

It seemed of interest, therefore, to carry out a few qualitative experiments on the stability of some of our solutions in ultraviolet light. To this end, 0.0005 *M* solutions of iodine in ethyl alcohol, *n*-hexane and carbon disulfide were irradiated in quartz flasks with ultraviolet light from a quartz mercury lamp for a period of six hours, after which their absorption curves were again determined spectrophotometrically. On comparing the resulting curves with those of the freshly prepared solutions, it was found that some change had occurred, the alcohol solution showing the most and the hexane solution the least photolysis. This is what might be expected with solvents containing oxygen which are known to decompose when exposed to ultraviolet radiation. Carbon disulfide on exposure to ultraviolet radiation has likewise been found by both Berthelot[19] and Bruhat and Pauthenier[20] to undergo partial decomposition, the walls of the containing vessel becoming coated with a

---

[19] Berthelot, *Ann. chim. phys.*, (VII) 19, 150 (1900).

[20] Bruhat and Pauthenier, Comfit. rend., 178, 1536 (1924); 180, 1018 (1925).

brown deposit. A similar deposit was observed in the present series of experiments. Hexane appears to be quite stable when exposed to ultraviolet radiation and the solution of iodine in this solvent was found to be equally stable. The behavior of iodine solutions on exposure to ultraviolet radiation, as far as our few experiments have been carried, appears to confirm the view put forward by Lachman that unsaturation in the solvent is a factor of considerable importance in determining not only the color but other properties of iodine solutions.

Summary

1. The extinction coefficients of iodine solutions in a series of carefully purified solvents have been measured at intervals of 10 mμ throughout the visible spectrum.

2. The solutions may be divided into two distinct groups, as follows: *(a)* solutions in n-hexane, benzene, toluene, carbon disulfide, carbon tetrachloride and chloroform give violet solutions with absorption maxima ranging from 520 mμ to 540 mμ; (b) solutions in ethyl alcohol, *iso*propyl alcohol, acetone, acetophenone and pyridine give brown solutions with absorption maxima ranging from 460 mμ to 480 mμ.

3. The first group of solvents are saturated compounds, while the second group of solvents are unsaturated compounds.

4. The intensity of absorption differs markedly in the two groups. The maximum intensity of absorption is found with the saturated solvents of the first group, and is practically constant throughout the group. The intensity of absorption varies appreciably between the unsaturated solvents of the second group and is in every case less than with saturated solvents.

5. Solutions of iodine tend to undergo change on standing, this change being accompanied by a corresponding change in their absorption spectra.

6. The color and stability of iodine solutions on exposure to ultraviolet radiation appear to be more or less dependent upon the degree of saturation of the solvent.

STAMFORD, CONNECTICUT

CATALYSIS IN THE HYDRATION OF ACETIC ANHYDRIDE[1]

BY MARTIN KILPATRICK, JR.

RECEIVED JULY 12, 1928 PUBLISHED NOVEMBER 6, 1928

In a general paper on reaction velocity, Skrabal[2] has regarded the hydrolysis of the organic oxides as made up of *(a)* a hydrogen-ion catalyzed reaction, (b) a hydroxyl-ion catalyzed reaction, (c) an uncatalyzed or water reaction. This classification was first made by Hudson, who applied it to the case of the mutarotation of glucose. Bronsted and Guggenheim[3] studied the effect on the mutarotation of glucose of other acid molecules than hydrogen ion, and of other basic molecules than hydroxyl ion; they showed that water may be considered to act catalytically both as an acid and as a base. Similarly, in the decomposition of nitramide, water may be classed as a basic catalyst,[4] since the constant for the decomposition of nitramide in acidified water lies on the straight line obtained when one plots the logarithm of the basic catalytic constant against the logarithm of the constant of basic strength. In all cases where catalytic effects of other acid molecules than hydrogen ion and other basic molecules than hydroxyl ion have been detectable, a water reaction has also been found to occur.[5] Conversely, it should be interesting to investigate from the point of view of acid and basic catalysis, a substance showing a particularly fast water reaction relative to the hydrogen- and hydroxyl-ion catalyzed reactions.

Acetic anhydride is such a substance. As Skrabal points out, the accurate determination of the catalytic effects of hydrogen and hydroxyl ion has not been possible because the minimum reaction rate already lies close to the limit of measurability. Skrabal[6] followed the hydration of acetic anhydride by coupling it with the iodide–iodate reaction; he assigns to the constant of hydroxyl ion catalysis the value $k_{OH^-} \leqq 4.4 \times 10^6$ at 25°. More recently Szabó[7] has studied the hydration of acetic and succinic anhydrides at 14 and 18° in the presence of electrolytes and non-electrolytes, using an interferometer to measure the change in refractive index which accompanies the reaction. Szabó reports catalysis by hydrogen

and acetate ions in the case of acetic anhydride and by hydrogen and succinate ions in the case of succinic anhydride. Practically all her experiments, however, were carried out in solutions of high electrolyte concentration and no proportionality between catalyst concentration and reaction rate is shown. Orton and Jones[8] studied the reaction in acetic acid, in acetic anhydride, in acetone, and in various mixtures of these solvents with water. From their experiments with different acids, they conclude that the non-ionized acids are effective catalysts in a solvent of over 90% acetic acid. They also notice the catalytic effect of sodium acetate in aqueous solutions but do not distinguish it from the effect of hydroxyl ion. The reaction has also been studied by Verkade,[9] who measured the change in the conductivity, and by Benrath,[10] who determined the change in the density of the solution as the reaction proceeded.[11]

It was thought that a dilatometric method might be convenient. Preliminary experiments showed that there was a considerable heat of reaction, a fact which appears often to have been overlooked and which is of the utmost importance in dilatometric work. A dilatometer was designed to take care of the heat of reaction and experiments were carried out at 0°. Here the half time of the reaction is twenty-six minutes. It was found possible to measure accurately the rate of reaction where the half time is as little as ten minutes.

Experimental Method

The apparatus as shown in Fig. 1 consists of a mixing chamber A connected by means of capillary tubing through the stopcock E to the two arms of the dilatometer F,F' and so to the calibrated capillary G. F and F' have a capacity of approximately 25 cc. each and the bore of the capillary G is 0.4 mm. In addition, the mercury filled chamber, J, is connected at D. A steel cap is sealed into the chamber J and the steel screw H turning through this cap acts as a plunger. By turning the screw the mercury can be raised through D and through E to K and K'. The whole apparatus is mounted and set in the Dewar P. Since the apparatus is packed in ice, and since it is necessary to observe the mercury levels at D and N, the tubes M and N extending to the walls of the Dewar are affixed with suitable supports. The stopcock E is encased; in addition it is fitted with a spring to hold the cock tightly in the barrel and with a mechanical arrangement for turning the cock.

A description of the procedure will further explain the apparatus. The glass rod B with a ground tip is set in place and 50 cc. of the solution run into the chamber A. A is then closed by a rubber stopper. The apparatus is packed tightly in snow ice and sufficient ice water added to fill the Dewar. After an hour a platinum stirrer and thermometer are placed in A. The stopcock E is opened and the level of the mercury adjusted to D by means of the screw H; this could be observed through M. When the solution has come to 0.0° ± 0.01°, the thermometer is removed and 0.35 cc.

of acetic anhydride is added from a small weight pipet, After mixing, the rod B is removed and a rubber stopper with glass tube inserted in the top of the mixing chamber. The tube is connected to a suitable pressure system and the solution is forced over through the cotton plug C into the dilatometer and up into the capillary G. The rubber stopper is then removed from A and the rod B replaced. By turning H mercury is forced up to K and K′. Any excess of solution is taken up with filter paper and by turning H the liquid is brought to a suitable level in the capillary, E is closed and B removed. The rubber stopper is replaced in A, the Dewar wrapped in an insulating jacket and at *a* convenient time the first reading is taken. The manipulation occupies from six to ten minutes from the time of mixing. If, as occasionally happens, an air bubble is trapped between D and E it appears on the surface of the mercury when the mercury is forced up to N and is easily seen. It is a simple matter to draw the mercury back, remove B, and after inserting a rubber stopper in the top of L remove the bubble by gentle suction at R. Very little trouble was experienced with air bubbles; on the whole the method of filling a dilatometer by pressure is superior to filling by suction.

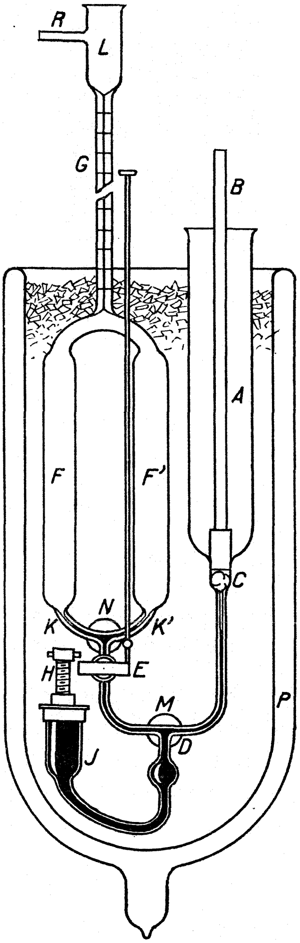

Fig. 1.—Apparatus.

Readings were taken at minute intervals for thirty minutes and at two minute intervals for another thirty minutes. One-half hour later a second set of readings was made, at the same intervals, and the velocity constant was calculated by the method of Guggenheim.[12] In those cases where the infinity reading was observed, the velocity constant was also calculated from the usual monomolecular formula. The observed infinity reading and that calculated from the velocity constant of Guggenheim's method usually agreed within 0.05 cm. for a total contraction of 6 cm. in the capillary. Since it is difficult to reproduce briefly an experiment calculated by the plotting method, Table I gives, for a typical experiment, the constant obtained from the observed infinity value and the formula $k = 1/t \ln (V_0 - V_\infty)/(V_t - V_\infty)$.

In no case was there a trend of more than 2% in the value of k during the course of an experiment. The change in k[13] with change in concentration of anhydride was not investigated, the initial concentration being 0 07 M ± 10% in **all** cases. The medium effect of acetic acid was investigated and will be discussed later. The anhydride used was a fraction of Kahlbaum's "für analytische

[a] All the remaining constants in this paper are given in terms of natural logarithms.

Zwecke" distilling between 137 and 138° at 753 mm. Other samples of anhydride gave constants not differing by more than 2% from 0.0269.[14]

On account of the high constant of the spontaneous or water reaction, the effects of H_3O^+ and OH^- ions are practically negligible over a wide range. Taking[15] k_{OH^-} as 4×10^5, $k_{H_3O^+}$ as 3×10^{-2} and k_0 as 3×10^{-2} at 0°, for a hydroxyl-ion concentration of 1×10^{-8} M, the effect of hydroxyl ion is only 1% of the total reaction and for a hydrogen-ion concentration of 1×10^{-2} M the effect of the hydrogen ion is 1% of the whole. As will be shown later, k_{Ac^-} is of the same order of magnitude as $k_{H_3O^+}$; any catalysis by the acetate is therefore negligible in the experiments carried out to determine k_0.

Table II shows the influence on k_0 of small amounts of hydrochloric acid and of neutral salts present in concentrations up to 0.2 N.

The salt effect is negative and varies with the individual salt. The

results for sodium chloride are plotted in Fig. 2; these results can also be expressed by the equation $k_0 = 0.0268 - 0.0052\,c$ (where c is the concentration of sodium chloride).

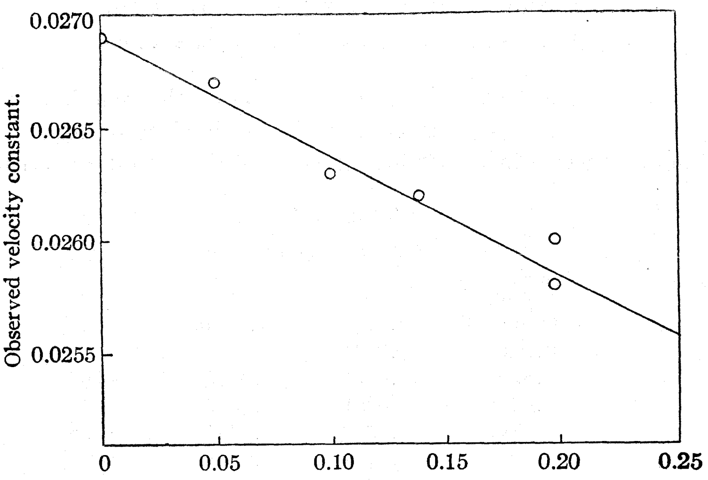

Fig. 2.—Effect of sodium chloride on reaction rate.

Figure 3 and Table III give the results of experiments carried out to determine $K_{H_3O^+}$. In Fig. 3 the observed velocity constants are plotted against the acid concentrations.

The plot shows approximate proportionality between acid concentration and increase in velocity constant; however, the correction for salt effect on the velocity constant remains to be made. In Table III the correction is made and $K_{H_3O^+}$ is computed.

The third column of Table III gives the observed velocity constant. The fourth gives k_0 corrected for salt effect, the effect for each acid being taken equal to the value shown in Table II for the corresponding salt. In the case of hydrochloric acid the effect is taken to be the same as that of sodium chloride. Col. 5 shows the portion of the reaction due to the hydrogen ion and $K_{H_3O^+}$ (sixth column) is obtained by dividing $k_{obs.} - k_0$ by the acid concentration. When it is considered that an error of 1%

Average deviation = 5%

in the observed velocity constant means an error of 7% in $K_{H_3O^+}$ as determined from an experiment in 0.1 N acid, and an even greater error in the case of experiments in more dilute acid, the agreement in the values of $K_{H_3O^+}$ is very good.

In order to measure the acetate ion catalysis it is necessary to work in a sodium acetate–acetic acid buffer solution. Here the medium effect of k_0 of the non-electrolyte acetic acid and the salt effect of the sodium acetate must be known. Since 0.2 M sodium trichloro-acetate has the same effect as 0.2 M sodium chloride, we may assume the salt effect of sodium acetate to be the same as that of sodium chloride. Table IV and Fig. 4 show the medium effect of acetic acid upon the velocity constant.

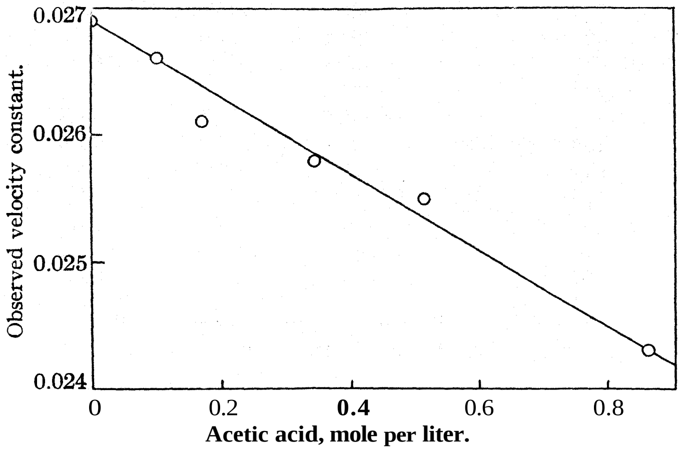

Fig. 4.—Effect of acetic acid.

TABLE IV

EFFECT OF ACETIC ACID

Init. concn. HAc, m./l.	0.000	0.100	0.170	0.343	0.514	0.860
k	.0269	.0266	.0261	.0258	.0255	.0243

These results may also be expressed by the equation $k_0 = 0.0269 - 0.0030\,m$, where m is the molarity of the acetic acid.

In Table V the results with sodium acetate–acetic acid buffers are given and K_{Ac} is calculated.

Here k'_0 (Col. 5) is k_0 corrected for the medium effect of the acetic acid and for the salt effect of the sodium acetate, upon the assumption that the two effects are additive. The corrected k_0 or k'_0 is then subtracted from the observed velocity constant, and the difference, divided by the acetate concentration, gives the constant of acetate ion catalysis. The concentration of acetate may be taken as equal to that of the sodium ion, since the hydrogen-ion concentration is less than 0.0002 M in all cases. An inspection of the acid–salt ratios in Table V shows that K_{Ac^-} is independent of the hydrogen-ion concentration. K_{Ac^-} is some 20% greater than $K_{H_3O^+}$.

Early experiments showed the formate ion to be a remarkably good catalyst, so good, in fact, that it was necessary to work at much lower concentrations of formate than of acetate and hydrogen ion. In studying the effect of formate ion the formic acid concentration must be sufficiently high so that the formateformic acid buffer equilibrium is not appreciably displaced by the acetic acid which is formed during the course of the reaction. The results of the experiments in formate–formic acid buffer solution are summarized in Table VI.

TABLE VI

EFFECT OF FORMATE

Composition of buffer

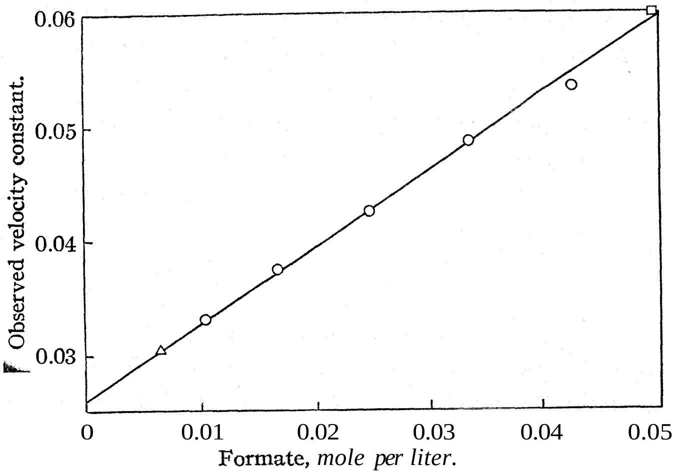
The formate-ion concentration (Col. 4) was calculated from the dissociation constant of formic acid, K_c, account being taken of the change in K_c with change in electrolyte concentration. For this purpose an equation given by Brönsted[16]

$$K_c = K_0\frac{f_0}{f_1^2} = 1.8\,(1 + 2.36\,\sqrt{m})\,10^{-4}$$

was used; in this equation m represents the molarity of a monomonovalent solvent salt. k', given in Col. 6, is k_0 corrected for the medium effect of formic acid (assumed to be equal to that of acetic acid, see Table IV) and for salt effect, and to this is added $K_{H_3O^+}[H_3O^+]$, or the amount of reaction due to the hydrogen-ion catalysis. The maximum total correction is 4%. In the last three experiments the concentration of formic acid was low and the observed velocity constant was obtained from the first part of the reaction.

In Fig. 5, $k_{obs.}$ is plotted against the formate-ion concentration.



Formic acid: ○, 0.495 mole/liter; △, 0.198 mole/liter; □, 0.024 mole/liter.

Fig. 5.—*Effect of* formate.

From the figure it is evident that the increase in rate of hydration or $k_{obs.} - k'$ is proportional to the formate-ion concentration. In other words, the acetic anhydride is disappearing by two paths as in the cases of hydrogen-ion and acetate-ion catalysis. The intercept on the axis of velocity constants is 0.0260, which represents the constant in a 0.495 *M* formic acid solution, the hydrogen-ion catalysis being included and the formate-ion catalysis excluded. The value chosen for k' on the assumption that the medium effect was the same as that of acetic acid was 0.0257.

It is to be noted that Szabó[7] does not report any-catalytic effect of formate ion. She did no experiments, however, in sodium formate–formic acid buffer solution where the effect is very apparent.

[16] Brönsted *and* Volquartz, *Z. physik. Chem.*, 134, 109 (1928).

At 14° her velocity constants are: in water alone, **133.5** $\times 10^5$ (time in seconds); in 2.07 M acetic acid, 85.9 X 10^5; in 2.07 M formic acid, 126.8 $\times$ 109 The medium effect of two molar acetic acid on k_0 is therefore 35% at 14°. Assuming the medium effect of acetic or formic acid on k_0 at 0° to be linear up to 2 *M* acid, the decrease amounts to 22%. In **2.1** M formic acid the formate-ion concentration is approximately 0.023 M. Since k_{formate} is 0.7, the formate-ion catalysis is 0.016, corresponding to a 60% increase in the velocity constant. Therefore, at 0° the rate of hydration in **2** M formic acid would be greater than that in water alone. Szabó found the opposite to be the case at 14°. Two explanations may be suggested: first, that the medium effect of formic acid on k_0 is greater at 14° than at 0° (which Szabó's figures indicate); and, second, that the temperature coefficient of the hydration in water alone is greater than the temperature coefficient of the formate-ion catalysis, that is

$$\frac{k_0^{14°}}{k_0^{0°}} > \frac{k_{F^-}^{14°}}{k_F^{0°}}$$

Szabó's few experiments in acetate buffer solution were made at such high salt concentrations that only an approximate value can be calculated for k_{Ac^-} at 18°. Expressing Szabo's constants in minutes^{-1}, and using her salt effects, one gets $k_{Ac} = 0.10$ at 18° and $k_0 = 0.096$ at 18°, whence

$$\frac{k_0^{18°}}{k_0^{0°}} = \frac{0.096}{0.027} = 3.6 \text{ and } \frac{k_{Ac}^{18°}}{k_{Ac}^{0°}} = \frac{0.10}{0.039} = 2.6$$

When one considers the magnitude of k_{F^-} it is evident that there is no simple relationship between basic strength and catalytic efficiency as there is in the cases of the mutarotation of glucose and the decomposition of nitramide which will include both the formate and acetate ions. Since formate is a weaker base than acetate, k_{F^-} should be less than k_{Ac^-}; the value found is over fifteen times greater.

Experiments were also carried out in sodium propionate–propionic acid and sodium butyrate–butyric acid buffer solutions. In these solutions the reaction rate is slower than in water alone, as is shown by the results summarized in Tables VII and VIII.

TABLE VII

EXPERIMENTS IN PROPIONATE–PROPIONIC ACID BUFFER

Composition of Buffer			Composition of Buffer		
Acid moles/liter	Sodium salt, moles/liter	$k_{\text{approx.}}$	Acid, moles/liter	Sodium salt, moles/liter	$k_{\text{approx.}}$

.500	.100	.0214	.150	.120	.0223

[a] In 0.2 *M* NaCl.

TABLE VIII

EXPERIMENTS IN BUTYRIC ACID–BUTYRATE BUFFER

Acid, mole/l.	0.50	0.50	0.50	0.50	0.50
Na salt, mole/l.	0	.050	.100	.150	.200
$k_{\text{approx.}}$	.0244	.0226	.0186	.0158	.0156

The reaction no longer exactly follows the monomolecular law and the constants have therefore been recorded as "approximate" in the tables. In addition, the contraction is much smaller.

From these results one may conclude that the acetic anhydride is no longer present wholly as such in the solution, but has combined with the propionate or butyrate to form an intermediate compound. The intermediate compound may be the mixed anhydride, for the rates of hydration are approximately the same as those calculated for the mixed anhydrides from the following considerations. Verkade has found 0.434 k for acetic anhydride at 25° to be 0.0713, the propionic anhydride 0.0372 and for the mixed anhydride 0.0524. The arithmetical mean of the constants for the simple anhydrides is 0.0542, which is approximately the constant determined for the mixed. Verkade's 0.434 k for propionic anhydride at 0° is 0.00700, and taking my value for acetic anhydride at 0° as 0.0117, the mean is 0.00935, or in terms of natural logarithms, 0.0215. In the absence of any actual determinations, 0.0215 may be taken as the approximate value of the constant for the mixed anhydride at 0°. In the fifth experiment of Table VII, that experiment in which there was a slight excess of propionate ion over acetic anhydride, the initial concentrations being 0.10 and 0.07 M, respectively, the constant found is 0.0214. According to a similar calculation for butyric acetic anhydride, k at 0° is 0.0189, while the value found in the third experiment of Table VIII is 0.0186. It must be mentioned, however, that before the kinetics of the hydration in solutions containing propionate or butyrate can be worked out, it will be necessary to know k_0, $k_{\text{H}_3\text{O}^+}$ k_{Ac^-} and possibly $k_{\text{propionate}}$ and k_{butyrate} for propionic and butyric anhydrides as well as for the mixed anhydrides, propionic–acetic and butyric–acetic.

There is considerable evidence[17] in the literature of organic chemistry for the formation of compounds between acetic anhydride and the carboxylic acids and their anions. Such compounds, however, have been formed under conditions quite different from those of the present experiments. The results of the experiments in formate–formic acid buffer solution do not preclude the formation of an unstable intermediate compound between the acetic anhydride and the formate ion.

The author wishes to thank the Rask-Ørsted Foundation, Copenhagen, for the grant which has made this work possible.

---

[17] For discussion and further references see Autenrieth and Thomae, Ber., 57B, 423 (1924); Van der Haar, *Rec. trav. chim.*, 47, 321 (1927); Verkade, *ibid.*, 37, 331 (1918).

Summary

1. The velocity of hydration of acetic anhydride has been measured by a dilatometric method at 0°.

2. The salt effect on k_0 has been determined for a number of neutral salts in dilute solution. The medium effect of acetic acid has been measured.

3. The constants of hydrogen, acetate and formate-ion catalysis have been determined. The formate ion is a remarkably good catalyst.

4. In propionate–propionic acid and in butyrate–butyric acid buffer solutions the hydration is slower than in water alone. It is hoped to make a further study of this effect.

THE INTERACTION BETWEEN NITROGEN TRICHLORIDE AND NITRIC OXIDE. REACTIONS OF COMPOUNDS WITH ODD ELECTRONS[1]

BY WILLIAM ALBERT NOYES

RECEIVED JULY 25, 1928 PUBLISHED NOVEMBER 6, 1928

In papers recently published,[2] the point of view has been presented that valence is a ***unitary*** atomic phenomenon. This is closely in accord with the original ideas of Frankland, Couper and Kekulé.

The endeavor has been made to show that for any given molecule, at any particular instant, the distinction between polar (or ionic) valences and covalences is sharp and definite. In the interest of clarity it has been proposed[3] to confine the term "polar valence" to the designation of valences which are actually ionic because of the complete transfer of an electron. The "semipolar" valences of oxygen in the sulfate radical, the amine oxides, etc., are, of course, half polar and half covalence.[4]

It has also been proposed to call those valences which have an electrical moment and which permit atoms held by a covalence to separate readily in the ionic form, "potentially polar," because the distinction between a covalence and an ionic valence is, theoretically, sharp and definite, while there may be all degrees of "potentially" polar valences.

This discussion seems to be a simple and logical development of the

positive and negative valences proposed, in part erroneously and vaguely in 1901[5] and 1904[6] and advocated by Professor Stieglitz,[7] Falk and Nelson,[8] Fry,[9] L. W. Jones[10] and others. It also furnishes an almost complete and satisfactory reconciliation with the octet theory of G. N. Lewis[11] and its exposition by Langmuir.[12]

If the hypothesis that a covalence is due to a pair of electrons which include the kernels of the two atoms which they unite in their orbits and that a polar valence is due to a pair rotating about the kernel of some negative atom or a deficiency of one electron in some positive atom[13] should receive further support and come to be generally accepted, the distinction between covalences and polar valences will become still more sharp than it is at present; but the distinction made in this and other papers is not dependent on that hypothesis.

Nearly all reactions of elements of low atomic weights occurring at ordinary temperatures seem to be, in reality ionic in character but we are compelled to assume odd electrons and reactions of a different type for a few compounds. For this reason, the interaction of nitric oxide, which has an odd electron, $\cdot\overset{\cdot\cdot}{N}::\underset{\cdot\cdot}{\overset{\cdot\cdot}{O}}$,[14] and nitrogen tri-chloride,  $\begin{array}{c}:\overset{\cdot\cdot}{Cl}:\\ :\underset{\cdot\cdot}{N}:\underset{\cdot\cdot}{\overset{\cdot\cdot}{Cl}}:\\ :\underset{\cdot\cdot}{Cl}:\end{array}$, an endothermic compound[15] with potentially positive[16] chlorine atoms, has proved to be of exceptional interest. Nearly all of the experiments with these compounds were carried out with a solution of the trichloride in a mixture of chloroform with enough carbon tetrachloride to prevent the mixture

from freezing at −80°. A few were tried at 0°, one at −20° and two in petroleum ether at −130 to −140°.

About a hundred experiments have been performed in the endeavor to develop a satisfactory technique for separating the products formed and analyzing them to establish the course of the reaction at the different temperatures and in the different media. One hundred samples of mixed gases have been analyzed by the methods described in a previous paper,[17] $N/10$ potassium hydroxide instead of water being used to absorb the gases, which were sometimes nearly pure chlorine.

Experimental Part

Nitrogen **Trichloride.**—The chlorine generated by dropping 300 cc. of concd. hydrochloric acid on 60 g. of potassium permanganate was passed into 225 g. of a mixture of chloroform and carbon tetrachloride containing 10 to 20% of the latter. The mixture was in a one-liter, round-bottomed flask and had above it 600 cc. of a 10% solution of ammonium sulfate. The flask was closed with a cork stopper carrying the wide delivery tube for the chlorine and a second glass tube connected with rubber tubing to the bottom of a 2.5-liter bottle to collect a slight amount of chlorine which might escape absorption. The chloroform and ammonium sulfate solution were shaken vigorously during the half hour required to generate the gas. The solution warms somewhat but if it is cool at the beginning this does no harm. The ammonium sulfate solution was poured off and the chloroform solution transferred to a 500cc. bottle and shaken for five minutes with a 5% solution of ammonium sulfate. After separating, this was repeated. The solution was then separated sharply, dried with a few grams of powdered calcium chloride and filtered on a dry filter.

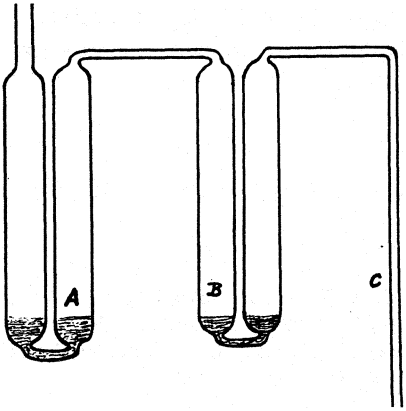

Fig. 1.

The solution prepared in this manner contains about 12% of the nitrogen trichloride, or one millimole per gram. If any unused portion is kept in the dark and in contact with a 5% solution of ammonium sulfate, there is little loss in strength for some days. It should be shaken vigorously with the sulfate solution before use.

Solutions as concentrated as 18% have been prepared and Hentschel's[18] statements seem to indicate that there is no danger of explosion in working with such concentrations.

Analysis.—Three to five-tenths of a gram of the solution was weighed in a U-tube having a capacity of less than 1 cc. and drawn out at right angles, on one side, to a small, thin capillary. The contents of the tube was transferred to A of the double U-tube shown in Fig. 1. A contained 2 cc. of concentrated hydrochloric acid and B, 0.5 cc. of water. The tube C dipped beneath the surface of 15 to 20 cc. of a 10% solution of potassium iodide. A slow current of air was passed through the apparatus until the chloroform was all evaporated and the liberated chlorine was swept out into the iodide solution.

---

[17] Noyes, This Journal, 47, 2162 (1925).

[18] Hentschel, *Ber.*, 30, 1434 (1897).

The iodine was titrated with $N/10$ sodium thiosulfate, the hydrochloric acid solution was neutralized with 10 cc. of 30% potassium hydroxide and the ammonia distilled over into $N/10$ hydrochloric acid. The equation for the reaction is

$$NCl_3 + 4HCl = NH_4Cl + 3Cl_2$$

If the nitrogen trichloride is pure and free from chlorine, the volume of thiosulfate used will be 6 times the volume of the $N/10$ hydrochloric acid. Any excess of thiosulfate furnishes a determination of the free chlorine present.

Nitric oxide was prepared by dropping sulfuric acid (1:1) into a 25% solution of sodium nitrite[19] and the gas was kept in an aspirator bottle having a capacity of 3.5 liters.

Technique of the Experiments.—A weighed quantity of the nitrogen trichloride solution, containing in different experiments from 28 to 82 millimoles, was introduced through D (Fig. 2) into the bulb F. B was connected with an aspirator bottle containing nitrogen purified by passing it through an acid solution of chromous chloride to remove a trace of oxygen, through a tower containing soda lime and through an effective wash bottle containing concd. sulfuric acid.

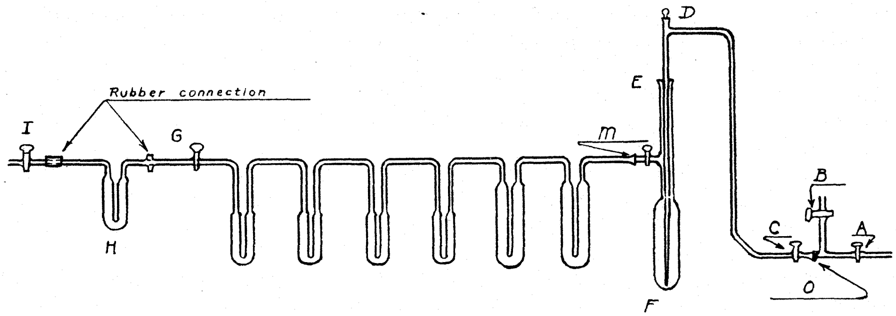

Fig. 2.—Ground glass joints at O, E and M.

After immersing F in a Dewar cylinder containing carbon dioxide-snow and acetone, the apparatus was evacuated with a good mechanical pump connected with I. By closing C and opening B, the T-tube was filled with nitrogen and after closing B and opening C this was pumped out. A few repetitions removed the small amount of oxygen remaining in the apparatus. The stopcocks m, G and I were then closed and nitric oxide was admitted through A. In many of the experiments nearly 3 liters of nitric oxide was admitted and the products absorbed without opening the stopcock m. The bottle containing the nitric oxide had been calibrated and the amount used was determined with an accuracy of 1 to 2%.

After introducing the gas, the apparatus was allowed to stand for an hour or more to permit the last of the nitric oxide to react with the nitrogen trichloride or chlorine present in the bulb. After this a variety of methods was used for separating and analyzing the products. The best of these is now thought to be the following.

The U-tube nearest to the bulb and U-tube H were immersed in liquid air, the U-tubes having all been evacuated. With the stopcocks I and G closed and m open, the nitrous oxide formed and some of the nitrosyl chloride and chlorine began to distil into the first U-tube. With the mechanical pump connected beyond I continually working, the stopcock G was opened and after closing it I was opened momentarily to allow nitrogen which had passed into U-tube H to escape. By this method a good

---

[19] Noyes, This Journal, 47, 2170 (1925).

vacuum was maintained with only a very slight loss of nitrous oxide. The solution in F was allowed to warm up to $-20°$ and a very slow current of nitrogen admitted through B. After the nitrous oxide and some of the chlorine and nitrosyl chloride had condensed in the first U-tube, the liquid air was transferred to the second and a carbon dioxideacetone cylinder placed around the first. When a considerable part of the chlorine and nitrosyl chloride had been distilled, the stopcock m was closed and the bulb F was cooled again to $-80°$.

In many of the earlier experiments the condensed gases were distilled and analyzed without contact with air in the endeavor to get evidence for the possible presence of nitrogen dichloride or monochloride. After many analyses had demonstrated that these compounds are absent or present in very small amounts, the manipulation was changed at this point and in subsequent experiments air was admitted to the U-tubes through I and G, the liquid air was transferred from the second to the third U-tube and the carbon dioxide–acetone to the second and a freezing mixture of ice and hydrochloric acid, giving a temperature of $-20°$, was placed around the first. By judicious use of these temperatures, it was possible to fraction the mixture through the tubes and finally secure all the nitrous oxide in U-tube H with comparatively little chlorine or nitrosyl chloride. The U-tube was disconnected, weighed quickly to about 0.01 g. (corresponding to about $^1/_4$ millimole of nitrous oxide) and the condensed gases were allowed to evaporate through an efficient wash bottle containing potassium hydroxide. The chlorine and nitrogen (from the nitrosyl chloride) were determined and by subtracting these from the weight of the contents of the U-tube the weight of the nitrous oxide was known.

The chlorine and nitrosyl chloride remaining in the U-tubes were sometimes allowed to evaporate and condense in U-tube H, weighed and then permitted to evaporate through a solution of potassium hydroxide and in other cases allowed to evaporate directly through the solution.

After this, liquid air was placed about the last of the U-tubes and the air in the tubes was removed by the pump. By opening m the remaining chlorine, nitrosyl chloride and chloroform were distilled back into bulb F. The contents of F was then hydrolyzed with ice water, the aqueous solution was analyzed for nitrogen and chlorine and the chloroform–carbon tetrachloride solution for chlorine and unchanged nitrogen trichloride. The results were calculated in milligram moles of the nitrogen trichloride which reacted or decomposed, of the nitric oxide used and in millimoles of the nitrous oxide and nitrosyl chloride and miligram atoms of the chlorine formed. In the table the results have been recalculated in ratios to one mole of nitrogen trichloride reacting or decomposed. From nearly 100 experiments, **23** performed after the technique and the methods of analysis had been pretty well developed are recorded.

The nitrous oxide, which had previously been found in a former investigation, from the action of phosphorus pentoxide on nitric oxide,[19] was identified by its effect on a glowing splinter, by condensation with liquid air and evaporation at $-80°$ and by its molecular weight, 44.4.

The experiments with petroleum ether suggest that either an intermediate compound, $NCl_3{\cdot}NO$, is formed, which decomposes directly to nitrous oxide and chlorine, or that hydrochloric acid formed by the action of nitrogen trichloride on petroleum ether[20] catalyzes the reaction

$$NCl_3 + NOCl = N_2O + 2Cl_2$$

That the second explanation is true was demonstrated by passing nitric

oxide into a chloroform–carbon tetrachloride solution of the trichloride until the trichloride present was exhausted and removing the nitrous oxide formed. More of the trichloride solution was then added and the mixture was allowed to stand for twenty hours at −80°; 5.5 milligram moles of nitrous oxide was formed. Three-tenths g. of hydrochloric acid was now added. After eighteen hours at −80°, 10.5 milligram moles of nitrous oxide was found and the trichloride was all exhausted, demonstrating that the acid catalyzes the reaction, as had been suspected.

Discussion

A rational explanation of the results is based on the following considerations.

1. Nitrogen trichloride is an endothermic compound which decomposes readily to nitrogen and chlorine. This means that the affinities of nitrogen for nitrogen and of chlorine for chlorine are much greater than the affinity of nitrogen for chlorine. Thermodynamically, it may be stated that the energy liberated when two isolated nitrogen atoms unite to form molecular nitrogen and six isolated atoms of chlorine unite to

form three molecules of chlorine is very much greater than the energy liberated when two isolated atoms of nitrogen combine with six isolated atoms of chlorine to form two molecules of nitrogen trichloride. It may be worth while to notice that our ignorance of the reason for these relations and, indeed, of the source of the energy liberated when atoms unite is still very profound.

2. Nitrogen readily forms compounds containing odd electrons, which are stable at ordinary and even at high temperatures but which react readily at low temperatures. Nitric oxide, $\cdot\ddot{N}::\underset{\cdot\cdot}{\ddot{O}}$, is an endothermic compound and even at 3000' the equilibrium is far on the side toward its decomposition; but nitric oxide will combine with oxygen to form nitrous anhydride even at the temperature of liquid air. The decomposition of nitrogen tetroxide, N_2O_4, to nitrogen dioxide, NO_2 (probably  $\begin{array}{l}\cdot N\underset{\cdot\cdot\,+}{:}:\ddot{O} \\ \;:\underset{\cdot\cdot}{O}\underline{:}\end{array}$), begins at ordinary temperatures.

3. At **0°,** 90% of the nitrogen trichloride decomposes to nitrogen and chlorine. The reaction is evidently catalyzed by the nitric oxide or the nitrosyl chloride.

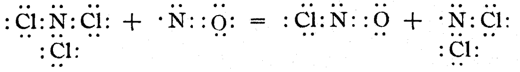
4. At −20° the reaction $NOCl + NCl_3 = N_2O + 2Cl_2$, which occurs slowly at −80° (see above), increases the amount of nitrous oxide and decreases the nitrosyl chloride present at the end.

5. At −80°, in chloroform–carbon tetrachloride, the results indicate that the normal course of the reaction corresponds to the equation $NCl_3 + 2NO = N_2O + NOCl + Cl_2$. This equation represents a trimolecular reaction and it seems much more probable that the action takes place in two stages. An intermediate stage in which nitrosyl chloride reacts with nitrogen trichloride is excluded by the slowness of that reaction at −80°, by the fact that two moles of nitric oxide are required before the trichloride is exhausted and because more than one mole of nitrosyl chloride is formed for each mole of nitrous oxide in every case except one. The excess must be due to the union of nitric oxide with chlorine.

The most probable steps seem to be the following: $NCl_3 + NO = NOCl + NCl_2$; $NCl_2 + NO = N_2O + Cl_2$.

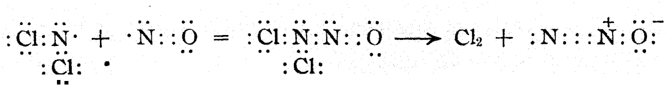
As already stated, many attempts have been made to isolate the nitrogen dichloride. The speed of the reaction between the dichloride and nitric oxide is evidently very great, as might be expected for two compounds with odd electrons.

In the primary reaction an atom of chlorine with an odd electron must separate from the nitrogen trichloride



$$:\underset{\cdot\cdot}{\ddot{Cl}}:\underset{:\underset{\cdot\cdot}{Cl}:}{\underset{\cdot\cdot}{\ddot{N}}}:\underset{\cdot\cdot}{\ddot{Cl}}: + \cdot\ddot{N}::\underset{\cdot\cdot}{\ddot{O}}: = :\underset{\cdot\cdot}{\ddot{Cl}}:\ddot{N}::\underset{\cdot\cdot}{\ddot{O}} + \cdot\underset{:\underset{\cdot\cdot}{Cl}:}{\underset{\cdot\cdot}{\ddot{N}}}:\underset{\cdot\cdot}{\ddot{Cl}}:$$

The second reaction may be represented electronically



$$:\underset{..}{\overset{..}{\mathrm{Cl}}}:\underset{:\underset{..}{\mathrm{Cl}}:}{\overset{..}{\mathrm{N}}}\cdot + \cdot\overset{..}{\mathrm{N}}::\underset{..}{\overset{..}{\mathrm{O}}} = :\underset{..}{\overset{..}{\mathrm{Cl}}}:\underset{:\mathrm{Cl}:}{\overset{..}{\mathrm{N}}}:\overset{..}{\mathrm{N}}::\underset{..}{\overset{..}{\mathrm{O}}} \longrightarrow \mathrm{Cl_2} + :\mathrm{N}:::\overset{+}{\mathrm{N}}:\underset{..}{\overset{..}{\mathrm{O}}}:^{-}$$

The formula for nitrous oxide is supported by the following facts and considerations.

The parachors of nitric acid and nitro compounds indicate a semipolar union in these compounds;[21] the parachor of alkyl cyanides and also the hydrolysis of these cyanides to organic acids and ammonia indicate a triple covalence between carbon and nitrogen and that such a triple covalence is a stable form of combination for nitrogen; the extreme unreactivity of molecular nitrogen points to a very stable tripe covalence, $:\mathrm{N}:::\mathrm{N}:$. The ease with which nitrous oxide gives its oxygen to a glowing splinter indicates that the oxygen is in a reactive form and also that the molecule already approaches the structure of the nitrogen molecule; the decomposition of an alicyclic diazo compound to form nitrogen **and** an azo compound[22] and the ready decomposition of all diazo compounds, $\mathrm{R_2}\underset{-}{\mathrm{C}}:\underset{+}{\mathrm{N}}:::\mathrm{N}:$ or $\mathrm{R}:\underset{+}{\mathrm{N}}:::\mathrm{N}:$, show that compounds whose structure approaches that of molecular nitrogen readily go over to that.

Summary

1. At 0° the interaction of nitric oxide and nitrogen trichloride results, chiefly, in the catalytic decomposition of the trichloride to nitrogen and chlorine.

2. At −20°, about one-fourth of the nitrogen trichloride is converted to nitrous oxide and chlorine. The comparatively small amount of nitrosyl chloride found at this temperature is probably due to the interaction of nitrogen trichloride with the nitrosyl chloride formed in the primary reaction, giving nitrous oxide and chlorine.

3. At −80° the reaction proceeds chiefly in accordance with the equation $\mathrm{NCl_3} + 2\mathrm{NO} = \mathrm{N_2O} + \mathrm{NOCl} + \mathrm{Cl_2}$.

4. Reasons are given for believing that this reaction occurs in two steps with the intermediate formation of nitrogen dichloride, although attempts to isolate this compound have not been successful.

5. The structure of nitrous oxide is probably $:\underset{..}{\overset{-\,..}{\mathrm{O}}}:\overset{+}{\mathrm{N}}::\mathrm{N}:$, with a semipolar union between the oxygen and nitrogen atoms. Facts and considerations are given in support of this formula.

6. In petroleum ether at −130 to −140° the reaction follows the course $\mathrm{NCl_3} + \mathrm{NO} = \mathrm{N_2O} + 3/2\mathrm{Cl_2}$.

The hydrochloric acid formed by the action of the trichloride on the

RADIUM AND GEOLOGY[1]

BY CHARLES SNOWDEN PIGGOT

RECEIVED JULY 26, 1928 PUBLISHED NOVEMBER 6, 1928

This article is a brief account of the general problem of the relation of radioactivity to geologic phenomena and of some of the experimental results so far obtained by the author in this field of investigation.

As soon as the experiments of Strutt (Lord Rayleigh) and Joly had revealed the apparently universal distribution of radium and its associated disintegration products throughout the lithosphere and perhaps throughout the entire earth, and when the work of Rutherford, Curie and others had demonstrated the extraordinary properties of these substances, it immediately became a subject of speculation as to the significance of so universal and so powerful an agent on the great earth phenomena which were known to have taken place.

The general problem has three main subdivisions:

1. The determination of the radium content of, and its distribution throughout, the lithosphere, and possibly an estimation of the amount and distribution throughout the earth.
2. The heat energy made available for the melting of the sub-crustal structure and its role in mountain building.
3. The radioactive disintegration of uranium into lead and its application to the determination of geologic time.

Since the problem was taken up by this Laboratory, there has not been time for the accumulation of any great quantity of data, but a satisfactory apparatus and technique have been developed and a number of measurements made in each of the above subdivisions.

Determination of Radium in **Rocks.**—For measuring the radium in ordinary rocks, where the quantity is of the order of 10^{-12} grams per gram of rock, the determination was made by decomposing the rock by fusing with a flux, collecting the radium emanation thereby liberated, and determining it by means of an electroscope.[2]

Calibration was accomplished by making a number of runs on a rock alone, and then another series, identical in every respect except that a

---

[1] In memory of Ira Remsen.

[2] A detailed description of the apparatus and technique, including drawings, dimensions, etc., will appear shortly in the *American Journal of Science.*

known amount of radium, in equilibrium with its disintegration products, was added. This added radium was secured by pipetting a standard radium solution[3] containing 32.2×10^{-12} grams of radium element per cubic centimeter into small thin-walled glass bulbs, evaporating slowly to dryness, and then sealing the bulbs. These were kept for more than thirty days to permit the radium to come into equilibrium with its emanation. Bulbs containing 1 and **3** cc. of solution, respectively, were used. A bulb would be embedded in the mix and the fusion carried out in the usual way.

The flux alone showed some radioactivity; 100 g. gave an electroscope reading of 0.0014 division per second[4] and a 200-g. sample of the same material gave a reading of 0.0020 division per second.

A sample of granite from Stone Mountain, Georgia, was used to calibrate the apparatus and procedure. Sixteen measurements on this rock gave an average of 0.01089 division per second; this less 0.0014 for the effect of 100 g. of flux, gave 0.0095 division per second for the rock alone.

On adding bulbs containing **1** cc. and **3** cc. of standard radium the results were, in divisions per second

	1 *cc*,	3 *cc*.
		0.0179
		.0179
	0.0137	.0197
	.0137	.0197
	.0131	.0179
Average	0.01350	0.01856
Less effect of flux and rock	.01089	.01089
		3) .00767
1 cc. of standard Ra solution	0.00261	0.00256

The average of the two series is therefore 0.00259.

Since 1 cc. of radium solution is equivalent to 32.2×10^{-12} grams of radium element, 0.00259 div./sec. is equivalent to 32.2×10^{-12}, or

$$1 \text{ div./sec.} = \frac{32.2 \times 10^{-12}}{0.00259} = 12702 \times 10^{-12} \text{ g. of Ra}$$

So that

$$\frac{(E - F) \cdot 12702}{W} = \text{grams} \times 10^{-12} \text{ of Ra per gram of rock}$$

where E = electroscope reading (corrected for natural leak), F = effect of flux alone and W = weight in grams of rock sample used.

---

[3] Tested and certified by the U. S. Bureau of Standards.

[4] The gold leaf of the electroscope is observed to pass across the field of a low-powered microscope in the image plane of which is a scale of 100 divisions. The rate across the same ten divisions is determined with a stopwatch.

Experimental

Using the above calibration and formula, the radium content of seven representative granites of the eastern seaboard of the United States, from Georgia to Maine, has been determined.

TABLE I

DETERMINATION OR THE RADIUM CONTENT OF SEVEN REPRESENTATIVE GRANITES OF THE EASTERN SEABOARD OR THE UNITED STATES

Locality	Description	G. of Ra per g. of rock
Stone Mountain, Georgia	Fine-grained, gray, biotite-muscovite granite	4.826×10^{-12}
Mt. Airy, North Carolina	Light-gray, coarse-grained biotite granite	0.655×10^{-12}
Woodstock, Maryland	Gray biotite granite with considerable allanite and epidote	1.448×10^{-12}
Ilchester, Maryland	Gray biotite diorite with accessory epidote	1.935×10^{-12}
Milford, Massachusetts	Very light pink, mottled, biotite granite	0.378×10^{-12}
Rockport, Cape Ann, Massachusetts	Hornblende-biotite granite	0.955×10^{-12}
Hurricane Island, Maine	Pinkish-buff, gray, coarse-grained biotite granite	3.65×10^{-12}

Complete chemical analyses and petrographic examinations were made on each rock studied.

The granite from Stone Mountain, Georgia, was separated into its constituent minerals by Kline's solution (aqueous solution of cadmium borotungstate) and each of these minerals examined separately for radium, with the following results in grams of radium per gram: quartz, 0.019×10^{-12}; potash feldspar, 1.129×10^{-12}; plagioclase, 1.657×10^{-12}; muscovite, 3.832×10^{-12}; biotite, 8.637×10^{-12}; from which it is apparent that in this rock, and presumably in others, the radium is associated more with those minerals having a high specific gravity rather than with those that have a low specific gravity, and that it is particularly associated with the micas.

Radioactive Heat.—Although the concentration of radium in the rocks of the lithosphere is very small, it seems to be universally distributed, and when one considers the masses involved there is a considerable amount of radium to be reckoned with. Since radium, in equilibrium with its disintegration products, produces 100 cal. per curie per hour, and since the heat conductivity of rocks is low and geologic time is long, there is good reason to believe that the accumulation of heat is sufficient to have a very real effect upon the earth's thermal gradient, and it is possible, as Joly believes, that there is quite enough heat from this source to furnish the heat of fusion of the subcrustal basaltic layer.[5]

---

[5] See J. M. Joly, "The Movements of the Earth's Crust," *Phil. Mag.*, [6] 45, 1167 (1923).

Also Holmes[6] has shown that potassium must be considered; that although its radioactivity is slight, its relative amount makes it of considerable importance.

Geologic Time.[7]—Of the various methods which have been used or suggested for obtaining a more or less accurate estimate in terms of years of geologic time, that one which uses the uranium–lead ratio is by far the most promising and the most definite.[8]

Theoretically a chemical analysis of a mineral containing uranium or thorium or both, together with their corresponding lead, should give all the data necessary for a calculation of the age of the mineral and presumably of the rock with which it was associated. However, the estimates made in this way vary greatly, due to a number of factors. The necessary separations are difficult and tedious, and the amounts of the significant elements are so small that legitimate analytical errors produce disproportionately great effects upon the ultimate results. The extrapolation in terms of years over vast geologic ages is so great that these analytical errors may cause, a difference of hundreds of thousands of years in the indicated age.

But the chemical analysis alone cannot show whether or not the lead obtained is all of radioactive origin, or whether it came partly from uranium, partly from thorium or partly from some other source. The possibility of enrichment by lead from some non-radioactive source must be considered, and also the partial removal of the lead already radioactively produced. However, these are problems for the geologist at the time of selecting the sample and are not part of the mechanism of age determination being considered here.

What is emphasized here is that the uranium–lead ratio method, as now applied, has two inherent uncertainties associated with it. They are

(1) The uncertainty associated with the disintegration of the thorium series—the time required and the amount and origin of the lead produced. The thorium series of radioactive disintegrations has not yielded to experimental examination as readily as the uranium series has. Consequently there is considerable uncertainty associated with the time required for a given amount of thorium to form its corresponding amount of lead. Also, the quantity of lead produced by a given quantity of thorium is not known with satisfactory accuracy. Therefore the presence of thorium in a mineral to be used for an age determination injects an element of uncertainty into the result, and as some thorium is always present this

[6] Arthur Holmes, *Phil. Mag.*, [7] *2,* 1218 (1926).

[7] For a general discussion of the problem and methods used, see Arthur Holmes, *Phil. Mag.*, [7] *1,* 1055 (1926).

[8] See "Factors Involved in the Calculation of the Ages of Radioactive Minerals," Arthur Holmes, *Am. J. Sci.*, [5] 13, 327 (1927).

cannot be avoided. The formula now used contains a corrective factor to take care of the thorium content, but it is admittedly unsatisfactory.

(2) The fact that there is no actual measure of that proportion of the total lead which is known to have been produced from the uranium alone.

If this latter could be determined by actual experimental measurement, the thorium uncertainty could be disregarded and the only other uncertainty which would remain inherent and unmeasured in this method would be the existence of possible isotopes of uranium which might have disintegrated more rapidly in the past than the uranium which we know today.

If the lead in any given mineral being studied could be obtained in sufficient quantity and converted into some compound capable of giving lines in the mass-spectrograph, and if the intensity of these lines could be accurately measured, we would then have a direct experimental method for determining the actual amount of uranium lead present. The position of the line would identify it with the uranium lead isotope and its relative intensity would furnish a measure of its relative amount, and since the actual weights of uranium and lead would be known from the chemical analysis, we should then have all the information necessary for a direct comparison of the amounts of uranium and uranium-derived lead. Other isotopes of lead could be disregarded and no reliance need be placed upon assumed proportions figured from atomic weight determinations of lead associated with uranium and thorium, while any enrichment by ordinary lead would probably be revealed by an abnormally intense "207 line."

With these considerations in mind the author secured the cooperation of Dr. F. W. Aston in a proposed plan to convert samples of lead into some volatile compound such as lead tetramethyl and to endeavor to secure with it the identification and determination of any isotopes by means of his mass-spectrograph. In July, 1927, the author took a sample of lead tetramethyl[9] prepared from ordinary laboratory lead to Dr. Aston, who shortly thereafter carried out several experiments with this material. The results were most satisfactory and were first published by Dr. Aston in a brief note to Nature dated July 30, 1927.[10]

The experiments demonstrated very clearly the existence of the three anticipated isotopes, namely, those of masses 206, 207 and 208 in the approximate ratios of 4, 3 and 7, respectively, and also revealed the existence of other isotopes of lead, present in very small proportions, of which 203, 204 and 205 were indicated and 209 was reasonably certain.

The isotopes having been thus definitely separated and identified, the

---

[9] Prepared for him by Mr. S. C. Witherspoon of the U. S. Chemical Warfare Service.

[10] Aston, *Nature*, 120, 224 (1927).

next step was to do the same for "radioactive lead," that is, lead which had been formed mostly or entirely by the radioactive disintegration of uranium and thorium.

For this purpose the author secured some very pure Norwegian bröggerite, a mineral containing considerable proportions of uranium and lead but a very small proportion of thorium. This material was carefully analyzed[11] for uranium, thorium and lead and a sufficient quantity "worked up" to yield about 15 g. of "radioactive lead" chloride.

Five grams of this material has been converted into lead tetramethyl[8] and sent to Dr. Aston, and he proposes to test this in the mass-spectrograph this autumn.

Meanwhile Dr. Aston has been developing an instrument for accurately measuring the relative intensities of the lines on the photographic plates from his mass-spectrograph. This will eliminate the personal equation from this determination and render it capable of exact repetition and comparison.

Since there is very little thorium, relative to uranium, in this broggerite, it is anticipated that these next experiments will show a very heavy line at 206, a very light one at 203, and possibly none at all at 207. It will be interesting to see whether any of the other isotopes show up stronger from this radioactive lead than they did with the ordinary lead.

From the data obtained from these two series of lead isotope measurements and from the determinations of the uranium, thorium and total lead of the broggerite, we hope to be able to determine directly the uranium: uranium lead ratio for this sample of broggerite and thereby secure a reliable estimate of its age, to determine definitely the thorium: thorium lead relationships with time, and possibly to throw some light on the other isotopes of lead and their origin. Experiments are now under way with the object of identifying and determining the isotopes of uranium. If these are successful the amounts involved at both ends of a radioactive series will be experimentally determined.

Summary

1. The significance of radioactivity in geologic problems is outlined.

2. A method for the determination of the radium in ordinary rocks is outlined and the radium content of seven representative granites of the eastern seaboard of the United States is given.

3. The geologic significance of the heat-producing power of radium is mentioned but the discussion of this should await the accumulation of more data.

4. A direct experimental means of determining the uranium and uranium-derived lead involved in an age determination is given.

[11] By Dr. C. N. Fenner of the Geophysical Laboratory.

5. The circumstances of the first determination of the isotopes of lead are given.

III. THE REVERSIBLE ADDITION OF ETHYL ALCOHOL TO PARA-BROMOBENZONITRILE CATALYZED BY SODIUM, POTASSIUM AND LITHIUM ETHYLATES[1]

BY C. N. MYERS AND S. F. ACREE

RECEIVED JULY 26, 1928 PUBLISHED NOVEMBER 6, 1928

Introduction

In earlier papers of this series it was shown that the quantitative data available in sixty-two examples of different types of chemical changes can apparently be coordinated on the theory of the activity of both the ions and the non-ionized forms of electrolytes. This hypothesis was advanced in 1907 by Acree[2] and by Senter,[3] who did not have the good fortune to put it on a firm experimental basis supplied later by the co-workers[8] of Acree, Lapworth, Arrhenius, Goldschmidt, Bredig, Dawson and more recently Bronsted.

In the study of many of these reactions the solutions were fairly concentrated and varied from $N/1$ to $N/32$. Certain physical properties were therefore different from those in very low concentrations and were partly the cause of those deviations from the mass law which are called changes in activity, abnormal salt effects, etc. In the more concentrated solutions the ionic mobilities, viscosities and other physical factors can neither be considered the same as in the dilute solutions nor used without proper modifications in calculating the percentage of ionization of the ethylate or other electrolyte present.

In view of these facts it seemed desirable to investigate the catalytic activities of sodium, potassium and lithium ethylates in very dilute solu-

tions ($N/32$ to $N/2048$) having practically constant viscosities, ionic mobilities, etc., in order to see whether a simple relation exists between the reaction velocities and the conductivities of the ethylates and harmonizes with the idea of the possible activity of both the ethylate ions and the non-ionized ethylate molecules. The reaction chosen was the reversible addition of ethyl alcohol to *p*-bromobenzonitrile to form p-bromobenzimido ethyl ester in which the concentrations of the catalyzing sodium, potassium and lithium ethylates are not appreciably altered with time. Since this work was finished[4] a similar quantitative study by Gruse and Acree[5] has been interpreted on the basis that $N/32$ to $N/512$ solutions of sodium, potassium, and lithium ethylates may cause the inversion of *l*- to *d*-menthone.

Let us now examine the reaction velocities and conductivities of the different ethylates to see whether one possible interpretation of this reaction is that both the ethylate ions and the non-ionized ethylate molecules are catalytically active. Let α represent the ionized fraction, $(1 - \alpha)$ the un-ionized portion of the ethylate present in the concentration of one gram molecule in V liters. Let K'_i and K''_i be the velocity constants for unit concentrations of ethylate ions in the two opposing reactions and K'_m and K''_m be the corresponding constants for un-ionized ethylates. Let A be the original concentration (0.15 N in all cases) of the nitrile and X be that concentration of the imido ester formed in t minutes. Let $K_i = K'_i + K''_i$ and $K_m = K'_m + K''_m$. Let K_V be the velocity constant of the reaction when the ethylate is α ionized in N/V concentrations and call K_N the value of VK_V. Let $K = X/(A - X)$ at equilibrium or at infinite values of t. Then the correct differential equation for expressing the reaction is

$$\frac{dx}{dt} = [K'_i\alpha + K'_m(1 - \alpha)](A - X)(1/V) - [K''_i\alpha + K''_m(1 - \alpha)][X/V] \qquad (1)$$

On integration and collection of terms, this equation becomes

$$\begin{aligned} K_N/V = K_V &= [K_i\,\alpha + K_m(1 - \alpha)]/V \\ &= (1/t)\log\frac{KA}{KA - (K + 1)X} \end{aligned} \qquad (2)$$

in which the constants are really complex, as shown earlier.[6] But the use of Equation (2) should really give constant values[2b,e,5] for K_V and K_N for any given concentration of ethylate when proper data for t, K, A and X are inserted. From *(2)* we readily get

$$K_N = K_i\alpha + K_m(1 - \alpha) \qquad (3)$$

for any ethylate. Our problem is to learn whether the value of K_i is

---

[4] Acree, *Am. Chem. J.*, 49, 127, 369 (1913).

constant for the ethylate ions, coming alike from all ethylates, and whether the values for K_m for the three unlike ethylate molecules are positive and of about the same order of magnitude as K_i, and perhaps differ among themselves because of the influence of the different metals sodium, potassium and lithium within such molecules. But even though we are testing this theory, as have Bronsted and Dawson,[7,3e,i,j,k] again, recently, we have also suggested other mechanisms[2e,5] and have scrutinized[Zb] various intermediate steps, the inter-relations of α, K_i, K_m and K_N,[8] and the possible activities of the cations and anions together.

Experimental Work

The *p*-bromobenzonitrile was prepared by treating cold diazotized pure *p*-bromoaniline slowly with a solution of solid cuprous cyanide dissolved in potassium cyanide. When distilled twice with steam, extracted in ether solution with dilute acid to remove any *p*-bromo-aniline and recrystallized from alcohol, a very white product is obtained with the melting point of 112.5° corrected. The ethyl alcohol was distilled twice from ignited calcium oxide as in earlier work[9,2i] and was 99.98% pure. Special experiments showed that the water need not be thoroughly removed as it does not here exhibit the marked influence shown in acid catalysis.

The concentration of the *p*-bromobenzonitrile was 0.15 *N* in all experiments. Sodium, potassium, lithium and thallium were dissolved in the pure cold alcohol and the ethylate solutions were made in duplicate and standardized as in the earlier work against hydrochloric acid accurately adjusted by gravimetric and volumetric methods. All volumetric glassware was accurately calibrated by the Bureau of Standards and by us. The very dilute ethylate solutions were made from the more concentrated ones by proper dilution with the pure alcohol while excluding the air. All ethylate solutions were rechecked just before use and were added to the nitrile solutions by means of a machine described earlier[10] for mixing solutions in proper amounts in flasks at the constant temperature of the reaction bath, 25°. When the desired reaction period had elapsed, the contents of the flasks were poured and washed into a slight excess of ice-cold standard hydrochloric acid in Erlenmeyer flasks and titrated back with standard alkali in the presence of methyl orange. By subtracting the known equivalent of the ethylate, the remaining acid used corresponded in cc. to the amount of imido ester, X, formed in t minutes or at equilibrium when A = 30.00 cc. expressed as possible complete transformation of the nitrile. The ester formed at equilibrium was about 27% of the maximum possible. The reaction velocity constants, K_V, were calculated by the special monomolecular formula in Equation (2), eliminating the equilibrium constants, and were then multiplied by V, the volume containing one gram mole of ethylate, to get K_N for a normal solution of ethylate having the α-ionization found for the $1/V$ concentration. Four tables, I, II, III and IV, are given here to show some of the representative data taken from the 75 tables marked out with sodium, potassium, lithium, thallium and tetramethylammonium ethylates. K_N and Kv are constant in all the tables. Data on the last two salts will be published when the conductivity and ionization measurements are completed. Tables V, VI, VII and VIII give the calculations of K_i and K_m and their relations to a and K_N for these three ethylates.

Discussion and Interpretation of the Results

Tables V, VI, VII and VIII give a résumé of all the results obtained with sodium, potassium and lithium ethylates in concentrations varying from $N/32$ to $N/2048$. Similar results for much more concentrated solutions showing a salt effect will be given in another paper, together with data on added neutral salts. Each table gives the essential facts regarding V, a, $(1 - a)$, the duplicate and average values for K_N calculated for all the different time periods used with each concentration of ethylate, the "K_N calculated" from $K_N = \alpha K_i + K, (1 - a)$ by substituting therein the values found for K_i and K_m for each ethylate in Table VIII, the experimental "Error in Per Cent," the percentage of the reaction $a K_i$ due to the ethylate ions and the percentage of the reaction $(1 - a) K_m$ due to the non-ionized ethylate molecules. Table VIII gives the individual and average values for the K_i and K, calculated by solving all the pairs of simultaneous equations obtained by substituting the proper data for K_N and a in the equation $K_N = K_i a + K, (1 - a)$. A study of all the tables will bring out a number of points bearing on the theory and discussed briefly in the summary.

Summary

1. The velocity of the reversible addition of ethyl alcohol to *p*-bromobenzonitrile at 25° has been measured in solutions of sodium, potassium and lithium ethylates in concentrations varying from $N/32$ to $N/2048$ to learn whether both the ethylate ion and the cations and the non-ionized ethylate molecules are catalytically active.

2. By substituting all the different values of α and K_N in the equation $K_N = K_i\,\alpha + K_m\,(1 - \alpha)$, we obtain a series of simultaneous equations whose solution gives us the corresponding individual and best average values for K_i and K_m for each ethylate in Table VIII.

3. It is found that the constants expressing the activity of the ethylate ion in unit concentration are the same for all three ethylates within the inherent experimental errors of about 2%. These values for K_i are about 0.161, 0.163 and 0.159 for sodium, potassium and lithium ethylates, respectively. The corresponding values for K_m are 0.163, 0.144 and 0.093.

This value of K_i is the sum of the activities of the ethylate ion in the two opposing reactions and K_m is the corresponding sum of the activities of the non-ionized metallic ethylate; both constants are independent of the equilibrium constant.

4. The substitution of these values of K_i and K_m for each ethylate in the above Equation (3) gives calculated values for K_N, which agree on the average with the experimental data within about 2% for all concentrations from $N/32$ to $N/2048$ (see Tables V, VI and VII).

5. By the use of this theory of catalysis and these values for K_i and K_m for the different ethylates, we can explain in a satisfactory manner the fact that the values of K_N are practically independent of a and dilution of sodium ethylate from $N/32$ to $N/2048$; change only slightly for potassium ethylate; increase 34% for lithium ethylate; and become substantially identical for all three of these alcoholate bases at $N/2048$ when only ethylate ions are present (see Tables V, VI and VII).

6. The above facts and studies with added halogen salts of these metals in dilute and concentrated solutions of ethylates show that in these dilute solutions any possible activity of the metal cations may be disregarded. In the more concentrated solutions a salt effect becomes apparent.

7. The broad equations have been developed for applying this theory of ion mole activity to reversible monomolecular reactions and determining the relation of the equilibrium and total velocity constants to the ionization of the catalyst and its separate ionic and molecular activities for the two opposing reactions. The same idea can be applied to all other reactions in pure or pseudo catalysis.

8. These conclusions agree with the application of this ion mole theory of catalysis to sixty-two quantitative studies of (a) reactions worked out by our associates and (b) our re-interpretations of the work of other investigators.

[COMMUNICATION NO. 366 FROM THE KODAK RESEARCH LABORATORIES]

THE FOGGING BY ACIDS AND OXIDIZING AGENTS AND THE INTENSIFICATION OF THE PHOTOGRAPHIC LATENT IMAGE[1,2]

BY E. P. WIGHTMAN

RECEIVED JULY 27, 1928 PUBLISHED NOVEMBER 6, 1928

It was discovered in 1901 by Luppo-Cramer that various strongly diluted acids produce latent fog on certain types of high speed plates,[3] especially if the solution contains potassium bromide. That sulfurous acid causes the same effect was noticed by him in 1908.[4] In addition to this it was found by him that acidified ammonium persulfate causes latent fog as well as acting as a desensitizing agent.[5] The explanation which Lüppo-Cramer gave for these phenomena was that the acids and oxidizing agents tend to destroy the ripening germs, or the latent image specks, on the grains, producing a more dispersed condition of the silver in them. This tends at first, he says, to make the speck more active in producing developability.[6]

Recently, the writer offered a different explanation for the action of certain oxidizing agents and acids in producing latent fog.[7]

Liippo-Cramer has since questioned this viewpoint[8] and reiterates his own hypothesis. He has also given some evidence which he considers supports his own view and is in opposition to that of the writer. The present paper offers a further discussion of the writer's hypothesis and some additional experimental evidence in its support. It also presents an explanation of the opposing facts cited by Liippo-Cramer.

The hypothesis of the writer was, and still is, that since most plates and films contain an excess of soluble bromide (KBr), the oxidizing agents give with this some free bromine, a trace of which remains in the gelatin after the excess oxidizing agent is destroyed and washed away. It then gradually returns to that portion of the silver sulfide sensitivity speck which had not been affected by the oxidizing agent, and reacts in a manner described in a previous paper on the intensification of latent image by hydrogen peroxide.[9]

That very dilute bromine solution causes the formation of latent fog was discovered by Lüppo-Cramer,[10] and was more recently verified by the writer, who found that it also causes, in a concentration of 1:200,000, marked intensification of latent image. In addition to this, it was observed, as S. E. Sheppard and others had already stated,[11] that bromine is strongly retained by gelatin, even when the latter was set and washed with sodium bicarbonate solution or with a solution of oxalic acid containing a small amount of manganous sulfate, the bromine which remained after this washing having the power to react with colloidal silver to give colloidal silver bromide.

That potassium iodide solution without acid present, and more so when it is present, soon turns yellow with the formation of free iodine is a well-known fact. Light is no doubt a catalytic agent in this reaction for even in a dimly lighted room the decomposition seems to take place slowly.

Light also has an effect on the acid solutions of the' alkali bromides. One per cent. potassium bromide solution containing sulfuric acid to $P_H = 3$, which when freshly made shows no trace of bromine, gives a definite free bromine reaction after standing for a few hours.[12]

Such a solution causes fog on the photographic plate, as Liippo-Cramer has previously discovered;[6b] although if present during exposure it also causes a lowering of sensitivity. Neutral bromide under corresponding conditions causes lowering of sensitivity without the fog formation. When the plate is bathed before or after exposure with either acid or neutral bromide, there is no sensitivity decrease or latent light image alteration but merely a fog effect from the acid bromide.

As an argument against the hypothesis of the writer that latent fog is produced through bromine formation, Liippo-Cramer cites the fact that a sulfurous acid solution or sulfur dioxide gas causes fog and that, obviously, bromine would not be formed in the presence of such a solution.[4,8c] When potassium bromide also is added the fog is increased, he found.

Another very interesting fact which he observed was that while ordinary plates of various kinds when bathed for two minutes in a solution containing 20 g. of potassium bromide and 1 cc. of concentrated sulfurous acid per liter showed marked fog on development in metol–hydroquinone; several different brands of ortho-chromatic plates showed even less fog than the control plate which was given no treatment before development.[8a]

[11] See S. E. Sheppard, "Gelatin in Photography," Monograph No. 3, Vol. 1, 1923, **pp. 153–156.**

[12] E. P. Wightman and S. E. Sheppard, "Effect of Certain Salts on the Photographic Sensitivity," paper presented at the Detroit Meeting, American Chemical Society, September, 1927, in press.

The same phenomenon was observed with special plates to which various color-sensitizing dye solutions were added for two minutes prior to the $KBr-H_2SO_3$ solution treatment. Even 0.1% hydrogen peroxide for two minutes did not cause fog on the dye-impregnated plates.

Recently, in another connection, the writer found that ordinary air containing up to 0.08% by volume of sulfur dioxide did not cause the formation of latent fog or appreciable change of sensitivity of either an Eastman Speedway plate or of a W. and W. panchromatic plate in fifteen hours of treatment; whereas an even less quantity of sulfur dioxide in air saturated with moisture in only a few hours caused bad fog on similar plates. Moderately dry air containing 0.16% sulfur dioxide caused a slight increase in sensitivity of a pan plate but no increase in fog.

It seems very likely that the action of sulfurous acid in producing fog is first an absorption into the plate and then an increase of solubility of the silver bromide grains on the surface. A certain amount of silver bromide goes into solution; the amount may be very minute, only a few molecules or ions. Then this in the presence of some of the larger sensitivity specks acting as nuclei oxidizes the sulfurous acid to sulfuric acid and a trace of silver deposits on the specks, increasing the size of the largest ones to the developable condition, thus[13]

$$2Ag^+ + 2Br^- + 2H^+ + SO_3^{--} + H_2O = 2Ag + 4H^+ + 2Br^- + SO_4^{--}; \quad \Delta F = -40{,}216 \text{ cal.}$$

The addition of potassium bromide increases this effect by increasing the solubility of the silver halide.[14] When the sensitizing dye is present it forms a protective layer, preventing the silver halide from going into solution and in some cases absorbing the sulfur dioxide.

As was said above, the author's hypothesis was based partly on a previously proposed mechanism of latent image intensification by hydrogen peroxide.[9] In a paper presented before the recent International Congress of Photography, some additional evidence for this mechanism has been set forth.[15]

It was found, for instance, that a latent image produced by x-rays on either fast or slow plates cannot be intensified by hydrogen peroxide. A. P. H. Trivelli had suggested that this should be the case since "an x-ray quantum of energy is of the order of 100 to 1000 times greater than

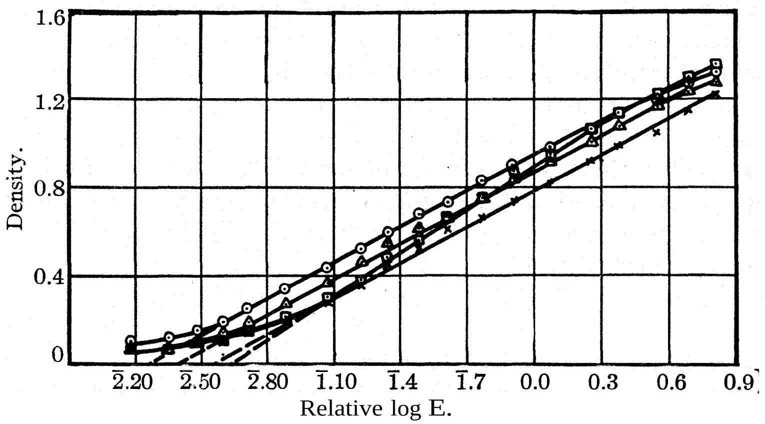
[13] The reason a sulfite containing developer does not do this is probably because of the interstabilizing effect of the developer reducing agent on the sulfite and vice *versa.*

[14] The solubility would be depressed only where very low concentrations of soluble bromide were used, that is, less than that already present in most emulsions. It is true that activity of silver decreases as solubility increases, but complex ions containing silver are formed which also may be reduced to metallic silver.

[15] E. P. Wightman and R. F. Quirk, "Intensification of the Photographic Latent Image," to be published in the Proceedings of the Seventh International Congress of Photography.

that of visible actinic light, so that even the smallest latent image speck produced by it is probably greater in size than that necessary to induce developability, and hence if there are no intermediate sized specks (as we had supposed to be present in the case of the ordinary light) there should be no intensification of an x-ray latent image."

Second, since the hypothesis supposed the formation of bromine by the acid–peroxide from the soluble bromide in the plate, the presence of a bromine acceptor along with the hydrogen peroxide should prevent or lessen latent image intensification. Acetone semicarbazone which Svedberg, Schunk and Andersson had used previously as such an acceptor to prevent solarization on the photographic plate[16] was tried. It was found, as anticipated, that since acetone semicarbazone increases developability of latent image to some extent in the middle and higher exposure regions, it does not prevent entirely intensification of latent image by hydrogen peroxide, but does lessen it instead of adding to it, as would be expected if there were no bromine absorbing action. The result is shown in Fig. 1.



□, Control, acetone semicarbazone treated; △, H_2O_2 and acetone semicarbazone treated; X, control, H_2O treated; ⊙, H_2O_2 treated.

Fig. 1.—Effect of acetone semicarbazone on latent image intensification by H_2O_2.

Third, it has been found that an organic peroxide, benzoyl peroxide, also intensifies latent image, although to a less extent than hydrogen peroxide. One reason for the less vigorous action is, no doubt, the low solubility of the former in water.

We have now found some further evidence for our viewpoint. An Eastman Speedway plate was exposed behind an Eder-Hecht wedge and then one-half of it lengthwise was treated with a solution containing 1 part

---

[16] T. Svedberg, O. H. Schunk and H. Andersson, *Phot. J.*, 64, 272–274 (1924).

of chromic acid and 0.4 part of sulfuric acid in 500,000 of water. The treated half was bathed for one minute in 0.1% bicarbonate solution and the two halves were developed together. There was a distinct intensification of latent image, about two steps or 4° E. H., and a faint increase in fog on the treated plate as compared with the control. This experiment will be repeated varying the concentration of oxidizing agent and time of treatment, also using some other oxidizing agents.

In one of Lüppo-Cramer's recent papers,[8b] he shows an interesting result obtained by treating a Kranz-Ultra-rapid plate which had been exposed behind a neutral gray wedge tablet with hydrogen peroxide for

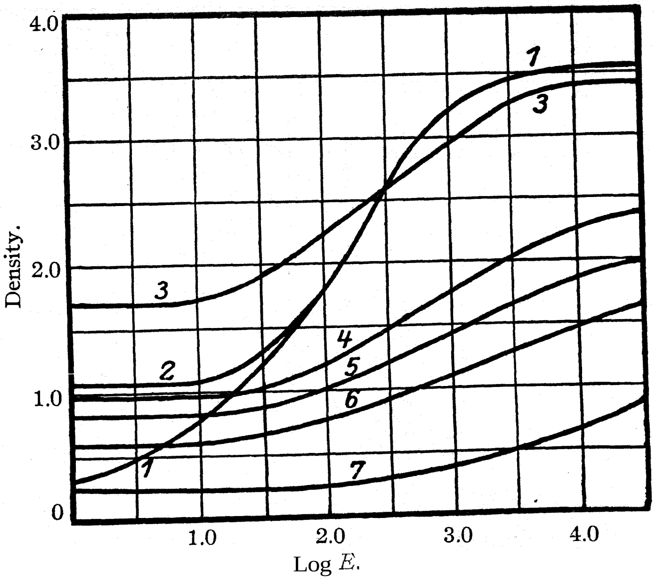


Fig. 2.—What Lüppo-Cramer calls intensification of latent image (Curves 2 and 3) and reversal of latent image (Curves 4 to 7) by hydrogen peroxide.

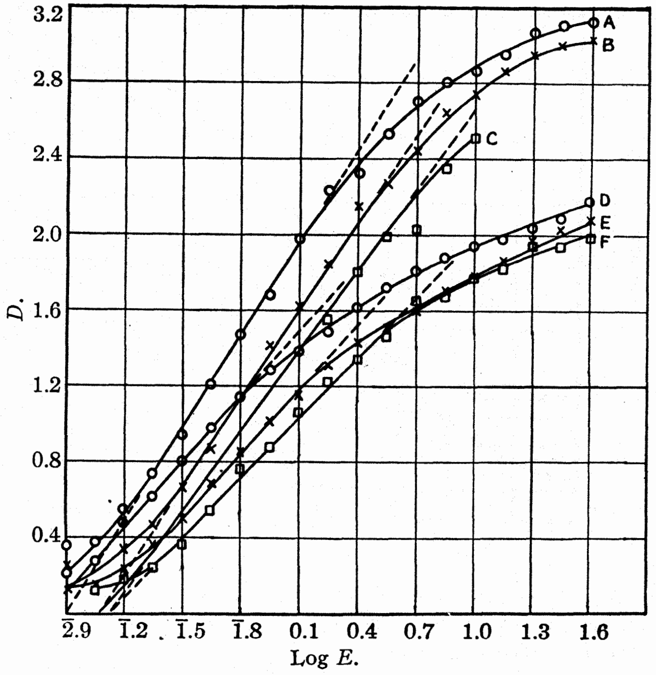
varying lengths of time as follows: 1—control, no treatment; 2—15 minutes in 1% H_2O_2 solution after exposure; 3—3 to 7—fifteen, thirty, sixty, ninety and two hundred and ten minutes in 5% H_2O_2 solution. The result is shown in Fig. 2. In discussing it he says: "Already in Curve 2, but outspokenly in 3, we find besides the intensive fog formation, at the beginning of the rise of the curves, what I had already described in principle in 1915,[17] and what Wightman and Quirk recently designated as intensification of latent image."

It would seem from this that there is a misunderstanding of what the latter investigators call intensification of latent image, since it was stated

---

[17] Lüppo-Cramer, *Phot.* Korr., 52, 135 *(1915).*

in their paper that the effect is produced by such a concentration of hydrogen peroxide as causes a practically negligible amount of fog. This happens to be, in the case of an Eastman Speedway plate, with which the Kranz-Ultra-rapid should more or less correspond, a concentration of about 0.008%, and the time of treatment is one minute. The intensification extends through most of the exposures. A comparison of Fig. 2 with Fig. 3, taken from Wightman and Quirk's paper, will show the fundamental difference. The entire effect in Curves 2 and 3, Fig. 2 (below where 3 crosses 1 and 2) appears to the writer to be a fog effect and not that of intensification as defined.



□, Blank; ×, H_2O treated; ○, H_2O_2 treated.

10-Minute development	Speed	λ	4-Minute development	Speed	λ
A, H_2O_2	876	1.60	D, H_2O_2	1102	1.12
B, H_2O	593	1.53	E, H_2O	593	1.15
C, Blank	516	1.42	F, Blank	516	1.05

Speed ratio: A/C = 1.70, B/C = 1.15, D/F = 2.15, E/F = 1.15

Fig. 3.—Intensification of latent image, high speed emulsion.

The reversal effect in the remaining curves in Fig. 2 is very interesting. As mentioned in a note in the British Journal of *Photography*[18] it seems likely that Lüppo-Cramer's idea of an increased dispersity of the latent image can be used to explain the reversal effect.

---

[18] E. P. Wightman, *Brit. J. Phot.*, **75**, 189 (1928).

Summary

Further arguments are given in support of the viewpoint of Wightman that the cause of latent fog formation from the action of certain oxidizing agents and acids is probably formation of bromine from the soluble bromide in the plate, with which hypothesis Lüppo-Cramer is in disagreement. The hypothesis was originally based on the fact, discovered by Lüppo-Cramer himself, that very dilute bromine solution causes fog and on a previously proposed mechanism of latent image intensification and fog formation by hydrogen peroxide, further evidence for which is now presented.

OBSERVATIONS ON THE RARE EARTHS. XXX. STUDIES IN THE ABSORPTION SPECTRA[1]

BY LAURENCE L. QUILL AND PIERCE W. SELWOOD WITH B. S. HOPKINS

RECEIVED JULY 28, 1928 PUBLISHED NOVEMBER 6, 1928

The purpose of this investigation was to make a careful examination of the effects of a common ion on the absorption spectra of solutions of certain rare earth salts. The spectra of the colored rare earths are an invaluable aid for the rapid estimation of these elements, and although there are several references in the literature to the fact that the absorption bands are displaced by the presence of other substances, yet there appears to be little definite information available as to the precise nature of the changes to be observed. These studies were therefore undertaken with the intention of determining the conditions under which the absorption spectra may be relied upon for the analysis of rare earth mixtures.

An extensive bibliography of the literature prior to 1920 is given by Yntema.[2] Since then methods of quantitative spectral analysis for the rare earths have been suggested by Inoue[3] and by Delauney.[4] Irregularities in the absorption spectrum of neodymium have been observed by Prandtl[5] as mentioned in his criticism of the discovery of illinium.

Delauney, on the assumption that Beer's Law is observed by rare earth salt solutions, has suggested a method of quantitative analysis based on the variation in the width of certain of the absorption bands with change in concentration. He made analyses of solutions of praseodymium and neodymium nitrates and his results were accurate to 5%, which is better

---

[5] Prandtl, *Z. angew. Chem.,* 39,897 (1926)

than can be done without a very careful equivalent weight determination. He also states that any changes in the neodymium nitrate bands on the addition of nitric acid are within the limits of experimental error.

Experimental

Procedure.—The absorption spectra were photographed on a Hilger quartz prism spectrograph with a dispersion of approximately 20 cm. Trichromatic "Spectrum Process" plates were used and the source of illumination was a tungsten ribbon incandescent lamp which gave a steady light and a continuous spectrum. The iron arc was used as standard of reference. The absorption spectra were exposed for five minutes in all cases. A Baly absorption cell with quartz windows was used throughout the investigation. The neodymium was atomic weight purity material which had been prepared in this Laboratory. The praseodymium contained about 1% of lanthanum. The samarium (except that purposely mixed with neodymium) was a few fractions removed from atomic weight material. The erbium was relatively impure, being several fractions removed from atomic weight material and containing thulium and yttrium. The various solutions were made up by weighing the freshly ignited oxides and dissolving them in nitric or hydrochloric acid as the case might be and evaporating just to dryness several times. The dry salts were then dissolved in water or in acid of the desired strength and made up to the required concentration in a volumetric flask. With the less basic samarium and erbium it was impossible to remove the last trace of acid without hydrolysis taking place. The trace left was insufficient to affect the absorption bands appreciably.

Neodymium Nitrate.—In the first part of the work 0.1 N neodymium nitrate solutions were prepared in various concentrations of nitric acid. The effect with the lower acid concentrations is very slight. Nevertheless, there is an unmistakable shift of 3 or 4 Å. toward the red in the 5700–5800 Å. region and the three bands visible tend to merge into one another. No change is observed in the 5200 Å. region, while the sharp band at 4272 Å. becomes very faint and is shifted about 1 Å. toward the red. As the acid concentration increases, the shifts become more and more pronounced until in 15.8 N acid the appearance of the spectrum is greatly altered. Spectrum No. 2 shows 0.1 *N* neutral $Nd(NO_3)_3$ through 5 cm. of solution and No. 1 shows 0.1 N $Nd(NO_3)_3$ in 15.8 N nitric acid through the same depth of solution. The three bands at 5710–5726 Å., 5731–5763 Å. and 5775–5780 Å. have merged together to 5758–5800 Å., while the region 5701–5758 Å. is only slightly absorbed.[6]

With increasing concentrations of neodymium the effect of adding nitric acid is similar, with, however, the addition of several new bands. Spectra 5, 6, 7, 8 and 9 show 0.5 *N* $Nd(NO_3)_3$ in acid concentrations of 15.8, 10, 5, 2.5 N and neutral, respectively, through 5 cm. of solution. A new band is to be seen in No. 5 at 5970 Å. In still more concentrated neodymium the addition of acid brings out a line between 5360 and 5370 Å. This is very plain in No. 3, while No. 4 shows the appearance of the neutral salt at the same concentration. These bands at 5970 Å. and 5360–5370 Å. are entirely distinct from any hitherto mentioned in the literature and might be mistaken by an inexperienced worker for bands characteristic of praseodymium and holmium, respectively. In addition to these changes the following were observed: the band at 6875–6908 Å. is spread out and shifted toward the red, while the band at 6774–6806 Å. is broadened and shifted toward the violet. The 5800 Å. region is broadened and shifted

---

[6] The figures given for the positions of the bands refer to the outer edges, rather than to the centers, and owing to the diffuse nature of the absorption edges the measurements are only approximate.

nearly 50 Å. toward the red. The bands in the region 5100–5200 Å. are in general broadened and shifted more to the violet than to the red. The band at 4744–4762 Å. is shifted to the violet to 4726–4763 Å. and becomes very faint; the band at 4683–4693 Å. is shifted to 4698–4709 Å. and the 4272 Å. band is broadened and shifted toward the red

The next examination was made on the influence of magnesium nitrate on the absorption bands of neodymium nitrate. This suggested itself not only because magnesium nitrate is very soluble but also because it is commonly associated with the cerium group rare earths in the form of the double magnesium nitrates used in fractional crystallization. The solutions, all of which were neutral, were made up as before with the addition of the calculated amount of magnesium carbonate, which was dissolved in as little nitric acid as possible. The 10 N $Mg(NO_3)_2$ solution was, of course, considerably supersaturated and after introduction of the hot solution to the absorption cell it was carefully cooled to room temperature and the photograph was taken without delay. The absorption bands of the neodymium were shifted by the magnesium nitrate in the same manner as by nitric acid. In a 0.25 *N* $Nd(NO_3)_3$ solution containing 0.25 N $Mg(NO_3)_2$, which corresponds to the composition of the neodymium double magnesium nitrate, the changes are slight but readily apparent. The most noticeable effect is the broadening of the bands in the 5800 Å. region.

While the changes produced by magnesium nitrate are similar to those produced by nitric acid, they are slightly more pronounced for a given normality. Spectrum No. 10 is of 0.5 *N* $Nd(NO_3)_3$ in 10 *N* HNO_3 while No. 11 is of 0.5 *N* $Nd(NO_3)_3$ in 10 *N* $Mg(NO_3)_2$. Both pictures were taken on the same plate and through the same depth of solution. The magnesium nitrate produces a slightly greater broadening of the 5800 Å. band, while the bands at 5089–5113 Å. and at 5190–5254 Å. are smaller, particularly the former. The differences become more apparent with solutions more dilute with respect to neodymium.

It was next desired to examine the influence of the nitrate of a tervalent metal and especially that of other rare earths on the absorption bands of neodymium nitrate. The extraordinary difficulty attendant upon the preparation of the pure rare earths made it undesirable to mix such pure salts as were at hand. However, by mixing lanthanum, of which a considerable amount was available, with neodymium, no very great damage was done because although these elements lie close together in the solubility series it is possible to introduce cerous salts between them in a fractionation series and so quantitatively separate the lanthanum from the neodymium. The cerium may then be removed by oxidation, lea ing pure lanthanum on the one hand and pure neodymium on the other. It was also desirable to examine the effect of a colored rare earth and especially that of samarium because it occurs close to neodymium in the natural sequence of the elements and because of the bearing it has upon the control of concentration of illinium in neodymium and samarium rich fractions. On no account was it desired to mix pure neodymium with pure samarium, but fortunately a large quantity of material was available which was free from neodymium and was composed chiefly of samarium and gadolinium with traces of europium, terbium and holmium. The chief interest lay in the 5800 Å. region and this material was free from absorption bands in that vicinity. Both lanthanum and samarium solutions were made up 0.5 *N* in $Nd(NO_3)_3$ and 5 *N* in $La(NO_3)_3$ and $Sm(NO_3)_3$, respectively. In order to show which bands are characteristic of samarium itself, a photograph (No. 12) was taken of its spectrum before the addition of the neodymium. Spectrum No. 13 shows the neodymium and samarium, while No. 14 shows the neodymium and lanthanum. As lanthanum has no bands in the visible region it was not necessary to photograph its spectrum alone. Spectrum No. 15 shows 0.5 N $Nd(NO_3)_3$ in the pure state. The differences between the changes caused by lanthanum nitrate and by samarium nitrate are slight and unimportant but they both produce changes similar to those brought about by the addition of magnesium nitrate. Compared with the pure neodymium it is found that the bands in the extreme red have disappeared, the 5800 Å. region is extended about 50 Å. toward the red, the 5200 and 5100 Å. bands are narrower, the 4690 Å. band has disappeared, while the 4272 Å. band is shifted slightly toward the red.

Several investigators have assumed that Beer's Law is observed by the rare earth salt solutions. In order to show conclusively that this is not the case, a comparison was made on the same plate of two neutral neodymium nitrate solutions, one 0.025 N the absorption spectrum of which was taken through a depth of 500 mm. of solution, and the other 10 N which was taken through a depth of 1.25 mm. The two solutions should be of equivalent thickness, that is, the incident illumination strikes an equal number of neodymium atoms or ions as the case may be in the two solutions. The changes in the absorption bands are very pronounced. Spectrum No. 16 shows the concentrated solution and No. 17 the dilute solution. In the former the 5800 Å. region has been extended about 30 Å. toward the red. The 5209–5231 Å. band is narrower and shifted toward the red. The 5198–5208 Å. band has disappeared, while the faint bands at 5082–5092 Å. and 5108–5131 Å. are more diffuse and much fainter. The 4744-4757 Å. and 46834692 Å. bands have disappeared. The 4272 Å. band is much fainter and shifted toward the red. In addition to these changes it is possible in the case of the concentrated solution to see a faint band at 5970 Å. (compare p. 2930) provided a spectroscope of low dispersion is used. This band does not appear to have been reported hitherto for neutral neodymium nitrate.

During the course of the work several absorption bands were photographed in the ultraviolet. These bands have received little attention from investigators in this field and are probably identical with the bands recently reported by Gardiner.[7] Inoue reports no bands for neodymium chloride in the ultraviolet.

Praseodymium Nitrate.—Since nitric acid had such a marked effect on the absorption spectrum of neodymium nitrate, it was decided to investigate its effect on other rare earth nitrates. The changes observed in the case of praseodymium were not as pronounced, in general, as in the case of neodymium. Spectrum No. 18 records the absorption of a 5 cm. layer of 1.0 N $Pr(NO_3)_3$ in the presence of 15.8 N HNO_3, while No. 19 is a neutral solution of the same concentration and depth. The band at 5985–5840 Å. suffers a marked decrease in intensity and is narrowed approximately 48 Å. to 5969–5872 Å. The band at 4839–4799 Å. is shifted slightly toward the red, the more refrangible edge being more so than the other. The band at 4725–4629 Å. is narrowed 35 Å., and the band at 44974380 Å. is narrowed 30 Å. The absorption edges were in all cases more diffuse. In the case of 0.1 N $Pr(NO_3)_3$, the shifts and variations in intensity were similar to those in the more concentrated solutions.

Samarium Nitrate,—The effect of free nitric acid upon the absorption spectra of samarium nitrate was also studied. Samarium does not exhibit as strong absorption in the visible region as do neodymium and praseodymium, except in highly concentrated solutions. It shows very strong absorption, however, in the violet and ultraviolet, especially from 3000 Å. to 4400 Å. The spectra of samarium reproduced here do not show below 4100 Å. but marked changes were observed as low as 3000 Å. upon the addition of nitric acid. Spectrum No. 20 is the absorption of 1.0 N $Sm(NO_3)_3$ in 15.8 N HNO_3, while No. 21 is that of the neutral solution through the same depth, 5 cm. The acid decreases the intensity of absorption in the 4823-4736 Å. region, as is also the case with the 4661–4613 Å. band. The two bands in the blue ordinarily listed as 4177 Å. and 4154 Å. are blended together in the acid solution, the resulting absorption area being about 20 Å. less in width than the total width of the two original bands.

---

[7] Gardiner, J. *Chem. Soc.*, 1926, 1518.

The 4154 **if.** band may be said to have shifted toward the red in forming the new band, The **4071** Å. and **4013** Å. bands are also blended into one by the acid. The decrease in width is marked by a shift toward the blue of the less refrangible edge. In general the absorption is less in the acid than in the neutral solution. Observations on other depths of solutions agree with the above, with other bands of less persistence appearing in the neutral solutions and also being changed by the acid.

Erbium Nitrate.—Erbium exhibits, with neodymium, the largest number of absorption bands of any of the rare earth elements. It seemed advisable, therefore, to study the effect of excess nitric acid on erbium nitrate, since the acid caused such decided shifts in the case of neodymium. Although the erbium material was impure, and the presence of foreign salts does affect the absorption spectrum of an element, the presence of nitric acid caused a marked change. As seen in spectrum No. **22,** there is a slight decrease in intensity of the band occurring at 6536–6486 **A.** with a shift toward the blue of about **5** Å. in the **15.8** N acid as compared with the slightly acid solution shown in No. **23.** The bands in the 5350–5400 Å. region are broader and more diffuse in the acid solution and are shifted toward the blue. The same is true of the 5170–**5240** Å. region, the absorption area being increased about **40** Å. and shaded off on both sides. The 4860–4878 Å. band is increased in width to 4830–4920 Å. with the heaviest absorption being shown from 4830–4855 Å. This is a decided shift toward the blue of the maximum of absorption and a broadening of the band at the same time. The 4495–**4500** Å. is shifted toward the violet about **10** Å. Whenever two bands are in close proximity in the neutral solution, they are blended together by the acid.

Neodymium Chloride.—In order to determine whether or not the changes in the absorption bands were peculiar to the nitrates, the effect of concentrated hydrochloric acid was studied on neodymium chloride. The changes in this case were different from what they were for neodymium nitrate, showing that the effect of different acids upon the absorption of a rare earth element is not the same. The concentration of the solution with respect to neodymium was that of a saturated solution of neodymium chloride in **12** N hydrochloric acid. As is the case with most chlorides, the solubility of the rare earth chlorides is repressed to a very considerable extent by the presence of free hydrochloric acid. The concentration of the neodymium chloride was approximately **0.4** N. Spectrum No. **24** represents the absorption of a neutral solution of **0.4** N $NdCl_3$ **5** cm. thick, and No. **25** is that of the same concentration of $NdCl_3$ in **12** *N* HCl. In the extreme red the acid brings out a new band at 6821–6848 Å. The change in the 5800 Å. region is very pronounced. The band shades off toward the red with an increase in width of between 90 and 100 Å. The **5200–5220** **if.** band is shaded off toward the red by the acid. The **5123** Å. band is narrowed about 5 Å. The **5091** Å. band is very much fainter and seems to be shifted to the blue slightly. The **4754** Å. band is fainter in the acid solution and is broadened toward the red. The **4691** Å. band is repressed and shifted toward the red. In the neutral solution there is ***only*** one distinct band at **4271** Å., while in the acid solution there are three faint, fuzzy bands at **4330** Å., **4297** Å. and **4271** Å.

Discussion of Results

In view of the present unsatisfactory state of our knowledge of atomic structure, it seems unwise to attempt any interpretation of **the** results presented here in terms of one of the current theories. It is known that even in the case of strong electrolytes the oppositely charged ions in a solution may approach close enough to one another to cause distortion of the outer electron shells. It is probable that this distortion may be

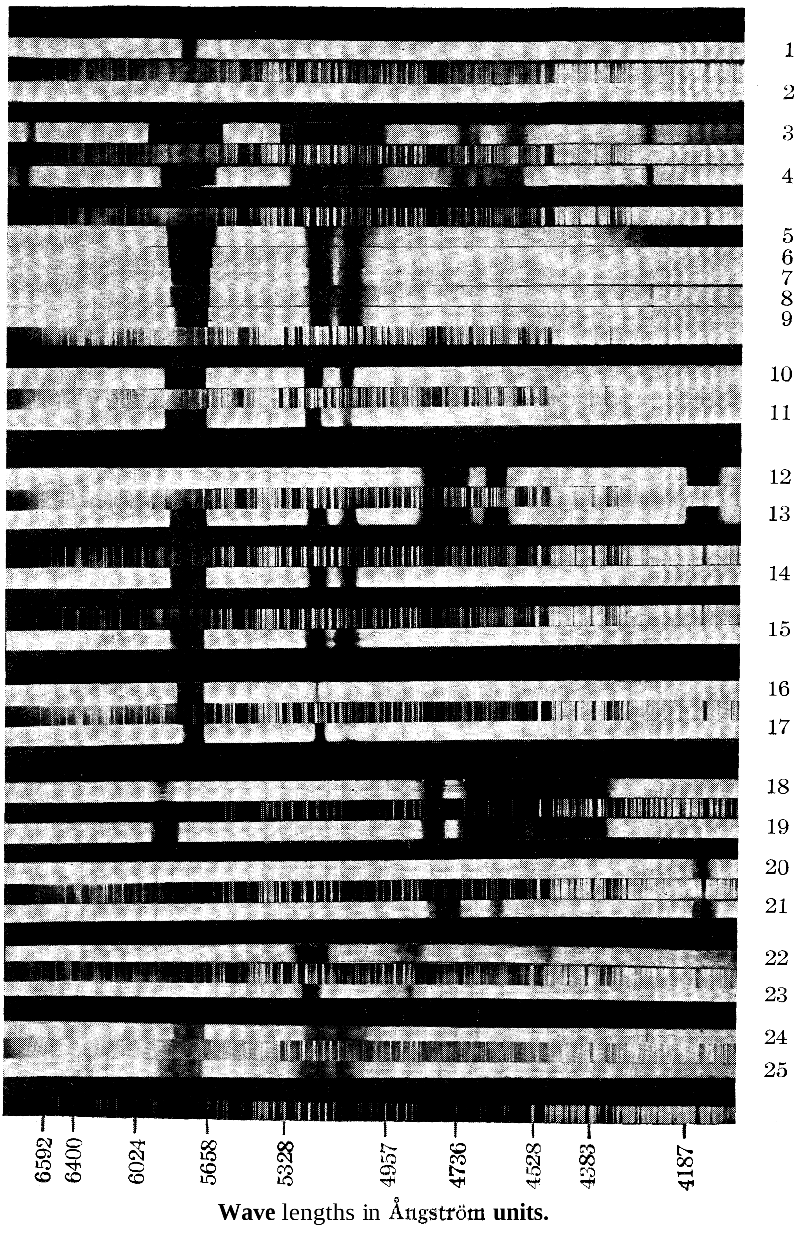
VARIATIONS IN THE ABSORPTION SPECTRA.



communicated in part, as small energy changes, to the electrons composing the inner sub-group which is thought to be the seat of the spectrum bands in the visible region.[8] Recent observations by Ephraim and Bloch[9] on the ammonia complexes of praseodymium chloride have been successfully explained by them on the basis of their theory of the deformation of the inner electron shell.

The idea is by no means original that the changes in the absorption bands are intimately connected with repression of ionization. This relation is certainly suggested by the similarity between the shifts produced by the addition of a common ion and those produced by increased concentration alone. In view of the fact, however, that the shifts reported here are neither uniform throughout the spectrum of a given salt nor of a similar nature in different salts, it seems that the theory of repression of ionization is inadequate to account for all the facts. Another difficulty is found in connection with the effect of magnesium nitrate. Magnesium nitrate is not commonly supposed to yield a high concentration of nitrate ion, yet there is unmistakably a greater change in the bands of neodymium nitrate upon the addition of 10 N magnesium nitrate than upon the addition of 10 *N* nitric acid. It was suspected that the metal ion might have something to do with the phenomenon and further investigation on this point is under way. No doubt we have more than one influence to deal with here and the formation of solvates, as suggested by Jones,[10] probably plays a part.

The large deviations observed from Beer's Law suggest that investigations wherein it has been assumed to hold are in error. It has been impossible to confirm Delauney's report on the effect of nitric acid on the absorption bands of neodymium nitrate. In the course of his work he used a spectroscope of only 2 cm. dispersion while the work here was done upon an instrument of 20 cm. dispersion. As the maximum shift observed was of the order of 2 mm., the greatest change which Delauney could have seen would have been about 0.2 mm. Inoue states that the characteristic bands of samarium at 4071 Å. and 4013 Å. remain unchanged upon mixing samarium chloride with the chloride of lanthanum, praseodymium or neodymium. We have found that in the case of the nitrate these bands are blended together and shifted toward the violet on the addition of nitric acid.

The effect of hydrochloric acid on neodymium chloride is interesting because while the changes in the absorption bands are in some degree

similar to those produced by nitric acid yet they are by no means identical differing both in intensities and in the positions of the new bands.

The portion of the work to which the greatest practical interest is attached is that in connection with the influence of one rare earth salt upon the absorption bands of another. It has been shown that in the presence of a colored or colorless rare earth the absorption bands of an element present in small proportions cannot be relied upon for its quantitative analysis and should be used for its identification with the utmost caution. In the cases observed the changes took the form of a distinct shift toward the red, particularly in the 5800 Å. region and of a marked diminution of intensity of the bands in the blue and violet. None of the changes observed was of such a nature as not to be distinct from the bands at **5816** Å. and **5123** Å. reported for illinium by Harris and Hopkins[11] and criticized by Prandtl. In dealing with relatively pure rare earth salts, it should be sufficient to remove all excess of the common ion and particularly to remove all excess acid before attempting spectroscopic analysis; but the quantitative estimation of a small amount of one rare earth in the presence of a large amount of another cannot be relied upon unless use is made of other means than the visible absorption spectra.

Summary

1. The absorption spectra of solutions of praseodymium, neodymium, samarium and erbium nitrates, which were the only ones investigated, are influenced by the addition of nitric acid. Salts of other rare earths showing absorption are undoubtedly affected.
2. No generalization can be made as to the effect of excess nitric acid on the nitrates of the different rare earths.
3. Hydrochloric acid does not produce the same effect as nitric acid on the corresponding neodymium salts.
4. Addition of magnesium nitrate to neodymium nitrate solutions produces a similar but slightly greater change than an equal normality of nitric acid.
5. Colored or colorless rare earth nitrates affect the bands of neodymium nitrate similarly to magnesium nitrate.
6. The deviations from Beer's Law of neodymium nitrate solutions resemble to some extent the effect of the addition of nitric acid.
7. Observations of Jones and others have been confirmed, while it has been impossible to confirm the work of Delauney.
8. Absorption spectra of solutions of rare earth salts should be used for qualitative analysis with the utmost caution and are not suitable for their quantitative estimation in the presence of one another.

---

[Contribution from the Chemical Laboratory of The Johns Hopkins University]

THREE LABORATORY DEVICES: A VACUUM STIRRER, A PRESSURE ALTERNATOR AND A GAGE FOR MEASURING LOW PRESSURES OF PERMANENT GASES IN CONDENSABLE VAPORS[1]

By Roger K. Taylor

Received July 30, 1928 Published November 6, 1928

An apparatus devised by the author for the stirring of liquids *in vacuo* has been of service in several researches at this University, and may be useful elsewhere. The purpose for which it has been used is the freeing of liquids from dissolved gases; periodic removal of the vapor above the liquid is ineffective, unless the liquid is stirred.

One form of the device is shown in Fig. 1. The liquid, resting above mercury, is contained in bulb A; above it is C, a tower of beads. By a method to be described, the level of the mercury is alternated between l_1 and l_2. The cycle of operation is this: when the mercury falls to l_2, it drains from the small bulb B, which fills with the liquid from **A.** Then, as the mercury rises again to l_1, it refills B, and the liquid contained is forced into C, where it spreads over and trickles through the beads and returns to A. In this way the establishment of equilibrium of dissolved gas between the liquid and vapor phases, which ordinarily is a very slow process, is rapidly effected. This results both from the large surface offered by the beads and the fact that the liquid is constantly being withdrawn from the bottom and returned to the top of A. Periodic removal of the vapor in A and C soon leaves the liquid practically free of dissolved gases.

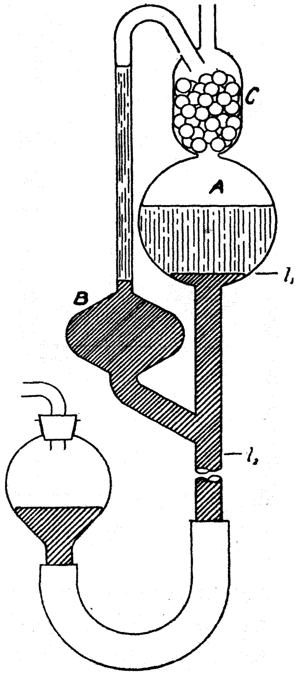

Fig. 1

In one case, where air was to be removed from an alcoholic soap solution, it was feared that the beads would occasion troublesome foaming. The difficulty was avoided by replacing C with a helix of tubing wide enough to permit the solution to flow along its bottom instead of filling it completely.

---

[1] In memory of Ira Remsen.

A pressure alternator, designed to operate the stirrer just described, is shown in Fig. 2. By its use atmospheric pressure, and a pressure less than atmospheric by any desired amount, may be alternately applied, the operation being automatic.

A water pump or other vacuum pump is attached to C; the apparatus in which the pressure is to change is connected to B, and A is open to the air. As the pump operates, the pressure in C and B decreases, and the mercury in A rises until it reaches the position a. Thus the pressure in B, originally atmospheric, falls by an amount represented by the vertical distance from a to the mercury level in A. Further pressure decrease causes the mercury to siphon rapidly into B, shutting off communication between B and the pump and leaving B open, through A, to the atmosphere. The distance h_2 is made greater than h_1, so that further decrease in pressure in C must take place before the mercury rises to b; that is, time is allowed for the pressure in the apparatus connected to B to rise fully to atmospheric. When the mercury finally carries over from B into C, it returns quickly through the bottom of C to A, stopping the admission of air, and the cycle starts afresh.

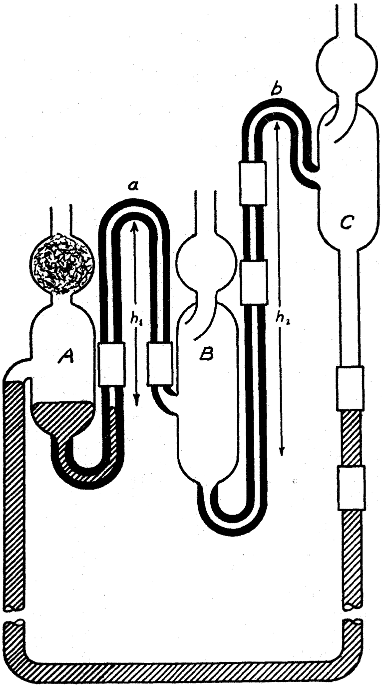

Fig. 2.

The amount by which the pressure changes is, of course, determined by the distance h_1. The time required for the pressure to decrease by this amount depends on the volume of the apparatus attached to B, and on the rate at which the pump is operating. The time that B remains open to the atmosphere depends on the rate of operation of the pump and on the difference between h_1 and h_2. All of these factors may be readily adjusted.

An apparatus of this sort may be used for various purposes. As an actuating mechanism for the stirrer previously described, B is simply attached to the leveling bulb, which is so placed that atmospheric pressure within it holds the mercury at l_1, and h_1 is made equal to the difference between l_1 and l_2.

This pressure alternator was designed without a search of the literature for similar devices; the fundamental principle, however, is not new. Maass[2]

---

[2] Maass, THIS JOURNAL, **41,** 53 (1919).

describes something of the sort and mentions a number of possible applications; and recently Weaver and Shepherd[3] depict a modification as the actuating mechanism for an automatic high-vacuum pump. The present device, however, contains one feature absent from Maass' apparatus, namely, the arrangement to cut off communication with the pump while the pressure in B is rising to atmospheric; and as compared with the corresponding part of Weaver and Shepherd's ingenious apparatus, this is of somewhat simpler construction.

A McLeod gage, slightly modified, may be employed to detect the presence and determine the partial pressure of small amounts of permanent gases in a condensable vapor, for instance, traces of air in water vapor.

The arrangement is shown in Fig. **3.** If the volume of the bulb and capillary is A, and the volume of the capillary above the mark is a, then when a permanent gas is present alone at low pressure and the mercury is brought to the mark on the central capillary, the pressure is given by the reading on the scale of the open capillary multiplied by a/A. It may also be determined by reading the position of the mercury on the scale of the closed capillary: if r is the latter reading, b the volume of the right-hand capillary above the mercury when the reading is taken, and B that of the entire side tube, then $\mathbf{P} = ar/[A - (Ba/b)]$. As B is small in relation to A, the ratio a/b does not need to be known accurately; since the capillaries are all supposedly of the same bore, a comparison of the corresponding lengths on the scale is close enough. When r is small, the simpler expression $\mathbf{P} = ar/(A - B)$ is approximately true.

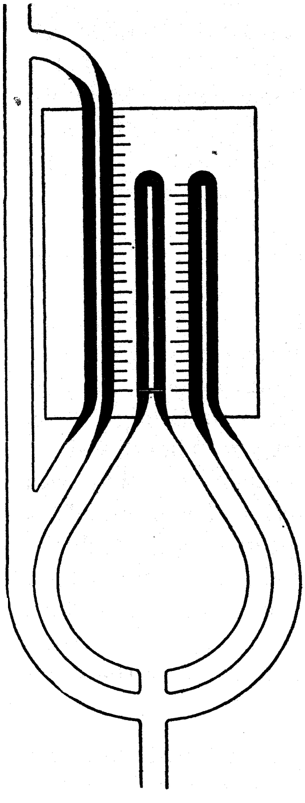

Fig. 3.

If now in addition to the permanent gas there is present a condensable vapor, in such amount that condensation takes place in the closed capillaries when the mercury is brought to the mark, *it contributes the same pressure,* namely, the vapor pressure of the liquid in question at the temperature of the gage, in *both capillaries;* accordingly, the partial pressure of the permanent gas is determined by

Weaver and Shepherd, THIS JOURNAL, 50,1829 **(1928).**

taking the same readings on the right-hand capillary and making the same calculations as when the condensable vapor is absent.

THE INFRA-RED ABSORPTION SPECTRA OF ORGANIC CARBONATES[1]

BY FREDERICK K. BELL[2]

RECEIVED AUGUST 1, 1928 PUBLISHED NOVEMBER 6, 1928

Introduction

There are few instances in which an acid, the metallic salts of which are available in large crystals, also yields a series of well-defined organic salts or esters. These conditions are fulfilled, at least partially, by carbonic acid. A number of inorganic carbonates are found in nature in crystals of sufficient size to permit cutting, polishing, etc., for optical examination. Similarly a considerable number of esters of carbonic acid have been prepared and are described in the literature.

In a rather recent paper Schaefer and his co-workers[3] have measured the infra-red absorption spectra between **1.0** and 17.0μ of six inorganic carbonates: $MgCO_3$, $CaCO_3$, $CaMg(CO_3)_2$, $FeCO_3$, $BaCO_3$ and $PbCO_3$. In view of this work it seemed to the present author that a similar examination of a series of organic carbonates would yield results of particular significance and interest. The absorption spectra of such a series of compounds might be expected to offer also further information concerning the $C{=}O$ bond, which is surely among the most' common linkages of organic compounds. The organic carbonates also represent one of the numerous series of compounds of organic chemistry which are especially suited for spectroscopic study of a systematic nature, one part of the molecule remaining unchanged as different hydrocarbon residues are introduced.

It is with these ideas in mind that the infra-red absorption spectra of seven organic carbonates have been examined between 1.0 and 12.0μ. The results of these examinations are presented and discussed in this paper.

Experimental

A detailed description of the experimental method employed in the present work has been given elsewhere.[4] The preparation of the absorption cells, however, has been altered. All cells were prepared from polished plates of rock salt.

---

[1] In memory of Ira Remsen.

[3] Schaefer, Bormuth and Matossi, *Z. Physik,* 39,648 (1926).

[4] F. K. Bell, THIS JOURNAL, 47, 2194 (1925).

The cleaved plates were first ground on emery cloth until all irregularities of the cleaved surface had disappeared. The grinding was then continued on a coarsely sanded glass plate (treated with crocus and water) until all of the deep emery scratches were removed. As the next step, the plates were polished on a cotton cloth which was stretched over a suitable plane surface and then treated with crocus and moistened with water. This procedure was repeated using jewelers' rouge instead of the crocus. The final polishing was accomplished in a similar manner using jewellers' rouge and 95% alcohol.

The construction of the absorption cell was carried out as previously described, but it was soon evident that the cement used could not contain much water. Thus, Le Page's glue, which was found to be quite satisfactory for cementing cells of cleaved plates, was entirely useless for present purposes. Similarly, a litharge–glycerol paste was found to contain sufficient water to ruin the polished surfaces. The cement finally used was DuPont Household Cement. The solubility of this material in certain non-aqueous solvents offers an important advantage in that cells may be readily taken apart for cleaning and repolishing without damage to the plates.

Three different cells were used in the study. No cell was used a second time until it had been taken apart, cleaned, repolished and cemented together again. A number of check experiments were made which failed to reveal any measurable variations due to differences in the cells. It therefore appears that this cell error which existed in the author's previous work has been eliminated, at least in relation to the other sources of error in the experimental method. The use of polished cells was prompted by a desire to reduce losses in the intensity of the transmitted radiation and to obtain some basis for a closer comparison of the intensity of absorption bands in different compounds. It is believed that the results obtained have entirely justified this point of view.

The carbonates selected for examination are the following: dimethyl, diethyl, dipropyl, dibutyl, di-*iso*butyl, di-*iso*-amyl and diphenyl. All of these substances were obtained from the Eastman Kodak Company and were used as received without any attempt at further purification. Diphenyl carbonate was examined in the molten state at 50°. All of the other carbonates selected, being liquids, were examined in the usual manner at room temperature. The thickness, *T*, of the absorption cell was 0.025 mm. in each case.

The absorption spectra obtained are shown graphically in Figs. 1 to 7 by means of the customary wave length–percentage transmission curves.

Discussion

The dimethyl ester is the only carbonate of the present study the infrared absorption of which has been previously described in the literature. A comparison of Coblentz'[5] curve for this substance with that shown in Fig. 1 demonstrates clearly the influence of the polished cell. Coblentz, using a cell made from cleaved plates of rock salt, employed a cell thickness of 0.01 mm. and his curve indicates a higher degree of general opacity than the present curve in which the cell thickness is 0.025 mm. In comparing the two curves it should also be noted that there is a difference in the resolving power of the optical systems employed in each case.

All of the compounds examined display a marked uniformity in general transparency as shown in Figs. 1 to 7 and it is to be recalled that one

---

[5] W. W. Coblentz, *Carnegie Inst. Publ.*, No. 35, 1905, p. 65.

aryl compound (diphenyl carbonate) is included. The regions between 1.0 and 3.0μ and between 3.6 and 5.0μ are particularly striking in this

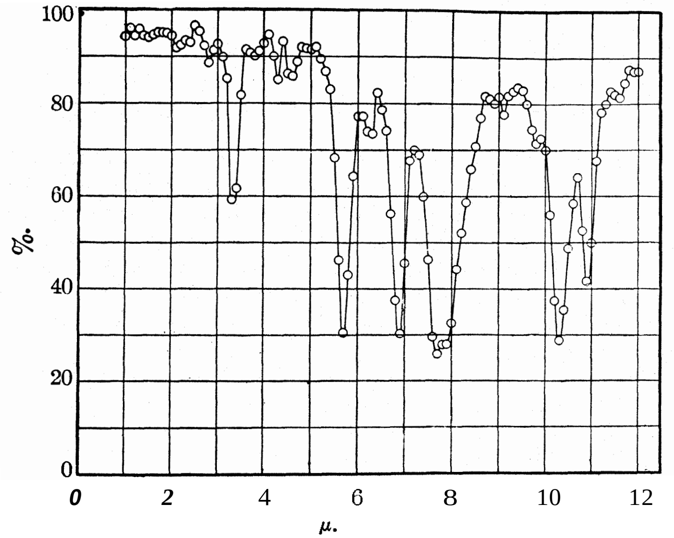

Fig. 1.—Dimethyl carbonate, T = 0.025 mm.

respect. A considerable increase in the thickness of the absorbing layer is undoubtedly necessary for a closer examination of these two transparent regions.

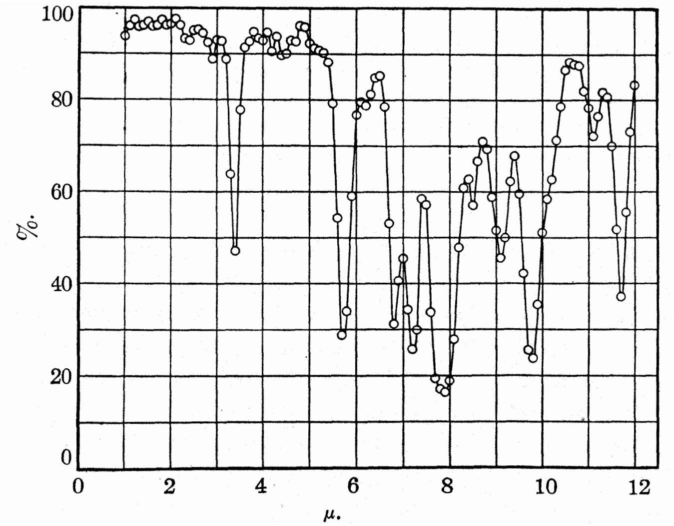

Fig. 2.—Diethyl carbonate, *T* = 0.025 mm.

In the region between 8.0 and 12.0μ marked differences occur in the absorption to such a degree that no difficulty would be encountered in differentiating between the various carbonates examined. However, between 3.0 and 8.0μ pronounced similarities appear. The C—H band at 3.4μ and bands at 5.7μ and 6.9μ are sharply defined in each curve. A broad region of absorption occurs in each spectrum at 7.8μ and the curve for di-isobutyl carbonate (Fig. 5) indicates the presence of two bands in this region. A weak absorption appears in the region of 6.2μ

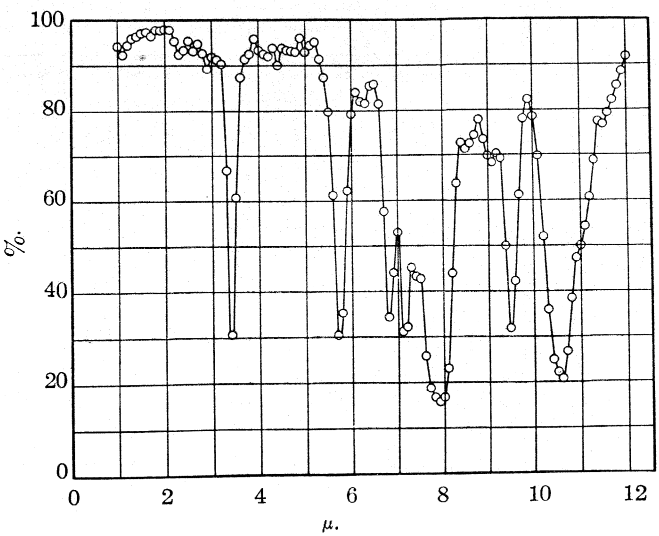

Fig. 3.—Dipropyl carbonate, $T = 0.025$ mm.

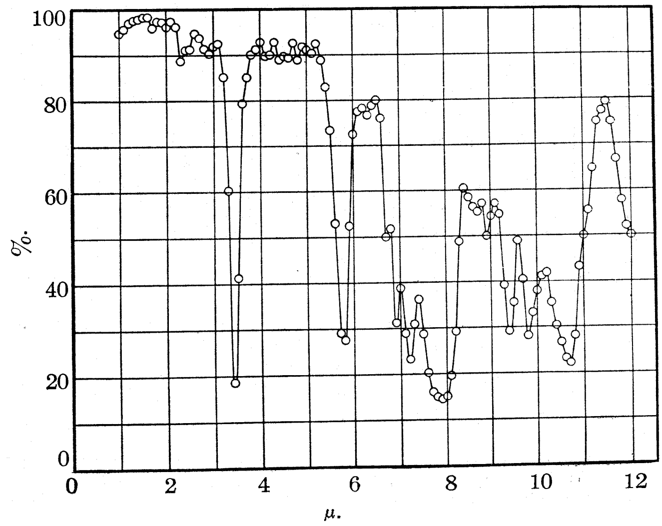

Fig. 4.—Di-n-butyl carbonate, $T = 0.025$ mm.

for each of the alkyl carbonates and in interpreting the more marked absorption in diphenyl carbonate (Fig. 7) at that wave length it is to be remembered that benzene derivatives have a characteristic absorption at 6.25μ.

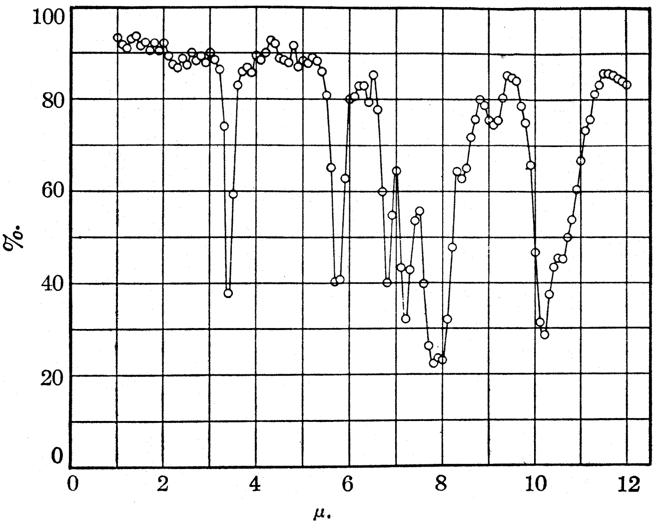

Fig. 5.—Di-isobutylcarbonate, T = 0.025 mm.

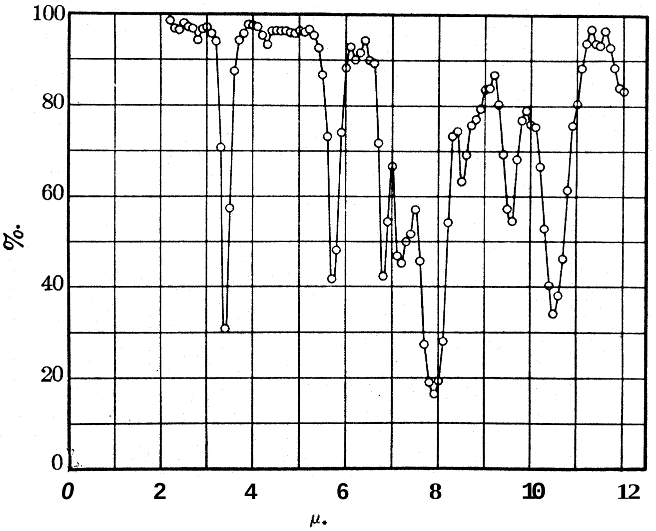

Fig. 6.—Di-iso-amyl carbonate, T = 0.025 mm.

Another region of interest is located at 7.2μ. In dimethyl carbonate (Fig. 1) no characteristic absorption occurs at that point, the transmission passing through a maximum; while in each of the other curves a well-defined minimum appears. This band, the location of which approximates that of the fourth member (at 7.0μ) of Ellis'[6] band series for the C—C linkage, may be regarded as characteristic of the C—C bond.

One of the components of the broad region at 7.8μ may be regarded as the 7.67μ band of methane, which Cooley[7] has examined with high dispersion. Dennison[g] regards this band as the result of one of the fundamental frequencies of the methane molecule. Similarly, the 6.8μ absorption band of the present curves corresponds to a frequency commonly attributed to one of the fundamental vibrations of the C—H pair. However, as will be noted below, another factor probably plays an important role in the absorption in this region.

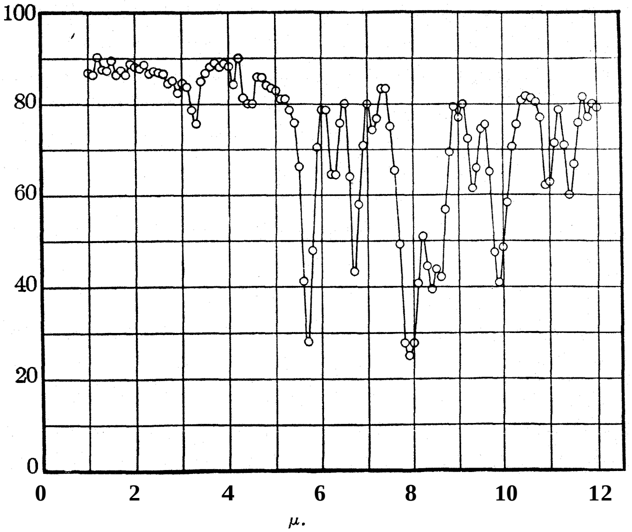

Fig. 7.—Diphenyl carbonate, T=0.025 mm., temp.=50°.

A well-defined absorption at 5.75μ which occurs with marked regularity in the spectrum of each of the compounds examined may- be regarded as characteristic of the C=O linkage. A survey of the absorption spectra of the large number of compounds containing the C=O group which have been recorded in the literature lends support to this opinion. Even in the rather complicated molecules of some of the tropine alkaloids, which the author[g] has examined, this band was sharply resolved (at 5.8μ).

In comparing the absorption spectra of the organic carbonates with those of the inorganic carbonates as measured by Schaefer and his collabo-

rators[3] it must be noted that the inorganic carbonates were examined as plates of 0.1 mm. thickness in comparison with the 0.025 mm. thickness used in the present study. Furthermore, the difference in density between these two types of carbonates must be considered.

In interpreting their experimental findings, Schaefer and his co-workers were guided by several factors: (I) the carbonates are characterized by five fundamental frequencies corresponding to (approximately) 7μ, 14μ, 30μ, 60μ and 90μ; (2) the CO_3 ion is characterized by four "inner" vibrations, according to Bresters[10] and Kornfeld,[11] at (approximately) 7μ, 11μ, 14μ and 8μ, which is the calculated wave length for an inactive frequency; (3) a combination of an inactive and an active frequency may result in an active frequency.

Between 2μ and 9μ the absorption of the inorganic carbonates is similar for each carbonate and this region, in which the influence of the metallic ion is apparently negligible, is regarded as the region of activity of the "inner" vibrations of the carbonate ion. A broad region of total absorption occurs at 7μ in each case and the authors have determined the location of the minimum by calculation from the first harmonic at approximately 3.5μ and checking this value against the reflection spectrum in the region of 7μ. Having determined the location of this 7μ band (frequency ν_1), the location of the inactive frequency (ν_0) was calculated from the absorption at 3.9μ, regarding this band as the resultant of the combination $\nu_1 + \nu_0$. The wave length corresponding to this combination lies between 9 and 10μ. The 14μ (frequency ν_2) and 11p (frequency ν_3) bands were definitely resolved. The authors thus determined the location of the four fundamental frequencies (ν_0, ν_1, ν_2, ν_3) for each carbonate. Other bands occurring between 2μ and 9μ are then satisfactorily accounted for as resulting from combinations of two or more of these four fundamental frequencies.

Difficulties are encountered at once in attempting to apply a similar method of analysis to the present curves. The relatively inactive metallic ions of the inorganic carbonates have been replaced by hydrocarbon radicals which are known to display characteristic absorption between 2μ and 9μ. Furthermore, the intensities of these hydrocarbon bands are relatively much greater than those of the carbonate ion. Thus the intensity of the 3.5μ (first octave of the 7μ band) band of the carbonate ion as shown in the absorption of the inorganic carbonates is not sufficiently great to affect the location of the 3.4μ of the C—H pair in the present curves. Likewise, the presence of the 3.9μ band of approximately the same intensity as that of the 3.5μ band cannot be detected in the spectra of the organic carbonates.

---

[10] C. I. Bresters, *Z. Physik*, 24, 324 (1924).

[11] H. Kornfeld, *ibid.*, 26, 205 (1924).

Another factor to be noted is that a number of the characteristic carbonate bands are located near or superpose characteristic C—H bands, for example, 3.5μ, 7μ and 14μ; so that both the location and intensity of the absorption bands of the organic carbonates are to be interpreted with caution.

The 5.75μ band of the present curves approximates, in location, a similar band which occurs in the inorganic carbonates, thus affording additional evidence that this band is characteristic of the C=O linkage. Schaefer and his collaborators regard this band as resulting from the combination $\nu_1 + \nu_0 - \nu_2$ (see above). As has been noted already, the broad region at 7.8μ of the organic carbonates has one component corresponding to the 7.67μ C—H band. Another component of this region may be located at 7.9μ. This band cannot be regarded as characteristic of the C=O linkage since an absorption of comparable intensity does not occur at that wave length in the spectra of the inorganic carbonates. It is suggested that this band is a combination band resulting from a combination of frequencies characteristic of the C—H and C=O linkages.

A consideration of the intensities of several of the more prominent absorption bands reveals some interesting relations. In Table I the transmissions (to the nearest per cent.) of the 3.4μ, 5.75μ, 6.8μ, 7.2μ and 7.85μ bands are given for each carbonate. It is at once seen that in the case of the normal alkyl hydrocarbon radicals the intensity of the 3.4μ band shows an increase with increase in molecular weight. Similar observations have been made by Henri and Bonino. Henri[12] examined a number of normal alcohols of the methane series. Although he failed to resolve the OH band at 3μ and the 3.4μ band, he found that the molecular coefficient of maximum absorption of the resultant band (at approximately 3.3μ) showed an increase with increase in molecular weight. By regarding this coefficient as an additive function and assigning values to the OH group and the CH_3 (or CH_2) group, he was able to obtain calculated values in good agreement with the observed data.

TABLE I

---

[12] V. Henri, "Études de Photochimie," Gauthier-Villars et Cie, Paris, 1919, p. 42.

Bonino[13] examined the absorption of several ketones containing only normal hydrocarbon residues of the methane series. He likewise found that the molecular coefficient of absorption of the 3.4μ band increased with increase in molecular weight. However, Bonino interpreted the intensity of the 3.4μ band as a function of the number of hydrogen atoms in the hydrocarbon radical and on this basis derived the empirical relation

$$\epsilon_2 = \epsilon_1 + C \log \frac{n_2}{n_1}$$

where ϵ_1 and ϵ_2 are the molecular coefficients of absorption and n_1 and n_2 are, respectively, the number of hydrogen atoms in the two homologs. By substituting the observed values of ϵ and the corresponding values of n, C was found to be a constant.

It is not necessary to express the absorption maxima of the present curves at 3.4μ in terms of the corresponding coefficients, in order to recognize at once that Bonino's empirical relation fails to hold; for it requires that the absorption maxima at 3.4μ should be the same for the butyl and *iso*butyl carbonates, since these two compounds contain the same number of hydrogen atoms. These two carbonates have approximately the same density and therefore the observed maxima are directly comparable and should be equal if Bonino's equation applies. The value for the dibutyl carbonate is approximately 0.19; that for the di-isobutyl carbonate is 0.38. The difference in these two values is, of course, far beyond the limit of experimental error. It is seen that the value of 0.38 falls between the values for ethyl and propyl carbonates. The value for di-iso-amyl carbonate is greater than that of the di-isobutyl carbonate and is approximately the same as the value for dipropyl carbonate.

A closer analysis of the intensity of the 3.4μ band would surely have to take into consideration the influence of the 3.5μ C=O band (as found in the inorganic carbonates). This influence should become more significant with decrease in molecular weight of the ester radical. The relative weakness of the 3.4μ band in dimethyl carbonate is striking, especially when it is considered that two methyl groups are present. Even more striking in this respect, is the aryl C—H band in diphenyl carbonate where the relative depth of the band is only ten percentage units.

The present curves, however, seem to show conclusively that the intensity of the 3.4μ band cannot be regarded merely as a function of the number of hydrogen atoms in the hydrocarbon radical, nor can it be regarded as a simple additive function depending upon the number of CH, CH_2 and CH_3 groups.

The intensities of the 6.8μ band, as shown in Col. **3** of Table I, are strikingly constant for the four normal esters. As has been noted above, this band, like the 3.4μ band, is regarded as resulting from one of the

---

[13] G. B. Bonino, *Gazz. chim. ital.*, **55, 335 (1925).**

fundamental vibrations of the C—H pair. It is therefore surprising that the intensity of this band fails to parallel the increase of that of the 3.4μ band with increase in molecular weight. This apparent discrepancy might be explained by assuming the presence of a carbonate band at 6.9μ (at 7.0μ in the inorganic carbonates) the intensity of which is considerably greater than that of the 6.81, band. Thus in dimethyl carbonate the 6.81, band would be expected to have a minimum intensity, which is probably less than that of the 3.41, band. The location of the observed band (at 6.9μ) would therefore be that of the relatively more intense C=O band and the observed intensity would be the summation of the intensities of the 6.81, and 6.9μ bands. The absorption of dibutyl carbonate (Fig. 4) may be interpreted to support this point of view. In this case the 6.9μ band has been definitely resolved and the 6.81, band appears to have been shifted to the shorter wave length region as indicated by the poorly defined minimum near 6.7μ.

The intensities of the 6.81, band in di-isobutyl and di-iso-amyl carbonates are approximately equal, but their value is considerably less than those of the normal esters.

The 7.2μ and 7.8μ bands do not display any consistent variations in intensity in passing from one carbonate to another, as shown in Table I. In addition to being poorly defined, the region of 7.8μ is too opaque to reveal clearly any differences in intensity. Thinner layers of the absorbing substances must be employed in order to obtain a satisfactory analysis of this region.

A consideration of the intensity of the 5.751, band as shown in Col. 2 of Table I offers a serious objection to the opinion, expressed above, that the 5.751, band is due to the C=O pair. The intensity values for the four normal esters are practically equal. Since the densities of these substances are of the same order of magnitude, it is obvious that the molecular absorption coefficient at 5.75μ will show an increase with increase in molecular weight. However, if the 5.751, band is due to the carbonate group, the molecular absorption coefficient should remain constant for each carbonate. The same reasoning may be applied to the case of the two *iso*-esters where, however, the intensity of the 5.75μ band, although the same for each of the two compounds, has a considerably smaller value than that of the normal esters.

It must also be noted that there is at least an approximate equality in the intensity values of the 5.751, band and of the 6.8μ band in each of the compounds (with the exception of diphenylcarbonate), a condition which can hardly be regarded as coincidental.

The most obvious explanation of these observations is the assumption that another absorption band (perhaps due to the CH pair) occurs near the location of the C=O band, so that the intensity of the observed band at 5.75μ is that due to the superposition of two bands. However, little evidence can be found in support of this assumption.

The present study includes the examination of only two iso-esters and therefore offers little conclusive information concerning the absorption of that type of compound. From the above discussion, however, it is difficult to avoid the generalization that the normal esters and the *iso*-esters of carbonic acid form two distinct types of compounds in which the factors determining the intensities of the absorption bands characteristic of the C—H and C=O linkages are the same qualitatively but differ quantitatively for each type.

The absorption spectra of the organic carbonates offer a further indication, perhaps more clearly than previous work, of the definite possibilities of utilizing the intensity of characteristic absorption bands for purposes of identification. For example, it is readily seen that there would be no difficulty in differentiating between the four normal esters of carbonic acid by means of the intensity of the absorption at 3.4μ.

Summary

1. The absorption spectra of dimethyl, diethyl, dipropyl, dibutyl, di-*iso*butyl, di-iso-amyl and diphenyl carbonates have been examined between 1.0 and 12.0μ, using absorption cells made from polished rock salt plates.

2. These absorption spectra show a marked similarity in the number and location of absorption bands between 3.0 and 8.0μ; while no consistent variations or similarities can be detected in the region between 8.0 and 12.0μ.

3. The absorption spectra have been discussed in their relation to the results obtained by Schaefer and his co-workers in the examination of some inorganic carbonates.

4. An increase in the intensity of the 3.4μ band with increase in the molecular weight of the ester radical has been observed. However, the intensity values of the 3.4μ band in di-isobutyl and di-iso-amyl carbonates are not satisfactorily accounted for by the relations derived either by Henri or Bonino.

5. The intensity relations of the 5.75μ band in the various organic carbonates offer an important objection to the idea that the 5.75μ band depends solely on the presence of the carbonate group.

6. An analysis of the variations in intensity of characteristic absorption bands in the various organic carbonates indicates that the normal and the iso-esters may be regarded as two distinct types of carbonates.

BALTIMORE, MARYLAND

[Contribution from the Physical Chemistry Laboratory of the State University of Iowa]

THE VAPOR PRESSURES OF AQUEOUS SOLUTIONS OF POTASSIUM IODIDE AND SODIUM BROMIDE AT 25°[1]

By J. N. Pearce, M. D. Taylor and R. M. Bartlett

Received August 2, 1928 Published November 6, 1928

In the study of the colligative properties of solutions use has been made of methods involving the lowering of the freezing point, the lowering of the vapor pressure and the elevation of the boiling point of the solvent by the solute, and the application of electromotive-force methods. Because of the ease and the accuracy of the measurements, most of the work hitherto has been confined to the freezing point and electrometric methods. Of all of the properties of solutions, however, none are more accessible to thermodynamic treatment than the vapor pressure. While the vapor pressure method is free from all of the disadvantages, and in addition possesses many advantages over the others named, chiefly in that it can be used at any temperature, the results obtained have not been all that could be desired.

Four general methods have been employed for measuring the vapor pressures of solvents and solutions: (1) static, (2) indirect, **(3)** differential and (4) dynamic. The principles involved and the difficulties met with in their application have been discussed in a previous paper.[2] Of these the most convenient and rapid is the dynamic, or air-saturation method; moreover, it is based on a simple application of Dalton's Law of partial pressures. The essential features of the method as commonly used are: **(1)** a measured volume of air is saturated with vapor by passing it over the surface of, or bubbling it through the liquid contained in the saturator; (2) the weight of the solvent evaporated is determined by the loss in weight of the saturator, or by the gain in weight of the absorber which removes the solvent vapor from the effluent air; **(3)** the total pressure exerted by the gaseous mixture in contact with the liquid is obtained from barometer and manometer readings. From the data thus obtained the vapor pressure of the solvent may be calculated.

A survey of the vapor pressure data obtained by the dynamic method shows not only a wide variation in the values reported by different investigators for a single liquid, but also very frequently a considerable variation in the data given by a single investigator. The chief reasons for these deviations are few, but they have been difficult to overcome. The Earl of Berkeley and Hartley[3] have concluded that the failure of the original Walker-Ostwald method is due to variations in the hydrostatic pressure in the several vessels. They also suggest that liquid spray is carried mechanically

---

[3] Earl of Berkeley and Hartley, *Proc. Roy. Soc.*, 77, 156 (1906).

from the solution to the pure solvent. Attempts to eliminate both of these sources of error have been made by a number of men.[2] Another difficulty is our inability to measure accurately, and at the same time conveniently, the large volume of air required for a single determination. The error thus introduced will be greater or less, depending upon the magnitude of the vapor pressure of the liquid studied. Owing to the surface film effect any form of apparatus which requires the passing of air over the surface of the solvent or solution must present a large liquid surface. Moreover, the surface should be in constant motion. Forms of apparatus involving the bubbling of air through the liquid are obviously more compact, but they introduce error for the reason that while a bubble may be saturated with vapor in the depth of the liquid, it will expand on rising and may leave the surface without becoming entirely saturated, Again, the mathematical formulas which have been used heretofore are often highly complicated; slight errors of observation are highly magnified in calculating the vapor pressures.

Pearce and Snow[2] have devised a rapid method which apparently eliminates all of the previous sources of error. The method introduces the following new features. Instead of measuring the volume of air which passes through the solution, hydrogen and oxygen are generated electrolytically and the volume of the mixed gases, as well as the number of moles of each, is calculated from the weight of silver deposited in a coulometer. The actual calculation of the vapor pressure requires the knowledge of three values only: the corrected barometric pressure, P, and the weight of vapor, W_W, taken up by the P_2O_5-absorber while W_S grams of silver are being deposited in the coulometer. The number of moles of water vapor, n_1, and the total number of moles of hydrogen and oxygen generated, n_2, are calculated from W_W and W_S, respectively. From these data the vapor pressure of the solvent can be calculated by means of the simple relation $p = [n_1/(n_1 + n_2)]P$.

Experimental Results

The experimental procedure is described in detail in the previous paper." It need only he said that the utmost care was taken to insure purity in all materials used. The pure "Analyzed" salts were repeatedly crystallized from conductivity water distilled from a large still containing a strong alkaline solufion of potassium permanganate. The solutions were accurately made up on the weight molal basis. The entire vapor pressure apparatus, except for the generators, preheaters and absorbers, was immersed in a large Freas water thermostat maintained at 25 ± 0.01° throughout the two-hour run.

The essential data are given in Tables I and II. Each vapor pressure value is the mean of at least three independently determined values which do not differ over all by more than a few 0.001 mm. The symbols used at the top of each column are self-explanatory.

^{a} Saturated.

In the present paper we intend only to show briefly the results obtained in the study of two salt solutions by the new dynamic method recently devised in this Laboratory. The general discussion of the theories involved will be left for a later paper.

The change in the vapor pressure, p, and in the fractional lowering $(p_0 - p)/p_0$ with increasing concentration, are shown graphically in Fig. 1. These curves show at once the influence of hydration upon the vapor pressure of solutions. The p-curve for sodium bromide is at all concentrations below that for potassium iodide; its curvature toward the concentration axis becomes more and more pronounced as the concentration increases. On the other hand, the curve for the fractional lowering, $(p_0 - p)/p_0$, produced by the sodium bromide lies at all concentrations above that given for potassium iodide. Solutions formed by such salts are far from ideal solutions; the positions and the slopes of the $(p_0 - p)/p_0$ curves show, perhaps more than anything else, the rate of change in the apparent mole fraction of the water actually present as solvent. Lewis defines an ideal solution as one which obeys Raoult's law at all concentrations and pressures, that is, $(p_0 - p)/p_0 = n/(N + n)$. A plot of the mole fraction

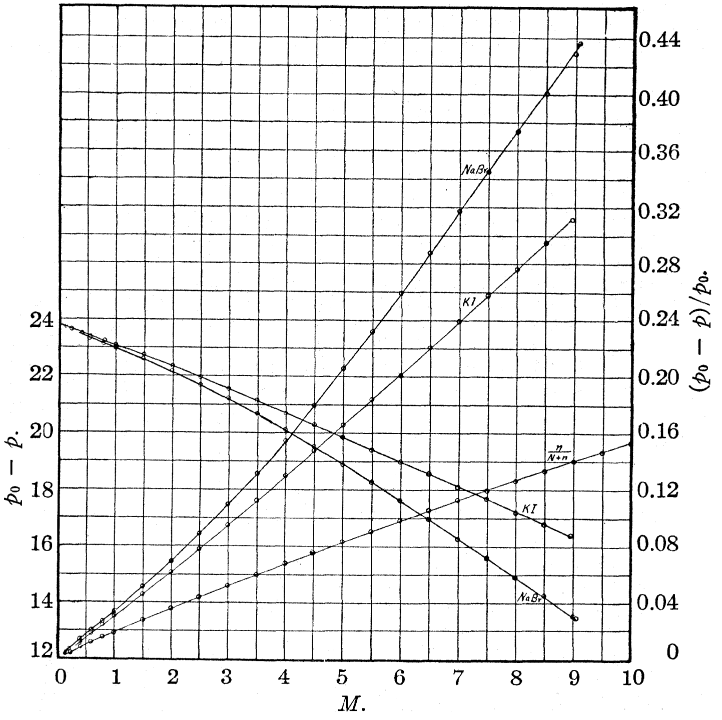

Fig. 1.

of the solute against the corresponding molalities should give us graphically the change in the fractional lowering with increase in concentration for an ideal solution. Such a plot is included in Fig. 1. As should be expected the curve shows a slight bend toward the concentration axis as the concentration increases,

The vapor pressures of solutions give us immediately a means of calculating osmotic pressures. The theories and the relations involved in the consideration of osmotic pressure have been most admirably discussed in a recent paper by Bancroft and Davis.[4] Of the many relations which have been suggested for calculating osmotic pressure from vapor pressure data, we shall mention only two for the present. The first is the one presented by Fraser,[5]

$$p_1 = \frac{RT}{V_0} \ln \frac{p_0}{p} \tag{1}$$

In this V_0 is the volume of one mole of the solvent, which, as we have used it, is the volume occupied by 18.016 g. of water at 25°. Fraser states that this is an exact expression even at large concentrations, provided the perfect gas laws apply to the vapor and the effect of pressure on the molal volume V_0 is negligible.

By thermodynamic means Lewis has derived a relation which holds more rigidly over a very wide range of concentration, namely

$$P - \frac{\beta}{2} P_2 = \frac{RT}{V_0} \ln \frac{p_0}{p} \tag{2}$$

Here β is the coefficient of compressibility of the water and V_0 is the molecular volume as before. For small values of P the effect due to the compressibility term vanishes and (2) becomes equivalent to (I). We have calculated the osmotic pressures by both equations. Within limits of error the osmotic pressures by the two formulas agree to within 0.01 atm. up to 0.8 M, but from this point on they begin to diverge. At saturation the value of P (1) for sodium bromide is 13.3 atm. greater than for P by (2); P by (1) for potassium iodide is 5.27 atm. greater than that calculated by (2). For the sake of brevity me are inserting only those osmotic pressures calculated by (2). The value of β for water at 25° was interpolated from compressibility data[6] at 20° and 30°.

The vapor pressure apparatus used makes possible the rapid determination of thermodynamic data. The activity of the solvent α_1 in a solution may be calculated from the fractional lowering of the vapor pressure by means of the series relation.[7]

[7] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 274.

$$\ln \alpha_1 = -\frac{p_0 - p}{p_0} - \left(\frac{p_0 - p}{p_0}\right)_2 - \left(\frac{p_0 - p}{p_0}\right)_3 - \ldots.$$

In very dilute solutions only the first term is of importance; in making our calculations of α_1 other terms were added until the influence of an added term became negligibly small. The values of α_1 and α_2/N_1 are given in Cols. 6 and 7, Tables I and II. For pure water $\alpha_1/N_1 = 1$ and the departure of α_1/N_1 from unity is the measure of the variation from a perfect solution.

Further, to calculate the activities of the solute α_2 and from these the activity coefficients, γ^*, we made use of the thermodynamic relation

$$\int d \ln \alpha_2 = -\int \frac{N_1}{N_2} d \ln \alpha_1$$

To this end we plotted the values of N_1/N_2 against log α_2 and from the area under the curve, measured by means of a planimeter, determined the difference between the values of log α_2 at given different concentrations and the value of log α_2 for a molality whose activity coefficient had been determined previously by other means. From these we have obtained quantities which are proportional to α_2. Upon taking the square roots of these and dividing by M we found another series of quantities, $k\gamma$, which are proportional to γ. To evaluate γ it was necessary to find the value of k. We did this by assuming the values of γ obtained by Harned and Douglas[8] for the two 1 M solutions. Dividing the value of k thus found for each salt into each of the products, $k\gamma$, we obtained the values of the activity coefficients given in Col. 8. These activity coefficients have been plotted against the corresponding values of M, Fig. 2. The agreement between the values of γ for sodium bromide and those calculated by Harned and Douglas for the same concentration range is exceptionally good; that between the values of γ for solutions of potassium iodide at the three

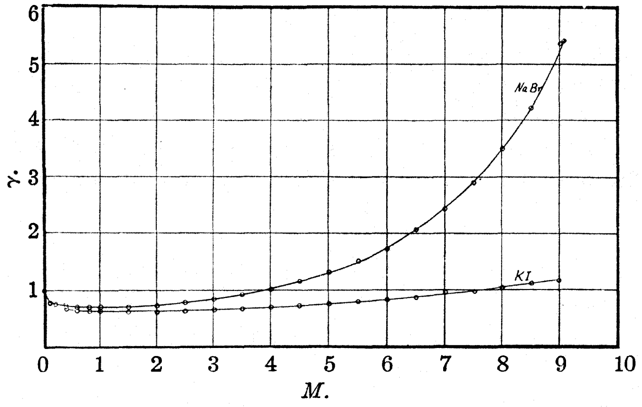

Fig. 2.

[8] Harned and Douglas, This Journal, 48, 3095 (1926).

lowest concentrations is not good. This is not surprising when we consider the roundabout way in which y is calculated. Even very slight errors in the vapor pressure readings are highly magnified when working with vapor pressures at concentrations less than 1 M.

From the activities of the solvent and the solute it is possible to calculate also three other important thermodynamic quantities. Thus the relation $-\Delta F_1 = \overline{F}_1 - F_1^0 = RT \ln \alpha_1$ gives the increase in free energy accompanying the transfer of one mole of water from the pure solvent to a solution of the given molality. Likewise, $-\Delta\overline{F}_2 = \overline{F}_2 - F_2^0 = RT \ln \alpha_2$ gives the corresponding change in free energy for the solute. The values of $-\Delta F_1$ and $-\Delta F_2$ thus calculated are given in Cols. 9 and 10. In making these calculations we have taken R = 1.9885 cal. and T = 298.12". In the last column of each table under $-\Delta F_2^0$ is tabulated the increase in free energy accompanying the dilution from any concentration M to one exactly 0.1 M.

In this paper we have made all of our calculations on the basis of "weight molal" concentrations, that is, moles per 1000 g. of water. While we have attributed the deviations from the laws of ideal solutions to hydration, we have not been oblivious to the newer development of the solution theory brought out by Debye and Hiickel. More recently Hiickel[g] has extended the interionic attraction theory to concentrated solutions and he states that the interionic attraction theory provides a better explanation for these deviations than does hydration. He also states that the variation of the activity coefficient with the concentration can be expressed by the relation

$$\log f = -\frac{0.354\sqrt{2c}}{1 + A\sqrt{2c}} + B \cdot 2c$$

where A and B are constants and c represents the concentration in moles per liter.

The experimental method presented makes it possible to determine vapor pressures for all concentrations from 0.1 M up to saturation. The data obtainable should give us a good opportunity to test the validity and range of application of the Hiickel equation to saturated solutions. Unfortunately, no accurate density data are available for converting our concentrations to the molar concentration basis used by Hiickel. We are now determining the densities of these solutions and will report our test of the Hiickel equation in a forthcoming paper.

Summary

1. The vapor pressure of solutions of sodium bromide and potassium iodide have been determined at 25° for concentrations lying between 0.1 M and the saturated solutions.

---

[9] **Hiickel,** *Physik. Z.,* **26, 93 (1925).**

2. From the data obtained we have calculated the osmotic pressures, the activities of the solute and solvent, the activity coefficients and various changes in free energy accompanying change in concentration.

3. For all concentrations the magnitude of these solution values is greater for solutions of sodium bromide than for solutions of potassium iodide.

A NEW METHOD FOR MEASURING OSMOTIC PRESSURE[1,2]

By R. V. Townend

Received August 2, 1928 Published November 6, 1928

Introduction

In the past the study of osmotic pressure has been hampered by the experimental difficulties involved in making exact measurements. At least partly for this reason, the possibilities of osmotic pressure as a means for investigating the nature of solutions of electrolytes have been largely overlooked. The subject is treated briefly in many textbooks of chemistry, although its fundamental importance in other lines, such as plant and animal nutrition, has long been recognized by botanists and others. As a means for determining the activity of dissolved substances it ranks with such methods as vapor pressure lowering, freezing point lowering, and boiling point raising. With the exception of vapor pressure measurements, it is the only method of directly measuring activity at any and all temperatures. The osmotic method also has certain advantages over that which depends on the estimation of difficultly soluble substances in the presence of other salts. In the latter case it is necessary to make certain assumptions, such as the "ionic strength principle," whereas this is unnecessary in the case of the osmotic method. Moreover, the fact that a thousandth molal potassium chloride solution has a freezing point lowering of about 0.00368°, whereas the same solution has an osmotic pressure of about 36 mm., indicates clearly that as a means for investigating dilute solutions it would be of unsurpassed value provided certain experimental difficulties could be overcome.

The Measurement of Osmotic Pressure

The ordinary method for measuring osmotic pressure and the only one which has so far given satisfactory results consists in the use of a porous

clay cell, which acts as a support for a copper ferrocyanide membrane. The solution is placed on one side of the cell, a suitable manometer attached and the equilibrium pressure determined when pure solvent is placed in contact with the other side of the membrane. The method has been refined so as to give reliable results with solutes of high molecular weight but up to the present it has not been applicable to solutions of electrolytes, on account of the difficulty in obtaining suitable membranes which would be impermeable to the ions.

The present method makes use of two general properties of liquids which are not ordinarily considered: first, that changing the pressure on a liquid surface changes its vapor pressure, and, secondly, that liquids possess an internal pressure or cohesion force so that (in the absence of excess dissolved gases) it is possible to place a tension on the two ends of a column of liquid.[3]

Outline of the Method

In the method to be described here, the solution to be measured—for example a salt solution—is placed in contact with its vapor. Some of the pure solvent is also placed in contact with the vapor. Since the vapor pressure of the solution is less than the vapor pressure of the pure solvent at the same temperature, in the case mentioned, water vapor will distil from the pure solvent into the solution. It is seen that the vapor phase may be regarded as a perfect semi-permeable membrane permitting the passage of the molecules of solvent only.

In order to permit the measurement of the osmotic pressure the liquid water is located within the capillaries of a thin porous plate. The capillaries are of sufficient size to permit the liquid water to pass readily to the surface of the plate, but so small that the maximum capillary rise is somewhat greater than the maximum osmotic pressure to be measured. Below the plate is a quantity of liquid water and below this a column of mercury. The weight of the water and mercury places a tension on the water at the surface of the plate. At equilibrium this force (corrected for any difference in heights between the water and solution) equals the osmotic pressure of the solution. The equilibrium point is determined by measuring the rates of distillation from the plate to the solution under different tensions. These rates are plotted against the corresponding tensions. The osmotic pressure, which corresponds to the tension at zero distillation, is obtained from the curve by extrapolating to zero.

There are several experimental details mentioned below which, in the course of working out this method, were found to be necessary for success. From the large amount of work carried out in this Laboratory on vapor pressure, it was known that in order to obtain a satisfactory distillation

---

[3] See also Washburn, *J. Am. Ceram. Soc.*, **1**, 29 (1918).

from (or into) the surface of a liquid, the system must be practically air-free.

In order to insure absolute uniformity (both of temperature and composition) throughout the solution at all times, gentle stirring was necessary. Violent agitation at the surface was to be avoided, as it might give high results due to the fact that potassium chloride is negatively adsorbed at the surface of water solutions.

The porous disk involved considerable experimentation in order to secure the required porosity, as pointed out above. In addition, the disk must be mechanically supported to withstand the stress applied and all surfaces must be thoroughly wetted by the liquid.

Temperature control is of primary importance. At 25° the vapor pressure of water changes approximately 1.4 mm. per degree, while a 0.001 *M* solution lowers the vapor pressure by approximately 0.00074 mm. Thus it is seen that a drop in temperature of about 0.00053" has the same effect on the vapor pressure as a 0.001 molal solution.

Since in the process of removing the air from the system, the concentration of the solution was changed by an unknown amount, the solutions were analyzed after the measurements were completed. These analyses were made by means of the Zeiss interferometer, after the instrument had been calibrated against solutions of the same salt of known concentration. In the case of the most dilute solution, the total amount of solid used was less than five milligrams and it was necessary to concentrate a portion of the solution by evaporation before a satisfactory reading could be obtained on the interferometer.

By this method the measurements of osmotic pressure are made on air-free solutions. Since the solubility of air in water under ordinary conditions is nearly 0.001 M, this may well affect the measurements which are made on dilute solutions, in which the solute is present to only a fraction of this amount. In the majority of instances this factor has been entirely neglected.

Details of the Apparatus

The thermostat used in this work was a cylindrical copper tank, sixteen inches high and of the same diameter. It was covered on the sides and bottom with a layer of asbestos. Vigorous circulation was effected by means of a three and one-half inch propeller with suitable baffles. No temperature difference could be detected with a Beckmann thermometer in various parts of the bath. The usual heating lamp in series with a lamp bank of nominally 300 volts, and coil carrying tap water for cooling were used. It was found necessary to shield the contents of the thermostat from strong light during the course of *a* run, due to local superheating. Consequently the windows and top were covered during these periods.

The thermoregulator was of the toluene–mercury type constructed as follows. Twelve feet of thin, one-quarter inch diameter copper tubing was coiled into a helix about twelve inches in diameter. One end was squeezed tightly together and soldered along the seam. To the other end a four-inch length of brass tubing of slightly larger diameter was fitted carefully and soldered. The other end of the brass tubing was attached to the glass part of the regulator by means of a "soldered joint." This was made as follows: the brass tube was reamed out sufficiently to allow the glass to slide inside for a distance of about an inch. The inside of the brass tube was "tinned" and a slight excess of solder melted into the inside. The glass was roughened slightly by rubbing with fine emery paper, carefully cleaned and dried. After having coated the surface of the roughened part with a layer of platinum (produced by evaporating a solution of platinum chloride on this surface and decomposing the chloride by heating to dull redness), the two pieces were heated to about the same temperature and pushed together.

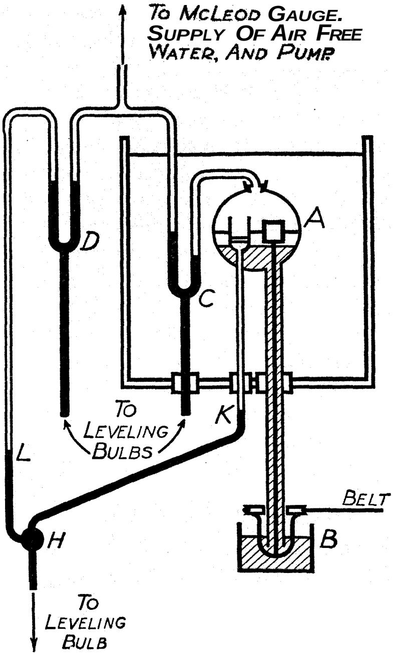

Fig. 1.

Under the best conditions the regulator described held the temperature of the bath sufficiently constant so that no movement of the mercury of the Beckmann thermometer was detected. The room temperature was held not more than two or three degrees from the temperature of the bath and in particular sudden fluctuations of temperature were avoided. It was found advantageous to make the measurements at night and in most instances this was done. In the experiments the bath varied slightly in temperature but not over two or three thousandths of a degree. As a matter of fact, due to the lag in registering, it is questionable whether the Beckmann readings are much more reliable than this. As will be shown later, this figure does not represent the difference in temperature between the solvent and solution, which is the important point. The temperature of the bath was determined by comparison with a thermometer standardized by the Bureau of Standards to 0.02°.

The porous disk was composed of equal parts by weight of the special clay used in this Laboratory for making osmotic pressure cells and Pyrex glass powder. The glass was first ground wet in an agate mortar, dried and sieved through a two hundred mesh sieve. The clay and glass were then thoroughly mixed together with the addition of the smallest amount of distilled water, moulded into a disk on a porous plate, dried at 100°, and then fired for about three-quarters of an hour at 850 to 900°. This is well above the melting point of Pyrex and it gave a disk of fair mechanical strength and good porosity. The sides and edges were ground smooth and the disk fused into a Pyrex glass funnel. The disks used were one inch in diameter and slightly less than an eighth of an inch in thickness. In preliminary tests, the capillaries in the disks held a pull of thirty-five inches of mercury and showed no indications of having reached their limit even at this figure.

In order to maintain the solution and the solvent in the porous disk at the same temperature, the glass funnel with its porous disk was placed within a large glass bulb of about 700 cc. capacity in the thermostat. Inside the bulb and surrounding the funnel was placed the solution which was floated on mercury. This arrangement gave the system a certain lag which—at least in part-counteracted the slight periodic changes in bath temperature incident to thermoregulator control and furnished good thermal contact between the solvent and solution.

The general arrangement of the apparatus is indicated in Fig. 1. A represents the bulb in the thermostat which holds the solution and the small glass funnel with its porous disk. Just to the right of the funnel is shown the stirrer, consisting of a small platinum paddle driven as indicated through a mercury seal at B.

From beneath the porous plate, a two millimeter capillary extended to a small bulb at H. This capillary contained the column of water which was placed under tension by the mercury in contact with it at K. In the absence of air no trouble whatever was experienced in getting the water to adhere to the plate, or the mercury to the water. Bulb H was connected by means of a length of rubber tubing to an ordinary leveling bulb which was open to the atmosphere. This permitted adjustment of the tension by moving the leveling bulb up or down by means of a screw.

Also from H a capillary tube extended vertically upward, giving a direct measurement of the zero reading of the mercury meniscus at I,. The upper part of this tube was completely evacuated and closed off by the mercury Y at D. By using the same size of tubing at K and I,, no correction for capillary depression was necessary.

A bulb of 300 cc. capacity was sealed into the system to provide a volume into which the vapor of the solution could be expanded. Another bulb containing air-free water was also sealed into the apparatus. This served as a source of water vapor to sweep the air from the system or to fill the space beneath the porous disk with water vapor. In the absence of air, it was a simple matter to distil water from one part of the system to another by a slight difference in temperature. Neither of these two bulbs is shown on the diagram.

The readings of the heights at K and at I, and of the surface of the solution in A were made by means of a cathetometer and a standard meter scale mounted vertically at a convenient distance.

Method of Procedure

Between 200 and 250 cc. of freshly redistilled water was collected in a Pyrex Erlenmeyer flask fitted with a cork stopper covered with tin foil. After cooling, the flask and water were weighed and an amount of pure salt was added to give approximately the desired concentration. This solution was run into a round Pyrex bulb of about 300 cc. capacity provided with a glass stopcock on one side. To the opposite side of the bulb, an ordinary mercury leveling bulb was attached by means of a rubber tube and about four inches of glass tubing. The height of mercury was adjusted so that the mercury came just to the glass bulb and the rubber tubing was closed with a screw clamp. The solution was then readily introduced by partially evacuating the bulb and connecting a glass funnel to the outer end of the glass stopcock by means of a short piece of clean rubber tubing. On opening the stopcock the solution was quickly drawn in.

The bulb was tilted at a slight angle and the solution brought to the boiling point by placing a small flame underneath. The solution was allowed to simmer for some minutes with the stopcock left open. The elimination of air from the solution is a direct function of the time and it was found advantageous to extend this simmering period for an hour or even longer. The solution was then heated to vigorous boiling for a moment or two in order to expell completely the air from the vapor space above the liquid, and while still boiling the mercury was allowed to run in rapidly from beneath, forcing the solution up past the stopcock, which was at once closed. After allowing the whole to cool, a short piece of rubber tubing was attached and sufficient mercury added from a small pipet to displace the solution above the stopcock and completely fill the rubber tubing. One end of a capillary glass tube about nine inches long was then forced into the rubber connection so that the mercury went part way up the capillary. The other end of the glass tube had previously been drawn out and the tip bent up at an angle.

In order to introduce the solution into the apparatus the system was evacuated completely and filled with water vapor to prevent the sudden evaporation of the first solution added. The tip of the capillary tubing was placed beneath the mercury, which sealed the stirrer column (at B in the figure), the screw clamp removed and the stopcock opened sufficiently to let a little of the solution by. This pushed a column of mercury down the capillary tube, which forced the air ahead of it. The tip was then hooked beneath the end of the glass tube carrying the stirrer shaft and the solution flowed in slowly and up the tube. Under these conditions it was possible to introduce the solution nearly air free and without spattering.

To remove the slight amount of remaining air, the solution was stirred and the vapor above the liquid drawn off at periodic intervals. The system beyond the trap C in the thermostat was evacuated by means of the pump. The mercury seal located between trap C and the pump was closed and C opened momentarily. This was repeated about every ten or fifteen minutes at first and less frequently as the amounts of air decreased. About a day was generally required to reduce the air to 0.0001 mm. pressure, as read on the McLeod gage, after standing for a fifteen-minute period. This was probably about one-third that actually present above the solution. On standing overnight less than 0.001 mm. developed.

It was found possible to make measurements with a somewhat greater amount of air than this (0.0001 mm.) and in most instances this was done. As far as could be noted the rates of distiilation observed were nearly independent of the amounts of air present at these very small concentrations.

As soon as the solution was practically air free, a small amount of water was evaporated over into the bulb at H, either from the solution or the supply in the bulb provided. It was found possible to distil this water directly through the disk and this had the advantage of partly sweeping any air ahead of it, so that the air could more easily be removed. All but the smallest trace of air had to be eliminated from beneath the porous disk or the water would not adhere. The last trace of air dissolved in the liquid and when once the liquid stuck no further trouble was encountered. In fact, the column of water beneath the disk could be left adhering to the disk from one experiment to the next even though the space above the disk was exposed to the atmosphere. In order to make the liquid break away from the under side of the disk it was necessary to force the water completely through the disk. Then the mercury column could be broken in the larger part of the column.

After the water had stuck to the lower side of the disk, if necessary, the mercury meniscus could be drawn up by opening the solution (and upper side of the disk) directly to the pump for a moment or two at a time. About one millimeter evaporation could be obtained at each opening. It was found best to adjust the mercury so it could be read beneath the bottom of the thermostat, since in this way greater accuracy could be obtained than by looking through several inches of water and, also, the necessity of directing a strong beam of light through the thermostat was avoided.

As soon as the mercury height at K had been adjusted, the space above I, was completely evacuated and closed off. Measurements could then be started when sufficient time had elapsed for the system to come to temperature. At least an hour, and frequently longer, was required for conditions to become constant after any removal of vapor or slight change in temperature.

By means of the leveling bulb connected to H, the desired tension (as indicated by the height of the mercury at L) was placed on the water. The reading at L was at once taken and the hair line of the cathetometer focused on the meniscus at K. The upward movement of the mercury was followed by means of the cathetometer screw and the readings were immediately plotted against the time. This had the advantage of indicating how soon constant conditions were obtained. A precaution was taken to approach the reading from the same direction in order to eliminate any possible play in the cathetometer. As soon as the desired number of readings had been taken, the zero point was generally redetermined and a new set of readings started. It was of interest to note the increased recession of the water into the capillaries of the porous disk as the amount of tension was increased.

As soon as the series of measurements on any one solution had been completed, air was admitted to the system and a sample of solution removed for analysis in the interferometer.

Determination of the Osmotic Pressure

The tension exerted was made up of three parts: first, a portion of the mercury column; second, the water from the meniscus of the mercury to the porous disk, and third, the net height of vapor between the surface of the porous disk and the surface of the solution. This last component will be equal to a column of water of the same height, for if we consider a column of water under tension separated from a column of vapor by a suitable membrane (for example, a porous plate) and that equilibrium exists at one point, it is seen that equilibrium must exist throughout the whole column. The fact must also be taken into account that the vapor pressure of the solution is present in the bulb and lacking above the zero reading at L.

The tension can then be calculated by adding together the vapor pressure of the solution at the temperature in question, the mercury equivalent of a column of air-free water from K to the surface of the solution, and the reading at K. The zero reading at L is subtracted from this total. Throughout, the measurements are corrected to the density of mercury at 0°.

Whenever the tension was closer to the equilibrium point than four or five millimeters, it was not possible to obtain good rates of distillation. The same held true if the total pull on the plate was reduced below about five millimeters. It was also not found possible to make measurements of back distillation, that is, from the solution to the plate.

In order to determine the osmotic pressure of the solution, the various rates of distillation were plotted as ordinates against the tensions as abscissas. The points fell on a straight line which could readily be extrapolated to zero.

During the distillation the high heat of evaporation acted to cool the surface of the disk and to warm the solution. Probably the small thermal head causing heat to return to the disk by conduction was largely responsible for the slow rates of evaporation found. However, the rate of heat flow will depend on the temperature difference between various parts of the system and this, in turn, on the evaporation and condensation of the liquid. Consequently, in the last analysis, the rate will be indirectly dependent alone on the differences in vapor pressure as controlled by the concentration of the solution and the amount of tension on the plate. Zero distillation must represent temperature as well as pressure equilibrium.

In conclusion, the author wishes to express his appreciation to Dr. J. C. W. Frazer and to Dr. W. A. Patrick, who suggested this investigation and under whose supervision it was performed.

Summary

A new method for measuring osmotic pressure has been described which can be applied to dilute solutions of any non-volatile solute in a volatile solvent.

This method makes use of the vapor phase as a diaphragm which separates the pure solvent from the solution and is permeable to the solvent only. The pure solvent is located at the surface of a porous plate in such a way that a tension can be applied to the liquid. This changes the

normal curvature of the surface so that the vapor pressure of the liquid is reduced. The rates of distillation from solvent to solution under different tensions were measured and these plotted to give the tension corresponding to equilibrium or the osmotic pressure.

This method extends the possibility of direct osmotic pressure measurement to aqueous solutions of electrolytes and possibly colloids, and to solutions in organic liquids. It is particularly applicable to extremely dilute solutions where a knowledge of the properties is desirable from a theoretical standpoint. Moreover, it has the advantage that measurements are made under air-free conditions.

A STUDY OF VAPOR PRESSURES IN SMALL CAPILLARIES. PART I. WATER VAPOR. (A). SOFT GLASS CAPILLARIES[1,2]

BY J. L. SHERESHEFSKY

RECEIVED AUGUST 2, 1928 PUBLISHED NOVEMBER 6, 1928

Introduction

When a liquid bounded by a curved surface is in a state of tension, the pressures on each side of the surface layer are not equal. The pressure on the concave side of the surface is greater than that on the convex. When such a system is in a state of equilibrium we know from the laws of mechanics that the algebraical sum of the work done by these forces when the body undergoes a small displacement is zero. This pressure difference as deduced on the basis of the well-known theory of Laplace, in the case of a sphere of radius r, is given by the equation

$$p = \frac{2\sigma}{r} \qquad (1)$$

where a is the surface tension.[3]

Suppose we have a capillary dipped into a liquid contained in a large vessel. At the plane surface, since the radius of curvature is infinite, the pressure difference, p, is zero. On the other hand, at the concave side of the meniscus

$$p = \frac{2\sigma}{r} \qquad (2)$$

r being assumed to be equal to the radius of the capillary. Since the vapor pressure of the liquid in the capillary is lower than the vapor pressure of

[3] "Scientific Papers," Vol. II, p. 564, by Clerk Maxwell.

the liquid over the plane surface, we may look upon the surface layer in the capillary as upon a semi-permeable membrane on which it is necessary to impose a pressure, p, in order to produce the above lowering of the vapor pressure.

The relationship between the pressure, p, and the vapor pressure, P, is expressed by the equation of Willard Gibbs

$$-\frac{dP}{dp} = \frac{v}{V} \tag{3}$$

which states that the change of vapor pressure, P, with respect to the pressure, p, is equal to the ratio of the molar volumes of the substance in the liquid state, v, and the gaseous state, V.

Assuming that at low pressures the gas laws hold, we obtain by substitution in Equation **3** and subsequent integration

$$\ln P = -\frac{v}{RT}p + C \tag{4}$$

When p is zero, that is, in the case of a plane surface, the vapor pressure is P_0, and

$$C = \ln P_0 \tag{5}$$

Substituting in the above, we get

$$\ln P = -\frac{v}{RT}p + \ln P_0 \tag{6}$$

or

$$\ln \frac{P}{P_0} = -\frac{V}{RT}p \tag{7}$$

Combining with Equation 1, we obtain the expression

$$\ln \frac{P}{P_0} = -\frac{V}{RT}\cdot\frac{2\sigma}{r} = -\frac{2\sigma v}{RTr} \tag{8}$$

which is the well-known equation first deduced by Lord Kelvin,[4] where P_0 and P are the vapor pressures over the plane and concave surfaces, respectively, at temperature T, R is the universal gas constant, a is the surface tension and v and r are as indicated above.

Laplace in his monumental work on capillarity assumes that the forces that give rise to capillary phenomena are "insensible for sensible distances, and sensible for insensible distances," that is, as far as surface tension is concerned, its value would be the same for small drops, or liquids in small capillaries, as for liquids in bulk. Thus surface tension would begin to undergo a change only when the radius of the drop or the capillary would approach the range of influence of molecular forces, which he assumed to be the same for all substances. This led many experimenters to measure the radius of molecular forces.

Plateau[5] observed the thickness of soap bubbles and concluded that the

---

[5] Plateau, "Statique experimentale et theorique des liquides."

range is not larger than 0.056μ. Drude's[6] observations assign a value of 0.009μ, while Reinold and Rucker[7] give about 0.006μ.

Quincke,[8] using a different method, measured the range to be about 0.05 and 0.08μ.

Here it is noteworthy to mention that Plateau also observed that the viscosity of the surface layer in thin films is different from that of the interior of the liquid, and that this viscosity change varies in sign with different liquids, a fact that would justify us in doubting whether the above values correspond to the magnitude of the range of molecular forces in the interior of the liquid.

In light of the above discussion of the fundamental assumptions of Laplace and the experimental facts concerning thin films, it would appear that the surface tension term in Equation 8 is constant and does not depend on the radius of the capillary, but this conclusion is not in conformity with many experimental facts and certain theoretical considerations that will follow.

Patrick and Eberman[9] in correlating the extensive work of the former and his collaborators on adsorption by silica gel from both liquid and vapor phases, express the internal volume of a gram of gel by the equation

$$V = Kr^{1/n} \tag{9}$$

since adsorption by silica gel is caused by the capillaries in the adsorbent. By combining this equation with Equation 8, they eliminate r and get a relationship between volume adsorbed, V and the equilibrium pressure, P. Calculating r from Equation 8 they plot V against the radius for many substances. They state "it is obvious that if we plot radius as found by Equation 8 against (V) as measured, we should obtain a parabolic curve which should be the same for all substances adsorbed by the same sample of gel whether from the gas or from solution—regardless of temperature. For, if adsorption consists in capillary condensation, the same volume of internal gel space must hold the same volume of liquid regardless of circumstances."

The curves that they obtain for water, sulfur dioxide at different temperatures and butane are parabolic but do not coincide. After a consideration of such factors as density and molecular weight that figure in Lord Kelvin's equation and also the possibility of polymerization, they come to the conclusion that "the surface tension of a liquid is a function of curvature; that a liquid existing in small drops has a much lower surface tension than ordinarily, and that the liquid has a much greater surface tension if its surface is highly concave. . . ."

Patrick, Preston and Owens[10] studied the adsorption of carbon dioxide at several temperatures by silica gel, expressing the adsorption equilibrium by the equation

$$V = K\left(\frac{P\sigma}{P_0}\right)^{1/n} \tag{10}$$

where V is the volume adsorbed, P_0 the saturation pressure and P the equilibrium pressure, and K and n are constants dependent upon the sample of gel used. Plotting log V against log $(P\sigma/P_0)^{1/n}$, they get a straight line, where $(1/n)$ is the slope of the curve and K the intercept on the log $(P\sigma/P_0)^{1/n}$ axis. They find that only when the surface tension term σ varies are they able to have the curves at the various temperatures coincide, that is, to get the same value for K. They also deduce that the change of a with the radius is greater at higher temperatures, that is, $d\sigma/dr$ is also a function of temperature. Further evidence as to the increase of surface tension with the decrease of the radius of the capillary is given by the reported changes in physical properties of liquids such as freezing point, critical temperature and density.

F. W. Parker[11] observed a depression of the freezing point of water, benzene and nitrobenzene when contained in capillary systems. Plotting liquid content against freezing-point depression, he obtained curves showing a gradual increase in depression with decrease in liquid content—in other words, with decrease of capillary radius—in case of the latter two liquids, and a rather steep curve indicating an enormous increase in depression with decrease of liquid content in case of water.

Bouyoucos and McCool[12] ascribe this phenomenon mainly to the dissolved impurities. While this cannot be true of benzene and nitrobenzene, it is surely the case with water; for, if we consider the phase diagram of the system, water and ice, we notice that the equilibrium curve is inclined toward the pressure axis, that is, the temperature increases with decrease in pressure and, inasmuch as the water in a capillary system is under a negative pressure, we should expect a rise in the freezing point.

A. S. Coolidge,[13] similarly, finds that the adsorption isotherm for benzene is continuous when the free liquid is below the freezing point, that is, the adsorbed material is in a liquid state even below the freezing point of the free liquid.

Patrick, Preston and Owens[10] observed no break in the adsorption of carbon dioxide and nitrous oxide between the temperatures 30° and 40°, thus indicating a rise in the critical temperature of the adsorbed substance. The significance of the above phenomena is very well pointed

out by Patrick and Eberman,[9] "if condensation of a gas does take place in a capillary above the critical temperature and, in other cases, at pressures always below the saturation pressure; and, if adsorption does take place from liquids above the critical solution temperature—it follows that the critical temperature for a fluid in a capillary is higher. If the critical temperature is higher, the surface tension must be correspondingly higher, inasmuch as the temperature–surface tension curve cuts the temperature axis at or near the critical temperature."

Leslie[14] was the first to show that the rise of a liquid in a capillary was due to the greater pressure in the stratum of liquid adhering to the wall. The direct result of the excess pressure normal to the side of the tube would be to spread the liquid over the surface of the solid. When we plunge a capillary into a liquid, the above pressure would cause the liquid to spread and cover all the surface of the tube were it not for the liquid adhering to the ascending film and balancing the pressure and in this way stopping further wetting of the solid. We may look upon this tendency to spread as a result of a negative pressure or a tension in the film, which is balanced in case of a capillary open at both ends. Were we to prevent by some method some liquid from adhering to the ascending film, the pressure would remain unbalanced, unless the tension in the adhering film increases. This is precisely the condition existing in a capillary closed at one end and partly filled with liquid. It is obvious that the tension would increase with decreasing radius. This theory was expressed by W. A. Patrick[15] as follows, "a film-of molecular thickness may have the same surface tension as the liquid in bulk, but when this film is stretched, it is certain that such an operation will cause, according to the principle of Le Chatelier, an increase in the surface tension of the liquid film." Independently and from different considerations Freundlich[16] arrives at the same conclusions.

Experimental

Let vessel A containing a capillary be in communication with vessel B containing some aqueous solution, and let us assume that the water vapor has wetted the walls of the capillary. If the vapor pressure of the solution is greater than the vapor pressure of pure water in the capillary, the vapor will condense and fill up the capillary. Now, if we concentrate by some method the solution in B until its vapor pressure is lower than the vapor pressure of pure water in the capillary, the process will be reversed and evaporation of the water in the capillary will take place. The condition under which no evaporation from or condensation into the capillary will take place will indicate a state of equilibrium at which the vapor

---

[15] Patrick, *Kolloid-Z.*, *36*, 276 (1925).

[16] Freundlich, "Kapillarchemie," Akademische Verlagsges., Leipzig, 1922, p. 63.

pressure of the pure water in the capillary is equal to the vapor pressure of the solution.

To attain a state of equilibrium by trying solutions of various strengths would be rather tedious and time consuming. Furthermore, it would involve a complication in the temperature control, since the attainment of an equilibrium state would extend over a period of hours beyond the constancy of any temperature regulating device.

This difficulty may be overcome by measuring the rate of condensation or evaporation. If we start with a dilute solution whose vapor pressure is known and which is higher than the vapor pressure of pure water in the capillary, vapor will condense into the capillary with a rate proportional to the vapor pressure difference, $\Delta p = p_1 - p_2$, where p_1 is the vapor pressure of the solution and p_2 that of water in the capillary. For a given capillary p_2 is constant. By concentrating the solution we decrease p_1 and simultaneously Δp, and also the rate of condensation. If we continue to concentrate the solution we may reach values for p_1 which will be lower than p_2, Δp being negative. In such cases we measure the rate of evaporation from the capillaries. Now, if we plot these values of Δp against the rate we get a curve that approaches assymptotically the rate axis from two directions. By extrapolation we may evaluate the point of equilibrium when $\Delta p = 0$ and $p_1 = p_2$. Since p_2, the vapor pressure of pure water in a given capillary, is constant, we plot p_1 against rate and the extrapolated value will be p_1 when $\Delta p = 0$, that is, it will give us the value for p_2.

In a system completely freed from air the rates of condensation or evaporation are measurable quantities, as it was shown in the course of this experiment. The vapor pressure was not measured directly. It was calculated from the measured concentration as determined by conductivity. For this reason we have used potassium chloride solutions whose vapor pressures for a wide range of concentrations have been very accurately measured in this Laboratory by Frazer, Lovelace and Sease.[17] For calculations of the vapor pressures of very dilute solutions we have also used the freezing point data collected by Noyes and Falk.[18]

Apparatus

The apparatus as shown in the accompanying Fig. 1 is merely an elaborated form of the simple scheme we have discussed in the previous section.

It is made of soft glass. The two bulbs A and B serve as reservoirs of pure water; their capacity is 500 cc. each. To one of the bulbs is attached a side arm, C, through which the liquid is introduced. The tube connecting the water reservoir with the rest of the apparatus is surrounded by a water jacket, D, to keep the liquid from spreading over the apparatus when it is distilled from one bulb into the other.

---

[17] Frazer, Lovelace and Sease, THIS JOURNAL, 43, 102 (1921).

[18] Noyes and Falk, *ibid.*, 32, 1020 (1910).

The rest of the apparatus consists of three branches. One branch connects (through the mercury trap F) the water reservoir with the conductivity cell E, designed for the purpose of measuring the change in conductivity of the pure water from time to time during the course of the experiment. The second branch connects the water reservoir, through the mercury traps, G, H and K, with the conductivity cell L, containing the potassium chloride solution. This cell is in communication with the mercury reservoir N, and the mechanical stirrer, O, designed to stir the solution. The third branch connects through the mercury traps, G, H and R, the water reservoir with the vessel, S, containing the capillaries. The capillaries may be brought in contact with the solution by closing trap H and opening the traps, K and R. The trap T connects or disconnects the whole apparatus, or each branch individually, with or from the mercury diffusion pump, J, and the auxiliary Cenco high vacuum pump (not shown on the diagram).

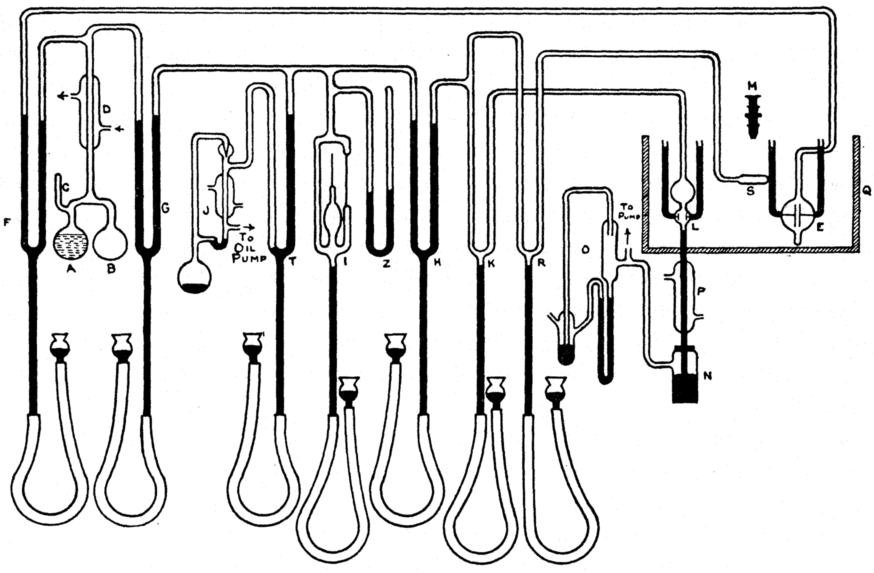

Fig. 1.

I and Z are a McLeod gage and a closed manometer, respectively. The vessels, L, S, and E are immersed in an accurately regulated thermostat, Q. The filling or the emptying of the capillaries is observed through the microscope, M, whose objective is an inch and a half below the surface of the water in the thermostat. The field is illuminated by a 150-watt lamp whose rays are made to pass through a vessel filled with water to absorb the heat rays, and then brought to a focus at a point on the capillary under observation by a system of lenses.

Capillaries

If we calculate from Equation 8, deduced by Lord Kelvin, the percentage lowering of the vapor pressure of water due to capillarity, we notice that the lowering is inappreciable until we approach the magnitude of 1×10^{-4} cm. for the radius of the capillary. As seen from Table I the percentage lowering increases very rapidly with decrease of radius.

TABLE I

CHANGE IN PERCENTAGE LOWERING

r, cm.	1×10^{-4}	0.8×10^{-4}	0.6×10^{-4}	0.4×10^{-4}	0.2×10^{-4}	0.1×10^{-4}
$100\Delta p/p_0$	0.01	0.14	0.18	0.27	0.53	1.06

Although a more pronounced effect in the lowering of the vapor pressure was expected, we were certain to have to work in about the same region of magnitudes. Furthermore, the capillaries had to be uniform in bore for a considerable length.

The method devised for producing such capillaries proved to be very successful. It consists of a string supported by two pulleys attached to the ceiling; on one end of the string a weight is hung and the other end is fastened to the top of a short length of capillary tubing of about 0.5mm. diameter. This tubing is clamped to the table top.

When a small area of the tube is heated up to a bright red heat the weight is allowed to fall, thus drawing out the heated portion of the tube to 4 meters—the distance between the table top and the ceiling.

The burner used in heating the tube consisted of a terra cotta cylinder with six evenly distributed perforations normal to the walls. Glass tubes with fine jets at one end are placed in these perforations in such a manner that the jets point toward the center of the cylinder. The ends that protrude outside the cylinder are connected by means of T-tubes, producing the effect of a wheel. A mixture of gas and air introduced into these jets produces a very intense and fine circular flame. The smallest capillary we have been able to draw by this method had a radius of 0.25μ.

Microscopic Measurements

The bore of the capillaries was measured microscopically. For capillaries ranging between 1 and 4μ in radius a combination of lenses giving a magnitude of about 900 is sufficient. Such a magnification was obtained by using a fluorite objective of focal length *2.6* mm. and initial magnification of 70 in combination with a filar screw micrometer eyepiece of a magnification of 12.5, giving a total magnification of 875 times.

The filar screw micrometer has been calibrated against an objective micrometer divided into 0.01 mm. Knowing the number of divisions on the eyepiece micrometer that correspond to one division on the objective micrometer, we may replace the latter by a capillary and determine its size.

The hollow of a capillary tube when observed under a microscope appears black at the sides of the wall and shades off into a gray toward the center of the capillary when the hollow is filled with a gas or a vapor. In case the capillary is filled with a liquid, the hollow appears bright and bounded by very thin black lines at the interface of the liquid and the glass.

Thermostat

The thermostat as shown in Fig. 1 contained the two cells and the capillary vessel. The former were in the main body of the thermostat; the latter was placed in a chamber projecting out at the side and in full communication with the rest of the thermostat. The projecting side chamber had a window through which the capillaries were illuminated.

The water in the thermostat was agitated by two stirrers symmetrically placed. The heating device was made up of two 150-watt Westinghouse heating lamps, and water running through a copper coil was used for cooling the thermostat.

The thermo-regulator was of the toluene–mercury type. It consisted of twenty feet of half-inch copper tubing coiled into a helix nine inches in diameter, filled with toluene and sealed to a glass head. The temperature of the thermostat was kept at 18° as read from Bureau of Standards thermometer No. **31091.**

The constancy of the temperature was read from two Beckmann thermometers graduated in **0.001°.** One was placed near the solution cell and the other near the capillary vessel, The thermometers indicated a temperature lower by **0.003°** at the solution cell. This was probably due to the fact that the solution cell was nearer to the cooling coil than the capillary vessel. For any one portion of the thermostat the temperature remained constant to 0.002° for over ten hours.

Observations

It was noted quite early in the course of the experiment that the condition of freeing the system of air was essential. Air present in the system clogged the capillaries and interfered with the formation of a uniform unbroken column of liquid. A capillary column formed under such conditions was invariably made up of a chain of intermittent air and water layers. As the system was made more air-free, this effect was minimized but even a slight trace of air remaining in the system was sufficient to cause the formation of broken columns of water.

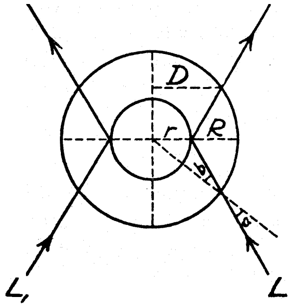

Fig. 2.

Although the above phenomenon prevented the measuring of the rate of condensation or evaporation, it did not interfere with the process of condensation per se.

Experiment I.—The capillary chamber was filled with water vapor by bringing it into communication with the water reservoir for a moment. The chamber was closed and allowed to stand for several hours until the capillaries were filled. The chamber was opened to the potassium chloride solution by closing trap H and opening traps K and R. The five capillaries were observed for several hours; no evaporation from any one occurred.

The chamber and the concentration cell were discommunicated, and the conductivity of the solution determined after the solution in the cell was thoroughly stirred. To verify the observation the process was reversed. The capillary chamber was evacuated and brought into communication with the solution cell by adjusting the traps as above. The capillaries seemed to fill up slowly. They were left in this condition for several hours until they filled up completely. Then they were discommunicated and the conductivity of the solution measured again.

TABLE II

MEASUREMENTS

X = 30.2; $(\Lambda_0-\Lambda)$ = 17.5; Concn. = 0.11; $(P_0-P_1)_X$ = 0.055

Capillary	I	II	III	IV	V
r (μ)	**1.076**	**2.284**	**2.443**	**3.019**	**4.052**
$(P_0-P_1)_K$	**0.015**	**0.007**	**0.007**	**0.0056**	**0.004**

Table II gives the observed measurements of the radii, r, of the capillaries; X, the resistance of the solution, $(P_0 - P_1)$ the vapor pressure lowering corresponding to the measured resistance, X, and $(P_0 - P_1)_K$ the vapor pressure lowering as calculated from the equation of Lord Kelvin.

Experiment 11.—The solution in the cell was concentrated by bringing the latter into communication with the reservoir which was subjected to an ice-bath. When the resistance indicated a concentration of about 0.13-0.14 N, the concentrating process was stopped.

The capillaries were allowed to fill up in a manner similar to Experiment I. When they were brought in contact with the solution, no signs of evaporation were observed. When the reverse process was carried out the capillaries filled up. Table III records the measurements of this experiment.

Experiment 111.—The solution was still further concentrated, and the experiment carried out as before. The data of this experiment are given in Table IV.

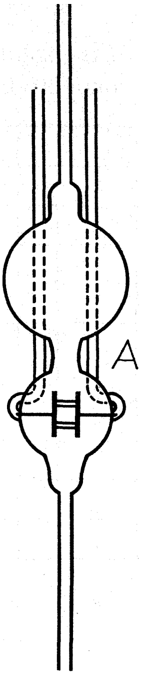

Fig. 3A.

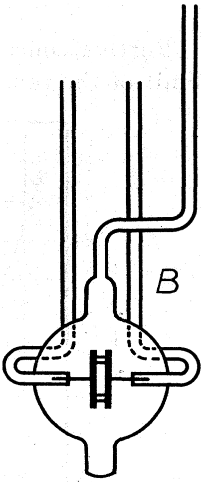

Fig. 3B.

Experiment IV.—When the solution was concentrated still further and the full capillaries were opened to the solution, Capillary V began to vaporize. The others did not show any change. When the procedure was reversed, Capillaries, I, II, III and IV filled up, but Capillary V remained empty. This observation was reproduced twice. Table V gives the data of this observation.

Table III

Measurements

X = 26.9; $(\Lambda_0 - \Lambda) = 18.45$; Concn. = 0.12; $(P_0 - P_1)_X = 0.060$

r (μ)	1.076	2.284	2.443	3.019	4.052
$(P_0 - P_1)_K$	0.015	0.007	0.007	0.0056	0.004

Table IV

Observations

$X = 23.4$; $(\Lambda_0 - \Lambda) = 19.35$; Concn. = 0.148; $(P_0 - P_1)_X = 0.074$

Capillary	I	II	III	IV	V
r (μ)	1.076	2.284	2.443	3.019	4.052
$(P_0 - P_1)_K$	0.015	0.007	0.007	0.0056	0.004

TABLE V

OBSERVATIONS

$X = 18.1$; $(\Lambda_0-\Lambda) = 20.95$; Concn. $= 0.183$; $(P_0-P_1)_X = 0.092$

Capillary	I	II	III	IV	V
r (μ)	1.076	2.284	2.443	3.019	4.052
$(P_0-P_1)_K$	0.015	0.007	0.007	0.0056	0.004

Further concentrating of the solution was not advisable since the higher limit of the range of the conductivity cell had been exceeded already.

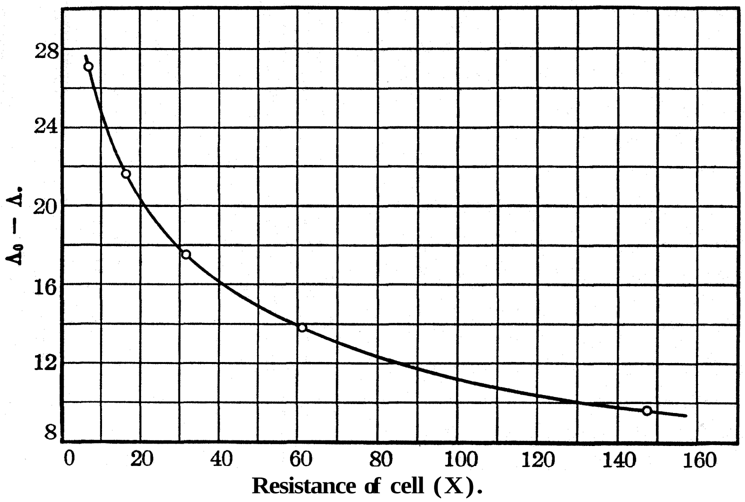

Fig. 4.

The values in Tables II, III, IV and V were obtained in the following manner. Knowing X and Λ_0 which is 129.5, the value for Λ was read from Fig. 4. Substituting these values, and also the relative viscosity read from Fig. 5, in the equation of Bates, the concentration was obtained. $(P_0 - P_1)_X$ was read from Fig. 6. The value for $(P_0 - P_1)_K$ was calculated from Lord Kelvin's equation.[19]

Since $V = M/D$, where M = mol. wt. and D = density

$$\log \frac{P_1}{P_0} = -\frac{0.4343 \times 2\sigma M}{RT\,d\,r} = \frac{-0.4343 \times 2 \times 73 \times 18.016}{8.32 \times 10^7 \times 291 \times 0.99862 \times 1.076 \times 10^{-4}} = 0.00044$$

$$\log P_1 = \log (P_0) - 0.00044 = \log (15.477) - 0.00044 = 1.18925$$

$$P_0 - P = 0.015 \text{ mm. of mercury.}$$

Although we have not as yet been able to determine quantitatively the vapor pressure lowerings corresponding to each capillary, we have definitely established that the lowering is enormously greater than can be accounted for by Lord Kelvin's equation.

---

[19] Calculation: $\ln \frac{P_1}{P_0} = -\frac{2\sigma V}{RTr}$, or $\log \frac{P_1}{P_0} = -\frac{(0.4343)(2\sigma V)}{RTr}$.

Experiment IV also indicates an approximate value for the lowering of the vapor pressure in a capillary of about 4×10^{-4} cm. in radius.

According to the classical equation, the vapor pressure lowering for a capillary of 4.052μ in radius is 0.004 mm. of mercury. The value we have obtained is approximately 0.092 mm. of mercury, *23* times as great.

Now, if we consider for a moment Equation 8 we see that its right-hand member contains two terms, a and V, surface tension and molal volume, respectively, properties of liquids that would be different in a capillary from liquid in bulk. Which term must be changed in order to account for the enormous increase in the term $\ln (P_1/P_0)$? While it is possible that the molal volume V would be increased due to the decrease in density, it is highly improbable that the decrease in density would assume such magnitudes. The increase in the left-hand term must therefore be due mainly to the increase in the surface tension term, a.

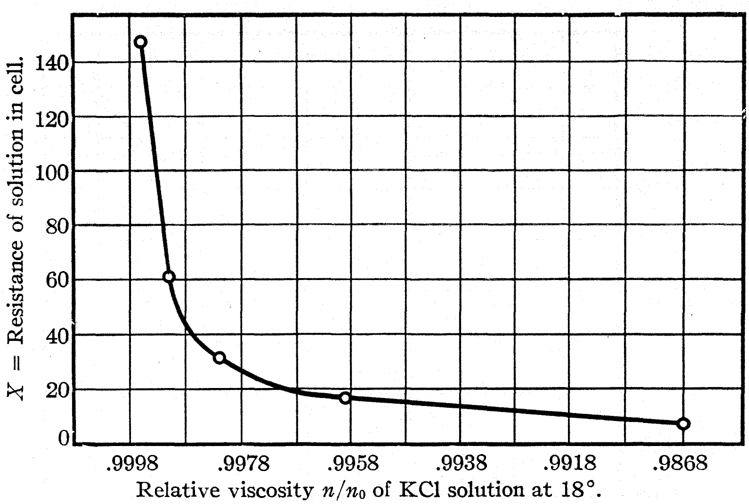

Fig. 5.

(B). Quartz Capillaries

If the depression of the vapor pressure in a given capillary is due to capillarity alone, then the rate of evaporation into a solution of a given concentration should stay constant irrespective of time. It was found, however, that in case of capillaries made of soft glass the rate of evaporation into a solution of a given concentration became smaller and smaller with time, the measurements being taken at one hour intervals. This indicated that the pressure became less and less. Since the solution was kept at the same concentration, the vapor pressure of the water in the capillary must have become lower. The latter could be due only to the solubility of the glass. In order to eliminate the effect of solubility mentioned above, it was decided to make similar studies in which the glass capillaries should be replaced by capillaries made of pure quartz.

Method

The apparatus was essentially the same as described in the foregoing work with the exception of the observing instrument, which consisted of a microprojector with a scale in the eyepiece instead of a microscope.

The procedure was to open a full capillary to the vapor of a concentrated solution of potassium chloride and observe the time required for a definite length of the water column in the capillary, as read on the scale in the eyepiece, to evaporate.

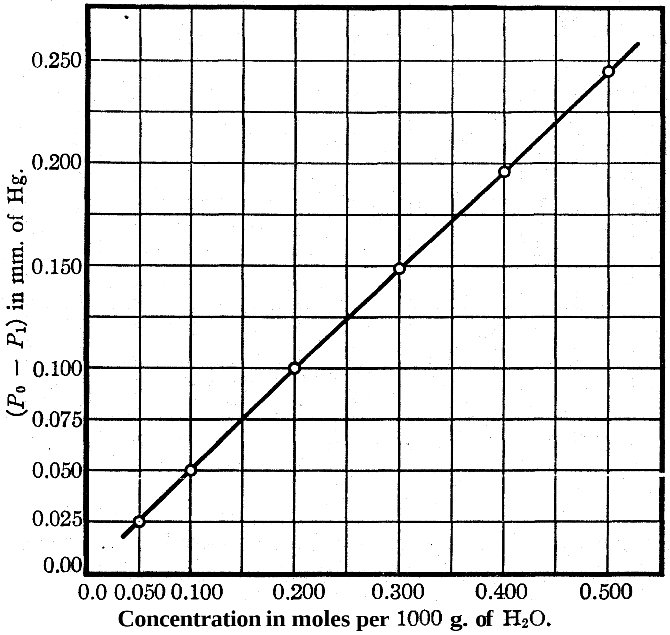

Fig. 6.

For a given capillary the rate of evaporation is proportional to Δp, the pressure difference between that of water in the capillary and the potassium chloride solution. Having obtained various rates corresponding to different concentrations of the solution, a curve was plotted of rate against Ap. The intercept on the Ap-axis will be the depression of the vapor pressure in the capillary.

Quartz Capillaries

These capillaries were drawn by the same method as described previously for the production of soft glass capillaries. Their size had been measured by means of a microscope supplied with a filar screw micrometer, and the true size calculated by using the approximate formula $r = D/n$, where D is the apparent radius and n the refractive index of the quartz.

Table VII gives the rates of evaporation from a capillary 5.51μ in radius, the corresponding concentrations of the potassium chloride solution and the lowering of the vapor pressure $P_0 - P_1$ where P_0 is the vapor pressure of water and P_1 is that of the solution.

TABLE VI

DATA WITH QUARTZ CAPILLARY

$r = 5.51\mu$ $t = 18°$

Expt.	Rate, mean value	Soln., N	$\Delta p = P_0 - P_1$, mm. Hg	Date of expt.
1	562	0.4105	0.205	Jan. 10 3 P.M.
2	284	.2154	.109	Jan. 6 4 P.M.
3	276	.2154	.109	Jan. 7 2 P.M.
4	235	.1815	.092	Jan. 8 11 A.M.
5	181	.1440	.074	Jan. 7 8 P.M.
6	179	.1345	.068	Jan. 11 3 P.M.
7	155	.1090	.056	Jan. 12 11 A.M.
8	127	.0930	.048	Jan. 11 8 P.M.
9	97	.0785	.041	Jan. 12 2 P.M.
10	93	.0690	.036	Jan. 13 11 A.M.

In the above table we observe that although there is a lapse of time of twenty-two hours between Measurements 2 and 3, there is a very slight change in the rate, showing that the solubility of the quartz is insignificant. When we plot the rate against Δp, a straight line is obtained which cuts the Δp-axis at 0.05 mm. of mercury. This means that at zero rate, when no evaporation takes place, that is, when the vapor pressure of the solution is equal to the vapor pressure of the water in the capillary, the depression is equal to 0.005 mm. of mercury.

The value calculated by means of Lord Kelvin's equation

$$\ln \frac{P_1}{P_0} = -\frac{2\sigma M}{RT\,dr}$$

is equal to 0.004 mm. of mercury.

TABLE VII

OBSERVATIONS

$r = 2.07\mu;\ t = 18°$

Expt.	1	2	3	4	5	6	7
Rate, mean value	471	340	288	270	213	144	78
Soln., N	0.4285	0.3508	0.3585	0.2982	0.2780	0.2304	0.1890
$\Delta p = P_0 - P_1$, mm. Hg	0.216	0.175	0.179	0.154	0.140	0.116	0.096

The curve derived from the data given in Table VII cuts the Δp-axis at 0.068 mm. of mercury, thus indicating that the depression of the vapor pressure in a capillary 2.07μ in radius is 0.068 mm. of Hg.

The straight line does not run parallel to the one for the larger capillary considered above but recedes from the rate axis with time, showing a slight solubility effect increasing with age of the capillary, that is, with the time the capillary is in contact with water. The value calculated by means of Lord Kelvin's equation for this capillary is 0.08 mm. of mercury.

In conclusion, the author wishes to express his appreciation to Dr. W. A. Patrick, who suggested this research and under whose supervision it was performed. He is also indebted to Dr. J. C. W. Frazer for his interest and advice rendered during this investigation.

Summary

1. A method is described for measuring vapor pressures of liquids in small capillaries.

2. By means of this method it has been established that the vapor pressure lowering of water in small capillaries is much greater than can be accounted for by Lord Kelvin's equation.

3. It is shown that the greater lowering of the vapor pressure is due to the increase in surface tension.

A STUDY OF VAPOR PRESSURES IN SMALL CAPILLARIES. PART II[1]

BY J. L. SHERESHEFSKY

RECEIVED AUGUST 2, 1928 PUBLISHED NOVEMBER 6, 1928

Paper I dealt with the direct measurement of vapor pressures of water in glass and quartz capillaries. It was found that in case of capillaries made of thermometer glass the lowering of the vapor pressure was abnormally great. It was first suspected and afterward shown that a great fraction of this lowering was due to the solubility of the glass. From this point the work proceeded with quartz capillaries. The quartz from which the capillaries were drawn was obtained from the General Electric Company and was of the highest purity. The lowerings of vapor pressure in this case were smaller than before, but still abnormally greater than can be accounted for by the Lord Kelvin equation.

There may or may not be any solubility effect in the case of quartz, but when the ratio of the surface to the volume in the capillaries we were dealing with is considered, any negligible solubility may assume considerable importance. Therefore, a non-polar liquid was employed, such that a solubility effect cannot reasonably be involved.

Apparatus

The method of measuring the depression of the vapor pressure and the underlying theoretical considerations are fully discussed in the first paper. Certain changes and

---

[1] In memory of Ira Remsen.

improvements in the original apparatus, necessitated by the use of the organic liquid, are described below. Referring to the diagram of the original apparatus, vessel I, was substituted by a cylindrical vessel of 200-cc. capacity, provided with a magnetic stirrer. There was no need for vessel E and trap F; they were therefore eliminated. The bulbs A and B, serving as a means for removing the dissolved air and as a reservoir for the liquid, were substituted by a vessel shown in the accompanying Fig. 1. This proved less troublesome and much more efficient in freeing the liquid from the last traces of air. It was operated by means of a suction interrupter similar to the one designated by O. When the water pump diminishes the pressure over the mercury in the reservoir, the column of mercury, over which the liquid in the lower bulb rests, falls and allows the liquid to fill up the small side bulb; when the suction is broken by the interrupter, the column of mercury rises to its original height, fills the side bulb with mercury and pushes the liquid into the upper bulb filled with glass beads. The spreading of the liquid in such a manner over a large surface facilitates the removal of the dissolved gases. Many repetitions of this procedure, followed by pumping, removed the last traces of air in the course of several days.

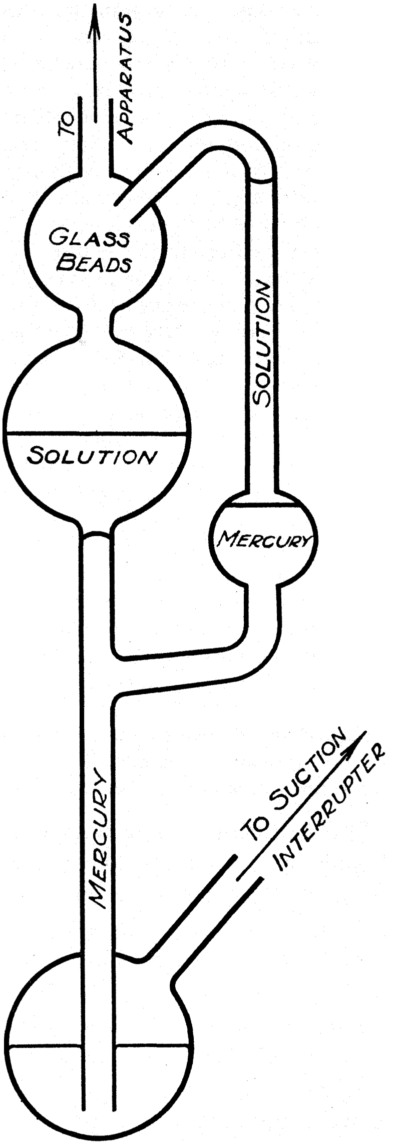

Fig. 1.

This apparatus used for the removal of air is essentially that devised by Dr. R. K. Taylor of this Laboratory in connection with the study of the vapor pressure of alcoholic soap solutions made by Dr. R. D. Drinkard, the results of which are to be published later.

In order to transfer desired amounts of liquid from vessels A and B into vessel L, calibrated bulbs of various sizes were sealed into the apparatus between traps T and H. By opening trap G and cooling one of these calibrated bulbs with an ice-water mixture, a desired volume of toluene was obtained. In closing trap G and opening trap K, the liquid was transferred by evaporation into the solution vessel L.

Microprojector.—The capillary was placed in a vertical position and observations were made upon it by means of a microprojector. This optical system consisting of a microscope in a horizontal position, and a low power objective placed between the object and the microscope so as to produce a real image in the focus of the microscope, was a great improvement upon the original method. The whole system was rigidly mounted on a slow motion stand to allow observations of various points along the length of the capillary. This arrangement has been utilized already in part of the work presented in the first paper, namely, the work on quartz capillaries.

Thermostat.—The temperature control was of utmost importance, and to obtain a fairly constant temperature for a considerable time very sensitive regulating devices were used. The thermo-regulator consisted of a coil of 50 feet of $^3/_8$-inch copper tubing filled with toluene. The electrical circuit was so arranged that sparking at the point of contact between the tungsten needle and the mercury was eliminated.[2]

Since the temperature maintained was below that of the room, a device was introduced that controlled the amount of cooling water passing through the cooling coil. This device shut off the cooling water when the heating unit was on and *vice* versa. It consisted of a long piece of heavy wire suspended vertically and fastened at the upper end to the circuit breaker of a strong relay, the coils of which were connected in series with those of the main relay. The lower end of the wire carried a rubber stopper cut to seat securely in the mouth of the cooling water pipe leading to the thermostat. This pipe was mounted in a wide glass tube provided with two side tubes, one near the bottom and above the mouth of the pipe serving as the water inlet, the other near the top as the overflow. By manipulating this device in conjunction with the heating unit, conditions were such that the latter went on and off every fifteen seconds for more than twelve hours.

Under these conditions two Beckmann thermometers, one graduated in 0.002° and the other in 0.001°, showed fluctuations not greater than 0.0015°. The temperature of the thermostat was maintained at 20°; at this temperature the vapor pressure of toluene is 21.60 mm. of mercury. Therefore, the fluctuation in the temperature corresponds to a change of the vapor pressure not greater than 0.0021 mm. of mercury.

In testing various parts of the thermostat by means of a constantan–iron thermopile connected to a galvanometer of 12,400 megohms resistance, a temperature gradient was detected between the part of the thermostat containing the solution vessel and the side compartment holding the capillary. These gradients are established by the currents caused by the stirrer and it was found that changing the direction of stirring reversed the direction of the temperature gradient. Thus, by stirring downward the compartment containing the capillary was colder than the one containing the solution vessel, and by stirring upward the conditions were reversed. Inasmuch as condensation of toluene vapor on the walls of the chamber containing the capillary was to be prevented, the thermostat was stirred upward.

The Solution.—The question of finding the proper solute was a perplexing one. Since Raoult's law was to be used in calculating the vapor pressure of toluene solutions, our first requirement was that the compound to be used as the solute should have as close a relation to the solvent as possible, that is, it should form a mixture close to the ideal. The second requirement was that it should have a high boiling point, so that its partial pressure in a saturated solution would be negligible. Third, it should be fairly soluble in toluene and, lastly, the compound should be stable in solution. Although the second and third demands are inversely related, we were inclined to compromise in favor of the second. Usually a compound related to benzene or toluene that satisfies the first and second requirements is unstable and sensitive to light. After a long search and many trials p-diphenylbenzene was selected. Its melting point and boiling

---

[2] A. T. Larson, This Journal, 44, 2893 (1922).

point are 212 and 383°, respectively, and, judging from the work of Hildebrand, its solution in toluene would deviate from the ideal very slightly.

However, the low solubility of p-diphenylbenzene in toluene imposed limitations upon the possible range of measurements as the vapor pressure of the toluene solution is balanced against the vapor pressure of pure toluene in a capillary.

The toluene used was refluxed over sodium amalgam for twenty-four hours; this was followed by distillation, the middle fraction being retained.

The p-diphenylbenzene was obtained from the Eastman Kodak Company.

Experimental

1. Manipulation of Apparatus (Radius of Capillary = 1.10μ; $n/(N - n) = 0.0038$). When vapor from the toluene reservoir was admitted into the capillary chamber, it condensed in the capillary instantaneously, that is, it shot down very rapidly from the mouth of the capillary in the form of a column. The excess liquid on the walls of the vessel (7 mm. Pyrex tubing) and on the outside of the capillary was removed by careful pumping and manipulation of the several mercury traps in the apparatus. The attainment of this condition was ascertained by lowering the mercury trap leading to the capillary so that only a slight amount of liquid near the mouth of the capillary was evaporated. If after some time the capillary did not fill up again, there was no excess liquid present. The trap leading to the solution vessel was lowered, thus bringing into communication the vapor of the solution with the vapor of the pure liquid over the capillary. The latter filled up immediately, indicating that the vapor pressure of the pure liquid over the capillary was less than that of the solution. The trap leading to the solution was then closed and the mercury in the trap leading to the capillary was slightly lowered. The liquid in the capillary began to evaporate, showing the reversibility of the process. The operation was repeated several times and each time the capillary filled completely.

The capillary is completely evacuated; that is, the liquid in it is made to vaporize and then the vessel containing the capillary is closed by means of the trap. By suitable manipulation of the mercury traps in the line leading to the solution vessel, the rest of the apparatus is filled with vapor from the solution. Upon closing off the solution vessel and lowering the mercury in the traps leading to the capillary, this vapor was greatly rarefied; the capillary did not fill up when brought in contact with the rarefied vapor. However, when the capillary was brought into direct contact with the vapor above the solution, it filled rapidly in the same manner as described above.

Similar observations were made on capillaries having radii of 2.13μ, 3.14μ, 4.84μ and 5.33μ. They were subjected to the same treatment as described above, and in every instance they behaved similarly. In other words, the lowering of the vapor pressure in these capillaries was also greater than in the solution. It is worthy of note that in case of the latter two capillaries the filling was much slower and somewhat different. First, a bright spot appeared slightly below the mouth of the tube. This grew to a column of liquid apparently an inch in length (the magnification was about 1000) which then fell rapidly to the bottom of the capillary. This procedure was repeated until the capillary was not quite full. After it reached this point, the level of the liquid slowly rose until the capillary filled up.

2. Observations (Radius of Capillary = 6.12 μ; $n/(N - n) = 0.0038$).—The capillary was filled in the usual manner, that is, by allowing vapor from the toluene vessel to condense into it. Care was taken to remove all the excess liquid, and then it was brought into communication with the solution by opening trap K. The liquid in the capillary began to evaporate; after a few seconds the rate of evaporation was obtained by determining the time required for a desired length of the liquid, as read on the scale in the ocular, to evaporate. The operation was repeated several times, each time beginning the measurement from the same point on the capillary.

Each division in the table below corresponds approximately to about 0.0005 cm. The volume of liquid evaporated in the measured time is about 2.4×10^{-8} cc.

Divisions	40	40	40
Time	1 min. 20 sec.	1 min. 15 sec.	1 min. 18 sec.

This capillary was also subjected to measurements when the thermostat was stirred downward, the thermopile indicating that the compartment holding the capillary was colder than the one containing the solution. Each time it was found that the capillary was filling up at a very slow rate, requiring about a minute longer for the same volume in case of evaporation.

TABLE I

TABULATION OR RESULTS

Solute, *p*-diphenylbenzene; solvent, toluene; temperature, 20°; vapor pressure, 21.60 mm. of Hg; density, 0.866 at 20°; surface tension, 28.56 dynes/cm.^{2}

Expt.	Radius of capillary, 0.0001 cm.	*Pk* in mm. Hg	*n* moles of solute	*N* moles of solvent	P in mm. Hg	Observations

In conclusion, the author wishes to express his profound gratitude to Professors W. A. Patrick and J. C. W. Frazer for their assistance in this work.

Discussion and Summary

These results may be best summarized by a consideration of the behavior of Expt. 5. In this experiment a capillary of 5.33μ radius was exposed to a toluene solution whose vapor pressure was lowered to 0.082 mm. by the addition of a solute. It was found that liquid toluene condensed in this capillary, which would indicate that the vapor pressure of the toluene in the capillary was less than (21.60 – 0.082). The classical theory of capillarity, however, tells us that the vapor pressure lowering of toluene at 20° in a tube of this radius should be only 0.009 mm. of mercury. It is therefore obvious that either our experimental work is in error or the classical theory as applied to vapor pressure in capillaries is not correct.

We believe the latter to be true and are convinced that this work has been done with sufficient care to warrant such a conclusion. At this point it may be well to add that such a view does not necessarily conflict with the thermodynamic treatment of this question. Thermodynamically the problem is simply the action of a negative pressure upon the vapor pressure of a liquid. This question is rigorously handled by the well-known relationship of Gibbs. What we have shown here is that the negative pressure in the case of small capillaries may be greater than has been assumed to be the case.

ZIRCONIUM. II. DETECTION OF POTASSIUM BY ZIRCONIUM SULFATE IN THE PRESENCE OF AMMONIUM IONS[1]

BY RUFUS D. REED AND JAMES R. WITHROW

RECEIVED AUGUST 6, 1928 PUBLISHED NOVEMBER 6, 1928

We have shown that zirconium sulfate can be used to detect potassium and that the test can be applied in the presence of sodium.[2] Ammonium ions must be eliminated prior to testing for potassium with other reagents such as sodium cobaltic nitrite, chloroplatinic acid or perchloric acid. The sensitivity of zirconium sulfate for potassium in the presence of ammonium ions was therefore investigated.

The results indicated that zirconium sulfate solution will detect 0.48 mg. of potassium in 2 cc. of reaction mixture in the presence of large amounts of ammonium sulfate. This was practically the same sensitiveness of this reagent for potassium in the absence of ammonium as in the previous work.

---

[1] In memory of Ira Remsen.

[2] Reed and Withrow, THIS JOURNAL, 50, 1515 (1928)

Concerning the action of alkali sulfates on zirconium sulfate, Fresenius[3] stated: "A concentrated solution of potassium sulfate rapidly produces a white precipitate of potassium zirconium sulfate. . . . Sodium sulfate and ammonium sulfate do not produce a precipitate." No reference was found indicating the effect of the presence of ammonium sulfate on the reaction between zirconium sulfate and potassium sulfate.

Experimental

In order to determine the sensitiveness of zirconium sulfate for potassium in the presence of ammonium it was necessary to prepare the following solutions.

Zirconium Sulfate Solution.—Impure zirconium sulfate was dissolved in water and the zirconium precipitated by a slight excess of sodium hydroxide. The hydroxide was washed by decantation and filtered and washed until 10 cc. of the filtrate evaporated to dryness and taken up with 2 cc. of water gave no test with sodium cobaltic nitrite. The moist zirconium hydroxide was dissolved in concentrated sulfuric acid. The somewhat dilute solution was concentrated overnight at 60° and allowed to stand for several days to reach constant composition. This solution was found to contain 0.1131 g. of zirconium sulfate and 0.0363 g. more sulfate per cc. due to excess sulfuric acid.

Potassium Sulfate Solution.—This was prepared from c. p. salt and water. Its strength was determined by evaporating a portion to dryness and igniting.

Ammonium Sulfate Solution.—The c. p. salt was dissolved in water. The solution was analyzed for ammonium by the distillation method.[4]

The solutions tested for potassium were prepared by mixing known amounts of the potassium and ammonium sulfate solutions.

Procedure

The procedure was exactly the same as given under the general procedure in the work previously published.[5] The results appear in the table.

TABLE I

SENSITIVENESS OR ZIRCONIUM SULFATE FOR POTASSIUM IN THE PRESENCE OF AMMONIUM IONS

Total volume 2 cc. $Zr(SO_4)_2$, 0.1131 g. per test

Expt.	K, g. per sample	NH_4, g. per sample	Results (time for appearance of a precipitate)
1	0.0000	0.05985	Clear and no ppt. in 5.5 hours at 0°
2	.0000	.01197	Clear and no ppt. in 5.5 hours at 0°
3	.0000	.00599	Clear and no ppt. in 3.5 hours at 0°. Tube broke
4	.02378	.02990	Ppt. in 10 min. at room temperature
5	.0158	.03990	Cloudy in 1 hour at room temp.; ppt. in 10 min. at 0°
6	.0048	.0539	Ppt. in 1 hour at 0°
7	.0024	.0569	Cloudy in 1 hour; ppt. in 1.5 hours at 0°
8	.00095	.0586	Cloudy in 1.5 hours; ppt. in 2 hours at 0°
9	.00058	.0591	Very slight ppt. in 2 hours; increased in 2.5 hours at 0°
10	.00048	.0593	Very slight ppt. in 2.5 hours; increased in 5.5 hours at 0°

[5] Ref. 1, p. 1516.

Discussion

The deposits in Expts. 9 and 10 containing 0.58 mg. and 0.48 mg. of potassium were very small but could be detected by comparison with a blank.

The results indicated that zirconium sulfate will detect 0.48 mg. or more of potassium in 2 cc. of reaction mixture in the presence of large amounts of ammonium ions. This is a distinct advantage over other tests, in all of which ammonium interferes. Bray[6] found "With 1 mg. of NH_4 a precipitate formed in about 10 minutes (with sodium cobaltic nitrite); with 0.5 mg. on standing several hours." Ammonium salts also give precipitates with tartaric acid, perchloric acid and chloroplatinic acid. With perchloric acid or chloroplatinic acid the amount of potassium must be large or alcohol must be added. Zirconium sulfate will detect potassium when present to the extent mentioned in the presence or absence of ammonium ions and no alcohol is needed.

Summary

The sensitiveness of zirconium sulfate for potassium in the presence of ammonium ions was found to be 0.48 mg. or more of potassium per 2 cc. of reaction mixture. This is practically the same sensitiveness of zirconium sulfate for potassium when no other metal ions were present. This detection in the presence of ammonium is a distinct advantage over the other tests for potassium.

THE THICKNESS OF ADSORBED VAPOR FILMS. II[1,2]

BY G. H. LATHAM

RECEIVED SEPTEMBER 10, 1928 PUBLISHED NOVEMBER 6, 1928

There are now three outstanding theories of adsorption, namely, the unimolecular theory of Langmuir, the multimolecular theory of Polanyi and the capillary theory of Zsigmondy. Experimental data in support of each of these theories have been submitted by different investigators. In this paper we are particularly interested in the work of McHaffie and Lenher[3] and in that of Frazer, Patrick and Smith.[4] Both of these investi-

---

[6] Bray, THIS JOURNAL, 31, 633 (1909).

[1] In memory of Ira Remsen.

[2] This paper has been taken from the dissertation submitted by the author to the Board of University Studies of The Johns Hopkins University as part of the requirement for the degree of Doctor of Philosophy.

[3] McHaffie and Lenher, J. *Chem. Soc.*, 127, 1559 (1925); 1785 (1926).

[4] Frazer, Patrick and Smith, J. *Phys. Chem.*, 31, 897 (1927).

gations are concerned with the adsorption of water vapor and of toluene on glass surfaces. This paper is a summary of some work recently done in continuation of that accomplished by these investigators.

McHaffie and Lenher studied the thickness of the water film adsorbed on the surface of a glass bulb which had been washed with strong acids and water. They also investigated the adsorption of water vapor upon platinum surfaces. In each case they found that the adsorbed film was multimolecular in thickness.

It was thought by Frazer, Patrick and Smith that the weak point in the work of McHaffie and Lenher was the assumption that the surface of the glass was plane from a molecular standpoint after treatment with acids and water. (McHaffie and Lenher had assumed that they were working with plane glass surfaces and that their results were obtained with such surfaces.) It appeared that such treatment would probably dissolve some of the alkali of the glass and form some amorphous silica on the surface, thus causing a general roughening of the surface. They believed, furthermore, that glass which has been thoroughly melted in a flame and allowed to cool without coming into contact with anything except dry air would present a plane surface for adsorption measurements.

In order to test the correctness of these considerations and to study the adsorption of vapor films upon such "fire-polished" surfaces, Frazer, Patrick and Smith undertook to repeat the work of McHaffie and Lenher using the same method of procedure and apparatus, toluene vapor and both fire-polished and acid-treated glass surfaces.

The results of their work indicated that the thickness of the adsorbed toluene film was never greater than unimolecular on fire-polished glass, while on acid-treated glass it was always multimolecular in thickness. These results confirmed the belief that fire-polished surfaces of glass were plane, while acid-treated ones were not.

There was, however, an objection to the general application of these ideas to adsorption on glass; that is, they did not necessarily hold good for other substances than toluene, especially in the case of polar substances. In other words, the results were true, possibly, of non-polar compounds only.

In order to ascertain whether this objection was valid or not and, if not, to eliminate it and complete the work of Frazer, Patrick and Smith by making the facts applicable to both polar and non-polar substances, the present investigation was undertaken.

The experimental procedure and the apparatus were essentially the same as those used by Frazer, Patrick and Smith, Acetonitrile and nitromethane were the two polar substances selected as well suited for the work; toluene was used also as a check on the work of Frazer, Patrick and Smith and, later, water vapor was used in the work with platinum and silver amalgam surfaces. The use of several other polar substances was abandoned because they were not suitable for the purpose.

The method consisted essentially in measuring the pressure exerted within a small glass bulb by a known amount of vapor at constant volume, through a temperature range such that at the upper limit all of the substance would be in the gaseous condition while at the lower limit some would be present in the form of liquid. By plotting graphically the data thus secured, two curves would be obtained—one the curve for change of pressure with temperature of the substance in the form of vapor, and the other the vapor pressure curve of the liquid. Obviously these two curves on the graph would intersect at the dew point. From the type of curve obtained by plotting these P-T data, it was simple to ascertain whether adsorption had taken place at any time during the measurements and, if so, to what extent.

Measurements were made with a given vapor in bulbs of both fire-polished and acid-treated glass. These bulbs were made of soft glass, blown after thorough cleaning and melting in a flame. All glass-blowing was done through a phosphorus pentoxide bulb to prevent access of moisture. The bulb was cooled while attached to the phosphorus pentoxide bulb and sealed into the apparatus, using a phosphorus pentoxide bulb. It was evacuated with a mercury pump in series with an oil pump, all pressures being read on a McLeod gage. The vapor to be studied, previously freed from air, was admitted to the bulb while the temperature was at the upper limit of the range used. The bulb was closed by a mercury U-tube which served also as a manometer, and keeping the volume constant while gradually reducing the temperature, the corresponding pressures of the vapor were read. Each point obtained was approached both from above and below so that all data would represent equilibrium pressures and temperatures. All readings were checked at least twice and within 0.05 mm. As the saturation point was approached, the readings were made every 0.5 to 0.25 of a degree in order to locate the point accurately. The approximate position of this point on the curve could be foretold from the temperature of the liquid used to fill the bulb with vapor.

The temperature of the vapor in the bulb was controlled by a constant-temperature bath accurate to 0.02°. Pressure readings were made with a cathetometer which was accurate to 0.05 millimeter.

Having made the pressure–temperature measurements with a fire-polished bulb, it was removed from the apparatus and its area and volume were determined as accurately as possible. The area measured was that which had been exposed to the vapor. These data were used later in calculating the amount of vapor in the bulb during the measurements and the thickness of the film adsorbed, if any.

The bulb was then filled with chromic acid and kept at 40–50° for twenty-four hours. It was washed with distilled water, filled with concentrated nitric acid and kept at about the same temperature for twenty-four hours longer. The bulb was next thoroughly washed out with distilled water, evacuated at 180° for five hours and again sealed into the apparatus with the same precautions as before. Another sample of vapor was admitted to the bulb as before and the pressure–temperature measurements were repeated. The data secured from these measurements were plotted graphically and the type of curve obtained was determined.

Before going further into the experimental work and results, it will probably be desirable to describe briefly the method of determining the amount of adsorption taking place on these glass surfaces.

If a definite mass of vapor be kept at constant volume while the temperature is gradually lowered, its pressure at any time will be given by the equation

$$P = P_0(1 + \alpha t) \tag{1}$$

provided, of course, the vapor obeys the perfect gas laws. In the equation P is the observed pressure, P_0 is the pressure of the vapor at 0° (provided none of it condenses above or at this temperature), t is the temperature at the corresponding pressure P, and α is a constant, $^1/_{273}$. From the equation it is clear that under such conditions a series of pressure-temperature data secured from measurements on this vapor will give a straight line so long as no vapor condenses or is removed from the vapor phase in any other way. The slope of the curve will be $P_0\alpha$ and P_0 will be its intercept on the pressure axis. At the dew point, however, part of the vapor will condense and thereafter, as the temperature is lowered, the measurements will give the vapor pressure curve of the liquid. Consequently, at this dew point there will be a sharp break in the curve and the two parts of the curve will intersect at this point as two essentially straight lines. Such a curve is illustrated in Fig. 1, AOB. The curve is purely a theoretical one.

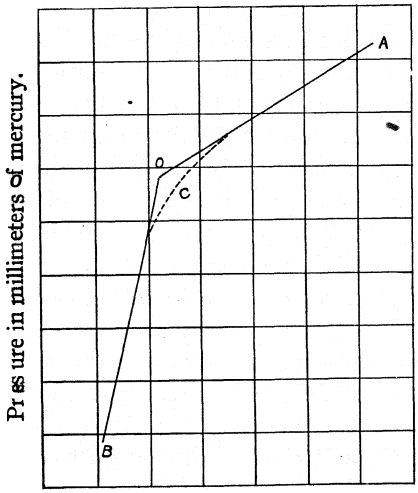

Fig. 1.

If, however, some of the vapor is adsorbed by the glass surface as the temperature is lowered, it is evident that the pressure will decrease more rapidly than is required by the gas laws, so that the curve will appear as shown in Fig. 1, ACB. The dotted line represents the portion of the curve where adsorption is taking place. From these considerations, it is clear that if adsorption occurs as the dew point is approached, there will be a gradual and more or less pronounced rounding off of one part of the curve into the other. The amount of this rounding off depends entirely upon the extent to which adsorption has occurred and from it the maximum pressure decrease due to such adsorption can readily be obtained by an inspection of the curve.

Now, if the decrease in pressure due to adsorption of a unimolecular film is known, it is only necessary to divide the total pressure decrease due to adsorption by this number in order to obtain the molecular thickness of the adsorbed film. As already stated, the volume and inside area of the adsorption bulb, together with the temperature and pressure at the point of maximum adsorption (that is, the dew point) are known, as are also the approximate molecular diameters of the substance worked with. By assuming that each molecule adsorbed is spherical and that it occupies an area on the glass surface included in a square whose side is the same length as the molecular diameter, it is a simple matter to calculate the pressure decrease caused by the adsorption of a unimolecular layer of such molecules. The thickness of the absorbed layer can then readily be calculated as already noted.

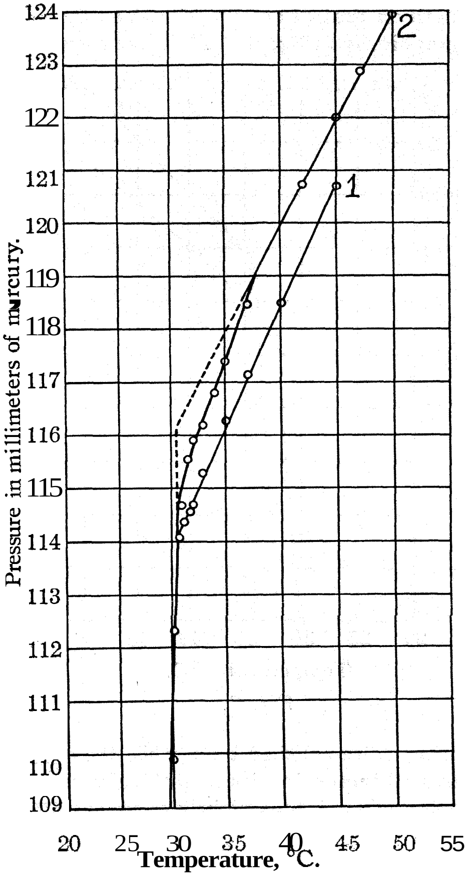

Fig. 2.

For the vapors and bulbs used during this work, the decrease in pressure caused by the adsorption of a unimolecular film varied from 0.01 to 0.04 mm., depending upon the size of the molecule.

Having thus pointed out the method by which the amount of adsorption was obtained, we can now turn to an examination of the experimental data.

The adsorption of acetonitrile vapor was first investigated. As already stated, both fire-polished and acid-treated bulbs were used. When the pressure-temperature data from measurements with a fire-polished bulb were plotted graphically, Curve 1, Pig. 2 was obtained. With the same vapor but after treating the bulb with acids and water, the measurements gave data which are shown graphically in Curve 2, Fig. 2.

Curve 1, Fig. 3, shows graphically the data obtained from measurements with nitromethane in a fire-polished bulb, while in the same figure Curve 2 is the corresponding one for an acid-treated bulb. The non-coincidence of the two vapor pressure curves is due to the fact that Curve 2 has been moved up vertically from its normal position in order to get both curves on the same graph.

The work of Frazer, Patrick and Smith with toluene was next repeated as a check both on that piece of work and on the present one. The data thus secured are shown graphically in Fig. 4. The curve shown as a solid line represents the data from the run using a fire-polished bulb, while the curve obtained from measurements with an acid-treated bulb coincides with this almost throughout except at points near the saturation point, where it falls slightly below, as shown in the dotted line. This was to be expected from the work done by Frazer, Patrick and Smith and also from the theory of this method.

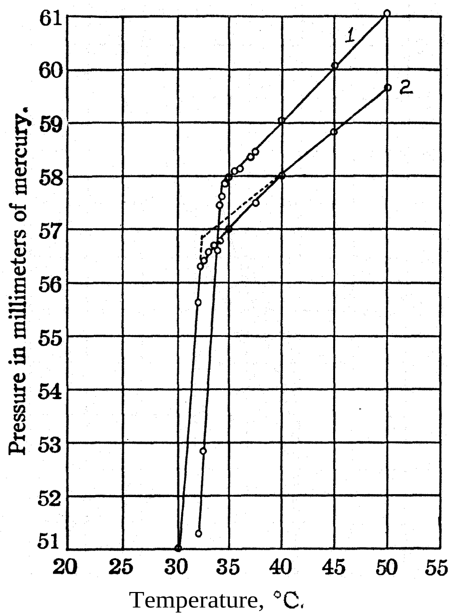

Fig. 3.

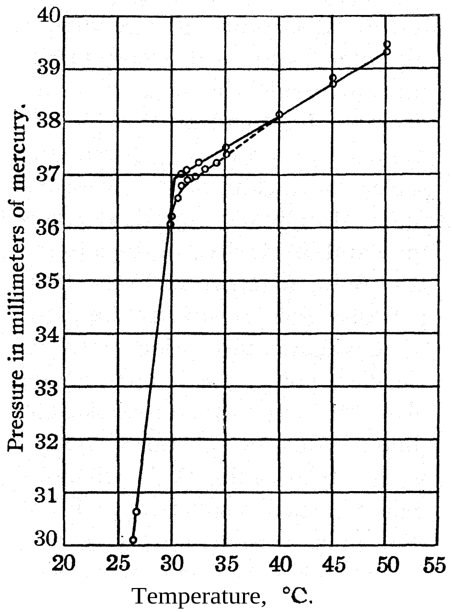

Fig. 4.

After an examination of the curves obtained (Figs. 2–4) it seemed that the amount of "rounding off" of the two parts of the several curves into each other was rather small-somewhat less than had been anticipated from the work of Frazer, Patrick and Smith. Accordingly, it was decided to make several experimental runs using different vapors in bulbs which also contained a small amount of activated silica gel. The bulbs themselves were of fire-polished glass. It was thought that since in this case we could be certain that adsorption was taking place strongly, the type of curve obtained would be interesting and instructive and might be of value in aiding one to interpret correctly the other curves. Two runs were made. One was made with 0.0003 g. of activated silica gel in a fire-polished bulb containing nitromethane as well in the vapor phase.

The other was run using the same amount of silica gel in a similar bulb with toluene vapor. The experimental results are shown graphically in Fig. 5 (for nitromethane) and in Fig. 6 (for toluene).

When we come to an examination of the experimental curves (Figs. 2–6), we see at once that in every case where a fire-polished bulb has been used, the pressure-temperature curve for the substance in the gaseous state is a straight line, and that where the two parts of the experimental curve intersect, there is a sharp break, with not the slightest trace of rounding off. On the other hand, wherever an acid-treated bulb has been used, the two parts of the curve do not intersect sharply but round off into each other more or less. Moreover, the curve for the substance in the form of vapor is not a straight line, but shows a pronounced tendency to round off near the saturation point. These facts can only be ascribed to adsorption on the acid-etched surfaces. Any other cause would show the same effect on each bulb.

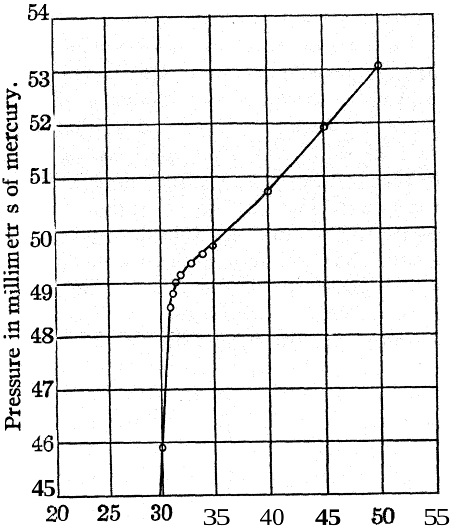

Fig. 5.

Since the pressure-temperature curves of the vapor are straight lines, it is permissible to calculate the number of moles of vapor present in the bulbs by means of the perfect gas laws. From this, together with the volume, area of the bulb, the temperature and pressure, the thickness of the adsorbed film of vapor can be calculated, as we have already indicated. These calculations have been made for each vapor. The results indicate that the adsorbed film is from 30 to 60 molecules thick at saturation pressures and temperatures on acid-treated glass, and not greater than unimolecular on fire-polished surfaces. The polar compounds appear to be somewhat more strongly adsorbed than toluene. This fact is indicated both in the character of the curves for these substances and in that for nitromethane and toluene in presence of activated silica gel.

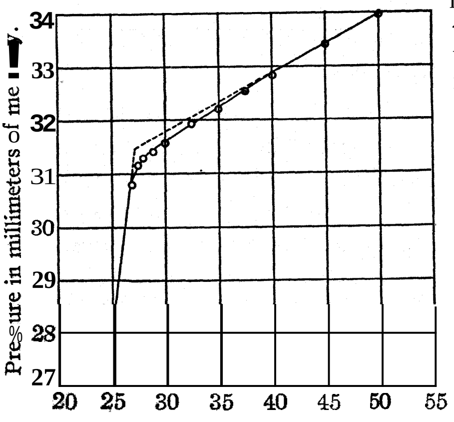

Fig. 6.

The calculation of the thickness of the adsorbed film was very simple. It was assumed that the film was of uniform thickness and that it covered the entire surface of the glass exposed to the vapor. The slopes of the curves obtained experimentally were in each case measured, and the theoretical slopes were calculated by means of Equation 1. The experimental and theoretical slopes agreed closely with the exception of those of the curves for nitromethane in presence of silica gel; this might have been expected. The dotted lines in the figures are prolongations of the straight portions of the curves and have the approximate theoretical slopes. These dotted portions represent the curves which would have been obtained had there been no adsorption at these points. Hence, the maximum distance, measured on the pressure axis, between the experimental and the dotted part of the curves is the maximum pressure decrease due to adsorption. This divided by the pressure decrease due to adsorption of a unimolecular layer gives directly the thickness of the adsorbed film.

In the case of the measurements with toluene and nitromethane in presence of silica gel, a calculation of film thickness is obviously out of the question, since the adsorption was presumably confined to the gel in the bulb, and the area of this is unknown. However, if we assume the adsorption to have taken place uniformly on the surface of the bulb as in the other experiments, the data for the run with toluene and 0.0003 g. of silica gel indicate a thickness of forty molecules for the adsorbed film, a result very closely agreeing with the other data. The curve (Fig. 6) bears a very marked resemblance to the curve for toluene vapor in an acid-treated bulb. These facts lead one to believe that it is not unreasonable to suspect that 0.0003 g. of silica may be formed on the glass by treatment with acids and water. In the case of the curve for nitromethane (Fig. 5) the similarity to that for the same vapor in an acid-treated bulb is not so clear; the adsorption of the vapor by the silica gel seems somewhat greater, especially at higher temperatures, than in an etched bulb, and also stronger than with toluene. It also seems from the curve that the silica gel was saturated with the nitromethane vapor just before condensation took place at the dew point.

It should be noted that this method does not and cannot show that there is no adsorbed film on fire-polished glass surfaces through the temperature range of 50 to 25°. It does, however, show that no additional adsorption occurs as the temperature is lowered—that is, none greater than a unimolecular layer. Calculation shows that adsorption of such a film causes a decrease in pressure within the bulb of from 0.01 to 0.04 mm., depending upon the vapor used. The pressure measurements made with the cathetometer were not accurate to more than 0.05 mm. Consequently, the method is not sufficiently sensitive to show the presence of a unimolecular layer but can detect anything essentially greater than that.

The Adsorption of Water Vapor upon Amalgamated Platinum and Silver Surfaces

After the conclusion of the adsorption experiments with glass surfaces, an attempt was made to prepare a plane metallic surface upon which the adsorption of water vapor could be studied. A platinum bulb upon the inner surface of which a film of mercury was deposited electrolytically seemed to offer hope of such a surface. Accordingly, such a bulb was prepared, similar in shape and size to those of glass already described. This bulb was sealed into a piece of clean soft glass tubing and was then filled with a solution of mercurous nitrate containing a few drops of nitric acid. Using the bulb as the cathode, the solution was electrolyzed by a current from two dry cells in series. Preliminary experiments had shown that upon clean platinum surfaces a thin mercury film could be deposited electrolytically and that this film would stay on during washing of the surface with water, subsequent drying and other handling incidental to preparing the bulb for measurements. When such a film attained greater thickness, it showed a marked tendency to break and to form globules of mercury which would fall off of the surface.

After electrolysis of the solution the bulb was carefully cleaned by washing repeatedly and gently with conductivity water. It was then dried at room temperature while it was evacuated for five hours and examined Its inner surface appeared to be evenly covered with a film of mercury. (The inside surface of the bulb was not polished but was used just as it came from the makers, with a somewhat roughened appearance. It was cleaned with hot nitric acid before deposition of the mercury film.) The bulb was at once sealed into the same apparatus used for the glass bulbs, all glass-blowing being done through phosphorus pentoxide. During sealing, the bulb was not allowed to become heated (the glass tube attached to the bulb made this possible).

Water vapor was admitted to the bulb so prepared (having previously been carefully freed from all traces of air). The measurements of pressure as the temperature was gradually lowered were made in the same manner as for glass bulbs. Necessarily this procedure required that a small portion of glass surface of the glass tubing connected to the bulb be exposed to the water vapor in order that the cathetometer could be used in reading the height of the mercury. The method used by McHaffie and Lenher in their work on platinum (that is, using a sensitive voltmeter and dry-cells connected to bulb and to mercury in the reservoir to indicate contact of mercury with the bottom of the bulb) was tried in this work but was abandoned because of troublesome sticking of the mercury when it touched the bulb, so that no dependence could be placed on this method of obtaining a constant level of mercury in the bulb.

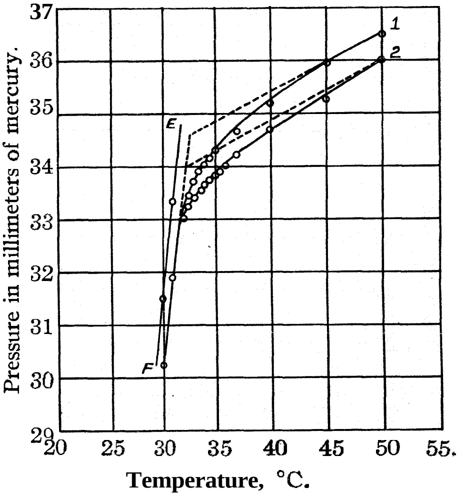

Fig. 7.

The data obtained during two runs using this apparatus and procedure are shown graphically in Fig. 7. Curve 1 was first obtained. The bulb was then evacuated, mercury was raised into it to fill it entirely for twenty-four hours, and after lowering the mercury out of the bulb again another sample of water vapor was introduced and a second run was made, with the results shown graphically in Curve 2 (Fig. 7).

It is evident from these curves that the mercury-platinum surfaces we are dealing with here adsorb water vapor strongly. The molecular thickness of the adsorbed film, calculated in the usual manner from Curve 1, is 28 molecules, and that from the second curve (2, Fig. 7) is **33** molecules. These two values may, on account of the approximate character of the calculations, be considered as a check.

It is interesting to point out here the fact that the parts of these curves which represent the vapor pressures of the condensed water do not coincide with the vapor pressure curve of water; the vapor pressure curve of water in this range is shown as EF, Fig. 7. This may be due to capillary effects in the surface or to the thin film of water, which would have a lower vapor pressure, as indicated in the experimental curves. These results obtained with amalgamated platinum are similar to those recently obtained by John William Smith, *J. Chem. Soc.*, 2045 (1928).

Having failed to obtain a plane surface with mercury-covered platinum, it was next decided to make a series of measurements with water vapor and a silver bulb upon the inner surface of which a film of mercury had been deposited as before. It was hoped that such a bulb would present a plane surface for the study of adsorption of water vapor. A silver bulb was prepared having a platinum band attached to its narrow neck so that it could be sealed into glass tubing and thus into the apparatus. The bulb, after careful cleaning by heating in a flame and repeated washing with conductivity water, was filled with a solution of mercurous nitrate within the case of the platinum bulb and was used as the cathode while the solution was electrolyzed. The solution was renewed twice during electrolysis. The bulb was then carefully cleaned with conductivity water, dried at room temperature and evacuated for five hours. Upon examination the inner surface appeared to be evenly amalgamated. The bulb was sealed into the apparatus without becoming heated, and a run was made with it, using water vapor as the substance to be studied. The resulting curve is shown in Fig. 8.

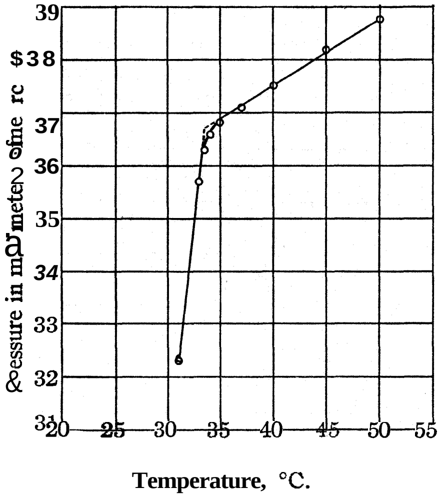

Fig. 8.

The upper part of this curve (that is, the curve for the pressure change with temperature for the water in the gaseous state) has the same slope as the theoretical value calculated for this amount of vapor from the gas laws and, as can be seen from the figure, is a straight line except for a very slight rounding off into the vapor pressure curve of the condensed vapor. This rounding off is, however, confined to the immediate temperatures at the dew point, and is very slight compared to the same phenomenon in the previous curves. Moreover, the slight adsorption may be explained by the fact that, as already stated, during the measurements a small amount of glass surface was exposed to the vapor as well as the silver amalgam surface. This was a necessary consequence of the way in which measurements were made. Moreover, this glass surface had been in contact with liquids and was undoubtedly not plane, so that it probably adsorbed vapor to the same extent that etched surfaces did in the previous work by McHaffie and Lenher, Frazer, Patrick and Smith and the author. If, then, the adsorption indicated in the curve (Fig. 8) is considered as upon the glass surface exposed only, calculation shows that the thickness of the adsorbed film upon the silver-mercury surface cannot be greater than unimolecular. If we are to consider that adsorption occurs only on surfaces that are not plane, then we are justified in considering the silver-mercury surfaces as plane, while those of platinum-mercury are not plane.

In conclusion, the author of this paper wishes to express his appreciation to Dr. J. C. W. Frazer and to Dr. W. A. Patrick who suggested this study and under whose direction it was performed.

Summary

1. The work of McHaffie and Lenher and of Frazer, Patrick and Smith has been continued, using various vapors and both glass and metallic surfaces.

2. Soft glass which has been thoroughly melted and cooled without coming in contact with anything except dry air may be considered as offering a plane surface for adsorption measurements, but acid-treated surfaces of such glass cannot be considered as plane from the standpoint of adsorption measurements.

3. The thickness of the adsorbed vapor film on fire-polished glass surfaces is not essentially greater than unimolecular for either polar or non-polar substances.

4. With acid-treated glass surfaces, the thickness of the adsorbed film appears to be about fifty molecules for both polar and non-polar substances investigated.

5. Platinum surfaces upon which mercury has been deposited electrolytically adsorb water vapor quite strongly. The thickness of the adsorbed layer appears to be approximately thirty molecules.

6. Silver surfaces amalgamated electrolytically may be considered as plane. The thickness of the film of water vapor adsorbed upon such a surface is never greater than unimolecular.

AN APPLICATION OF THE RULE OF DULONG AND PETIT TO MOLECULES[1,2]

BY DONALD H. ANDREWS AND ELLIS HAWORTH

RECEIVED SEPTEMBER 29, 1928 PUBLISHED NOVEMBER 6, 1928

A little over one hundred years ago Dulong and Petit[d] announced the empirical rule that the heat capacity per gram atom is about the same for all solid elements. Since that time the theoretical significance of this rule has been made apparent and the exceptions to it explained by the development of classical kinetic theory and quantum theory. For solids other than the elements, however, very little progress has been made in accounting for the heat capacities. With the hope of throwing some light on this latter problem, particularly for the compounds of carbon, the senior author and his associates have been measuring the heat capacities of a number of compounds. The results for the series of halogen derivatives of benzene presented here seem to show that the principles, of which the rule of Dulong and Petit is a part, can be applied to complicated molecules when the nature of the molecule is sufficiently understood.

The Calorimetric Measurements

The measurements of heat capacity were made in a calorimeter which operates on the principle of calibrated heat conduction, described in a paper by Andrews[4] where a general description of the method may be found.

The Calorimeter used for these observations embodies a number of improvements over the one previously described. As shown in Fig. 1 the inner vessel, which contains the substance to be studied, is a gold-plated copper can equipped with vanes to facilitate the conduction of heat throughout the material. This can is supported by four adjustable wooden pegs inside a heavy copper cylinder, also gold-plated. Both inner and outer can are equipped with covers not shown in the figure.

Temperature is measured by means of thermocouples of No. 30 constantan wire attached to the inner and outer cans.[5] There is a heating coil of the same wire wound on the outside of the outer can.

The Method.—The calorimeter is placed in a gallon Dewar and liquid air is poured on it until the whole apparatus is at constant temperature at about 90°K. Then a current is passed through the heating coil of such strength that the whole apparatus is

[4] Andrews, THIS JOURNAL, 48, **1287 (1926).**

[5] The calibration of the thermocouples is described in a paper by Andrews, *J. Franklin Inst.*, **206, 285 (1928).** Measurements made with the thermocouple junction directly in the material studied as compared with those where the junction was soldered to the walls of the container indicate that errors of temperature measurements due to poor thermal conductivity of the material are not appreciable.

warmed at the rate of about half a degree a minute until 50° is reached. The heat capacity at different temperatures is calculated from the rate of heating of the inner can and the temperature head between the two cans, the constants for heat conduction of this particular apparatus being determined by calibration with hydroquinone.[6]

The Materials.—The substances which were studied were secured from the Eastman Kodak Co. The freezing point curves[7] indicate less than 1% impurity in every case.

The Results

The values of the heat capacity for mono-, di-, tetra- and hexachlorobenzene and for mono- and dibromobenzene are given in Table I. The relative accuracy seems to be about 1 or 2%. The absolute accuracy may not be quite as good as this in certain measurements because of uncertainties in the temperature scale. Comparison with the very limited data available from other sources indicates that at any rate the errors are not large enough to affect appreciably the conclusions drawn from the data.

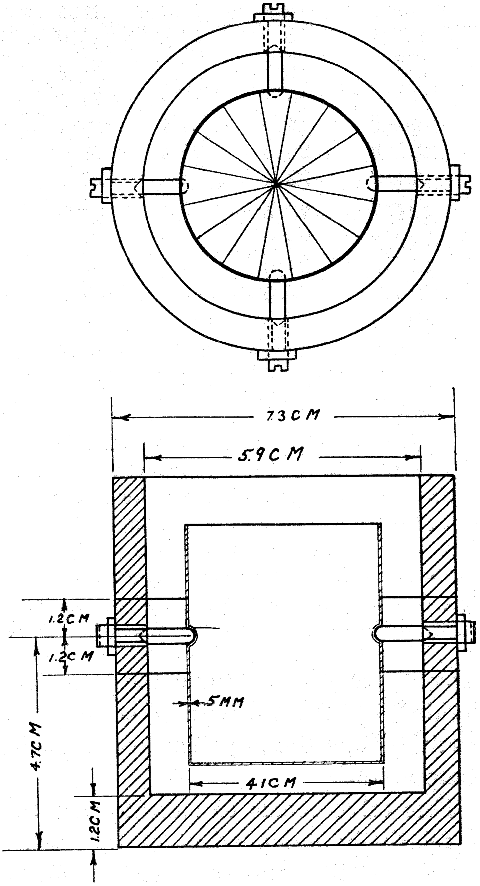

Fig. 1.—The calorimeter.

Conclusions

The principal interest in these two groups of compounds centers in the values we may secure for the heat capacity of the halogen atoms attached to the benzene ring. The rather complicated factors entering into the heat capacity of the ring itself have been discussed by Andrews.[8]

It seems very likely that since the heat capacity of the hydrogen atoms is practically negligible, the ring itself always has about the same heat capacity regardless of the groups attached to it. This conclusion is substantiated by the data in Table II, where the difference between the heat

335.8	32.8			55.4	71.8		48.7

[a] J. Narbutt, Z. Electrochem., 24,339 (1918), has measured the mean heat capacity of p-$C_6H_4Cl_2$ and p-$C_6H_4Br_2$ between various temperatures (—78 to 80°) and 0° by the method of mixtures. He finds, for example, the heat capacity at 217°K. to be 26.8 for $C_6H_4Cl_2$ and 27.8 for $C_6H_4Br_2$, and at 273°K., 32.4 and 33.0. The difference between these values and the authors' is probably due to the different methods employed, Narbutt's being below and the authors' above the true values. It is believed, however, that the accuracy of the authors' measurements, especially relative to one another, is amply sufficient to justify the conclusions drawn from the data.

capacity of the ring[g] and the heat capacity of each compound is shown divided by the number of substituent groups in the compound. The result is thus the apparent heat capacity per halogen atom in each of the compounds.

This table seems to indicate that the heat capacity per halogen atom is relatively independent of the *number* of halogen atoms attached to the ring. The apparent lack of effect on the heat capacity of *position*, that is, *rut-*, *p-*, etc., has been pointed out before.[4]

The fact that the values approach 6 cal. per degree at about room temperature suggests that Dulong and Petit's rule may be applicable. The plausibility of this may be shown in the following way. We believe that

---

[9] The values of the heat capacity of the ring are those calculated from the infrared frequencies as explained in the paper by Andrews, ref. 8. These differ slightly from the observed values for benzene, but were used instead of the latter because of the uncertainty of the observed values in the neighborhood of the melting point and the obvious lack of observed values for the solid above the melting point. For a somewhat similar reason the term for the work of expansion (see reference above) is taken for hydroquinone rather than for benzene. The accuracy of the heat capacity of the ring so calculated should suffice, however, for the present purpose.

the halogen atom is attached to the ring by a normal non-polar or so-called homopolar bond. There is considerable evidence[10] that all bonds of this type are of almost identical nature and strength even when in such apparently different circumstances as joining H—H, C—C, or C—Cl. Now one of

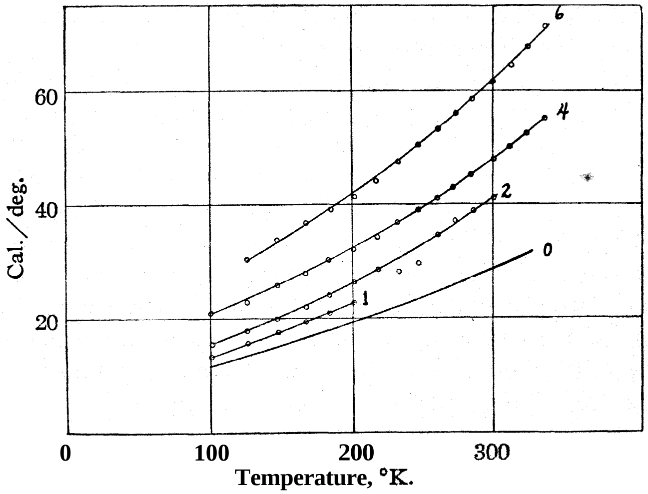

Fig. 2.—C_p for (0) C_6H_6, (1) C_6H_5Cl, (2) $C_6H_4Cl_2$, (4) $C_6H_2Cl_4$, (6) C_6Cl_6.

the characteristics of this type of bond is its spring-like nature. We may indeed think of the chlorine atom as joined to a carbon atom of the ring by a short spiral spring. In this case there should be two characteristic frequencies of vibration; one for motion parallel to the direction of the bond, which stretches the bond directly; the other perpendicular to this, which bends the bond without directly stretching it. This latter type of motion should involve a smaller restoring force than the first type and should have a lower frequency.

---

[10] Bates and Andrews, *Proc. Nat. Acad. Sci.*, *14,* 124 (1928).

The values of frequencies such as these can be secured from absorption spectra, as both Salant[11] and Andrews[8] have shown. Thus Ellis[12] has found characteristic absorption in the infra-red corresponding to fundamental frequencies of 1.79 X 10^{13} sec. for C—Cl and 1.74 × 10^{13} sec.^{-1} for C—Br. Now it seems quite likely by analogy with other compounds that this is the frequency of motion parallel to the bond. If we assume as a very rough first approximation that the ratio of parallel frequency to perpendicular frequency is the same for C—Cl, or C—Br as for C—C, namely,[8] 1470/568, we get values for the frequency perpendicular which are $\theta = 334$ and $\theta = 325$ for C—Cl and C—Br, respectively, expressed in the notation for use in the Einstein specific heat equation for harmonic oscillation. The values for the frequency parallel are $\theta = 856$ and $\theta = 845$. Using these values we can calculate with the help of the Einstein equation what the heat capacity of the halogen atom is if these conditions are all fulfilled. The results of this calculation are given in the last rows of Table II. The agreement is certainly as good as can be expected and shows that atoms attached to a heavy group like the benzene ring do approach the Dulong and Petit value in a manner similar to the elements.

It is a little venturesome to draw conclusions as to what this picture of the molecule will tell about chemical activity, but it seems worth pointing out that since the effective masses are about the same for all the C—Cl vibrating systems, the values of the frequency and consequently of the heat capacity must depend only on the strength of the bond in each case. Since the heat capacities are so nearly the same in all cases we must conclude that the strengths of the bonds are also about the same. Thus, though changes occur in the molecule as we increase the number of substituent groups, such as changes in directive influence to produce different chemical activity, there is no evidence that these changes have any marked effect on the actual mechanical strength of the bonds.

Summary

Measurements have been made of the heat capacities of mono-, di-, tetra- and hexachlorobenzene and of mono- and dibromobenzene. The heat capacity per halogen atom in these compounds seems to approach the Dulong and Petit value of 6 cal. per degree at room temperature in a way predictable from optically observed frequencies in the infra-red. The strength of the carbon–halogen bond in every case seems to be about the same, there being no evidence of directive influence upon it.

THE REFRACTOMETRIC ANALYSIS OF SOLUTIONS OF PURE COMPOUNDS

BY FRANK URBAN AND V. W. MELOCHE

RECEIVED APRIL 12, 1928 PUBLISHED NOVEMBER 6, 1928

I. Telluric Acid

Instrumental analysis continues to play an ever increasing role in the field of analytical chemistry. The reason for this probably lies in the fact that it quite often combines a satisfactory degree of accuracy with a substantial saving of time. Some of the methods of instrumental analysis have, in spite of their excellence, gained favor only slowly. Analysis by means of the immersion refractometer may be given as an example. When one reviews the interesting applications of this method of analysis to the determination of the concentration of solutions of pure compounds, its value becomes more apparent. In addition to the analysis of solutions containing only one pure compound as the solute, it has been possible to analyze mixtures of two salts in solution, one known and one of unknown concentration, mixtures of two salts in solution, both of unknown concentration and the mixtures of three salts in solution, one of known and two of unknown concentration.[1] Of equal interest is the application of the immersion refractometer to the analysis of blood serum,[2] sugar solutions, alcohols, oils, fats and waxes. Still wider application of analysis by means of the immersion refractometer is encouraged by the fact that if there is only a very small sample available, the immersion refractometer may be converted into an Abbé of high precision by an auxiliary prism which is provided with the instrument.

No rigorous relationship has been shown to exist between the refractive index and the molecular weight of the solute, the concentration and the temperature.[3] It is therefore necessary to represent the change of refractive index with concentration by such tables as are illustrated by the publications of Wagner.[4]

In this contribution, we are submitting additional data which we hope will give the immersion refractomcter still wider application in the laboratory. This is intended for the analysis of solutions of the materials mentioned and not for a ready reference for refractive indices.

Preparation of Materials

Although telluric acid of a high degree of purity can be prepared by the

direct application of Staudenmaier's[5] chromic acid oxidation to the nitric acid solution of crude tellurium dioxide, the acid used in this research was prepared from pure elemental tellurium, which in turn was obtained from tellurium basic nitrate and tellurium dioxide.

Tellurium Basic Nitrate.--Crude tellurium dioxide containing about 95% of tellurium dioxide together with sodium sulfate and traces of iron, copper and selenium, was dissolved in concentrated hydrochloric acid. Thii solution was then saturated with sulfur dioxide and the precipitated selenium removed by filtration. The filtrate was diluted so that the concentration of the hydrochloric acid was 8 to 10% and sulfur dioxide was again passed into the solution until the tellurium was completely precipitated. After washing repeatedly by decantation, the precipitate was transferred to a Biichner funnel and the washing continued until the filtrate was shown to be free of chlorides. The moist tellurium was then dissolved in dilute nitric acid (1:1) and the characteristic crystals of tellurium basic nitrate were obtained by evaporation and subsequent cooling of the saturated solution.

Tellurium Dioxide.——Tellurium basic nitrate was heated at a temperature of 500° for five hours. The material obtained was anhydrous tellurium dioxide of a very high degree of purity.

Elemental Tellurium.—Tellurium dioxide was dissolved in concentrated hydrochloric acid, diluted until the acid concentration was 8–10%, and the solution saturated with sulfur dioxide. The precipitated tellurium was washed by decantation and finally transferred to a Büchner funnel, where it was further washed until free from chlorides. This slightly moist elemental tellurium was used for the preparation of telluric acid without further drying.

Telluric Acid.[5]—**Elemental** tellurium was dissolved in an excess of dilute nitric acid (1:1). An excess of chromic acid was added and the solution concentrated by evaporation until crystals began to form. Upon cooling this solution the impure brown crystals of telluric acid were deposited. Although eight recrystallizations of the product from distilled water were sufficient to remove the chromic nitrate and free nitric acid, the crystals used were from a portion which had been prepared for conductance measurements and had been recrystallized twenty-four times. The white, air-dried crystals which contained a small amount of occluded water were ground to eighty-mesh and dried further in a calcium chloride desiccator.

Analysis

In order to establish the purity of the dried telluric acid, it was analyzed for water and tellurium. The water content was determined by passing a current of dry air over a weighed sample which was heated at 450° in a porcelain tube. The water which was evolved was collected in a U-tube which contained concentrated sulfuric acid. Tellurium was determined by the Lenher-Homberger[6] method in which elementary tellurium is precipitated from a hydrochloric acid solution of telluric acid by the addition of sulfur dioxide and hydrazine hydrochloride. The following results offer reasonable evidence of the purity of the telluric acid.

Anal. Calcd. for H_6TeO_6: Te, 55.54; H_2O, 23.55. Found: Te, 55.58; H_2O, 23.50.

Method

Since temperature was an important limiting factor in the use of the immersion refractometer, precautions were taken to keep it constant, The refractometric examination of the telluric acid solutions of various concentrations was made in a constant temperature bath at 25 ± 0.03°, while the temperature of the room was 22.5 ± 0.3°. In order to correct the scale readings for possible realignment of the prism of the instrument with respect to the scale in the ocular, the zero of the instrument was determined at least once and sometimes twice for each twelve readings. The reference value for distilled water was taken as 13.20 scale divisions at 25°.

Inasmuch as the analysis of the acid indicated that it was relatively pure and free from occluded water, requisite amounts of the dry acid

TABLE I

TELLURIC ACID, H_6TeO_6

The values given in the table were taken from a curve which was prepared by plotting concentraton values against their corresponding scale readings of the immersion refractometer. Zero for distilled water, 13.20 at 25°. Values in grams per 100 cc. of solution.

were weighed, dissolved in distilled water and diluted to the proper volume in flasks which had been previously calibrated at 25°. It was found that the use of the conventional type of trough did not afford a uniform temperature. Additional circulation was then provided by pumping water from a constant temperature bath through a glass tube which contained a series of openings and was laid on the bottom of the trough. The excess of water was allowed to drain through the overflow. The refractometer was suspended with the prism immersed in the liquid to be examined a few minutes before a reading was attempted. After the instrument had acquired the temperature of the bath, the reading was taken. Each scale reading reported for a single concentration was the mean of several independent settings of the instrument. Each scale reading used to locate a point in the graphical representation of the data was the result of the examination of two independent solutions for each concentration. Between each set of readings, the prism of the refractometer was washed with distilled water and polished with lens paper. Since this operation changed the temperature of the prism, it was again necessary to suspend the instrument with the prism in the liquid to be examined and allow a few minutes for the temperature to become uniform. In the course of the experiments, it was found that two observers using two different instruments for the examination of the same solutions could obtain an agreement of scale readings of ±0.025 scale divisions. An excellent definition of the border was obtained when the temperature of the bath was uniform.

II. Selenious Acid

Preparation of Selenium Dioxide.—Crude selenium dioxide was dissolved in 10% nitric acid and the insoluble material removed by filtration. The solution was evaporated to dryness and the selenium dioxide sublimed by heating the residue in a six-inch evaporating dish and collecting the sublimed oxide on the sides of a five-inch funnel which was placed over the evaporating dish. The sublimation was repeated three times. Due to the hygroscopic character of selenium dioxide, the product always contained a small amount of water but was otherwise pure.

Method of Analysis

The concentration of the stock solution prepared from the selenium dioxide was determined by analysis for elementary selenium. The method used included the conventional separation of elementary selenium by hydroxylamine hydrochloride, filtration, drying the selenium at 105° and weighing as such. The results were calculated in terms of grams of selenium dioxide per hundred cubic centimeters of solution.

Procedure

The manipulation of the refractometer was identical with that already described for telluric acid. Since the solid selenium dioxide has a pronounced affinity for water, it was desirable to prepare the series of solutions from a standardized stock solution rather than attempt to weigh individual samples of selenium dioxide. The stock solution was measured in a calibrated buret and diluted to the desired volume in calibrated flasks at a temperature of 25°.

TABLE II

SELENIOUS ACID

The values given in the table were taken from a curve which was prepared by plotting concentration values against their corresponding scale readings of the immersion refractometer. Values are grams of SeO_2 per 100 cc. of solution.

III. Potassium Ferrocyanide

Preparation and Analysis.—Ordinary "chemically pure" potassium ferrocyanide was recrystallized three times from aqueous solution and the resulting product pulverized and finally dried in a calcium chloride desiccator. The dry material was then analyzed for potassium and iron.

Potassium.—A 0.5g. sample was digested with concentrated sulfuric acid until the cyanide was destroyed. The sample was treated with water until the acid strength was about 10% and the iron was removed by double precipitation with ammonium hydroxide. The combined filtrates from the precipitated ferric hydroxide were evaporated to dryness and the residue was heated at 450°. The resulting potassium sulfate was weighed and the results were calculated to per cent. of potassium.

Iron.—For this determination the sample was dissolved in 10% sulfuric acid and **the** ferrous iron titrated with $N/10$ potassium permanganate, following the details of the potentiometric method described by Kolthoff,[7] and Hostetter and Roberts.*

Anal. Calcd. for $K_4Fe(CN)_6$: K, 42.46; Fe, 15.16. Found: K, 42.40; Fe, 15.13.

Procedure

Solutions of the concentrations desired were prepared by dissolving weighed samples of the dry material in water and diluting to the proper volume in calibrated flasks, maintaining the temperature at 25°. The same precautions were followed in the use of the refractometer as have been described for telluric acid.

Discussion

The results recorded were obtained by the graphical method of interpolation. Scale readings were plotted against concentrations, the concentration being given in terms of grams of solute per 100 cc. of solution.

---

[7] Kolthoff, *Rec.* trav. *chim.*, 41, 343 (1922).

[8] Hostetter and Roberts, THIS JOURNAL, 41, 1337 (1919).

Forty to fifty points were plotted to establish the slope of each curve. In the range of concentrations given in the tables, there are no apparent irregularities. A change of concentration of telluric acid corresponding to 0.1 of a unit in scale divisions is equivalent to about 0.037 g. per 100 cc. of solution. Likewise for selenious acid, a change of concentration corresponding to 0.1 of a unit in scale divisions is equivalent to 0.029 g. of selenium dioxide per 100 cc. of solution. For potassium ferrocyanide, 0.1 of a unit in scale divisions is equivalent to 0.019 g. of the salt per 100 cc. of solution. As has been previously noted, two individuals can obtain readings whose mean values are within a range of ±0.025. It is therefore believed that a proper control of the method assures rapid analysis with reasonable precision for solutions of the materials mentioned.

The writers wish to acknowledge the kindness of Bausch and Lomb in providing one of their new instruments for this work.

Summary

1. The results in Table I correlate the scale readings of an immersion refractometer and the concentration of aqueous solutions of telluric acid thus making possible a rapid and reasonably accurate determination of the concentration of telluric acid solutions of unknown strength.

2. The results in Table II for selenious acid and those in Table III for potassium ferrocyanide also afford a rapid and accurate means of determining the concentration of these solutions.

THE INCOMPATIBILITY BETWEEN ANY THEORY OF COMPLETE DISSOCIATION AND MIGRATION DATA FOR DIVALENT IONS

BY JAMES W. MCBAIN AND PIERRE J. VAN RYSSELBERGE

RECEIVED JUNE 13, 1928 PUBLISHED NOVEMBER 6, 1928

In 1814 Porrett electrolyzed solutions of mixtures of "prussides" **and** observed that the potassium and the iron moved in opposite directions, the iron going toward the anode. Ever since, the ferrocyanide ion has been the model of a complex anion. The use of migration is, on account of its simplicity and unambiguity, one of the most powerful tools of the physical chemist in the cases where it can be applied. We wish to adduce it in deciding the rival claims of incomplete and complete dissociation in solutions containing divalent ions.

The object of this communication is to present experimental data which show that all divalent ions take part to a certain extent in such phenomena as those illustrated in extreme form by the prussides above, and familiar to us since Hittorf in the behavior of cadmium iodide. The new data show that all divalent ions, even the simplest, such as magnesium ion and sulfate ion, can form complex anions in such appreciable amount that the ordinary migration of the cation is completely submerged.

When to a **0.05** M solution containing a divalent ion sufficient quantity of anion is added, the divalent ion forms a complex anion, and we have the striking and highly significant result that the usual movement of the cation toward the cathode is suppressed or even reversed. Thus when an excess of sulfate ion is added to a **0.05** M solution of magnesium or cadmium sulfate, the magnesium or cadmium migrates toward the anode. Such facts constitute a disproof of the applicability of any hundred per cent. dissociation hypothesis to solutions containing divalent ions.

The almost non-conducting mercuric cyanide has never been included in the hundred per cent. hypothesis, and the same remark applies to the mercuric halides and cadmium iodide. The cadmium of cadmium iodide exhibits a migration to the cathode in dilute solution of +0.45 equivalents per faraday of current, but upon the addition of sufficient iodine ions, or indeed upon merely concentrating the cadmium iodide, the cadmium reverses the direction of its movement and now goes to the anode. Thus the migration of cadmium in a molar solution of cadmium iodide is −0.22. This has always been taken as incontrovertible evidence of the formation of complex ions such as CdI_3^-, whose movement carries more cadmium toward the anode than is simultaneously being carried by cadmium ions proper toward the cathode.[1] Since solutions of cadmium iodide are poor conductors, even in such dilutions as 0.1 M, and since their activity is correspondingly small, it is evident that much of the cadmium iodide is undissociated and that the undissociated molecules are capable of uniting with iodine ion to form complex anions.

The present communication shows that all of the divalent salts differ only in degree. Thus in a **0.05** M solution of magnesium chloride to which a sufficient concentration of chlorine ions has been added, the magnesium goes to the anode just like the cadmium and presumably for the same reason—certainly not because it is hundred per cent. dissociated into simple magnesium ions. The two ions, magnesium ion and sulfate ion, have been specially chosen for study because they are the simplest known divalent cation and anion, respectively, and if even they must be regarded as forming appreciable amounts of undissociated molecules and of complex anions, it is futile to extend any hypothesis of hundred per cent. dissociation to polyvalent ions. The result is not in conflict with the conception of interionic attraction but it is at once a disproof of the unwarranted assumption of hundred per cent. dissociation and a recognition of the molecules and ions really present.

---

Experimental

The results here communicated consist of measurements of migration of cadmium, magnesium, lithium, potassium and calcium in 0.05 *M* solutions of one of their salts containing at feast one divalent ion. In each case there is added a large amount, usually 0.95 *M*, of a sulfate or chloride. The movement of the element present to the extent of 0.05 M in the mixture is measured. The analysis gives the actual direction, whether toward anode or cathode, unequivocally. A calculation of the distribution of the current between the two salts from known conductivity data gives an approximate value for the migration number. The important fact is that the movement is usually toward the anode. The actual numerical value is of far less interest.

The apparatus was that used and described by McBain and Coleman.[2] It is made of borosilicate glass, has an internal diameter of about 2 cm. and a capacity of 190 cc. The anode is of copper and the cathode of platinum. A very large hollow tap in the middle serves to separate the anode and cathode compartments; the solution just on the anode side of the tap served as middle portion. The current was measured with a silver coulometer.

The first experiment was carried out on 0.05 *M* cadmium sulfate in the presence of 0.95 M magnesium sulfate. This particular mixture is of interest because Brönsted[3] showed that the e.m.f. of the cell

$$\text{Cd amalgam}\ \left|\begin{array}{cc}\text{CdSO}_4, & \text{MgSO}_4\\ c_1 & 2-c_1\end{array}\right|\begin{array}{cc}\text{CdSO}_4, & \text{MgSO}_4\\ c_2 & 2-c_2\end{array}\right|\ \text{Cd amalgam}$$

could be calculated by the ordinary Nernst formula $E = k \ln c_1/c_2$, where c_1 and c_2 represent various dilute solutions of cadmium sulfate, the total concentration being 2 M. This was adduced as evidence in support of the 100% dissociation theory.[4]

In these experiments the solutions taken for analysis were not weighed (the only strictly correct method) but were measured by volume, making the assumption that the total volume in the cathode compartment was the same as that originally measured in. Cadmium deposited on the cathode was dissolved with a little sulfuric acid before the analysis, which was made by titration with $N/10$ ferrocyanide. There was less total cadmium in the cathode compartment after the experiment than before, showing that the net movement was toward the anode and that the cadmium was largely in other forms than positively charged cadmium ion. A previous experiment determining cadmium as cadmium sulfide, not quoted in the tables, gave a migration value of —0.34, that is, again toward the anode.

Having determined that the net movement toward the anode amounted to **1.22** mg. during the passage of 198.5 coulombs of current it is necessary to decide what fraction of the current has been carried by the cadmium sulfate in the mixture, We have done this as a first approximation by assuming that the amount of current carried by each constituent is proportional to its concentration multiplied by the specific conductivity which it exhibits when alone in 1.0 M solution. For the present mixture this fraction is $(19.8 \times 0.05)/[(19.8 \times 0.05) + (21.4 \times 0.95)] = 0.0484$. The final migration number is therefore $(96500 \times 0.00122)/(198.5\ X\ 0.0464\ \text{X}\ 56.2) = -0.227$, where 56.2 is the equivalent weight of cadmium.

[4] Ebert, "Jahrbuch Radioakt. Elektronik," 18, 134–196 (1921).

Since the vital consideration was not the accurate determination of the migration but the demonstration of the movement of these supposed cations in the wrong direction, a direct comparison was made in most of the other experiments between the amounts of the element in question contained in a definite volume of the original compared with the same volume of solution drawn from the anode or cathode compartment after thorough mixing within that compartment. A diminution in the analytical value in the cathode compartment and a similar increase in the analytical value in the anode compartment meant movement away from the cathode toward the anode Finally, experiments were carried out in which the solutions were all determined by weight and based upon the amount of water actually present before and after electrolysis. Kahlbaum's or Baker's purest chemicals were used throughout. The current was passed for between three and four hours.

The experimental data are collected in Table I. Magnesium was determined as pyrophosphate, potassium as cobaltinitrite, lithium as sulfate (after evaporation of the ammonium sulfate present in the mixture) and calcium as oxalate Cadmium and copper are not precipitated in the phosphate method on account of the solubility of their phosphates in ammonia. The phosphate precipitates were allowed to settle for from four to twelve hours before filtration and the filter was put into the crucible when wet, before calcination. The cobaltinitrite method for potassium could be used in the presence of magnesium and copper sulfates and it was always carried out under strictly comparable conditions. The reagent was prepared by dissolving **220** g. of sodium nitrite in **440** cc. of water, then dissolving **113** g. of cobalt acetate in **300** cc. of water and **100** cc. of glacial acetic acid. The two solutions were mixed just before using

the reagent and the nitrogen peroxide was removed by thorough stirring The reagent was used in large excess, the precipitate allowed to settle for over an hour before filtering on a weighed filter, washed with aqueous acetic acid, dried and weighed by difference.

Discussion

The results of the migration determinations are collected in Table II and the more they are studied the less compatible do they appear with any assumption of 100% dissociation into simple independent ions.

TABLE II

MIGRATION DATA TO SHOW THE PRESENCE OF MOLECULES AND COMPLEX IONS IN SOLUTIONS CONTAINING DIVALENT IONS

Concn of mixture, moles per liter	Element	Obs.[a] migration, n	Remarks

[a] 0.05 salts when alone give $CdSO_4$ +0.37; $MgSO_4$ +0.36; Li_2SO_4 +0.39; K_2SO_4 +0.49; $MgCl_2$ +0.39; $CaCl_2$ +0.40.

[b] Plus a few drops of H_2SO_4 to dissolve the K_2SO ; 0.0017 g. moved to the anode.

[c] Complete measurements of all constituents results based upon absolute amount of water.

The result is to show that in the majority of cases more of the metal studied is being carried to the anode than is migrating as simple ion to the cathode. This proves the presence of complex anions in relatively large amount. The complex anions have been formed by adding to such a solution as 0.05 M $MgSO_4$ or 0.05 M $MgCl_2$ a large excess of sulfate ions or chlorine ions, respectively. Thereupon these ions have combined with the $MgSO_4$ or $MgCl_2$ to produce the complex ions, showing the presence of the undissociated molecules with which they are thus combining.

For the last five or six years the complete dissociation of strong electrolytes has been generally assumed, and a fundamental separation has thus been made between strong and weak electrolytes. The weak electrolytes consist of weak acids and bases and a few individual salts such as mercuric chloride and cyanide. Acids of every degree of strength up to hydrochloric acid are, however, still recognized. In concentrated solution of sulfuric acid it is customary to explain formation of persulfuric acid on electrolysis as due to combination of two of the incompletely dissociated ions, HSO_4^-. All hypotheses, including that of Arrhenius, agree that in sufficiently dilute solution the dissociation is complete. In the development of the Debye and Hückel theory[5] of interionic attraction, the degree of dissociation α was, for lack of definite evidence, assumed to be unity. The present results indicate that the real value of α is less than unity and that the numerical values of the coefficients must be altered accordingly. Indeed, a sound physical explanation of the different coefficients introduced in that theory for higher concentrations is lacking.

The recent widespread use of activity coefficients has induced many scientists to leave the problem of the true degree of dissociation of strong electrolytes completely unsolved, although activity coefficients are completely empirical and their numerical values depend upon arbitrary conventions. It must remain a primary aim to determine the actual molecular species present and their real concentrations.

Recently Nernst[6] has rightly argued that some strong electrolytes must be incompletely dissociated because their heats of dilution are of the opposite sign to that predicted from interionic attraction alone. He even suggests a degree of dissociation for strong electrolytes which agrees with the mass law. His hypothesis, however, is not yet completely developed. Fajans[7] deduces from optical measurements that neutral molecules and complex ions are present in solutions of strong electrolytes. Several writers[8] have adduced migration data to show that 100% dissociation, even if it occurs for some salts, cannot be general. For solutions of different salts with a common ion at any definite molality, the product of the conductivity (μ) and the transference number of the common ion (n) must be the same for all the salts if they are completely dissociated. In this way MacInnes and Cowperthwaite showed that even if alkali chlorides are assumed to be completely dissociated in 0.1 N solution, such nitrates as those of sodium, potassium and silver must be incompletely dissociated or at least their ions must be partly paired or associated in Bjerrum's sense. Tables III and IV show similar calculations for the sulfate and chlorine ions, using the data of Landolt-Börnstein.

Deficient conductivity might be explained in terms of "associated ions"

if one desired to deny the existence of undissociated molecules, but this does not appear to be adequate to explain the new migration data of Tables I and II, where the outstanding effect is the ready movement toward the wrong electrode. A new kind of "association" of ions in clusters containing one kind of ion in excess might be assumed, but this new assumption is of little value until, firstly, it is proved to be a legitimate possibility; secondly, the further consequences have been faced; and, thirdly, it has been shown capable of explaining the migration data.

The first thing is to demonstrate that it does not contradict existing knowledge of solutions and the laws of electricity. In other words, it has to be shown that such clusters of ions can be formed stably in relatively large amount and remain in stable units when placed in an electric field in which the constituent ions will travel together although pulled in opposite directions. Further, there is no reason apparent for explaining why clusters merely of three ions should occur. If ternary clusters can form in large amount, then larger ones would seem to be possible up to indefinite sizes, up through colloidal dimensions to complete crystals, in solution far from saturation. Indeed the conception is difficult to harmonize with solubility data (compare, for example, $ZnSO_4$, $MgSO_4$ and $BaSO_4$).

The second thing is to realize the consequences of denying undissociated molecules and true complex anions in favor of clusters of ions. It is obvious that since by hypothesis such clusters are largely broken down into independent ions by thermal vibration, they are less stable in an electric field where the components are pulled in opposite directions. The strain must increase with the slope of potential. Hence we must deduce that the transference numbers should change with the voltage applied—a possibility, although not yet recorded. If the voltage were high enough this conception would therefore seem to predict a reversal of direction of the movements observed, and a return to migration data such as are characteristic of ordinary dilute solutions A similar influence of voltage would be expected in conductivity measurements, which might afford an easier method of testing the existence of such an effect.

A third consequence of the conception, which shows that the occurrence or non-occurrence of ionic "association" is in general irrelevant to our main inquiry, is the fact that it predicts almost equal numbers of positively and negatively charged clusters. This is because the same Coulomb's Law and the same ionic radii or distances are used alike in calculating the electrostatic forces acting in a cluster of two positive with one negative as in a cluster of two negative with one positive ion.[9] The attractive forces and the repulsive forces are substantially identical in the two cases, thus giving cationic and anionic clusters in equal numbers—whose effects on migration would almost cancel each other, whereas the proportion of anionic clusters would have to be overwhelmingly greater than that of the cationic clusters if the observed data are to be accounted for.

Professors Parks, Bray and Latimer in conversation have suggested to us the possibility that the assumption of excessive hydration of all the cations might explain our results, and save recourse to recognizing complex anions.[10] Usually hydration has an almost negligible effect, but here its effect is multiplied about 19-fold, since 0.05 M salt is studied in presence of a 19-fold higher concentration of the other salt. For this purpose it is necessary to assume that each cation is much more hydrated than the sulfate or chloride ion; that is, that the cations actually take along with them large quantities of water during migration. Suppose, for example, a divalent cation carries ten molecules of bound water more than the anion. During migration this water is carried to the cathode, thus displacing the whole solution bodily toward the anode. Hence for each faraday of current carried by the divalent cation, there would be an apparent movement toward the anode of the amount of each constituent contained in one-half of 10 moles or 90 g. of water. For the 0.05 M salt (divalent) this would be $2 \times 0.09 \times 0.05$ equivalents = only 0.009 equivalents change

---

[9] This becomes evident for ions whose charges are central or symmetrical when one draws three circles in contact, with centers lying on a straight line, the two outer circles representing ions of charge opposite to that of the ion between them. The opposite ions need not be of the same size.

[10] Such large movement would be readily tested by experiments such as those of Nernst, Washburn and others One of us (J. W. M.) carried out such measurements at the University of Toronto in 1904 with cadmium sulfate, using acetone as reference substance [see McBain, *Z. Elektrochem.*, 11, 216 (1905), also *Proc. Wash. Acad. Sci.*, 9, 7 (1905)], where the general formulation is discussed. Unfortunately the result was to show that the sulfate ion is *more* hydrated than cadmium ion, an experimental finding in the opposite direction from that required for the hydration explanation. If necessary one can arbitrarily discount this by saying that acetone cannot have been a suitable reference substance but must have combined with the cadmium ion, and that the uncombined acetone may have been moving in the opposite direction, of course to a less extent.

in apparent migration. But this is reduced in proportion to the migration number of the 0.95 molar cation, and then increased by the approximate 19-fold, because the whole movement of the 0.05 M cation is referred to the current carried by the 0.05 *M* salt. For 0.95 *M* $CuSO_4$ the migration number of the copper is 0.30. Hence the approximate effect on 0.05 M $MgSO_4$ in its presence would be 19 X 0.30 $\times$ 0.009 = 0.05. This is wholly inadequate to explain our results, where a ten times larger correction would be required to explain them away. This cannot be done, for we have already assigned nearly one-fifth of the total water to the excess hydration of copper ion (and similarly for Mg^{++}, Cd^{++}, Cu^{++}; K^+ and NH_4^+) above that of SO_4^{--} or Cl^-. Hence even if *all* the water in the aqueous solution were combined with the cation, the effect on the migration observed would be only half that required to explain away our results.

It is less forced to admit that we are here dealing with complex ions, particularly when it is universally admitted that numerous complex ions such as the silver cyanide ion $Ag(CN)_2^-$, are to be taken for granted.

Lastly, if undissociated molecules and complex ions are present in such large amounts under the conditions obtaining in our experiments, it must be admitted that they cannot be considered as negligible in much more dilute solutions. A similar conclusion follows from an inspection of graphs of migration numbers of divalent cations plotted against the logarithm of the concentration. This will be illustrated in a further communication dealing with cadmium salts.

Summary

It is shown that when a sufficient excess of chlorine ions or sulfate ions is added to 0.05 M solutions of salts containing a divalent ion, the migration of the anion is suppressed or often reversed, showing that the sulfate or chlorine ions have combined with undissociated molecules to form complex ions. Such migration is incompatible with the assumption that salts containing polyvalent ions are completely dissociated, except in extreme dilution.

THE QUANTITATIVE DETERMINATION OF PALLADIUM BY MEANS OF 6-NITROQUINOLINE

BY S. C. OGBURN, JR., AND A. H. RIESMEYER[1]

RECEIVED JULY 19, 1928 PUBLISHED NOVEMBER 6, 1928

The use of certain organic complexes in the formation of stable coordinated salts with metals of the platinum group is well known. Those of the oximes, aromatic nitroso-amines and hydroxyquinolines are of great value in the quantitative removal of these metals from solution. This is particularly true with platinum and palladium.[2]

Bargallini and Bellinois[3] state that in the case of the hydroxyquinolines, the condition $\equiv C-O-M-N=$ (where M is one metallic equivalent and in which the ring is closed by a secondary valence) must be met. Thus the metal replaces the hydrogen of the hydroxyl (which must be in the eighth position) and is connected with the N of the quinoline molecule.

One of us[4] found that other substituted quinolines would also act with the formation of coordinated salts with palladium. The best of these is 6-nitroquinoline. The metallic grouping formed in this case is not with the nitrogen of the quinoline structure, but with the nitrogen of the nitro group. The structural condition here is  $\equiv C-N\langle{}^{O}_{O}\rangle M\langle{}^{O}_{O}\rangle N-C\equiv$,[5] in which the metal, palladium, exhibits a coordination number of four. This compound has been found to be so stable and so insoluble in aqueous solutions that it may be used as a means of quantitatively removing palladium. As it has no precipitating effect on solutions of ruthenium, rhodium, osmium, iridium and platinum, it may also be used in separating palladium from the entire platinum metal group.

Experimental Part

Preparation of Palladium Chloride Solution.—To insure the purity of the palladium chloride used, a few grams of the dry c. p. salt as purchased from a leading supply house was dissolved in hot water acidulated with hydrochloric acid. The metal was precipitated from this solution by the addition of previously tested pure zinc dust. The spongy metal

[5] This grouping is in accord with Lowry's (*J. Soc. Chem. Ind.*, 42, 462 (1923)) interpretation of the structural formula for the precipitate of nickel with dimethylglyoxime, except that in this case nickel has a coordination number of six.

was washed free from chlorides and dissolved in freshly prepared *aqua regia* (1:3). After evaporating this solution to dryness and extracting with hydrochloric acid, several repeated evaporations with the latter reagent were carried out in order to expel all nitrogen oxides. The dihydrate, $PdCl_2 \cdot 2H_2O$, thus obtained was dissolved in a small quantity of distilled water and the palladium precipitated as $Pd(C_4H_7O_2N_2)_2$ by means of a 1% alcoholic solution of dimethylglyoxime in the *cold*.[6] After stirring, this bright yellow precipitate was filtered, washed with a small quantity of cold water containing a few cubic centimeters of alcohol and dried in an electric oven at 105°. It was then carefully ignited in air, heated for twenty minutes at red heat in a stream of hydrogen, cooled and the metallic palladium thus obtained weighed. A definite quantity (**4.780** g.) of this metal was subsequently dissolved in aqua *regia* and the solution evaporated to dryness. The residue was taken up with hydrochloric acid; this was followed by several evaporations with the latter reagent to remove all nitrogen oxides, and the solution diluted to one liter. The resulting palladium chloride solution, which was only slightly acid, was analyzed for its metal content per cubic centimeter by treating a known portion with zinc dust until all color was removed from the solution. (The colorless solution gave no precipitate with dimethylglyoxime, hydrogen sulfide, mercuric cyanide or 6-nitroquinoline—thus the absence of palladium was assured.) Excess zinc was dissolved in dilute hydrochloric acid and the spongy palladium was filtered, washed free from chlorides, dried, heated at red heat in a stream of hydrogen, cooled and then weighed. Results of two such determinations were

Weight of boat plus metal, g.	3.2723	3.2724
Weight of boat, g.	3.2484	3.2485
Weight of metal, g.	0.0239	0.0239
Amount of solution used, cc.	5.0	5.0
Weight of metallic Pd per cc., g.	0.00478	0.00478

This solution was used in the following work.

Preparation of 6-Nitroquinoline Solution.—In the analytical determinations recorded below, a hot saturated aqueous solution of this reagent was used.

The Removal of Palladium from a Solution of Palladium Chloride.—A measured amount of palladium chloride solution was heated to boiling and treated with a hot saturated solution of 6-nitroquinoline. After stirring, the mixture was allowed to boil for about five minutes. More of the reagent was then added until no further precipitation was observed. After standing for fifteen to twenty minutes, the thick, flocculent yellow precipitate was filtered. (A small portion of the filtrate was treated with

---

[6] To prevent any platinum from being precipitated.

more reagent to assure the complete precipitation of the palladium.) The precipitate was washed with distilled water until free from chlorides (as ascertained by the silver nitrate test), dried, ignited carefully in air, then heated for thirty minutes at a red heat in a stream of hydrogen, cooled[7] and the metallic palladium weighed. The results were as follows:

Weight of boat plus metal, g.	8.0769	5.9559	6.8619
Weight of boat, g.	8.0531	5.9322	6.8524
Weight of metallic Pd, g.	0.0238	0.0237	0.0095
Amount of $PdCl_2$ solution used, cc.	5.0	5.0	2.0
Weight of metal per cc., g.	0.00476	0.00474	0.00475
Weight of metal per cc. (theoretical)	0.00478	0.00478	0.00478

These results show conclusively the accuracy which is attained by the use of 6-nitroquinoline as a reagent for the removal of palladium from solutions of its salts in which there is present only a small amount of the metal.

The Removal of Palladium from a Solution of All the Platinum Metals.—Solution number 1 below was made to contain 95% by weight of palladium and 1% of each of the other platinum metals, that is, ruthenium, rhodium, osmium, iridium and platinum. The solutions of each of these used were those of the chlorides of the metals which were prepared in this Laboratory directly from the pure metal, except in the case of the osmium, which was prepared from pure crystalline OsO_4. Solution number 2 below was made to contain equal quantities of each of the six metals. The procedure of analysis was followed as shown above. The results obtained were as follows:

	Solution No. 1		Solution No. 2	
Weight of boat and metal, g.	3.2686	3.1350	3.6574	3.3210
Weight of boat, g.	3.2476	3.1262	3.6359	3.3123

Weight of metal per cc. (theoretical), g.	0.00478	0.00478	0.00478	0.00478

These determinations, while showing a slight influence of the other metals of the platinum group on the removal of palladium from such a mixture by means of 6-nitroquinoline, are sufficiently close to indicate its usefulness as a quantitative procedure. With larger quantities of metals present it could, in all probability, be made more accurate.

The Separation of Palladium from Platinum.—As platinum is the most common metal of this group which is prevalent with palladium both in nature and in commerce, it would seem important to know whether large amounts of this particular metal would influence this separation. Also, it is with platinum, especially, that most of the organic coordinated salts are formed.

[7] Cooling the spongy metal in carbon dioxide is preferable to cooling in hydrogen.

Solution number 1 below was made to contain 20% of palladium and 80% of platinum, while solution number 2 was made to contain 80% of palladium and 20% of platinum. Following the above procedure, the results were

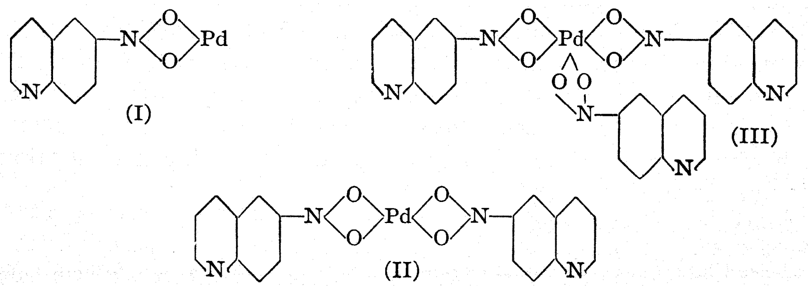
	Solution No. 1		Solution No. 2	
Weight of boat and metal, g.	**3.1352**	**3.2534**	**3.3326**	**3.5449**
Weight of boat, g.	**3.1260**	**3.2487**	**3.3096**	**3.5359**
Weight of metallic Pd, g.	**0.0092**	**0.0047**	**0.0230**	**0.0090**
Amount of $PdCl_2$ solution used, cc.	**2.0**	**1.0**	**5.0**	**2.0**
Weight of metal per cc. (recovered), g.	**0.0046**	**0.0047**	**0.0046**	**0.0045**
Weight of metal per cc. (theoretical), g.	**0.00478**	**0.00478**	**0.00478**	**0.00478**

These determinations show that platinum does not interfere with the quantitative removal of palladium by this reagent.

The Determination of the Empirical Formula **of the** Palladium Compound.—With such organic substances, palladium forms either an additive (double) salt or a coordinated (inner) one. If the precipitated compound formed in the above determinations should contain chlorine, it would indicate an additive compound. If no chlorine were found, the indications would point strongly toward a coordinated one.

Sufficient fuming nitric acid was added to a small quantity of the compound, *which had been washed free from chlorides* from the precipitating mixture, to insure its solution.[8] Excess nitrogen oxide was removed by boiling. When the solution had attained a clear straw yellow color, it was diluted and a portion taken and treated with silver nitrate. No trace of silver chloride precipitate was observed. This process was repeated on several samples of the compound with the same result.

Three possible structural formulas were then considered. These represented the palladium with coordination numbers of two, four and six, and were as follows: $Pd \cdot C_9H_6NNO_2$ (1), $Pd \cdot (C_9H_6NNO_2)_2$ (2) and $Pd \cdot (C_9H_6NNO_2)_3$ (3).



(I)

(III)

(II)

The molecular weights of these compounds are as follows: (1) 280.813, (2) 454.926 and (3) 629.039. Their percentage composition with respect to palladium, carbon and hydrogen is

---

[8] **Concentrated hydrochloric acid has no effect on the compound.**

	(1)	(2)	(3)
Palladium, %	37.99	23.45	16.96
Carbon, %	38.47	47.50	51.53
Hydrogen, %	2.16	2.66	2.88

An analysis of the yellow compound was then made which included determinations for palladium, carbon and hydrogen.

The palladium content was obtained by the reduction of the compound at red heat in a stream of hydrogen, after it had been previously washed, dried and ignited carefully in air. After cooling the spongy metal was weighed.

The carbon and hydrogen were determined by the usual combustion method,[9] in which the complete oxidation of the organic compound was attained with the formation of carbon dioxide and water, which were collected separately and weighed.

Six such determinations were made. A typical pair of analyses gave

Palladium, %	23.45	23.42
Carbon, %	43.79	44.33
Hydrogen, %	2.58	2.62

By comparing these results with the percentage composition of the three compounds immediately above, it is readily seen that number two, representing the formula $Pd(C_9H_6NNO_2)_2$ is identified.

The gravimetric factor for palladium in this compound is 0.2345. Instead of reducing the precipitate in a stream of hydrogen, it may be more conveniently washed free from chlorides, dried and the percentage of the metal calculated by the use of this factor.

Summary

A new quantitative method for the determination of palladium is given. The metal is removed from a chloride solution by means of a saturated solution of 6-nitroquinoline. The composition of the compound formed is $Pd(C_9H_6NNO_2)_2$, a coordinated salt in which palladium exhibits a coordination number of four. By use of the gravimetric factor, 0.2345, the percentage content of palladium may be had by direct weighing of the precipitate. The reagent does not react with the other metals of the platinum group, hence it may be used in effecting a separation of palladium from these metals.

SOLUBILITY. XI. SOLUBILITIES OF LIQUID STANNIC IODIDE IN SEVERAL LIQUID PARAFFINS

BY MIRIAM E. DICE AND J. H. HILDEBRAND

RECEIVED JULY 23, 1928 PUBLISHED NOVEMBER 6, 1928

Stannic iodide has been shown by Dorfman and Hildebrand[1] to have a sufficiently high internal pressure to cause incomplete miscibility in the liquid state with paraffin hydrocarbons. Since cases of incomplete miscibility are not numerous among non-metallic liquids of low polarity, and accurate data concerning such systems are lacking, a study of this sort seemed very desirable. We wished, first, to determine the way in which internal pressure varies among the paraffin homologs; second, to study the relation between the solubility of stannic iodide in the liquid and in the solid state in the light of methods recently proposed by the senior author[2] for dealing with deviations from the ideal solution laws.

Purification of Materials

Chemically pure stannic iodide was distilled twice under reduced pressure and then crystallized several times from hot carbon tetrachloride. As a further check, another sample of stannic iodide was prepared according to the method of McDermott.[3] A solution of c. p. resublimed iodine in pure carbon tetrachloride and an excess of c. p. tin were heated together. The stannic iodide solution resulting was decanted through a folded filter and crystallized three times from hot carbon tetrachloride. After each crystallization, the crystals were rinsed free from mother liquor on a small-holed Biichner funnel without filter paper. The crystals were finally dried by heating them under reduced pressure to a temperature slightly above their melting point.

The melting point of each preparation was found to be 143.6°, which agrees well with the value of 14'3.5" found in the "International Critical Tables." The purity was further checked by analysis. The stannic iodide was converted into hydrated stannic oxide by hydrolysis with ammonium hydroxide in the presence of ammonium sulfate. After standing overnight, the solution was neutralized with dilute nitric acid, methyl orange being used as an indicator, and was filtered through a Gooch crucible which had previously been ignited to constant weight. The crucible was then placed on a nichrome triangle in a large nickel crucible and heated to a red heat to drive off the water of hydration. The ratios of stannic iodide to stannic oxide were found to be for preparation I, 4.156, 4.161; and for preparation II, 4.155, 4.149, 4.158. The averages are 4.159 and 4.154, agreeing well with the theoretical value of 4.157.

The tin used in the above preparation was obtained as analyzed sticks containing, as impurity, a very small percentage of lead. This tin was further purified by electrolysis, using the tin sticks as electrodes and a slightly acid solution of stannic chloride as the electrolyte. The current density used was such that the tin was deposited at the cathode in the form of long crystals, the lead remaining at the anode.

Ammonium hydroxide was prepared by passing ammonia gas into distilled water. Carbon tetrachloride was purified by shaking it with sodium hydroxide to remove all

acidic constituents and then by distilling it from phosphorus pentoxide. The normal hexane used was from Kahlbaum, prepared from propyl iodide; the octane, from the same source, had been prepared from normal butyl iodide from butyl alcohol. The *iso*-octane, 2,2,4-trimethylpentane, was obtained from the Ethyl Gasoline Corporation. The preparation and properties of this substance were described by Edgar.[4] Dr. Lachman, of this Laboratory, had tested our sample for the presence of butyl alcohol and unsaturated bodies, finding them practically absent. The constancy of boiling point also showed the liquid to be sufficiently pure for all ordinary purposes. The heptane was from a supply of high purity prepared for a previous investigation in this Laboratory.[5] All of the liquids used were distilled using a fractionating column and the middle fractions only were taken. All gave boiling points in close agreement with the values in the "International Critical Tables."

Experimental Procedure

Pyrex glass tubes were closed at one end, drawn out into a capillary for subsequent sealing and opened into a funnel at the other end. A tube was weighed, an appropriate amount of stannic iodide was placed in the funnel, melted into the closed end of the tube and weighed. The liquid paraffin was then added so as nearly to fill the tube below the constriction; the tube was then cooled in liquid air, sealed off and the sealed tube weighed along with the rejected portion. From these weights the mole fractions of stannic iodide given in Table I were calculated.

These tubes were rocked back and forth in an oil-bath in an electric oven

equipped with small glass windows and illuminated from the rear. The rate of heating and cooling was regulated by varying the resistance in the circuit. A sufficiently slow rate was maintained so that the mean of the readings taken at the point where the two liquid phases disappeared and of those taken where they appeared agreed, in every case, within 0.2°. At least six observations were made upon each tube, the averages being recorded in Table I. These observations seldom differed from one another by more than 0.4°.

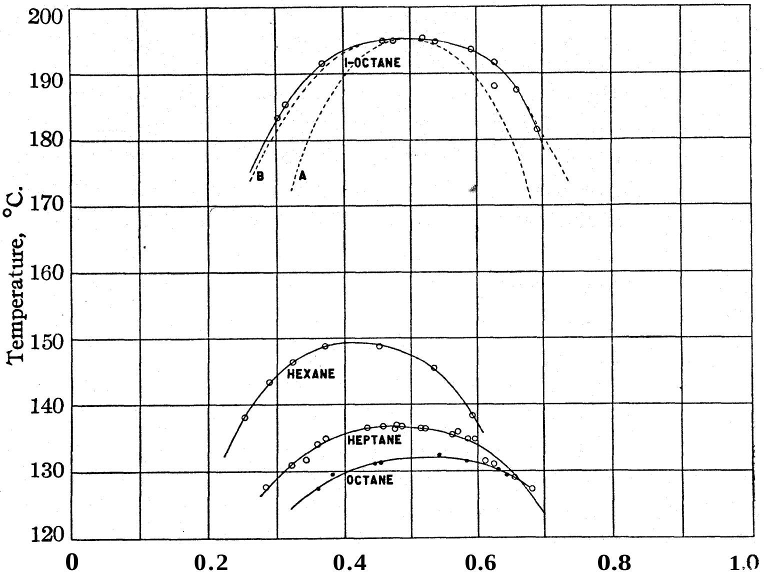

Fig. 1.—Mole fraction of stannic iodide.

From these values mole fraction–temperature curves were plotted, as shown in Fig. 1. It was impossible to determine the shape of the curves at much lower temperatures than those given, due to the crystallization of the stannic iodide. The maxima give the critical mixing temperatures recorded in Table II.

[a] 2,2,4-Trimethylpentane.

Discussion

We may note, first, that the order of critical temperatures is in rather good agreement with such data as we have regarding internal pressures. For estimating the latter, we have only the boiling points, t_b, using a relation previously given by the senior author[a] $(5200 + 30t_b)/v$, where v is the molal volume of the liquid at 20°. For the liquids here employed, we have the data in Table III.

TABLE III

RELATIVE INTERNAL PRESSURES

	Density at 20°	Molal vol.	B. p., °C.	$(5200 + t_b)/v$	t_c
i-Octane	0.690	165.5	99.3	49.4	195.3
n-Hexane	0.660	130.5	69.0	55.7	149.4
n-Heptane	0.683	146.5	98.4	55.6	136.8
n-Octane	0.701	162.8	124.6	59.4	132.0
Stannic iodide	4.16	150.7	340	102	...

The figures in the next to the last column for relative internal pressures agree with the order of critical solution temperatures repeated in the last column except for the minor difference between hexane and heptane. In view of the lack of accurate figures for the heats of vaporization, it is believed that the critical temperatures best represent the true order of the internal pressures. We may note, further, that heptane does not quite fall midway between hexane and octane, although the difference is so small that it may not be significant. It is especially striking that the iso-octane has an internal pressure much lower than n-octane. The generally lower boiling points of iso-paraffins indicate that their internal pressures will probably be found lower than those of the corresponding normal paraffins. These trends in internal pressure may be expected to determine rather accurately the general solubility relations of the paraffins.

In a paper by the senior author now in preparation, there is set forth a method for calculating mutual solubility curves for non-polar liquids. As a first approximation, the equation

$$\log \frac{1 - N_1'}{N_1'} = \frac{k}{T}(1 - 2N_1') \qquad (1)$$

has been derived, where N_1' is the mole fraction of component 1 in one phase, T the absolute temperature and k a constant depending, in part, upon the difference in internal pressure of the two components. The mole fraction of component 2 in this phase is $1 - N_1'$, while in the second phase the two mole fractions are interchanged. This equation applies to symmetrical systems only, that is, to those whose critical composition is 0.5. When the critical composition is not 0.5, an additional constant must be used and two simultaneous equations are obtained whose solution is mathematically very laborious. Consequently, we will illustrate the treatment by using the curve for iso-octane, which is practically symmetrical. The dotted curve in Fig. 1, marked A, represents Equation 1, using $k = 407$. In solving this equation arbitrary values are assigned to N_1', and the equation is solved for T, since the reverse procedure would

[6] Hildebrand, "Solubility," Chemical Catalog Company, New York, 1924, p. 108.

require a method of successive approximations. It is seen that Curve A is too steep; however, the equation is of such a nature that slight changes in k greatly affect the spread in N, and it is known from other systems as well as from theoretical considerations that k is likely to diminish with increasing temperature.

A determination of the solubility of solid stannic iodide in this *iso*-octane, to be presented in the paper now in preparation, has given a value of k of 503 at 25°. If we represent the variation of k with temperature by the equation $k = 671 - 0.565\ T$, we get the dotted curve, B, Fig. 1, which agrees excellently with the experimental points, although this makes k vary only 2% in 15°.

In the case of heptane, we have not carried through the troublesome calculations, since the curve is unsymmetrical, but it is evident from a few figures that the rate of change of k necessary to give the value obtained from the solubility of stannic iodide, 130° lower, also gives the proper spread to the liquid solubility curve.

Summary

1. Critical solution temperatures of stannic iodide have been obtained with liquid paraffins as follows: n-octane, 132.0°; n-heptane, 136.8'; n-hexane, 149.4'; i-octane (2,2,4-trimethylpentane), 195.3°.

2. The mole fractions of stannic iodide at the critical solution temperatures are, respectively, 0.52, 0.48, 0.42 and 0.50.

3. The internal pressures increase for the normal hydrocarbons in the order of increasing molecular weight.

4. The normal octane has a higher internal pressure than the *iso*-octane used; this difference between a normal and an iso-paraffin is probably general.

5. The form of the liquid–liquid solubility curve has been calculated.

THE DETERMINATION OF REACTION AFFINITY IN SYSTEMS OF SOLID SALTS

BY J. N. BRÖNSTED AND W. T. RICHARDS

RECEIVED AUGUST 2, 1928 PUBLISHED NOVEMBER 6, 1928

1. A Thermodynamic Relation for Partially Saturated Solutions[1]

If $\pi_0, \pi_1, \ldots\ldots$ indicate the chemical potentials of the components K_0, $K_1, \ldots\ldots$, and $n_0, n_1, \ldots\ldots$ indicate the number of gram molecules of each in a homogeneous solution, the Gibbs equation for this solution reads

$$n\,d\pi_0 + n_1 d\pi_1 + \ldots\ldots = 0 \qquad (1)$$

If the potentials $\pi_2, \pi_3, \ldots\ldots$ are held constant, $d\pi_2 = d\pi_3 = \ldots = 0$, and consequently Equation 1 becomes merely

$$n\,d\pi_0 + n_1 d\pi_1 = 0 \qquad (2)$$

Equation 2 is applicable to homogeneous mixtures of $K_0, K_1 \ldots$ when saturated with the pure solid components $K_2, K_3, \ldots$ It has often been applied to simple binary mixtures. According to the above, however, it retains its validity when the binary mixture is saturated with an arbitrary number of solid substances while the concentration n_1/n_0 varies.

In order to define n_0 and n_1 in a solution saturated with other substances $K_2, K_3 \ldots$ it is necessary to remove the latter from the solution so far as is stoichiometrically possible. The solution will then consist stoichiometrically of K_0 and K_1 only. This is also true if one or several of the saturating substances are molecular compounds of K_0 or K_1.

By means of Equation 2 it is possible to calculate, from vapor pressure measurements of the solvent, the free energy change of reaction of solid salts. The principle of this method is described in section 2.

2. The Principle of the Affinity Measurement

Where the reaction, in the solid state, is the formation of a double salt from its components as A + B ⟶ AB, the affinity of the process equals the chemical potential of A in the solid system A + AB minus the potential of A in the solid system B + AB. Representing these systems by (1) and (2), respectively, the affinity may, therefore, be expressed, $\pi = \pi_{A\,(1)} - \pi_{A\,(2)}$, or $\pi = \pi_{B\,(2)} - \pi_{B\,(1)}$. With water present as a solvent, when the amount of A in the solution is gradually changed from saturated solution (1) to saturated solution (2) while equilibrium with the solid AB is maintained, we have, $\pi = -\int_1^2 d\pi_A$, where $d\pi_A$ indicates the increase in chemical potential for A in the solution corresponding to a small increase in n_A. Introducing equation (2), we obtain

$$\pi = \int_1^2 \frac{n_0}{n_A}\,d\pi_0 \qquad (3)$$

---

[1] J. N. Bronsted, *Kgl. Dansk. Vid. Selsk. Medd.*, *1*, *Nr.* **5** (1918).

where n_0 refers to the solvent. In order to integrate this expression, π_0 must therefore be known as a function of n_0/n_A from (1) to (2). Or, since $\pi_0 = RT\ln p_0$, we must know the vapor pressure of the solution over this interval. It is of value to note in the construction of this vapor pressure curve that, contrary to the case of simple binary mixtures, $d\pi_A/dn_A$ is finite for $n_A = 0$, owing to the existence of A in solutions containing only AB in a stoichiometrically pure state.

If the reaction considered is one between four solid salts, A + B $\longrightarrow$ C + D, the affinity is measured by a method which is entirely similar, the stable salt pair C + D fulfilling the function of the double salt in the example considered above, and (1) and (2) therefore corresponding to the two triads A + C + D and B + C + D, respectively. The affinity is therefore obtained by integration of Equation (3) between these two limits on the basis of vapor pressure measurements in a solution saturated with C + D, the amount of A or B varying from one triad solution to the other.

To test this relation experimentally, a distinction must be made between two possible cases, which may be called the congruent and the incongruent, respectively.[2] When a saturated solution of A + AB and B + AB may be made by means of positive amounts of these respective salts, the solution is congruent. If, however, the solution saturated with B + AB can be made by positive quantities of A and AB, the solution is incongruent, and a saturated pure double salt solution will be unstable.

The latter case, which is the simplest experimentally, is illustrated by Fig. 1, n, the number of moles of A per mole of water, being taken as abscissas and p, the vapor pressure of the saturated solution, being ordinates. The point AB on this diagram corresponds to a solution saturated with double salt and points AB + B and AB + A to saturation with each of the indicated solid systems. Starting with the solution saturated with AB + B and evaporating off water, p will remain constant as long as two solid phases are present, but will finally begin to fall when all solid B has been converted into solid AB. On further evaporation of water the pressure will fall until AB + A is reached, when solid A will separate and p will again become constant. When the original amounts of AB, B and water are known, and the amount of water evaporated has been determined, a curve for vapor pressure as a function of concentration between AB + B and AB + A may be constructed of the type necessary for the calculations outlined above.

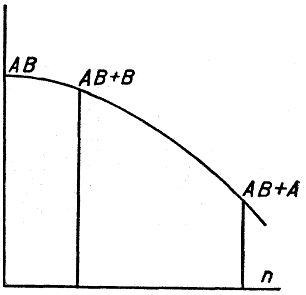

Fig. 1.

---

[2] Meyerhoffer, *Sitz. Aknd. Wiss. Wien*, *104*, IIb (1895); Neyerhoffer and Saunders, *Z. physik. Chem.*, 28, 471 (1899).

In the congruent case, which has been treated experimentally in this communication, much the same reasoning applies. Here, however, the evaporation of water from a single solution containing AB + B will be insufficient to give the desired solution saturated with AB + A. From Fig. 2 it may be seen that a determination of the concentration–vapor pressure function involves, in this case, the evaporation of water from two separate solutions saturated with AB which contain small amounts of A and B, respectively. Here p will fall increasingly with increasing concentration of A or B until the two points A + AB and B + AB are reached, where constancy of p will in each case be attained. A knowledge of the amount of water, double salt and single salt present, and of the vapor pressure of each of the two solutions is therefore necessary in order that the affinity may be computed for the double salt.

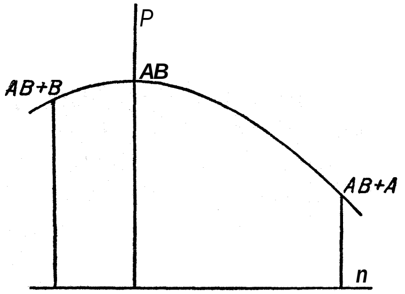

Fig. 2.

3. Apparatus and Procedure

The apparatus used is illustrated in Fig. 3. It consisted, in essence, of two flasks A and B, a condensing bulb M, and a manometer H, these being connected by a system of stopcocks which enabled each part of the apparatus to be evacuated separately. A Gaede pump, the connection for which only is shown in the drawing, was used for evacuation. The flasks, mounted together on a strong support which gave them a motor-driven horizontal agitation of about 3 cm., were connected to the bulb M and the mano-

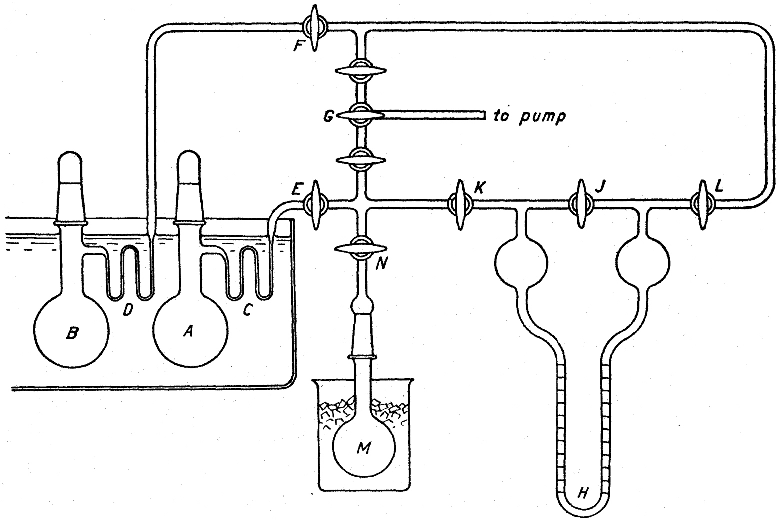

Fig. 3.

meter system by the long, thin-walled glass tubes, or springs, C and D, sufficiently elastic to permit the agitation. They were immersed to their necks in a thermostat giving a temperature of 19.93 ± 0.01°. The rest of the apparatus was at room temperature, care being taken to prevent the condensation of water vapor on the walls of the tubes. Flask **A** contained the solution the vapor pressure change of which with changing concentration was under observation. Flask B contained a saturated reference solution of constant vapor pressure. The saturating component used in all experiments in this communication was ammonium chloride. The spring C and the stopcock E were made of as large a bore as possible to permit the ready passage of water into the condensing bulb M.

In operating the apparatus the oil in the manometer, β-bromonaphthalene, was first carefully freed from air by warming and prolonged evacuation. The flasks were then appropriately filled and freed from air by prolonged evacuation and agitation. The remainder of the system was then evacuated with the stopcocks E and F closed. After about five minutes the solutions had come to temperature equilibrium after evacuation, and the stopcocks in the bridge G were closed and, with K, J and I, open, E and F were opened. J was then closed and the difference of level in the manometer H read with a lens and recorded when it had become constant. The process of evacuation and measurement was repeated to constancy of the vapor pressure difference between the two solutions, when air had adequately been removed from the system. With K closed, about 2 cc. of water was then transferred from **A** into the ice-cooled bulb M by distillation. N was then closed and M weighed to determine the quantity of water transferred, after which M was dried and reattached to the apparatus. With E and K closed M was again evacuated, and the pressure difference between the two solutions again determined. Thus, by successive small increments, the concentration of the single salt in the saturated double salt solution was made to approach saturation. Finally a point was reached where the solid single salt separated from the solution and further evaporation of water caused no further decrease in vapor pressure. When this point was clearly established the experiment was discontinued and the contents of the flask A were analyzed by one of several methods given hereinafter in order to find the amount of water present at the start. If the solution became inconveniently thick, the experiment was discontinued before the double point had been reached and more water and weighed single salt were added. The process of measurement and concentration was then repeated. From the data so obtained was calculated the vapor pressure of the solution as a function of its concentration.

A few precautions deserve brief note. Obviously, for instance, the apparatus must not be evacuated during the progress of a determination since this would entail an indeterminate loss of water. Again, after the removal of water by condensation there was, in the presence of much solid salt, a lag in the attainment of equilibrium which often necessitated a wait of two hours. Finally, the stopcocks K and L were kept closed when the apparatus was not in use to prevent the solution of water in the oil of the manometer H.

4. Measurements

Preliminary experimentation having demonstrated that carnallite was unsuitable for the purposes of measurement, the double salt $CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O$ was finally selected as having convenient properties. Measurements were made with and without NaCl as an additional saturating component of constant potential. The following reference points were then determined.

The saturated ammonium chloride solution used throughout in the reference flask B had a vapor pressure, at 19.93°, of 12.32 cm. of oil or 13.65 mm. of mercury. The last of these two figures is based on a pycnometric determination of the density of β-bromonaphthalene, which showed it to be 0.1108 that of mercury at room temperature.

The vapor pressures of the saturated points of the systems under investigation were found to be:'

Saturating salts	p, mm. of Hg
$CuCl_2 \cdot 2H_2O + CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O$	11.80
$NH_4Cl + CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O$	13.63
$CuCl_2 \cdot 2H_2O + CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + NaCl$	10.80
$NH_4Cl + CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + NaCl$	12.11
$CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O$	14.75
$CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + NaCl$	12.73

These points serve as the integration limits for the equation developed above. The concentrations of the salts at the various points were determined analytically, as described below.

The purity of the salts prepared commercially for analytical purposes was found sufficient for the experiments. Proof of this is, of course, the constancy of the double-point vapor pressures on the evaporation of successive increments of water. That the double salt (which was prepared from its single constituents recrystallized together from solution in stoichiometric proportions), the ammonium chloride and the copper chloride contained, in the solid state, no more than their theoretical amount of crystal water was demonstrated by gravimetric analysis to 0.1%.

The four sets of measurements, which are summarized below, were then made. Actual readings of vapor pressure and concentration have been omitted in the interests of space conservation, the figures in the several tables having been obtained from curves constructed in each case from separate concordant series of observations. The initial amounts of double and single salts, which were always weighed before their introduction, and the different methods of obtaining the initial water content are recorded in each case to give a complete picture of the measurements.

In the tables **Ap** signifies the difference in vapor pressure, in cm. of oil, between the solution under observation and the saturated ammonium chloride reference solution, gH_2O indicates the number of grams of water present in the solution at each reading, p indicates the vapor pressure of the solution in mm. of mercury, $\log_{10} p$ the logarithm of this quantity, **and** n_1/n_0 the ratio of moles of single salt to moles of solvent at each vapor pressure.

Determination I.—Copper chloride, 4.826 g.; double salt, 9.63 g.

The amount of water present at the double point was found to be 9.77 g. by adding a weighed quantity of water to the salt–water mixture after the conclusion of the determination, and analyzing the resulting solution for ammonium content by distillation and for chlorine content by a standard silver nitrate solution.

TABLE I

RESULTS OF DETERMINATION I

Δp	H_2O, g.	p	$\log_{10} p$	m_1/m_0
−1.67	2.64	11.80	1.0719	0.1931
1.45	2.97	12.04	1.0806	.1709
1.14	3.48	12.39	1.0930	.1464
0.87	3.98	12.69	1.1035	.1280
.63	4.48	12.95	1.1123	.1136
.32	5.23	13.30	1.1239	.0958
.11	5.98	13.53	1.1312	.0853
+ .12	6.98	13.78	1.1393	.0731
.41	8.48	14.10	1.1492	.0598

.88	21.98	14.63	1.1653	.0232
..	...	14.75	1.1688	0

Determination 11.—Ammonium chloride, 0.9153 *g.*; double salt, 9.96 g. The amount of water present at the double point was found to be 8.10 g. by saturating a solution with ammonium chloride and double salt and analyzing for ammonium and chlorine concentration as in Determination I. From these data the weight of water present when the double point is reached with 0.9153 g. of ammonium chloride was calculated. In this determination, therefore, the weight of double salt present during the vapor pressure measurements played no part since it was saturated throughout.

TABLE II

RESULTS OF DETERMINATION II

Δp	H_2O, g.	p	$\log_{10} p$	n_1/n_0
−0.02	8.10	13.63	1.1345	0.1193
+ .25	9.38	13.93	1.1439	.1029

5. Computation of the Affinity of Formation

The results given in the tables of the preceding section permit the calculation of two values for the affinity of formation of the double salt $CuCl_2\cdot$-

$2NH_4Cl \cdot 2H_2O$, one in the presence of sodium chloride as a saturating component of constant activity, and the other in its absence. The necessary integration is most easily effected by throwing Equation (3) into the form

$$A = \frac{RT}{0.4343}\int_0^n \frac{d \log p}{n}$$

where n = (n_1/n_0). Then Determinations I and III may be integrated by the relationship

$$\log p_0 - \log p = \alpha n^2 + \beta n^3$$

and Determinations II and IV by the expression

$$\log p_0 - \log p = \alpha n^2$$

where α and β are constants for each determination and p_0 refers to the saturated double salt solution. The values for these constants are:

Detn. **no.**	I	II	III	IV
α	7.05	2.4	10.7	3.75
β	−22.5	...	−46.0	..

Integration yields the following results

Detn. **no.**	I	II	III	IV
A in cal.	**1960**	**767**	**2060**	**785**

The two concordant values for the affinity of formation follow directly

$$A_{(\text{abs. NaCl})} = 2A_{\text{ii}} + A_{\text{i}} = 3494 \text{ cal.}$$
$$A_{(\text{pres. NaCl})} = 2A_{\text{iii}} + A_{\text{iv}} = 3630 \text{ cal.}$$

The average value for the affinity of formation of one molecule of double salt from its solid components, that is, the change in free energy by the reaction

$$CuCl_2 \cdot 2H_2O_{\text{solid}} + 2NH_4Cl_{\text{solid}} \longrightarrow CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O_{\text{solid}}$$

is **3560** cals.

Summary

1. **A** thermodynamic relationship for the dilution affinities of partially saturated solutions has been advanced.

2. The change in vapor pressure with changing concentration of single salt in the systems $CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + CuCl_2 \cdot 2H_2O$, $CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + NH_4Cl$, $CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + CuCl_2 \cdot 2H_2O + NaCl$, and $CuCl_2 \cdot 2NH_4Cl \cdot 2H_2O + NH_4Cl + NaCl$, saturated with double salt and NaCl, has been determined by means of a differential tensimeter of novel design.

3. The validity of the principle desired has been demonstrated within experimental error, a free energy of formation of **3560** cal. being found for the double salt in question.

THE VAPOR DENSITY OF FORMIC ACID

BY H. C. RAMSPERGER[1] AND C. W. PORTER

RECEIVED AUGUST 31, 1928 PUBLISHED NOVEMBER 6, 1928

Papers on the vapor density of formic acid have been published recently by Wrewsky and Glagoleva[2] and by Coolidge.[3] In a paper entitled "The Ultraviolet Absorption Spectrum of Formic Acid," published by Ramsperger and Porter in May, 1926,[4] the vapor densities of formic acid at temperatures between 25 and 80° were reported. Since, in the title of this paper, no reference was made to vapor density, it was overlooked by Coolidge who credits Bineau and Pettersson and Ekstrand with the only earlier work in this field.

The purpose of this communication is to make a graphical comparison of all the data on this subject. Equilibrium constants for the reaction $(HCOOH)_2 = 2HCOOH$ have been calculated from the data of Pettersson and Ekstrand,[5] of Wrewsky and Glagoleva,[2] of Coolidge,[3] and of Ramsperger and Porter.[4] The equilibrium constant is given by the expression $K = p_m^2/p_b$, where p_m is the pressure in atmospheres, due to the unimolecular form, and p_b is the pressure of the bimolecular form.

In Fig. 1 $R \ln K$ is plotted against $1/T$. The line drawn approximately through the experimental points of Wrewsky and Glagoleva is the graph of an equation given by Willard Gibbs[6] which he found would fit the experimental values of Bineau[7] fairly well, and it is seen that it also fits most of the data of Wrewsky and Glagoleva. The recent, very accurate determinations of Coolidge do not fit this equation at all. Constants have not been calculated for all of the large number of experiments of Coolidge. We have selected those having about the same pressures at low temperatures as were used in our own work. At the higher temperatures his lowest pressures experiments were chosen so as to minimize errors due to deviations from the gas laws. The straight line drawn through his points is also the best straight line through the points obtained by Ramsperger and Porter. The slope of this line corresponds to a heat of dissociation of 14,100 cal. per mole, which is identical with the average value published by Ramsperger and Porter. The equation of Gibbs gives a heat of dissociation of 17,400 cal. per mole, and Pettersson and Ekstrand's data give 16,000 cal. per mole.

Coolidge took very great precautions as to the purity of his formic acid. This is a matter of importance. In our early experimental work it was observed that considerably lower constants were obtained at low temperatures and at pressures approaching the saturation pressure than under other conditions. Adsorption on the glass walls could have been responsible for only a small part of this, since the addition of broken pieces of the same kind of glass gave only a small increase in density. An impurity such as a trace of stopcock grease greatly increased the apparent density. Our final results were obtained with a sample of Kahlbaum formic acid which was analytically pure. This was distilled in vacuum and was free from non-condensable gases. It was passed through glass wool which apparently helped to remove those impurities which favored incipient condensation on the walls. It seems very likely that traces of impurities were responsible for the lower constants of earlier investigators.

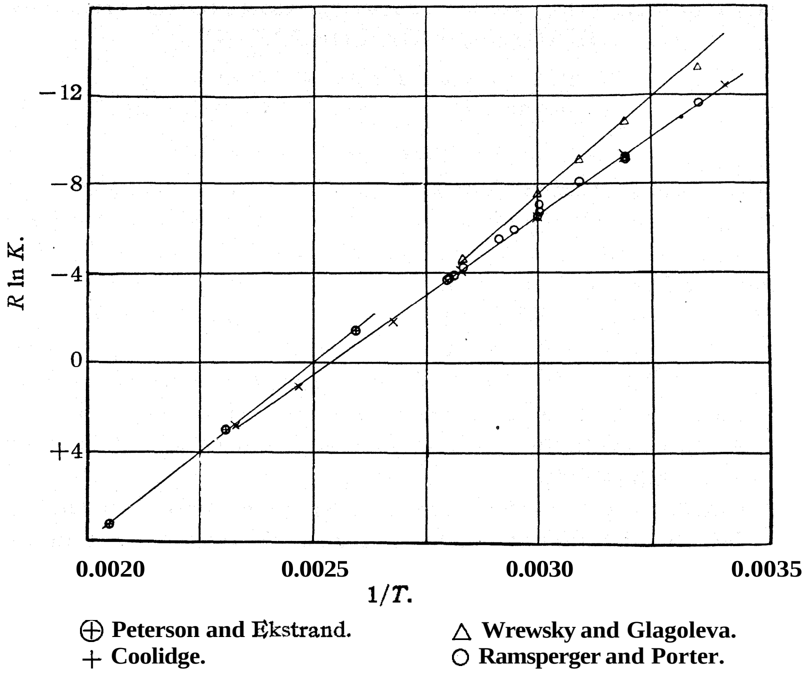

Fig. 1.

The experiments of Wrewsky and Glagoleva were made by a method in which the vapor density was determined by an analysis of air which had passed through liquid formic acid. The higher densities may have been due to small fog-like particles of liquid which were carried over with the vapor. Such particles are not easily eliminated.

Summary

A survey has been made of all existing data on the vapor density of formic acid. There is complete agreement between the measurements made by Coolidge and those of Ramsperger and Porter. Traces of impurities were probably responsible for the discordant results of the earlier investigators.

SOME PROPERTIES AND TRANSFORMATIONS OF ORTHO-DICHLORO-4-NITROBENZENE[1,2]

BY L. MCMASTER AND A. C. MAGILL

RECEIVED JUNE 18, 1928 PUBLISHED NOVEMBER 6, 1928

Introduction

Beilstein and Kurbatow[3] found that 4-nitro-o-dichlorobenzene formed in two modifications when o-dichlorobenzene was treated with fuming nitric acid. They describe a semi-fluid mixture from which the solid part settles out and can be crystallized from alcohol in long needles of m. p. 43° and b. p. of 255–256°. Holleman[4] has studied the nitration of the dichlorobenzenes and found that when the ortho compound is dropped into nitric acid cooled to 0 or 30° the 1,2-dichloro-4-nitrobenzene is the principal product along with small amounts of isomers. His work on its physical constants agrees with thosd of Beilstein and Kurbatoff but he makes no mention of a liquid form.

In connection with some work to prepare o-chloro-p-nitraniline, we found that the nitration of o-dichlorobenzene always gave us a mixture of the liquid and solid forms of o-chloro-4-nitrobenzene. Since Beilstein and Kurbatoff give no information regarding any changes of the one form into the other and since the literature records no other nitro-o-dichlorobenzenes as liquids we decided to make a study of some of the properties and transformations of o-dichloro-4-nitrobenzene.

Experimental

Purification and Nitration of *o*-Dichlorobenzene.—The o-dichlorobenzene used in this work was prepared from the commercial material supplied us by the Monsanto Chemical Works. It was first distilled to remove any mono- and trichlorobenzene, the fraction between 165 and 200° being retained. One liter of this fraction was then cooled to −15° so that any of the para compound present would crystallize out and could be

[2] Presented before the Organic Chemistry Division of the American Chemical Society at the St. Louis Meeting, April, 1928.

[3] Beilstein and Kurbatow, *Ann.*, 176, 41 (1875).

[4] Holleman, Rec. trav. *chim.*, 23, 357 (1904).

filtered off. The filtrate was distilled, the fraction boiling between 174 and 180" being collected and cooled to −15°. This procedure was repeated and the fraction boiling between 177 and 180° was found to be free from the para isomer[6] by sulfonating a portion of the liquid with fuming sulfuric acid and pouring the mixture into water. By this process the ortho only is sulfonated. Any *p*-dichlorobenzene present would be unchanged and separate out in the water. If the aqueous solution of the o-dichlorobenzenesulfonic acid is then steam distilled, the o-dichlorobenzene will pass over. After drying and distilling, it was water white and had a sp. gr. of 1 299 at 20°.

In order to purify the material further it was nitrated and distilled with steam. p-Dichlorobenzene does not readily nitrate and, if present, can be blown out with steam. The nitro compound was then reduced with tin and hydrochloric acid. The reduced product was not removed from the mixture but was diazotized at once and boiled with water and an excess of caustic soda. The o-dichlorobenzene separated out, was drawn off, dried and distilled. In order to replace the diazo group by hydrogen we found that alcohol and other reducing agents were not necessary. The crystallizing point of the compound was found to be −17.5". The "International Critical Tables" give it as −17.6°, whereas the Monsanto Chemical Works[6] have recently found it to be −16.7" on a sample prepared by a different method than just described.

One hundred and twenty-five cc. of the pure o-dichiorobenzene was nitrated, using 200 cc. of sulfuric acid of sp. gr. 1.84 and 175 cc. of nitric acid of sp. gr. 1.42. Nitration at 60° was easily effected in two hours with stirring. The nitro compound was separated, washed a number of times with water, dried over calcium chloride and distilled, the fraction between 254 and 257° being collected; yield, 95% of the theoretical. Nitration of 125 cc. of the o-dichlorobenzene was also accomplished in two hours at 60° by using 370 cc. of commercial mixed acid containing 57.3% of sulfuric acid and 33% of nitric acid; yield, 94% of the theoretical. A mixture of the liquid and solid forms was obtained.

Some Properties of **o-Dichloro-4-Nitrobenzene.**—The solid portion obtained above, when crystallized from alcohol or carbon tetrachloride, melts at 43°. When o-dichloro-4-nitrobenzene is kept at 15° the liquid form changes entirely to the solid form as long yellow needles of m. p. 43°. This would seem to indicate that no other isomer is present in the liquid form. We recognized the fact that a small amount of the *o*-dichloro-3-nitrobenzene (m. p. 62°) might be present. If, however, the material is kept at 25°, all of it changes to the liquid modification mentioned by Beilstein, the solid phase disappearing. Twenty g. portions of the material were kept for periods of eight hours each at various temperatures between 15 and 25". It was found that an appreciable amount of the liquid was present at 17°. At 22° the material appeared to be half liquid and half solid. At 24" a very small quantity of the solid remained. The portion at 22° was rapidly filtered and the solid weighed. The crystals obtained weighed 10.1 g. Apparently the solid and liquid are present in equal quantities at this temperature. When the crystals were allowed to stand at 22° they gradually changed until about 50% of liquid was present. When the liquid was allowed to stand at this same temperature about 50%

---

[5] The b. p. of the o-compound is 179–180° and that of the para 172°.

[6] Carswell, *Ind.* Eng. *Chem.*, 20, 728 (1928).

of crystals formed. Of course the solubility of the solid form in the liquid is to be considered, but a number of experiments gave the same results. When the solid material was crystallized from alcohol or carbon tetrachloride, the crystals obtained did not change to the liquid modification. If some of the other o-dichloronitrobenzenes were liquids, it is quite possible that the liquid form of the 4-nitro compound would be a mixture of the solid form and the liquid dichloronitrobenzene, but such is not the case.

Action of Alcoholic Potash on o-Dichloro-4-Nitrobenzene.—There is no mention in the literature of the action of alcoholic potash on *o*-dichloro-4-nitrobenzene. Twenty g. of the liquid-solid mixture was refluxed with 40 g. of potassium hydroxide in 200 cc. of ethyl alcohol. When the reaction mixture reached 80°, a vigorous reaction set in and within five minutes was complete. The solution turned red and a dark red solid precipitated out. The solid, which proved to be 3,3′,4,4′-tetrachloro-azoxybenzene, was filtered off and recrystallized from carbon disulfide; 14 g. of crystals of m. p. 139° was obtained. The filtrate was poured into water and acidified with hydrochloric acid. A black, tarry mass formed. This was filtered off, warmed with caustic soda to dissolve the phenol and again filtered. The filtrate, when acidified with hydrochloric acid, had a very pronounced phenol odor. The liquid was extracted with ether and 0.5 g. of 2-chloro-4-nitrophenol, melting at 110°, was obtained. The residue obtained by heating the tarry mass with caustic soda was extracted with ether, from which was obtained 1.8 g. of 3,4-dichloro-aniline of m. p. 72°. The literature records 71.5°.

3,3′,4,4′-Tetrachloro-azoxybenzene was prepared by G. M. Kraay[7] by the oxidation in air of 3,4-dichloro-phenylhydroxylamine. He found the melting point to be 139–139.5°.

Action of o-Dichloro-4-Nitrobenzene with Sodium **Alcoholates.**—When o-dichloro-4-nitrobenzene is treated with solutions of various sodium alcoholates in the corresponding alcohol, ethers are formed, a chlorine group being replaced by O–R. In each case given in the adjoining table, 10 g. of o-dichloro-4-nitrobenzene was refluxed for two hours with the alcoholate, the mixture cooled and the solid which formed filtered off and washed with the corresponding cold alcohol. The solubility of the resulting ether in methyl alcohol, ethyl alcohol, benzene, ether and acetone was determined, as was also the melting point. A determination of the percentage of nitrogen in the compound also was made. Five g. of each nitro-ether was reduced with tin and hydrochloric acid. The resulting amine in most of the cases was diazotized and coupled with an alcoholic solution of β-naphthol, giving a dye.

We can find in the literature none of the ethers described except the

---

[7] G. M. Kraay, "Dissertation," Amsterdam, 1926.

2-chloro-4-nitro-anisole which was prepared by Griess[8] by replacing the amino group of 2-amino-4-nitrophenyl methyl ether with chlorine. He records its m. p. to be 93–94°.

TABLE I

DATA ON THE ETHERS

Ether, 2-chloro-4-nitro-	Color and cryst. form	Yield, g.	Nitrogen, Calcd.	% Found	M. p., °C.	Color of amine dye
Anisole	Cream flakes	9.0	7.46	7.44	94	Purple
Phenetole	Dark brown cryst.	4.0	6.94	7.00	142	...
Isopropyl ether	Light brown flakes	4.5	6.49	6.45	128	Dark red
Phenyl-n-butyl ether	Brown flakes	8.4	6.10	6.10	136	Purple-red

The first of the above ethers is insoluble in cold or hot water, slightly soluble in ethyl alcohol and acetone and very soluble in these latter solvents when hot. It is also soluble in ether and benzene. The second ether is insoluble in water, cold ethyl alcohol and acetone but soluble in the last two when hot. The third ether is insoluble in water and slightly soluble in cold ethyl and isopropyl alcohols and acetone. It is also soluble in ether, benzene, hot ethyl alcohol and acetone. The last one is slightly soluble in acetone, soluble in ether and benzene and very much so in hot methyl and ethyl alcohols.

Summary

1. o-Dichloro-4-nitrobenzene was found to exist in a liquid and a solid modification, the two existing in approximately equal quantities at 22°.
2. Alcoholic potash on the compound gives mainly 3,3′,4,4′-tetrachloro-azoxybenzene and small quantities of 3,4-dichloro-aniline and 2-chloro-4-nitrophenol.
3. Four ethers of the compound were prepared, three of them for the first time. The 2-chloro-4-nitro-anisole had been previously prepared by a different method. Some of their properties are described. Three of these were reduced, diazotized and coupled with β-naphthol, giving red and purple dyes.

THE REACTIVITY OF ATOMS AND GROUPS IN ORGANIC COMPOUNDS. VII. THE INFLUENCE OF CERTAIN SOLVENTS ON REACTION VELOCITY—ADJUVANCE

BY JAMES F. NORRIS AND SPENCER WARD PRENTISS[1,2]

RECEIVED JUNE 23, 1928 PUBLISHED NOVEMBER 6, 1928

It has long been known that the rate at which a reaction takes place in solution is markedly affected by the solvent. This fact has been studied by a number of investigators, but no adequate explanation has as yet been offered. The object of the work about to be described was not to attempt to solve this problem, but to get definite information in regard to the relative effects of the members of a series of alcohols on the rate at which a reaction took place in solutions in which the alcohols served as solvents.

In order to facilitate the consideration of the effects of solvents on reaction velocity, it seemed desirable to coin a new word which would serve to express this kind of action. The word adjuvance, from the Latin adjuvans from *adjuvare,* to help or to assist, has been found convenient in expressing the behavior of solvents from this point of view. For example, reactions, in general, take place more rapidly in nitrobenzene than in benzene; the adjuvance of the former is greater than that of the latter. It is impossible to measure the absolute adjuvance of a solvent but the word can be used in a derived sense to express quantitative relationships. We have found, for example, that the adjuvance of nitrobenzene is 26 times that of benzene when the reaction involved is that between pyridine and ethyl iodide. This means that the rates at which the reaction takes place in the two solvents are in the ratio of 26 to 1.

The desirability of studying the adjuvance of aliphatic alcohols is evident from the following facts. In most of the determinations of the rates at which alcohols enter into reaction with other substances, the alcohol studied has been used in excess as the solvent. This is notably the case in the large amount of work on rates of esterification. The values obtained are specific and express the behavior of the alcohol under the conditions of the experiment. They cannot be used in making absolute comparison between any two alcohols. The velocity of esterification, when measured in the way just indicated, is determined by the nature of the alcohol and its adjuvant effect. If the adjuvance of methyl alcohol is different from that of ethyl alcohol, the observed velocity constants of esterification of these alcohols with the same acid cannot be used to express the relative quantitative behavior of the alcohols in esterification. It has been found

---

[1] In memory of Ira Remsen.

[2] From the thesis of Spencer Ward Prentiss, submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1925.

by several investigators that reactions, in general, take place more rapidly in methyl than in ethyl alcohol. It is probable that this difference in adjuvance exerts its effect in reactions in which the alcohols serve as both reactant and solvent.

In 1887 Menschutkin[3] discovered the phenomenon of adjuvance when he was investigating the rates at which certain alcohols react with acetic anhydride. The reaction was carried out in an "indifferent" solvent, benzene. When xylene and hexane were used in place of the latter he was surprised to find that the rates observed were not the same as before. This led to a detailed study of the subject.[4]

No systematic study of the adjuvance of alcohols has been made. As such information was needed in the interpretation of the results of work being carried out in this Laboratory, eight alcohols were examined. In addition, the adjuvance of nitrobenzene, acetone and benzene were determined.

In order to reduce experimental difficulties to a minimum and obtain results that would probably be susceptible of interpretation, a comparatively simple reaction was first studied—the addition of ethyl iodide to pyridine.

Especial care was taken in the purification of the substances used. The effect of concentration of the reactants on the velocity constant was found to be small within the limits studied, 0.23 and **1.0** *M*. In Table **I** are given the results obtained.

TABLE I

SECOND ORDER VELOCITY CONSTANTS OF THE REACTION PYRIDINE + ETHYL IODIDE = ETHYL PYRIDONIUM IODIDE

Temp., 25.00". Time in hours

Solvent	Velocity constant	Relative values, Benzene = 1	Solvent	Velocity constant	Relative values, Benzene = 1
Benzene	**0.0028**	**1**	*n*-Propyl **alcohol**	**0.0031**	**1.11**
Nitrobenzene	.070	**25.0**	*n*-Butyl "	.0031	**1.11**
Acetone	.036	**12.8**	**Isopropyl** "	.0030	**1.07**
Methyl alcohol	.0070	**2.50**	*Sec.*-butyl "	.0028	1.00
Ethyl "	.0039	**1.40**	*Tert.*-butyl "	.0026	**0.93**

The results show that nitrobenzene and acetone have a high adjuvance relative to that of benzene. Menschutkin found in the study of the reaction between trimethylamine and ethyl iodide at 100° the value **10.4** for acetone, whereas with pyridine and ethyl iodide at 25° we find **12.8.** He did not study nitrobenzene.

Methyl alcohol has a distinctly higher adjuvance than ethyl alcohol, which in turn is higher than *n*-propyl alcohol. Further increase in molecular weight has little or no effect. It is a striking fact that the adjuvance

---

[3] **Menschutkin,** *Z. physik.* **Chem., 1, 611 (1887).**

[4] **Menschutkin,** *ibid.,* **5, 589, and 6, 41 (1890).**

of tertiary butyl alcohol is so close to that of the isomer with the normal structure. The two alcohols differ widely in chemical properties. It is also noteworthy that the adjuvance of these oxygen compounds approaches so closely that of benzene. The facts suggest that adjuvance may be related more to physical forces set up between the molecules involved than to chemical attractions.

The only previously determined values with which the results here given can be compared are those obtained by Menschutkin. In his study of the reaction between trimethylamine and ethyl iodide at 100°, he used a variety of solvents, among which were benzene, methyl alcohol and ethyl alcohol. His values for these substances are, respectively, 1, 8.8 and 6.3. Results at 100° are not strictly comparable with those at 25°. Further, it is highly probable that at 100° a reaction fakes place between the alcohols and ethyl iodide, as a result of which hydriodic acid is liberated. Any ionizable iodine formed in this way would have been included in the analyses made and calculated as produced in the primary reaction. We are convinced that this error came into the work, because it has been found in this Laboratory that n-butyl bromide reacts at a measurable rate at 100" with n-butyl alcohol to form the ether and hydrobromic acid. The relative adjuvance of the two alcohols measured at different temperatures and by means of different reactions with the possible source of error just indicated are in the two sets of experiments 1 to 1.8 and 1 to 1.4.

No results have been reported in regard to the other alcohols with which ours can be compared. It is planned to study the adjuvance of these alcohols in a reaction of a different type to see to what extent the nature of the reaction affects the results. The values that have been obtained will be used in the interpretation of the results of experiments which will be published later.

Experimental Part

The determinations of the velocity constants were made in the following manner. Equimolecular quantities of the reactants were added to the amount of the solvent necessary to produce a solution of the desired concentration. Measured amounts of the mixture were then placed in ampules, which were sealed and put into a thermostat at 25.00° The time at which the second reactant was added was taken as zero. This was justifiable because the reaction was a very slow one and the temperature of the solutions before being placed in the thermostat was close to 25°. The first analyses made at the end of about half an hour showed that the reaction had taken place to less than 0.5%.

From time to time an ampule was broken under water. The solution was acidified with nitric acid, silver nitrate was added and the excess of the latter was titrated with a solution of potassium thiocyanate. Check titrations of solutions in different ampules frequently agreed to within 0.5%. All the measuring apparatus used was carefully calibrated and care was taken to prevent contamination from the moisture of the air.

Second order velocity constants were calculated in the usual way. It was found that the values obtained as the reaction proceeded slowly increased. In order to get the true constant these values were extrapolated to zero time, using the following method. The values of t and of k were separated into two groups as nearly equal as possible. The average values of *t* and k in each group were computed, and from the differences between the *t* value.: and between the *k* values was obtained a linear equation in *t* and *k*. The value sought is the value of *k* when *t* is placed equal to 0. This method will be seen to be the two point method of obtaining the equation of a straight line.

In Table II are given the data used in a typical experiment.

TABLE II

THE VELOCITY CONSTANT OF THE REACTION BETWEEN PYRIDINE AND ETHYL IODIDE DISSOLVED IN *n*-PROPYL ALCOHOL

$d_{4°}^{25°}$ = 0.7998. Time in hours

	Moles	G.	No	Time	Fraction converted	K
Propyl alcohol		34.998	(0)	0 6	0 002	. . .
Pyridine	0 0350	2 771	1	24	.054	0 00336
Ethyl iodide	.0350	5.459	2	24	055	,00342
		———	3	72	153	,00356
Solution		43 228	4	72	1.54	,00358
Density of solution		0 872	5	122	,253	.00394
Molality (per 1000 g. of			6	122	.246	.00378
solution)		1 000	7	168	.337	.00428
Moles of solvent		16 65	8	168	334	,00423
		0.706	9	216	.404	.00444
Weight of sample analyzed (average of 3)		2 864 g.	10	216	.405	.00446

CALCULATIONS

Average point from 1 to 6 $t_1 = 72.7$ $K_1 = 0.00361$

Average point from 5 to 10 $t_2 = 126.7$ $K_2 = 0.00419$

t = 960 K = 0.00058

Whence 0.00361 − 0.00000605 X 72.7 = $K = 0.00318$

In Table III are given the results of the several experiments. In the first column are the numbers of the experiments. In the second the solvents used are listed. In the third, values of the density of the solvent used and the best recorded density are given. In the case of benzene, for example, the figures $^{22}/_{36}$ signify that the density of the benzene used was 0.8722, whereas the most probable figure for the true density is 0.8736. In the fourth column (M) are given the molalities of the solutions expressed as moles of each solute per 1000 g. of the solvent. In the fifth column

(N) the normality is expressed as moles per 1000 cc. of solvent. In the sixth and seventh columns are the values of the velocity constants found.

TABLE III

SECOND ORDER VELOCITY CONSTANTS OF THE REACTION BETWEEN PYRIDINE AND ETHYL IODIDE IN THE SOLVENTS LISTED

Temperature, 25.00°. Time in hours

25	*Tert.*-butyl alcohol	07/06	1.000	.688	.00258	.0026
26	*Tert.*-butyl alcohol	07/06	1.002	.689	.00272	

In experiments numbered 1 and 2 a sample of acetone containing a trace of water was used. The constant is higher than that obtained in 3 and 4. Menschutkin found in his experiments that the presence of 8% of water in acetone increased the velocity constant about 46%.

The values obtained in Expts. 5, 6, 7 and 8 indicate that the effect on the constant of a change in concentration of the reactants is slight. From Expts. 11 and 12 it is seen that a sample of benzene having the density 0.8722 gave the same result as a sample with true density, 0.8736.

Since a knowledge of the purity of the substances used in the determination of velocity constants is of paramount importance, a brief account will be given of the methods employed in this research. The determinations of boiling points were made with thermometers which were checked against standards from the Reichsanstalt of Berlin. Fractional distillations were carried out with efficient columns. Densities were determined with a Sprengel pycnometer, capacity about 13 cc., provided with ground glass caps. A counterpoise was used and the weighings were reduced to vacuum.

Pyridine.—Eastman's White Label pyridine was converted into the ferrocyanide, which was washed with a mixture of water and ether containing enough alcohol to make a homogeneous liquid. Pyridine was liberated by potassium hydroxide and taken up in ether. The latter was removed by boiling, the residue dried over quick lime and fractionated. A fraction was obtained, 90% of which on redistillation boiled within 0.2' around 115.3°. The densities of the material used varied between 0.97753 and 0.97764 at 25°/4°.

Ethyl Iodide.—Eastman's White Label ethyl iodide was shaken with cold sulfuric acid (3 vols. c. p. concd. H_2SO_4 and 1 vol. H_2O), separated and distilled from a flask containing silver powder and a few small lumps of marble, after preliminary heating for an hour at 60". The distillation was carried out in an atmosphere of carbon dioxide. A fraction was obtained, 95% of which boiled on redistillation within 0.1" around 72.3°. The material was kept in the dark in a bottle containing carbon dioxide It remained colorless for a long time. The density of the samples prepared varied between 1.9234 and 1.9241 at 25°/4°.

Acetone.—Eastman's White Label acetone from the bisulfite compound was distilled from potassium permanganate. The process was repeated until a sample was obtained which did not give a precipitate with the permanganate after standing for twenty-five hours. The acetone was distilled off and allowed to stand with a small amount of c. p. anhydrous potassium carbonate. When there was no evidence of any action the acetone was distilled. A fraction was obtained that boiled on redistillation almost completely within 0.1° around 56.1'. The density of the sample was 0.7855 at 25°/4°.

Benzene.—A high grade sample of "reagent quality" benzene was purified by the method described by Richards.[5] The product melted sharply at 5.42°. Its density was 0.8736 at 25°/4°.

Nitrobenzene.—Eastman's Blue Label nitrobenzene was distilled under diminished pressure. The product was alternately partially melted and the liquid poured off. This process was repeated until a small amount was obtained which gave good melting and freezing curves; m. p. 5.75°; density, 1.1978 at 25°/4°.

The Alcohols.—The alcohols were purified in general by the procedures used in this Laboratory in previous investigations. The values for the densities obtained at 25°/4° were as follows: methyl, 0.7866; ethyl from 0.78507 to 0.78511; propyl, 0.78998; isopropyl, 0.7811; n-butyl, 0.8058; *sec.*-butyl, 0.8025; *tert.*-butyl, 0.7807 (m. p. 24.5°).

Summary

1. It is pointed out that the results of the determination of the velocity constants of reactions in which an alcohol serves simultaneously as a reactant and as a solvent cannot be correctly interpreted without a knowledge of the effect of the solvent on the rate at which the reaction takes place.

2. *Adjuvance* is suggested as a convenient word to be used in expressing the property possessed by liquids of affecting the rate at which reactions proceed when the liquids are present as solvents.

3. The velocity constants of the reaction between pyridine and ethyl

CATALYTIC STUDIES ON ACETOACETIC ESTER[1,2]

BY F. O. RICE AND JOSEPH J. SULLIVAN

RECEIVED JUNE 27, 1928 PUBLISHED NOVEMBER 6, 1928

Ethyl acetoacetate was discovered in 1863 by Geuther[3] and since then has been the subject of research by numerous workers. One phase of this work has comprised the identification of the two forms, their preparation in the pure condition, the equilibrium ratio of the liquid and of solutions in various media, and, in a semi-quantitative way, the rate of change of one form into the other. The purpose of the present work was to make a quantitative research on the rate of attaining equilibrium of the ester when rigorously purified according to the best technique available, and also when definite amounts of known catalysts were present. In our experiments we used Martin's method of distillation without ebullition:[4] by keeping a high vacuum (10^{-5} mm.) in our apparatus, we had no difficulty in distilling the ester at room temperature; in this way no bumping occurred and there was slight, if any, decomposition. Before allowing air to enter the apparatus, it was first bubbled through sulfuric acid to remove traces of aminic impurities and water, and then filtered to remove dust particles and sulfuric acid mist. Various kinds of containers were used, Pyrex, quartz and soft glass, either etched by corrosive cleaning agents, or with their inner surfaces smoothed by heating almost to the point of collapse. Using this special technique, we found that we could prepare samples of the ester of high enol content, which had a stability far greater than heretofore obtained. Our best samples had a half life of about 500 hours, as compared with rates less than one-tenth of this value reported by previous workers. There are no indications that we have reached the limit of stability, since the lowest rates appear to be due, at least in part, to traces of catalytic impurities still remaining.

Historical

As late as 1905, Brühl[5] considered the pure form of acetoacetic ester to be the keto form, although Wislicenus[6] had earlier proved that the two forms existed in dynamic equilibrium. Perhaps the most important point in this connection lies in devising an exact method of estimating the ratio keto/enol in samples of the esters. Methods involving some physical property or other[6] have been proposed, especially refractive index, which has been used by Knorr[7] and also by Meyer.[8] Of the chemical methods three may be mentioned. The first makes use of the formation of a purple enolate with ferric chloride,[9] and is really a colorimetric method. In the second method the enol form is titrated with a standard bromine solution, using ferric chloride, if desired, as indicator.[10] The third method is that perfected by Meyer and his collaborators[11] and takes place in the following steps: the ester, dissolved in alcohol, is treated with a slight excess of an alcoholic bromine solution, and the excess bromine is immediately removed by β-naphthol. The bromine adds quantitatively to the double bond of the enol, which then splits off hydrobromic acid giving the bromoketone. This is estimated by adding potassium iodide, warming slightly and titrating the liberated iodine by thiosulfate.

The analytical difficulties cleared, the next step was the preparation of the pure isomers. It had long been known that the freshly distilled ester contains from 20–25% enol,[12] and Meyer and his collaborators,[8,13] using a method of successive distillations *in vacuo,* finally obtained an ester of 99.8% enol. The last distillations were performed in a quartz apparatus, in which they found that only slight isomerization occurred. Other methods of preparing the pure isomers are extraction of the keto form with hexane,[14] and freezing out the keto form at −78° as employed by Knorr.[6]

But little quantitative work has been done on the rate of rearrangement. A sample of freshly distilled ester, at 15°, followed by Meyer[10] for forty hours, shows on calculation a half life of 24.2 hours. In dissociating solvents, such as alcohol, the rate increases about 100 times, but the rate in these solvents is not much affected by halogen acids. In non-polar sol-

vents the rate is practically the same as for the pure liquid, but traces of halogen acids increase the rate enormously in these solvents. Meyer and Schoeller[8] give one specimen of work showing absence of isomerization in the vapor phase. In Table I we have collected the results of previous workers. For ease of comparison we have calculated the rate of change of enol → keto according to the method given later in the paper. The half life is the time in hours taken by the pure enol to fall to 50%. In the first three cases we have assumed the initial enol content to be 25%.

TABLE I

PREVIOUS WORK ON RATE OF ISOMERIZATION

Observer	Change in enol	Hours obs.	k_1	Half life, hours	Remarks
Traube[12b]	1.0244–1.0247	24	0.170	4.2	Density
Schaum[12a]	1.0278–1.0287	6	0.685	1.1	Density
D. and M.[15]	1.0209–1.0213	0.5	2.1	0.35	Viscosity
Meyer[10]	18.5%–7.9%	40	0.032	24	In quartz
M. and S.[8]	0%– 3%	20	.023	32	In quartz
Rumeau[16]	43%–33%	2	.15	5	In quartz
	52%–33%	4	.13	6	In quartz
	83%–58%	28	.013	58	In Pyrex
	52%–52%	4	...		In Pyrex
	52%–50%	4	.011	74	In Jena
	83%–10%	0.5	6.5	0.12	Soft glass

Quantitative investigation on the catalytic effect of impurities on the rate of rearrangement is also meager. Meyer and Willson[17] use oxalic acid (a trace) and Meyer and Hopff[13] phthalic anhydride (a few mg.) to stabilize a mixture of the isomers against aminic impurities, but give no measurements showing a relative improvement of conditions by their use. Hydrochloric acid and hydrobromic acid catalyze enolization, especially in non-polar solvents;[10] quartz is non-catalytic, but soft glass brings a mixture to equilibrium in a few hours. Alkalies act instantaneously.[10] A recent paper by Rumeau[16] concurs with the above in general, but he finds that phthalic anhydride is not a stabilizer, nor is a residue from the distillation of an ester previously treated with oxalic acid. Yet he notes that oxalic acid is an energetic stabilizer.

Apparatus and Experimental Method

To obtain the aseptic conditions mentioned by Meyer and, if possible, to improve on them, we planned to distil the ester in accordance with the method first used by Martin. The final form of our apparatus is shown in Fig. 1. This simple form of apparatus gave quite as good results as very much more complicated forms in which elaborate precautions were taken to prevent any possible contamination of the ester. The tubes A and B were connected to the apparatus by pieces of Gooch tubing. The

[16] Rumeau, Bull. *soc. chim.*, 35, 762 (1924).

[17] Meyer and Willson, *Ber.*, 47,832 (1914).

tubes could therefore be easily removed and transferred to a thermostat for rate measurements. Our distillations were performed at pressures of 10^{-3} to 10^{-5} mm. of mercury. By keeping tube B at −78° and tube A at room temperatures, or a little higher, satisfactory rates of distillation were obtained. When distillation was completed we allowed air to enter the apparatus, the air having first been bubbled through sulfuric acid and then passed through an asbestos filter to remove acid mist and other suspended particles.

Analytical and Materials.—We found the analytical procedure perfected by Kurt Meyer[11] very satisfactory and used it without any important modifications throughout the work. We avoided as far as possible the use of violent cleaning reagents on our glass apparatus; our usual method was to give a final rinse in distilled water followed by heating nearly to the melting point. The acetoacetic ester used in our experiments was a commercial sample which we washed several times with distilled water, dried with calcium chloride and anhydrous copper sulfate and distilled; only the middle portion was used in our work.

Calculation **of** Rates.—In order to compare the stability of samples of ester prepared in different ways, it was necessary to measure the velocity constant of the change enol ⟶ keto.[10] Let x be the mole fraction of enol in any mixture and $1 - x$ the mole fraction of keto. Let k_1 be the rate of change of pure enol and k_2 the rate of change of pure keto. Then in any mixture, we have

$$\text{rate of change of enol to keto} = k_1x, \text{ and}$$
$$\text{rate of change of keto to enol} = k_2(1 - x)$$

Therefore,

$$-\frac{dx}{dt} = k_1x - k_2(1 - x)$$

If we put $k_1/k_2 = \alpha$ and integrate, we obtain

$$k_1 = \frac{\alpha}{t(1 + \alpha)} \ln \frac{x_0 - 1/(1 + \alpha)}{x - 1/(1 + \alpha)}$$

Throughout our work we took $\alpha = \mathbf{11.82}$, so that this equation becomes

$$k_1 = \frac{2.12}{t} \log \frac{x_0 - 0.078}{x - 0.078}$$

For ease of comparison of different samples we found it convenient to calculate a quantity that we refer to as the "half life," namely, the calculated time taken for a sample of pure enol to become a mixture of 50% enol and 50% keto. This is given by the formula

$$t_{1/2} = \frac{0.72}{k_1}$$

Experimental Results

In our earlier experiments extreme precautions were taken to prevent contamination of the ester, even to the extent of building the apparatus of fused silica. We finally found that we could relax these precautions and, in particular, use Pyrex glass instead of silica. Our first quantitative experiments were directed toward testing out the velocity equation which we have developed in the previous section. A sample of the ester was distilled in the apparatus shown in Fig. 1. The distillate was placed in a thermostat and samples were withdrawn for analysis at noted time intervals. A few of the results are given in Table I. It will be seen that k_1 shows a fairly satisfactory constancy over a period of several hundred hours.

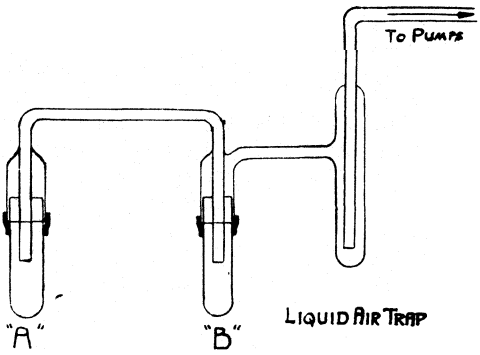

Fig. 1.

During this time, the tubes were opened many times to withdraw samples for analysis.

Our next experiments were directed toward finding if it were possible to transfer the ester from one container to another without contamination (Table II). The experiments usually show a fall in stability but the effect is not very great.

TABLE II

EFFECT OF TRANSFERENCE ON STABILITY OF ESTER

	Series A (Pyrex)				Series B (Quartz)			
Half life before transf.	175	175	175	175	131	131	131	131
Half life after transf.	156	161	151	158	108	124	116	150
Hours observed	17	17.5	18	18.5	545	470	470	640

In Series A the ester was transferred from a Pyrex container to four other Pyrex containers using a Pyrex pipet; in Series B from a Pyrex container to four quartz containers using a quartz pipet.

Series B is instructive because it shows that there is comparatively little difference in stability whether the ester is kept in quartz or Pyrex.

We made three runs in soft glass containers. The results are shown in Table III, which illustrates the great catalytic power of soft glass.

TABLE III

RATE OF CHANGE OF ESTER IN SOFT GLASS

Init enol, %	k_1	Half life	Hours obs
18.7	1 76	24 min.	1.4
18.7	2 66	16 min.	1.2
17.3	7.58	6 min.	0.8

From our experiments with different kinds of containers we concluded that any catalytic surface action in quartz or Pyrex was small compared to the effect of impurities dissolved in the ester. We therefore turned our attention to removing traces of dissolved impurities. Table IV shows the results obtained when we distilled a large portion of ester and examined the stability of the successive fractions.

TABLE IV

RESULTS ON FRACTIONATED ESTER

Frac.	Initial enol, %	k_1	Half life	Hours obs.
1	41.5	0.021	34	286
2	32.4	.032	21	165
3	22.6	.055	13	165
4	12.1	.140	5	20
5	38.4	,0014	515	335
6	34.8	.0058	124	424
7	32.0	.012	61	330
8	31.6	.004	180	422

It will be seen that the stability increases as the distillation progresses, with possibly a maximum at the middle portions. Our experiments so far indicate that more efficient fractionation would result in a considerably diminished rate of isomerization. The erratic results shown by fractions 4 and 7 (in this particular experiment) are probably due to accidental contamination of some kind or other.

We next turned our attention to the addition of substances to the ester with the hope of stabilizing it. Our experiments in this direction, however, did not meet with any success. The addition of small quantities of substances like phthalic anhydride, oxalic acid and acetyl chloride, whether before or after distillation, had the effect of increasing the rate of change instead of diminishing it. The observed rate of change is probably largely due to the presence of a minute trace (a few parts per million of ester) of aminic impurities, and a trace of acetyl chloride might be expected to remove these.[18] However, further consideration shows that a small trace

---

[18] See Lowry and Magson, J. *Chem. Soc.,* 93,107 (1908).

of water present would hydrolyze the acid chloride probably at a faster rate than the latter would react with the aminic impurity. The removal of the last traces of water from a substance like acetoacetic ester is a difficult matter since violent dehydrating agents will decompose the ester. We tried the effectof activated silica gel on the ester, but there was obvious decomposition, the ester becoming brownish-red. The distillate from this had a half life of about one hundred hours.

In our final experiments we decided to add various substances in known amounts, and compare the rate of isomerization of the ester before and after this addition. The results are shown in Table V. The third column contains a list of the ratios of the rates k_2/k_1, where k_2 is the rate after addition of the catalyst, and k_1 is the rate before addition.

TABLE V

EFFECT OF CATALYSTS ON THE RATE OF ISOMERIZATION OF ACETOACETIC ESTER

Catalyst	Conc. × 10^{-5}	k_2/k_1	Catalyst	Conc. × 10^{-5}	k_2/k_1
Piperidine	4	11,400	Phthalic anhydride	40	6
Ammonia	4	4,000	Oxalic acid	1	3.2
Pyridine	4	264	Water	100	1
Quinoline	4	17	Dehydracetic acid	4	36
Bromine	4	>1,300	Residue	4	3
Acetyl chloride	4	157			

The extraordinary effectof small quantities of bases is at once apparent. Thus, one part in a million of piperidine increases the rate by three orders. It is somewhat surprising to find that bromine is an extremely good catalyst, being even more effective than some of the bases. Occasionally in the course of our work we would meet with very anomalous behavior which we may ascribe to accidental contamination since it is obviously very difficult to make quantitative measurements with materials so sensitive to small traces of basic substances.

We also made a study of the temperature coefficientof the rate of change of the liquid ester, since this does not seem to have been measured by previous workers. Measurements by Meyer[10] for aqueous solutions of the ester gave $k_{10}/k_0 = 3$, and by Meyer and Willson[17] for alcoholic solutions gave $k_{25}/k_0 = 1.3$. We made measurements on two samples at 25 and 35°, and obtained for k_{35}/k_{25} the values 4.9 and 6.3. Taking a mean value of 5.6 we obtain the value of 31,200 for the heat of activation. This is surprisingly large, especially when we compare it with the value for the aqueous solution.

Summary

1. We have made a quantitative study of the rate of isomerization of acetoacetic ester in the liquid condition. Distillations were carried out in high vacuum and every precaution was taken to prevent contamination of the ester.

2. The rate of change of the enolic form of the ester when prepared in this way was over 10 times slower than the (calculated) best values previously reported.

3. The velocity constants for the change have been measured in presence of known amounts of various substances.

FLUOSILICATES OF SOME ORGANIC BASES[1]

BY C. A. JACOBSON AND H. A. H. PRAY

RECEIVED JULY 11, 1928 PUBLISHED NOVEMBER 6, 1928

Introductory

It is well known that fluosilicic acid is a relatively strong acid which yields insoluble salts with most inorganic bases, a large number of which have been prepared. However, few attempts have been made to prepare the salts of this acid with organic bases. E. Ebler and E. Schott[2] have described a fluosilicate of hydrazine, $N_2H_4 \cdot H_2SiF_6$, and of hydroxylamine, $(NH_2OH)_2 \cdot H_2SiF_6$. On the other hand, a number of hydrofluorides of organic bases have been isolated and found to be well-defined, crystalline compounds. Weinland and Lewkowitz[3] report upon the hydrofluorides of aniline, aminophenol, aminophenetole, aminobenzoic acid, etc.

This paper describes the preparation and properties of fluosilicates of aniline, methylaniline and *o*-, *m*- and *p*-toluidine.

Experimental

For the preparation of the aniline salt, redistilled aniline, dissolved in about three times its volume of 95% ethyl alcohol, was treated with a 30% aqueous solution of fluosilicic acid in such a way that the aniline was kept in excess. The precipitated product was washed free from excess aniline with cold 95% ethyl alcohol. The precipitate was then recrystallized twice from hot 95% alcohol and dried, first in the air and finally in a desiccator over sulfuric acid.

The product thus prepared was found to be a snow-white powder composed of small plate-like crystals of irregular shape. Upon heating it sublimed, the sublimation being rapid at a temperature of about 230°. It was insoluble in absolute ethyl alcohol, methyl alcohol, acetone, carbon tetrachloride, chloroform, ethyl ether and carbon disulfide, slightly soluble in hot acetone, but extremely soluble in water. When heated a gas was evolved which when passed into water caused the precipitation of gelati-

nous silicic acid, thus indicating that the material was a fluosilicate. Inorganic fluosilicates behave in the same way. A further indication that the substance was a fluosilicate lies in the fact that in water solution it reacts quantitatively with a solution of sodium hydroxide as do the other fluosilicates.

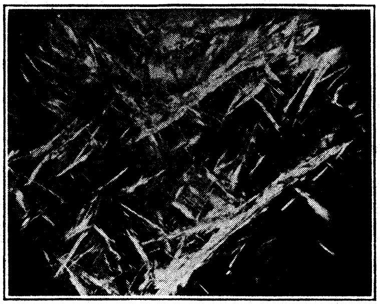

Fig. 1.—Di-aniline fluosilicate.

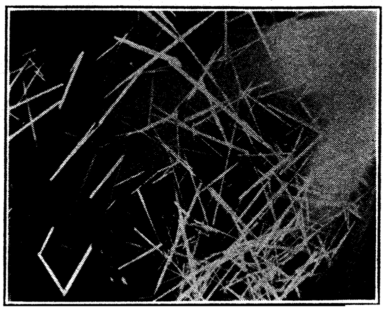

Fig. 2.—Di-methylanilinefluosilicate.

In order to arrive at the empirical formula of the compound, quantitative determinations of nitrogen by the Kjeldahl-Gunning-Arnold method, as well as quantitative determinations of the fluosilicic acid radical, by a method previously devised by one of us,[4] were employed. The latter method consists of the titration of a weighed quantity of the salt dissolved in hot water by a standard solution of sodium hydroxide. An electrometric titration showed the end-point to be within the range of phenol red; consequently, this indicator was used for the determinations of the acid radical part of the salts. These determinations show that the compound under investigation is a di-aniline fluosilicate whose formula is $(C_6H_5NH_2)_2 \cdot H_2SiF_6$.

Anal. Calcd.: N, 8.49; H_2SiF_6, 43.68. Found: N, 8.48, 8.60; H_2SiF_6, 43.60, 43.21.

---

[4] Jacobson, J. Phys. *Chem.*, 28, 506 (1924).

It has already been mentioned that this di-aniline fluosilicate sublimes at a relatively low temperature, and it seemed of importance to learn if the composition of the sublimed product was the same as that of the recrystallized. The following nitrogen determinations show that the composition is not changed by sublimation.

Anal. Calcd.: N, 8.49. Found: N, 8.32, 8.33.

In a similar manner it mas shown that, unlike the fluorides, no other fluosilicate compound with aniline is obtained by precipitating with excess of the acid. A product so obtained showed the same composition and properties as described above.

The method of preparing and purifying the other salts of fluosilicic acid was identical with that described for the di-aniline fluosilicate. The following table gives the analytical data obtained for the five new salts prepared, together with their crystal forms.

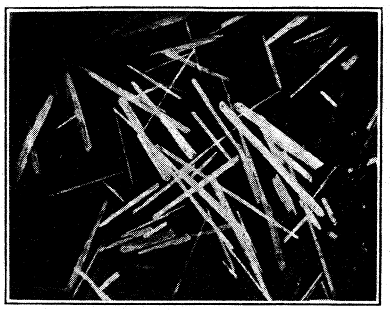

Fig. 5.—Di-*p*-toluidine fluosilicate.

Work is now in progress on other basic fluosilicates such as tolidine and urea. These two compounds are also obtained in nice crystalline form.

The di-p-toluidine fluosilicate (No. 3) is the most unstable. The crystals are at first pure white but in a few days they begin to turn yellow and after two or three months assume a deep brown color at the surface of the glass which has been exposed to diffused sunlight, and more and more yellow toward the center of the mass. The irregular outline of the crystals shown in Fig. 5 also indicates the unstable character of this compound.

TABLE I

ANALYTICAL DATA AND CRYSTALLINE FORM

No.	Fluosilicate	Nitrogen, % Calcd.	Nitrogen, % Found	H_2SiF_6, % Calcd.	H_2SiF_6, % Found	Crystal form
1	Di-aniline	8 49	8 48, 8 60	43 68	43.60 43.21	Irreg. plates
2	Di-methylaniline	7 82	7.85, 7.80	40.22	40.05, 39.97	Monoclinic needles sharp outline
3	Di-o-toluidine	7 82	7.68 7.69	40.22	40.14, 39.90	Orthorh. plates
4	Di-*m*-toluidine	7.82	7.73, 7.98	40.22	40.03, 40.18	Rect. plates
5	Di-*p*-toluidine	7.82	7.50, 7 59	40.22	39.90, 40.30	Needle-like, irreg. outline

Summary

Five new crystalline compounds have been made and analyzed. They are the fluosilicates of aniline, methylaniline, o-, *m*- and *p*-toluidine, and are the direct addition products of two molecules of the base with one of fluosilicic acid.

The physical properties of these salts have been investigated and microphotographs taken which depict a wholly different crystalline form for each one. The fact that the salts crystallized easily from hot alcohol enabled us to prepare them in very pure condition.

ALKYL ORTHOSILICATES[1]

BY A. W. DEARING[2] AND E. EMMET REID

RECEIVED JULY 24, 1928 PUBLISHED NOVEMBER 6, 1928

Though ethyl orthosilicate was discovered as long ago as 1846 by Ebelmen,[3] it has not been extensively studied. Khotinsky and Seregenkoff[4] found that one and only one of its ethoxy groups is exchanged for the radical of the Grignard reagent. It seemed desirable to learn more about the preparation and reactions of alkyl orthosilicates.

Results

The method of preparing ethyl orthosilicate has been improved, the yield being brought up to 70%. New esters were made from n-butyl, n-amyl, n-heptyl, n-octyl and β-chloro-ethyl alcohols, though the last two were impossible to purify as they are liquids which could not be distilled Attempts to obtain orthosilicates from secondary alcohols proved unsuccessful, the reaction taking another course. With mercaptan silicon tetrachloride reacts only partially, even when heated to 200° for twenty hours.

It has long been known that ethyl orthosilicate ethylates water and acetic acid. It has been found to yield diethyl phthalate with phthalic anhydride, according to this equation:

$$C_6H_4(CO)_2O + (C_2H_5O)_4Si \longrightarrow C_6H_4(CO_2C_2H_5)_2 + (C_2H_5O)_2SiO$$

Similarly ethyl acetate is obtained with acetanhydride. With sulfuric acid, diethyl sulfate is formed. Benzoic acid reacts with it very sluggishly but ethyl benzoate is formed. *p*-Nitrobenzoic acid could not be made to react. It could not be made to react with phenol, β-naphthol or thiophenyl. In the presence of aluminum chloride benzene is ethylated by it even up to hexa-ethylbenzene.

When ethyl, or methyl, orthosilicate reacts with water or acetic acid under the proper conditions, the silicic acid produced separates as a gel. This is of interest since it does not contain electrolytes which are so difficult

---

to wash out of the gel from sodium silicate. The silica obtained from methyl orthosilicate is 50% of the weight of the ester. The shrinkage of the gel prepared from this or the ethyl ester is only a fraction of that of the gel precipitated in the usual way from sodium silicate. This suggested the possibility of obtaining disks of silica gel which might be used for osmotic pressure measurements. Disks were obtained, best by the action of moist air on the ester. but none perfect enough for the desired purpose. In parallel experiments in which a mixture of the vapors of acetic acid and ethyl alcohol was passed over silica gel at 180°, the gel from ethyl orthosilicate proved to be decidedly more active than a carefully prepared specimen of the gel from sodium silicate. More recently, gel purified by Patrick by boiling with nitric acid has appeared to be about as active as our gel. As the gel from the alkyl orthosilicates can be made in benzene solution by the action of the calculated amount of water or acetic acid, a product is obtained the surface of which has never been wet by water. It was thought that such a gel might show different absorptive power from that precipitated in water solution. This did not prove to be the case.

Experimental

The difficulty in the preparation of alkyl orthosilicates is that four molecules of hydrogen chloride are eliminated for each molecule of silicon tetrachloride that reacts. The large evolution of gas causes a considerable loss of the volatile reactants. The method which proved to be best is to add the silicon tetrachloride, which must be free from higher boiling compounds, dropwise to the alcohol cooled in a freezing mixture. The alcohol must be perfectly anhydrous and is used in about 10% excess to insure the reaction of all of the chlorine. The escaping hydrogen chloride is led through a small amount of cold alcohol to recover the silicon tetrachloride that is carried off. After the reaction is judged to be complete, dry air is drawn through the product for several hours to rid it of hydrogen chloride. The ester is then fractionated in a vacuum with the careful exclusion of moisture. To avoid decomposition the esters of the higher alcohols must be distilled at very low pressures.

Ethyl orthosilicate was obtained in 70% yield. It boils at 165–167° at 760 mm. The properties of the new esters are given in tabular form.

TABLE I

ESTERS OF ORTHOSILICIC ACID

Alkyl	B. p., °C.	Press., mm.	Density		Silicon, %		
			0°/4°	25°/4°	Calcd.	Found	
n-Butyl	160–5	20	0.9353	0.9194	8.82	8.75	8.63
n-Amyl	145–50	3	.9117	.8933	7.53	7.45	7.49
n-Heptyl	200–15	3	.9097	.8958	5.79	5.99	6.03
n-Octyl	240	3	...	...	5.19	5.23	5.09

Phenylethyl alcohol reacted as was expected but the product could not be purified, as it decomposed when distillation was attempted even with a good vacuum. It was heated at 90° in a vacuum for some hours, which eliminated most of the excess of the alcohol but even then it was only about *88%* pure, as analysis for silicon showed 4.88 and 4.84% instead of the calculated 5.53. Its density is about 1.00.

Silicon tetrachloride was added to four equivalents of anhydrous ethylene chlorohydrin. Reaction took place as usual. As the products could not be distilled, it was purified by heating in a vacuum for some hours, which gave a product which analysis showed to be 94% pure.

This product was refluxed for several hours with an excess of aniline hydrochloride and a white amorphous material was obtained. This resembled silicic acid in appearance but is soluble in alcohol and ether. It could not be recrystallized and hence little weight can be attached to the analysis for silicon, which corresponded to the formula $(C_6H_5NHC_2H_4)_4Si$. Very similar products were obtained with dimethylanilinc and pyridine.

Silicon tetrachloride reacts vigorously with isopropyl alcohol but converts it to propylene and isopropyl chloride. With mercaptan it gave no reaction under the usual conditions. A mixture of mercaptan and silicon tetrachloride was heated at 200° in a sealed tube for twenty hours. The evaporation of the reactants left a small amount of liquid boiling at 125° but this still contained chlorine, which shows that the replacement takes place very slowly.

Ethyl orthosilicate was heated with one molecule of phthalic anhydride for eight hours at 160°. The ethyl phthalate formed was separated by fractionation in *vacuo* and identified by boiling point, density and saponification number. A similar experiment was tried with acetanhydride and ethyl acetate identified.

To a mixture of benzene and ethyl orthosilicate, aluminum chloride was added. A reaction took place at once. The mixture was heated for several hours, poured onto ice and extracted with ether. Hexa-ethylbenzene was identified by its melting point. The intermediate ethylated benzenes were present but not in sufficient amounts for separation.

Silica Gel from Ethyl Orthosilicate.—A shallow layer of the ester reacts with water vapor and finally sets to a gel, but more uniform results are obtained by adding the calculated amount of water to the ester diluted with 1.5 times its volume of alcohol. If too much alcohol is used the gel does not set properly.

A on-aqueous gel was prepared by refluxing a mixture of four parts of acetic acid to one of the ester for an hour and allowing it to stand overnight. The excess of acetic acid was gotten rid of by soaking the gel in dry benzene, which was poured off and replaced by fresh benzene every day for four days. The gel was then dried in a vacuum and the soaking and drying repeated every three or four days for three weeks. The gel prepared in this manner was excellent in appearance and proved to be an excellent catalyst for vapor phase esterification, but its absorption from water solution was practically identical with that of the regular gel.

A variation of this method was to dissolve the ester and the required amount of acetic acid in dry benzene and boil until. gel formation took place on cooling. Usually about eight hours' boiling was required. The gel formation seems to take place rather suddenly after long heating. In one experiment the mixture was boiled for seven and three-fourths hours and gave no appearance of gel formation on cooling. Further heating'for fifteen minutes caused it to become viscous and to set to a stiff gel on cooling. This gel was purified as described above and had the same properties.

Acids higher up in the acetic acid series were used for preparing the gel but these acids did not give as good a product. In one case paraffin wax was dissolved in the benzene with the idea that it might coat the gel and diminish its affinity for water.

In whatever way the gel was prepared it acted the same when put into water and showed the same absorption as the regular silica gel.

Esterification experiments similar to those of Milligan and Reid[5] were run to compare the special gel obtained as described above with the regular silica gel. The whole aim was to get comparative results. The sample of gel was contained in a tube surrounded by the vapor of boiling cyclohexanol. A mixture of equivalent amounts of absolute ethyl alcohol and acetic acid was dropped at the desired rate from a calibrated capillary tip into a bulb which served as a vaporizing chamber from which it passed into the catalyst tube. The products were condensed, weighed and titrated immediately. The results are given in the table below.

TABLE II

PERCENTAGE ESTERIFICATION OVER REGULAR AND SPECIAL SILICA GEL

Time of contact, sec.	Regular gel	Special gel	Time of contact, sec.	Regular gel	Special gel
11.3	20.5	29	26.4	34	46.5
11.3	28	29.5	26.4	35	49
11.3	29	29	123	49.3	82.5
11.3	29	30	123	50	78.5
26.4	43	47	123	53	89
26.4	33	46.5			

There are considerable irregularities in the results but the special gel shows decidedly greater activity at the slower rates.

Summary

The preparation of ethyl orthosilicate has been improved and a number of new orthosilicate esters have been prepared. The reactions of ethyl

SOME 1,2-DIALKYL CYCLOPENTANE DERIVATIVES[1,2]

BY FRANCIS H. CASE[3] AND E. EMMET REID[4]

RECEIVED JULY 24, 1928 PUBLISHED NOVEMBER 6, 1928

As cyclic hydrocarbons are found in some petroleums it is important to know more of the chemistry of this class. The derivatives of cyclopentane have not been extensively studied; it seemed desirable to synthesize more of them so as to extend our knowledge of the properties of the members of this group. The particular line chosen was the 1,2-dialkyl cyclopentanes. The reaction chosen for the preparation of these hydrocarbons led quite unexpectedly to the formation of the corresponding unsaturated hydrocarbons. Due to the expiration of the grant, time was not available for the reduction of the latter to the saturated derivatives, and it was deemed best to publish the results obtained.

The necessary intermediate for the study was a-ethyl-cyclopentanone. This compound is supposed to have been obtained by Best and Thorpe[5] by the hydrolysis of 2-cyano-2-methyl-cyclopentane-one-1. They described it as boiling at 149° at 756 mm. and gave the melting point of its semicarbazone as 177". This compound prepared by our method boils at 160–161° (755 mm.) corr. and its semicarbazone melts at 189° corr. We started with ethyl adipate (I), which was made to undergo an internal acetoacetic ester condensation to form the ethyl ester of α-carbethoxy-cyclopentanone (II). The sodium compound of this[6] reacted with ethyl iodide to give the ethyl derivative (111), which by the ketone splitting left a-ethyl-cyclopentanone (IV). By the Grignard reaction this ketone was converted to the tertiary alcohol (V). This was transformed into the iodide. It was intended to remove the iodine by reduction to obtain the 1,2-alkyl-ethyl-cyclo-pentane (VI). When this was attempted an unsaturated hydrocarbon was obtained.

---

[1] In memory of Ira Remsen.

[2] This paper presents the results of an investigation of cyclopentane derivatives listed as Project 15 of the American Petroleum Institute. Financial assistance has been received from a research fund of the American Petroleum Institute donated by the Universal Oil Products Co. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

[3] American Petroleum Institute Research Fellow.

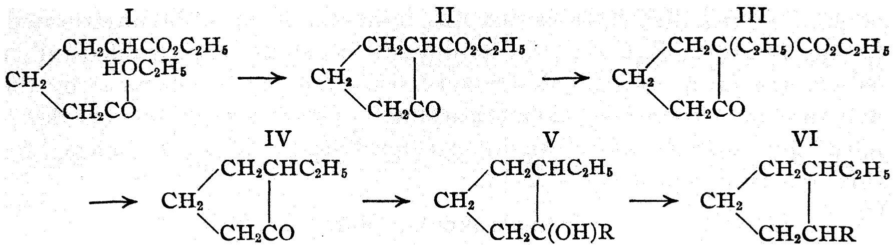
[5] Best and Thorpe, J. Chem. *Soc.*, **95**, 713 (1909).

[6] Rysselberge, Bull. *sci. acad. roy. Belg.*, [5] **12**, 171 (1926).



In the preparation of a-methyl-a-carbethoxy cyclopentanone, Bouveault[7] treated one mole of a-carbethoxy-cyclopentanone with one equivalent of sodium dissolved in absolute alcohol and added methyl iodide to the cooled mixture. Whereas the method was generally satisfactory for the methyl derivative, it sometimes miscarried, giving almost exclusively ethyl-a-methyl adipate. For higher alkyl groups such as the *iso*propyl, no reaction occurred unless heating in a sealed tube was resorted to. In this case a large amount of ethyl-α-*iso*propyl adipate was obtained. Indeed Bouveault was unable to prepare the isopropyl keto ester in a state of purity. It was prepared, however, by Kotz and Schüler[8] by treating a-carbethoxy-cyclopentanone with a finely divided alloy of sodium and potassium and refluxing the mixed salt thus formed for seventy hours with isopropyl iodide.

We have been able to prepare the various alkyl derivatives of a-carbethoxy-cyclopentanone in a reasonable time by adding the alkyl iodide to the sodium salt of the keto ester suspended in an aromatic hydrocarbon and refluxing. It was found that as the size of the alkyl group increases it is necessary to use a higher boiling solvent and to heat for a longer time. Thus an 82% yield of methyl derivative was obtained in three hours using benzene as solvent, 74% of ethyl keto ester in six hours in toluene and 59% of isopropyl in twelve hours in xylene.

The yields of substituted cyclopentanols obtained by the action of various Grignard reagents on a-ethyl-cyclopentanone were found to be very low, due perhaps to the steric effect of the ethyl radical in the α-position to the carbonyl group. In each case much of the ketone was recovered unchanged and much high boiling material was found. Thus, with ethyl magnesium bromide, the yield of 1,2-diethyl-cyclopentanol-1 (V) was 27%, with propyl magnesium bromide the yield of 1-propyl-2-ethylcyclo-ethyl-cyclopentanol-1 was only 8.5% and with *iso*propyl magnesium bromide no alcohol was obtained. In an attempt to prepare 1,2-diethyl-cyclopentane from 1,2-diethylcyclopentanol-1, the latter compound was converted to the iodide and this reduced with zinc and hydrochloric

acid. The resulting hydrocarbon was, however, shown to be unsaturated, having the formula C_9H_{16}. In its physical constants it resembled rather closely the unsaturated hydrocarbon C_9H_{16} prepared by Kishner[9] by the dehydration of diethyl-cyclobutylcarbinol. This hydrocarbon was designated by Kishner as 1,2-diethyl-cyclopentene-1, although evidence for this structure appears to be lacking.

Experimental Part

α-Carbethoxy-cyclopentanone.—The directions of von Rysselberge[6] were used.

α-Methyl-α-carbethoxy-cyclopentanone.—To 20.7 g. of sodium, finely divided by shaking in hot xylene, suspended in 400 cc. of benzene, 140 g. of α-carbethoxy-cyclopentanone was added with cooling and the mixture allowed to stand overnight. To the sodium salt thus formed, 131 g. of methyl iodide was added and the mixture refluxed for three hours. The sodium iodide was then filtered off and the benzene solution fractionated The yield of material boiling at 106–107° (17 mm.) corr. was 125 g., or 82%. The semicarbazone melted at 152–153° corr.

α-Ethyl-α-carbethoxy-cyclopentenone.—This was prepared in the same way as the methyl derivative except that toluene was used as solvent instead of benzene. The proportions used were 29.6 g. of sodium, 200 g. of a-carbethoxy-cyclopentanone, 500 cc. of toluene and 210 g. of ethyl iodide. The yield of material boiling at 100° (7 mm.) corr. was 174 g., or 74%; $d_4^0 = 1.0531$, $d_4^{25} = 1.0310$.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.17; H, 8.76. Found: C, 64.68; H, 8.74.

Semicarbazone.—The semicarbazone of or-ethyl-a-carbethoxy-cyclopentanone melts at 148–149° corr.

Anal. Calcd. for $C_{11}H_{19}O_3N_3$: C, 54.73; H, 7.94. Found: C, 55.13; H, 8.00

α-*Iso*propyl-α-carbethoxy-cyclopentanone.—To the sodium salt prepared by treating 14.7 g. of sodium suspended in 300 cc. of xylene with 100 g. of α-carbethoxy-cyclopentanone was added 100 g. of *iso*propyl iodide. The mixture was refluxed for twelve hours, the sodium iodide filtered off and the xylene removed by distillation. The yield of *iso*propyl keto ester boiling at 136–137 (34 mm.) corr. was 75 g., or 59%. The semicarbazone melted at 141–142° corr., which agrees with Bouveault's observations.

α-Ethyl-cyclopentanone.—A mixture of 100 g. of α-ethyl-α-carbethoxy-cyclopentanone, 200 cc. of water and 100 cc. of concd. sulfuric acid was refluxed for five hours. After cooling the mixture was extracted with ether and the ethereal extract washed with sodium bicarbonate solution. After removal of the ether, 39 g. of crude ketone, b. p. 161–164°, was obtained. The pure ketone boils at 160–161° (755 mm.) corr.; $d_4^0 = 0.9469$; $d_4^{25} = 0.9260$.

Anal. Calcd. for $C_7H_{12}O$: C, 74.93; H, 10.70. Found: C, 74.76; H, 10.71.

The semicarbazone melts at 189° corr.

Anal. Calcd. for $C_8H_{15}N_3O$: C, 56.76; H, 8.94. Found: C, 56.95; H, 9.29.

1,2-Diethyl-cyclopentanol-1.—To the cooled Grignard reagent prepared from 28.8 g. of magnesium and 160 g. of ethyl bromide, 120 g. of a-ethyl-cyclopentanone was slowly added with stirring. After several hours the mixture was decomposed with dilute acetic acid, extracted with ether and the ether solution washed with sodium bicarbonate solution. Alter removal of the ether, the resulting liquid was fractionated *in vacuo*. The lower boiling fraction was found to be unchanged ketone. The fraction

[9] Kishner, J. *Russ. Phys.-Chem. Soc.*, **43**, 1149–1157 (1011).

boiling at 100–102° at 49 mm. was 41 g. This on redistillation boiled at 101–102° corr. at 46 mm. and proved to be the desired diethyl-cyclopentanol; yield, 27%. There was a higher boiling fraction which was not investigated; $d_4^0 = 0.9250$; $d_4^{25} = 0.9041$.

Anal. Calcd. for $C_9H_{18}O$: C, 75.98; H, 12.77. Found: C, 75.79; H, 13.24.

1-Propyl-2-ethyl-cyclopentanol-1.—To the cooled Grignard reagent from 28.8 g. of magnesium and 200 *g.* of n-propyl bromide, 100 g. of α-ethyl-cyclopentanone was added slowly with stirring. After four hours at room temperature, the mixture was decomposed with dilute acetic acid, extracted with ether and the ether layer washed with sodium bicarbonate solution. After removal of the ether, the mixture was fractionated several times in *vacuo*. A large low boiling fraction proved to be unchanged ketone. The fraction boiling at 112–115° at 48 mm. was 14 g. On redistillation, the pure alcohol boiling at 115–116° at 42 mm. corr. was obtained, yield, 8.5%; $d_4^0 = 0.9156$; $d_4^{25} = 0.8949$.

Anal. Calcd. for $C_{10}H_{20}O$: C, 76.84; H, 12.81. Found: C, 76.77; H, 13.12.

1,2-Diethyl-cyclopentene, C_9H_{16}.—1,2-Diethyl-cyclopentanol-1, 48 g., was saturated in the cold with hydrogen iodide. The resulting mixture was dissolved in 310 cc. of alcohol and 40 cc. of water and 50 g. of zinc dust was added. After refluxing for two hours, 70 cc. of concd. hydrochloric acid was added and the refluxing continued for four hours. At the conclusion of this time, the mixture was cooled, extracted with ether and the ether solution washed with sodium bicarbonate solution. After removal of the ether, 25 g. of a liquid boiling at 147–149° at 761 mm. corr. was obtained. On redistillation'the pure hydrocarbon, boiling at 148–149° corr. at 761 mm. resulted; $d_4^0 = 0.9331$; $d_4^{25} = 0.8136$.

Anal. Calcd. for C_9H_{16}: C, 87.00; H, 13.00. Found: C, 86.84; H, 13.14. Mol. *wt.* (Freezing point in benzene): calcd., 124. Found: 125.

This hydrocarbon was highly unsaturated, reducing bromine and permanganate instantaneously.

The boiling point of the hydrocarbon described by Kishner as 1,2-diethyl-cyclopentene-1 was 151–152° (751 mm.); $d_4^{20} = 0.8124$.

Summary

a-Methyl-, a-ethyl- and a-isopropyl-a-carbethoxy-cyclopentanones have been prepared by an improved method. From a-ethyl cyclopentanone the 1,2-diethyl- and the 1-propyl-2-ethyl-cyclopentanol-1 have been obtained. On conversion into the iodide and treatment with zinc and acetic acid, the unsaturated hydrocarbon was obtained rather than the desired dialkyl cyclopentane.

THE DECOMPOSITION OF ORGANIC COMPOUNDS AT HIGH TEMPERATURES AND PRESSURES[1,2]

BY LEE R. HERNDON[3] AND E. EMMET REID

RECEIVED JULY 30, 1928 PUBLISHED NOVEMBER 6, 1928

Introduction

The purpose of this investigation was the determination of the effect of high temperatures upon organic compounds at constant volume.

Numerous experiments have been carried out on decomposition of organic compounds at high temperatures by various methods, such as passing the vapors through hot tubes in the presence of catalysts or by electrical discharge, but, for the most part, these have been carried out under atmospheric pressure. Sealed tubes and autoclaves have been used but these are not designed to withstand extremes of temperature and pressure. Very few experiments have been made at temperatures above 250" and at pressures greater than a few hundred atmospheres. It seemed desirable to study the decomposition of pure organic compounds when heated at constant volume and the consequent pressure at temperatures from 250–525°.[4]

Apparatus and Procedure

The apparatus used in these experiments was designed to withstand a pressure of 20,000 atmospheres at 400°, at which temperature the tensile strength of the chrom-vanadium5 steel used is at a maximum. The design was such that at the weakest place in the structure the wall was three-fourths of an inch in thickness. The bomb which was used was of the same design as that used by Morey[6] except that the chamber was made longer so as to contain 100 cc. A thermocouple well was bored down the center of the plunger to within one-half inch of the reaction chamber. The bomb was heated in an electric furnace which was controlled by means of an automatic regulator? to which the thermocouple was connected, and in series with three lamp-banks, two of which were connected to the regulator through relays. By this means it was possible to maintain any given temperature between 250 and 525°, within ±2° for any desired length of time.

The threads were dusted with graphite, which was used as a lubricant. The bomb was then sealed with a copper gasket and made tight by means of a long handled, double ratchet wrench. The heating was usually for two hours for the initial run, the

[3] From the Ph.D. dissertation of Lee R. Herndon, June, 1928.

[4] This was made possible by the use of a type of bomb developed in the Geophysics Laboratory and brought to our attention by Dr. F. R. Bichowsky.

[5] Procured from the Midvale Steel Co., Philadelphia, Pa.

[6] Morey, THIS JOURNAL, 36, 215 (1914).

[7] Leeds and Northrup Co., Philadelphia, Pa.

time being lengthened if necessary to effect decomposition. At the desired time the bomb was removed from the furnace and allowed to cool spontaneously to room temperature. It was then set in the holding device, and the wrench applied very slowly until the gaseous products could be heard to escape, then the wrench was quickly removed and the bomb transferred to the water-bath and gas collecting apparatus. This was an inverted 14-liter bottle filled with water. Through the stopper passed a funnel and a tube to discharge the water displaced by the gas. After the gas had escaped the bomb was taken from the bath, dried, opened and the liquid products were removed by means of a pipet. If there were two layers, these were weighed separately. The gaseous products were measured and analyzed and the liquid products subjected to distillation and the products identified as far as possible.

The bombs withstood all pressures to which they were subjected except in one case. In one run with ethylene glycol at 400° the bomb burst. A slit about three inches long opened in the side. The furnace was wrecked but little other damage was done as there were no flying pieces of metal. The bursting was probably due to the thermal expansion of the liquid glycol due to the bomb being too nearly filled with the charge.

Results

Alcohols.—The aliphatic alcohols, methyl-, ethyl-, propyl-, isopropyl-, *n*-butyl-, isobutyl-, *sec.*-butyl-, *tert.*-butyl- and n-amyl-; the aromatic, benzyl- and phenylethyl; and the terpene, fenchyl alcohol have been decomposed by heating at temperatures above 400° for two hours. Temperatures were chosen such that decomposition was not quite complete in this time. All of the above mentioned alcohols yielded a great variety of products. There seem to be two simultaneous reactions: (1) dehydration and subsequent polymerization of the hydrocarbon residues, and (2) dehydrogenation followed by the splitting off of carbon monoxide and then polymerization. Three distinct types of compounds were derived from these decompositions: (1) gaseous, (2) water-insoluble portion, **(3)** water and water-soluble portion.

The gaseous products were analyzed in a number of cases, the results of which are given in the following table.

TABLE I

PERCENTAGE COMPOSITION OF THE GASEOUS PRODUCTS FROM ALCOHOLS

Alcohol	CO_2	CH_4	$CH_2{=}CH_2$	CO	C_2H_6	H_2
Methyl	8.1	41.8	0.8	3.1	..	39.4
Ethyl	10.2	31.8	8.0	7.6	36.6	..
n-Propyl	9.8	36.8	2.0	21.6	..	20.0
Isopropyl	8.6	..	18.4	2.8	51.2	12.6
Benzyl	14.2	4.2	0.6	64.6	..	11.0
Phenylethyl	10.4	5.8	..	44.6	..	33.0
Fenchyl	10.0	32.2	2.4	51.0	..	..

Methyl alcohol gave exceptional results in that no liquid hydrocarbon or insoluble portion was obtained, the products of decomposition being gaseous with the exception of water. Peytral[8] and Ipatiev[9] state that

---

[8] Peytral, *Compt.* rend., 165, 703 (1917).

[9] Ipatiev, Ber., **34,** 3579 (1901); **35,** 1047 (1902).

the products are all gaseous, the decompositions taking place according to the following reactions

$$CH_3OH = H_2 + CH_2O \qquad (1)$$
$$CH_2O = CO + H_2 \qquad (2)$$

In the bomb the above reactions appear to be accompanied by hydrogenation. That reaction (2) takes place is proved by the presence of carbon monoxide in the gaseous product; however, the dioxide is present to a greater extent than the monoxide. This may be accounted for by the reaction:

$$2CO = CO_2 + C \qquad (3)$$

which Briner and Wroczynski[10] found to take place at 320–330° and 400 atmospheres.

Ethyl alcohol showed dehydrogenation, dehydration and polymerization of the hydrocarbon residue to compounds of wide boiling range, as shown in Table II, which also shows the density and bromine absorption for each cut.

TABLE II

FRACTIONAL DISTILLATION OF 591 G. OF UPPER LAYER PROM 30 RUNS OF 59 G. EACH OF ETHYL ALCOHOL AT 425° FOR TWO HOURS

Fraction	2'. °C.	G.	Density	Br abs , g. per cc.	Fraction	T, °C.	G.	Density	Br abs , g. per cc.

[a] At 15 mm.

Unsaturation was also evident in the gaseous product. This unsaturation cannot be entirely credited to the lack of hydrogen in the decomposition products because the gaseous portion from isopropyl alcohol was even more unsaturated than that from ethyl alcohol and still contained about 12% hydrogen.

Sec.-butyl alcohol was exceptional in so far as no gaseous product was obtained.

Tert.-butyl alcohol was almost completely decomposed when heated at 400° for two hours, yielding nearly the theoretical quantity of water, showing that the primary reaction is dehydration. This was the lowest temperature at which any of the alcohols underwent complete decomposition.

---

[10] **Briner and Wroczynski,** *Compt.* **rend., 150,** 1324 (1910).

Benzyl alcohol yielded carbon monoxide as the chief gaseous product. The toluene formed must have resulted from hydrogenation, since both water and hydrogen were present in the final products of the decomposition.

Hydrocarbons.—Normal heptane, the only aliphatic hydrocarbon subjected to 400° for two hours, underwent slight decomposition into simpler products as well as some of more complex character. The simpler products were gaseous, while the most complex were of the character of lubricating oil. The mechanism given by Thorpe and Young[11] for butane is

$$CH_3CH_2CH_2CH_3 = CH_3CH_3 + CH_2{=}CH_2$$

but Pease[12] has shown it to be

$$CH_3CH_2CH_2CH_3 = CH_4 + CH_3CH{=}CH_2 \tag{1}$$

$$CH_3CH_2CH_2CH_3 = H_2 + CH_3CH_2CH{=}CH_2 \tag{2}$$

In the bomb the normal saturated hydrocarbon yields simpler saturated hydrocarbons together with unsaturated hydrocarbons, which under the influence of heat and pressure polymerize to give higher hydrocarbons. Each fraction contained some unsaturates, since each took up an appreciable quantity of bromine.

Benzene is quite stable at 400° and was only slightly decomposed when heated at 500" for two hours. More complete decomposition was effected by heating at 525" for forty-eight hours, but even then the decomposition was incomplete, 27% of the benzene being recovered. With the exception of the hydrogen the decomposition products were solids. Diphenyl, *m*-diphenyl- and *p*-diphenylbenzenes were formed in quantities sufficient for identification, while other products of higher boiling point did not yield readily to the action of solvents or the formation of derivatives.

Toluene decomposed almost completely when heated at 525° for ten hours, with the deposition of some carbon. Distillation of the resulting product indicates the formation of xylenes and a number of isomers with the empirical formula $C_{14}H_{14}$, which boil over the range of 278--300°.

Other aromatic hydrocarbons with side chains, such as ethylbenzene, *iso*propylbenzene, *tert.*-butylbenzene and unsymmetrical diphenylethane behave much as does toluene.

Acids.—Acetic acid at temperatures above 400° decomposes into gaseous products rather than yielding liquid products of varied boiling points, as is shown by the distillation range of the product.

Adipic acid at 450" for three hours breaks down completely into liquid and gaseous products with the deposition of carbon. The liquid portion was in two layers, the upper being a dark brown oil, while the lower layer was colorless and mostly water.

Benzoic acid heated at 400° for two hours yielded a thick, black sub-

---

[11] *Thorpe and* **Young,** *Proc. Roy. Soc., 21, 184* (1873).

[12] Pease, THIS JOURNAL. 50, 1779 (1928).

stance which was chiefly undecomposed benzoic acid with a little carbon and some gas as decomposition products.

Citric acid decomposes at 400° into two liquid layers, a large quantity of gas and a little carbon. The upper layer was composed of hydrocarbons, while the lower layer contained acetone, acetic acid and water.

Stearic acid when heated at 400° for two hours gave a pale yellow, soft solid which appeared to be the unchanged acid.

Aldehydes.—Acetaldehyde at 335° for two hours gave two liquid layers of almost equal volume and two liters of gas. The upper layer gave a wide variety of products, as indicated by the boiling range of 55–360". The lower layer distilled over a narrow range, 79–100°, the major portion within the last 5°. The gaseous product contained carbon dioxide, carbon monoxide, unsaturated hydrocarbons and methane.

Benzaldehyde at 400° for two hours gives benzene as the principal product as well as other higher boiling products.

Chloroform.—Chloroform decomposed at 425° yielding chlorine, and possibly hydrogen chloride, with two liquid layers and a pale yellow solid which had the correct melting point for hexachloro-ethane. Work was discontinued on this product because of the corrosive effect of the products of decomposition on the bomb.

Ester.—Ethyl acetate above 400" for two hours decomposes into two liquid layers, a little gas and a small-amount of carbon. The upper layer, consisting mostly of hydrocarbons, had a very wide boiling range, indicating a large number of compounds. The lower layer was chiefly water with some acetic acid formed by hydrolysis and a soluble ferrous salt, possibly the acetate.

Ether.—Diethyl ether decomposes when heated at 400° for two hours yielding acetaldehyde, considerable gas and a liquid distilling over the range of 22–48°.

Glycols.—Ethylene glycol decomposes into two liquid layers and some gas when heated at temperatures considerably below 400°.

Diethylene glycol undergoes almost complete decomposition at 400° for two hours. The products of decomposition consist of some gas and two immiscible liquids. The liquids show a very marked change in character from the original. In addition to having distillation ranges lower than the boiling point of pure diethylene glycol, the lower layer is chiefly water, as is the case with the lower layers of the alcohols, while the upper layer is composed of hydrocarbons of a wide boiling range.

Acetone.—Acetone at 400' for two hours decomposes into two layers, the lower of which is chiefly water and the upper layer of an oily consistency.

Benzophenone.—Benzophenone appears to be quite stable at 400° for two hours.

Phenol.—Phenol is stable at 400° and decomposes only slightly when heated at 525° for two and one-half hours.

Quinol.—Quinol undergoes some decomposition at 400° in two hours. The product from one experiment was not of sufficient quantity to justify attempts at identification.

Sucrose.—Cane sugar gave a black, porous mass when heated at 425° for two hours.

Table III

Summary

A study has been made of the decomposition of organic compounds at constant volume, constant temperature (between the limits of 300–525°), at consequent pressure and for periods of time ranging from two to forty-eight hours, the temperature and duration of heating depending upon the stability of the compound under investigation.

The following substances have been heated: methyl-, ethyl-, n-propyl-, isopropyl-, n-butyl-, isobutyl-, *sec.*-butyl-, *tert.*-butyl-, *n*-amyl, benzyl-, phenylethyl and fenchyl alcohols; acetic, adipic, benzoic, citric and stearic acids; acetaldehyde and benzaldehyde; n-heptane; benzene, toluene, ethylbenzene, isopropylbenzene, *tert.*-butylbenzene; unsymmetrical diphenylethane; chloroform; ethyl acetate; diethyl ether; ethylene and diethylene glycols; acetone and benzophenone; phenol; quinol; and sucrose.

The products of decomposition have been separated and identified as far as possible.

THE NOMENCLATURE OF PARENT RING SYSTEMS[1,2]

BY AUSTIN M. PATTERSON

RECEIVED JULY 30, 1928 PUBLISHED NOVEMBER 6, 1928

General Principles

1. *Any attempt to construct a strictly logical system of names for the large number of parent ring systems now known seems impractical, at least so far as common use is concerned.* Brief special or "trivial" names (Trivialnamen) for many systems have become well established and have proved their convenience, while systematic names tend to become long and to be complicated with numbers and letters in order to distinguish isomers.

J. J. Sudborough, J. *Indian Inst. Sci.*, *7*, 145–195 (1924); C. A., 19, 825–826, has developed a scheme of nomenclature for ring systems, He names each form by selecting a peripheral ring as a basis and indicating how it is bridged, which is possibly the simplest method that could be chosen. According to his plan the name for what has been called 9,10-diphenylenephenanthrene (a six-ring parent hydrocarbon) is "5B–1:1:22, 2:2:15, 3:3:8, 9:9:14, 16:16:21,-*cyclo*-hexacosa-$\Delta^{4:6\ 10:12:17:19:23:25}$-octene." T. S. Wheeler, Chem. *News*, **126**, 33–35, 49–50, 66–67, 113–115 (1923), proposes to proceed in *a* linear manner from one component ring to another, characterizing each on the way. His name for the compound just mentioned is "hexar-3,4-hexar′-2,3-hexar″-2,3-hexar; 4′,5′-hexar; 4″,5″-hexar." It is hard to imagine that such names as these could ever come into extended use. They might conceivably be employed in a telegraphic code or in some systematic form of indexing.

2. *On the other hand, it would not be wise to coin a special name for each parent compound known.* The number of such names would be large. Ingenuity would be taxed to find names that should aptly characterize each one. Such names make demands on the memory or require access to a reference book, and they throw little or no light on structural relations.

3. *Consequently, any practical system of naming parent ring compounds will be a compromise between brevity and logical system.* A parent compound that has an important family of derivatives or that has become prominent for any other reason should have a name of convenient length. On the other hand, it is an advantage to name ring systems so as to indicate

[1] In memory of Ira Remsen.

[2] The substance of this article was communicated in manuscript form in March, 1926, to the other members of the Comité de Travail on Organic Nomenclature of the International Union of Pure and Applied Chemistry. It has now been revised for publication, with comments on an article since published by Prof. Robert Stelzner. The writer found, on visiting Hofmannhaus (Berlin) in 1925, that the workers there and those of *Chemical Abstracts* had arrived independently at some of the same ideas, especially as regards the naming of heterocyclic systems, while differing rather definitely on certain points. He takes this opportunity of expressing his appreciation of the cordial attitude and cooperation of Professor Stelzner, Professor Prager, Doctor Kuh and Doctor Stern.

their structure, either as to component atoms (as in "triazole") or as to component rings (as in "benzopyran"). "Triazole" happens to be both brief and systematic. It should be possible to name some compounds in more than one way; for example, it is useful to be able to say that camphane is, 1,7,7-trimethyl-norcamphane and that norcamphane is bicyclo[2.2.1]-heptane. If our names are to be both convenient and logical, there must be some flexibility. In what follows, only the possibilities for systematic naming will be discussed.

4. *Existing* names and usages *should* be conserved in so far as they can be adopted into a *fairly* consistent *general* plan. Nomenclature in use must be reckoned with. No matter what is substituted for it, it will persist for a certain time. The more such confusion can be avoided, the better. Really discredited names will slowly drop out.

5. In general, the *presence* of all the component rings of a ring system should be clearly indicated in its name. It is very easy to disguise the presence of rings by using a prefix denoting a multivalent radical. Thus, thiodiphenylamine suggests two separate benzene rings but actually is the name of a three-ring complex; benzoyleneguanidine contains a two-ring complex; while malonylurea, at first sight an aliphatic compound, is the derivative of a six-membered ring. Such names not only do not express clearly the nature of the ring system; they often prevent a compound from being indexed with other compounds of related structure and they often fail to provide sufficiently for naming derivatives. There are exceptions to the principle stated at the head of the paragraph. Names like malonylurea have their uses and should not be suppressed. Moreover, some compounds, as lactones and acid anhydrides, are more suitably named with reference to the compound from which they are formed than with reference to the cyclic system which they contain, Also, it may at times be desirable to use a multivalent radical prefix to name a bridge, as in 1,4-*imino*-benzene. Nevertheless, the general principle of naming compounds so as to recognize clearly all rings present, unless there is definite reason to the contrary, seems valid.

6. There should be a clear distinction between the *names* of ordinary substituting atoms or radicals and the names of *atoms* or rings used *in* forming the names of parent ring systems. This becomes immediately evident when one attempts to index substances under the names of their parent compounds. "Thio," for example, is used to denote the replacement of oxygen (or sometimes hydrogen) by sulfur; but it may also denote the replacement of methylene by sulfur in *a* ring (as in "thiodiazole"). Similarly, "oxy" may mean replacement of hydrogen by oxygen (or even by hydroxyl), and also the replacement of methylene by oxygen in a ring. In order to avoid confusion with the ordinary meanings of oxy-, thio-, azo-, etc., it is recommended that the forms oxa-, *thia-*, aza-, etc., be employed to indicate the presence of hetero atoms in a ring (the *a* being dropped before a vowel).[3]

Thus one would have thiadiazole, oxadiazole (which is more euphonious than oxdiazole), thiazine, oxazine. Combining forms to indicate the presence of rings in a complex are usually clear enough (for example, benzo-, naphtho-) and not liable to confusion with the names of corresponding radicals (as phenyl, phenylene, naphthyl).

7. *There is a useful analogy between the naming of individual compounds as derivatives of a parent compound and the naming of complex ring systems as derivatives of a less complex parent system.* For example, the names dichloro-ethane and dibenzocarbazole we analogous, even though in the one case there is replacement of hydrogen by chlorine, while in the other case two benzene rings are regarded as having been "fused" with the carbazole complex (a highly theoretical assumption). It is worth while to follow out this analogy (see especially p. **3081**).

8. *With regard to terminations, three general methods of naming parent ring systems are in vogue.* The first is illustrated by such names as ethylene oxide, tetramethylene, hexamethylenetetramine. It consists in juxtaposing the names of the radicals or atoms that make up the system without much regard to consequences, and must therefore be regarded as rather unsatisfactory, especially for naming derivatives. The second is based on analogy with aliphatic hydrocarbons. According to it, saturated carbocyclic systems form names ending in -ane, while unsaturation is indicated by -ene, -diene, etc., depending on the number of double bonds present; examples: cyclopropane, bicyclononene, spiroheptadiene. Such names are convenient and systematic and are much used for non-aromatic systems. The third method, which is used for the great majority of ring

---

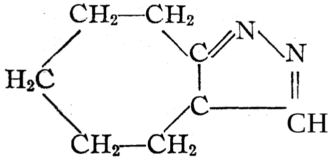
[3] As previously stated, the proposals in this article were made to the Comité de Travail on Organic Nomenclature in 1926. A similar scheme for the use of oxa-, thia-, aza-, etc., was published in the same year by Professor R. J. Stelzner (Literatur-Register der *organischen* Chemie, 5, ix–xv). The *a* endings had previously been used by Bouveault (Ber., 31, 3373 (1898); Beilstein's "Handbuch," 3rd ed., Vol. 4, p. 1 (1899)); Ingold (*J. Chem. Soc.*, 125, 87 (1924)), Sudborough (J. Indian *Inst. Sci.*, 7, 182 (1924)), and probably others.

Both Professor Stelzner and the writer would employ the principle for various classes of heterocyclic ring compounds (see the following pages). It might also be extended to open chains of mixed composition. For example, the compound $CH_3N{=}NNHCH_3$ could be called 2,3,4-triaza-2-pentene, semicarbazide would be 1,2,4-triazabutan-3-one, and $CH_3OCH_2OCH_3$ would be 2,4-dioxapentane. Such a nomenclature would provide much simpler names for certain polyethers, polysulfides, etc., than we have at present; this is mentioned merely to show its possibilities. The same idea has already been used to some extent for aliphatic silicon compounds (for example, siliconpremium, $C_8H_{20}Si$).

The use of such forms as thiona-(–SO–) and sulfona-(–SO_2–) in making ring names does not seem advisable. It would be better to use thia-(–S–) and treat the sulfoxides and sulfones as oxides of the fundamental form, systems, assigns to unsaturated hydrocarbons the ending -ene, no matter what the degree of unsaturation, and to heterocyclic compounds such endings as -ine, -ole and -an. This system has arisen largely in connection with aromatic and quasi-aromatic compounds, in which a stage of low saturation is looked on as the fundamental form, as naphthalene, pyrrole, furan. Increasing stages of saturation are usually represented by "hydro" or "hydride" names (as, dihydronaphthalene) but in some cases by special endings (as, pyrroline, pyrrolidine). Although the last two methods are to some extent contradictory,[4] a continuation of both seems inevitable.

Simple Carbocyclic Rings (Class A I)[5]

The Geneva names for monocyclic saturated hydrocarbons, namely cyclopropane, cyclobutane, etc., and also the corresponding names cyclopropene, cyclobutadiene, etc., have been well accepted. They are unquestionably superior to the older names such as trimethylene, and they also seem to be preferred to Zincke's names (R-pentene, etc.), which are seldom seen nowadays. The "cyclo" names are clear and systematic and they correlate cyclic with aliphatic compounds. Nevertheless, it should be pointed out that these names are unlike those of the majority of ring systems (see p. 3076). There is a chemical reason for this in the distinction between aromatic and non-aromatic properties. It would, however, conduce to uniformity of cyclic names and numberings if we had, for example, a basal name for cyclopentadiene and named cyclopentene and cyclopentane as the dihydro and tetrahydro compound, respectively. The "cyclo" names do not yield very convenient prefixes for use in naming complex systems. For instance, derivatives of the compound exist, and it has been called "cycloheptanopyrazole" by its discoverer. Less saturated stages would presumably be called "cycloheptenopyrazole," "cycloheptadienopyrazole," etc. Thus there is a multiplication of prefixes and parent forms, which does not occur with benzo-, naphtho, pyrrolo-, etc. In the *Chemical* ***Abstracts*** indexes the form of lowest saturation, that is, cycloheptatrienopyrazole, has been called "cycloheptapyrazole" and the more saturated forms are treated as hydro derivatives, but the name is not altogether satisfactory, as it might be taken to imply the combination of seven pyrazole rings into one grand cycle. There is therefore a certain lack due to the



---

[4] For a discussion of one difficulty caused by their conflict, see Patterson, THIS JOURNAL, 47, 553–554 (1925).

[5] The classification is that adopted in "Proposed International Rules for Numbering Organic Ring Systems," THIS JOURNAL, 47, 543–561 (1925).

absence of brief names for cyclopropene, cyclobutadiene, cyclopentadiene, cycloheptatriene, etc.

Simple Heterocyclic Rings (Class A II)

About a dozen three-membered heterocyclic rings are known. Those that are named at all are given such titles as ethylene oxide, hydrazimethylene (see general principle 8, p. 3076); there is no systematic way of naming them. Almost the same is true of the four-membered rings, of which there are about two dozen. Some are called trimethylene oxide, trimethylene sulfide, etc.; others are called betaine, thetin and "phosphorbetain." Hale[6] has coined the name "urete" for a four-membered parent ring, $C_2H_2N_2$, and the Chemical *Abstracts* indexes, following this lead, have adopted *-ete* as an ending for other four-membered rings (azete, triazete).

For five-membered rings proposals made by Widman,[7] Bouveault[8] and others have found their way into use. The ending *-ol* or -ole appears in such names as pyrrole, imidazole and even dioxole (which is non-nitrogenous). It conflicts with the ending *-ol* for alcohols and phenols (hence the modified spelling -ole), but its use to denote a five-membered ring is well known. Perhaps the most easily understood names are those that prefix to this ending syllables denoting the kind and number of hetero atoms present, thus: diazole, triazole, thiodiazole (better, thiadiazole). The suffixes -oline and -olidine are in use for the hydrides of these rings (as pyrroline, pyrrolidine).

In the field of six-membered rings are found names corresponding to the above systematic names for five-membered rings, but with the suffix *-ine* or *-in* replacing -ole (or -ol), as: triazine, oxazine, thiodiazine, dioxin (the latter being non-nitrogenous). Thus the ending -ine (or -in), although regarded as properly the ending for bases, has a specific sense in which it indicates a six-membered ring. For rings of more than six members there is no system in use, beyond names like trimethylene tetrasulfide, diethylene tetrasulfide, trimethylene-ethylenediamine, etc. (see general principal 8, p. 3076). Crowther, McCombie and Reade[9] have used the name "dioxazseptane" for a seven-membered ring.

Such is the present state of affairs. Convenient special names like pyrrole, thiophene and pyridine are not likely to be displaced, but systematic names are needed for many simple heterocyclic systems. In what **way** can progress be made? Ingold[10] has proposed to form names according to the first method mentioned under general principle 8 (p. 3076), as trimethyleneimine, oxatrimethylene (trimethylene oxide), 1,3-dioxadi-

[10] Ingold, ibid., 125, 87-88 (1924).

imine. He deals with four-membered rings only, but the same principle could of course be extended. The objections to the plan are that the names are made up of names of radicals and atoms and therefore do not present the parent ring systems clearly as entities (see general principle 5, p. 3075), that hydrogenation or dehydrogenation changes the names rather profoundly, and that the names do not lend themselves well to indexing or to the formation of prefixes for naming more complicated forms. Stelzner[11] would use the combining forms oxa-, thia-, etc., referred to under general principle 6 (p. 3075), prefixing them to *the* name of *the carbocyclic form* of the same number of members and same saturation. Thus, ethylene oxide would be oxacyclopropane; pyrrole would be aza-5-cyclopentadiene-1,3. This plan has much to recommend it, being easy to understand and apply. It should at least prove useful in systematic works of reference. The disadvantages of the method are: *(a)* the names of bases are not given a characteristic ending, but terminate like those of the hydrocarbons. This might perhaps be obviated by arbitrarily adding the ending -ine. Thus, ethylenimine might be called, not azacyclopropane but azacyclopropanine. (b) Tautomeric compounds such as pyrrole, isopyrrole and pyrrolenine (which Stelzner calls, respectively, aza-5-, aza-1- and aza-2-cyclopentadiene-1,3) do not have the same number for the hetero atom. This could be remedied easily by assigning varying positions to the double bonds, and in the writer's opinion this would be preferable, as chemists are accustomed to regard the position of the hetero atom as fixed. Stelzner, however, does not favor this solution and it could not well be applied to complex systems like indole and pseudo-indole (belonging to Class B; see p. 3084). (c) The names tend to be rather long and do not yield convenient combining forms if these should be desired for naming complex systems.

An alternative method would be to improve and extend the existing practice of using characteristic *syllables* to indicate the *number* of members in the ring. In spite of objections that might be urged against it, this method furnishes many neat names and combining forms (as triazole, triazolo-, oxazine, oxazino-). With a precedent already set for et (four members, compare "tetra") and with *ol* (five members) and in (six members) already confirmed by usage, it would only be necessary to supply three syllables more to cover all but rare cases. These might be *ir* (from "*tri*," reversed) for three members, ep (from "*hepta*") for seven members, and oc (from "octa") for eight members. The series could be extended if desired by selecting on (from "nonus") for nine members, and *ec* (from "*deca*") for ten members. Some of these syllables are not acceptable as *endings* because of prior use (for example -ol for alcohols) but they may be used in the middle of a name without objection. Examples of the resulting names and combining forms are: oxirene, oxirane (ethylene oxide),

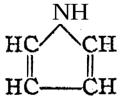
---

[11] Stelzner, "Literatur-Register der organischen Chemie," 5, ix–xv (1926).

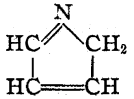
ox*iro*-, azetine, azeto-, oxetane (trimethylene oxide), oxeto-, tetrazepine, tetrazepo-, 1,2,4,6-tetrathi*ep*ane (trimethylene tetrasulfide), s-tetrazocanine (tetramethylene tetramine), 1,3,5-triaz*oc*anine (parent substance of acetonylbiuret). In the last two cases the ending -ine (characteristic of names of bases) has been attached to names that would otherwise have terminated in -ane. The wide use that such names have attained in the five- and six-membered series illustrates the fact that an extremely compact systematic name is often better than either a more extended systematic name or an arbitrarily coined special name.

Order of Hetero Elements.—In the "Rules for Numbering,"[12] the order of hetero elements is determined according to a descending order of groups in the periodic table and an ascending order of atomic numbers in each group. This results in the following order for commonly occurring hetero elements: O, S, Se, Te, N, P, As, Sb, Si, Sn, Pb, Hg. A majority of names in the literature conform to this order (cf. oxazine, thiodiazine), but not all (cf. thioxole). In the judgment of the writer it is better than an order based on valence, since the latter is a variable property. It is important that changes in valence, hydrogenation, etc., should not affect names and numberings profoundly.

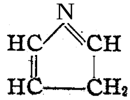
Distinguishing Isomers.—Various methods are now employed to distinguish isomeric heterocyclic rings, among which may be mentioned: Arabic numerals (e. g., 1,2,4-oxdiazole), Roman letters (e. g., pyrro[ab]-diazole), Greek letters (e. g., γ-pyran), abbreviations denoting structure (e. g., as-triazine), prefixes (e. g., isothiazole), suffixes (e. g., pyrrol*enine*), and different special names (e. g., pyrazole and imidazole). In important cases the isomers should probably have different names; in the others Arabic numerals indicating the positions of the hetero atoms seem to be clearest, though sometimes a little cumbrous. The numerals are often made to indicate at the same time the position of methylene groups when this is necessary. It would be well, however, to reserve some prefix, preferably *iso*-, to indicate isomerism caused by change in position of hydrogen. For example, if the two isomers of pyrrole had not already established names they might be called, respectively, 2- and 3-isopyrrole



Pyrrole



2-Isopyrrole
(*Iso*pyrrole)



3-*Iso*pyrrole
(Pyrrolenine)

Complex Ortho-Fused Ring Systems (Class B)

Many systems of this class have well recognized special names, as naphthalene, phenanthrene, quinoline. Where such names do not exist it is

---

[12] Patterson, This journal, 47, 545 (1925).

customary to build up names from the simpler systems which may be regarded as present in the complex system to be named, as benzo-pyran. As the Meyer-Jacobson "Lehrbuch"[13] points out, there is no generally observed system for doing this. Certain principles may, however, be laid down (some of these are corollaries of general principle 7, p. 3076):

(1) Other things being equal, the largest component having a simple name is to be taken as the parent form, to which the other rings or complexes are regarded as being attached. Thus we would naturally say "pyridocarbazole," not "carbazolopyridine."

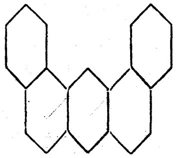
(2) A heterocyclic component is to be preferred to a carbocyclic as the parent form, even though smaller. Thus we say "naphtho-thiophene," not "thiophenonaphthalene."

(3) A nitrogenous component, if present, is preferred as the parent form, in order that the name of the system may have a termination indicating a base. Thus it is customary to say "furo-pyrrole" not "pyrrolofuran."

(4) No ring in the complex system should be expressed more than once in the name of the complex.[14]

Thus, "naphthacridine" most appropriately designates a five-ring system composed of a naphthalene complex and an acridine complex, united by ortho fusion. The name has been used (unwisely, as it seems to the writer) to designate a four-ring system in which a naphthalene complex and an acridine complex exist, to be sure, but having one benzene ring in common; in other words, there is overlapping and this benzene ring is expressed twice in the name. Meyer and Jacobson[14b] also disapprove of the overlapping method ("the Grabe-Skraup use of prefixes") and favor the non-overlapping plan (of Hantzsch and Widman).

(5) Like components should be treated alike if possible. Thus, for the system



the name "dibenzanthracene" would be chosen in preference to "naphthophenanthrene" (this is analogous to the choice of "diphenyhethane" in preference to "benzylbenzene)."

(6) Other things being equal, the parent form should be so chosen as to make the "substituents" as simple as possible. Like (5), it would lead to the name "dibenzanthracene" in preference to "naphthophenan-

---

[13] Meyer and Jacobson, "Lehrbuch der organischen Chemie," 1920, Vol. 2, Part 3, p. 31.

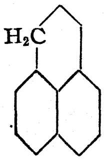
[14] (a) Cf. Patterson, **This Journal, 39, 1632** (1917); (b) Meyer and Jacobson, 1920, Vol. **2**, Part 3, pp. 31–32, 1105.

threne." This principle is questionable, since it might lead to longer names, for brevity is of great importance in naming ring systems.

(7) For each important "substituent" component there should be a recognized prefix. In general this would be formed from its name with use of o as final vowel; as, pyrrolo-, pyridino-, fluoreno-. Some well established contractions should be accepted, as anthra-, benzo-, naphtho-, but none that is ambiguous; thus, it would be better not to use pyrazo- at all but to employ the more exact pyrazolo- and pyrazino-. It should be noted that the prefix pheno- or phen- has been used to indicate *two* benzene rings (as in phenazine, phenoxazine) and also in other ways (as in phenanthrene, phenobarbital); the natural conclusion is that "benzo" should always be used when one wishes to denote the attachment of a single benzene ring by ring fusion.

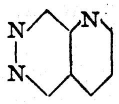
(8) In accordance with the aromatic nature of the compounds, the basal names of ring systems of this class are usually given to the least saturated form, stages of greater saturation being named as hydro derivatives or hydrides. In the writer's opinion it is well to adhere to this rule even when a non-aromatic ring is a component of such a system. For instance, it seems simpler to have one combining form "cyclopenta-" or "cyclopento-" for the five-membered carbon ring than to attempt to distinguish between cyclopentano-, cyclopenteno- and cyclopentadieno- when this ring is attached, say, to a quinoxaline complex (cf. "cycloheptano-pyrazole", p. 3077). The whole system can be reduced to lowest hydrogenation and hydro derivatives indicated.

(9) The true names of components should be used in forming the name of the complex system. This statement seems obvious yet it is frequently disregarded in practice. For example, the system



has been called *peri*-naphthindene, yet it does not contain the indene structure as a component; it is *peri*-benzonaphthalene.[15]

Again, the form

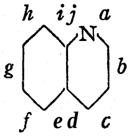


---

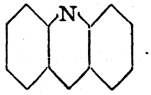
[15] Meyer and Jacobson and Stelzner and Kuh have sought to avoid naming "peri" systems in the same manner as ordinary ortho-fused systems because the two classes are not isomeric; e. g., *peri*-benzonaphthalene is $C_{13}H_{10}$, while the ordinary benzonaphthalenes (anthracene and phenanthrene) are $C_{14}H_{10}$, but the writer feels that any advantage gained by distinguishing the two classes by such prefixes as benzo- and benzi-, or benzo- and benzolo-, are at least offset by corresponding drawbacks.

is not a benzotriazine, even though it is an isomer of those systems; it is a pyridopyridazine.

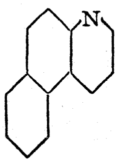
Distinguishing Isomers.—As in the case of simple heterocyclic rings, isomers in the complex ortho-fused systems are at present distinguished in a very opportunist way: by numbers, by Roman, italic or Greek letters, by prefixes (as iso-, pseudo-, lin-, ang-), by different special names, etc. Here again the more important isomers may well have names of their own (as anthracene and phenanthrene). For the other cases there should be some general system. Following out the analogy of general principle 7 (p. 3076), it would seem that such a system should be based on the numbering of the "parent" component[16] and that of the "substituent" components The "Rules for Numbering"[17] would furnish a standard for this purpose. The following plan is suggested: for the numbering of the "substituents" retain their Arabic numerals; for the numbering of the "parent" component start with the side 1,2 and letter the sides of the complex with Greek, or rather (since chemists seem to be less and less familiar with that language), small italic or Roman letters. Letter every side, even where there are no numbered positions, as fusion may occur on any side. Then use only such of these symbols as are needed to indicate where the fusion has occurred. Place them in the heart of the name, as Baeyer did in naming the "bicyclo" compounds, so as to avoid confusion with other symbols. A few examples will make the plan clear:



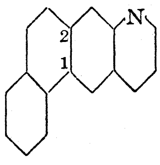
Quinoline



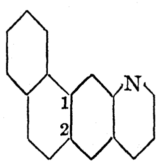
Benzo[*b*]quinoline (Acridine)



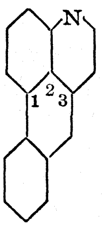
Benzo[*f*]quinoline



Naphtho[1,2-*g*]quinoline



Naphtho[2,1-*g*]quinoline



Naphtho[3,2,1-*d e*]quinoline

As all six positions on the benzene ring are equivalent, it is not necessary to introduce numbers in the benzoquinoline names. In the last three examples the order of the numbers (1,2 and 2,1, etc.) indicates whether

---

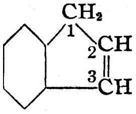
[16] Cf. Bally and Scholl, *Ber.*, **44**, 1662–1665 (1911).

[17] Patterson, THIS JOURNAL, 47, 543–561 (1925).

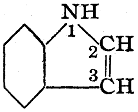
the numbering of the "substituent" (naphthalene) travels *with* or against that of the "parent" on the side where fusion occurs.[18]

This method of distinguishing isomers has been experimented with in the indexes to *Chemical* Abstracts and has been found satisfactory and of very general application. It applies to "peri" systems, in which case more than one letter is used (see the last example on p. 3083), and to the rare spiro systems of this class.

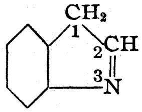
Use of the Aza-, Thia-, etc., Names.--For heterocyclic systems of this class, Stelzner proposes to use the same method as already described (p. 3079), that is, basing the name on the corresponding carbocyclic form and using prefixes to indicate the hetero atoms. The plan has the same advantages and disadvantages as outlined above (p. 3079), with two additional considerations. The first is, that it does not remove the necessity for coining names for the carbocyclic compounds, which must still be handled by some other method. The second and more serious consideration relates to the effect of the plan on complex ring systems differing only as to the position of hydrogen atoms. The remedy suggested on page 3079 cannot be applied here. Indole, for example, would be (if the "Rules for Numbering" are followed) aza-1-indene, while ordinary pseudo-indole (indolenine) would be aza-3-indene.



Indene



Aza-1-indene
(Indole)



Aza-3-indene
(Indolenine)

This causes the numberings of the two systems to become quite different, although they are desmotropes. Chemists would naturally much prefer that the nitrogen atom retain the number 1 in both cases.

Simple Bridged Systems (Class C I)

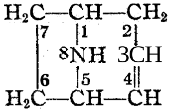
Carbocyclic Systems.—The method proposed by Baeyer[19] for naming and numbering the carbocyclic systems of this class has been adopted into general use. One very slight change could be made to advantage, namely, reversing the order of the figures in the middle of the name: e. g., bicyclo[0,1,3]hexane would become bicyclo[3,1,0]hexane. As Baeyer himself remarked, the order of these figures is not significant; but the decreasing order is in accord with Baeyer's numbering of the system and also is the appropriate one in Class C III (see p. 3086).

---

[18] The orientations here given are intended to show relationship to quinoline. Each ring system has, according to the "Rules for Numbering," an orientation and numbering of its own and the symbols in the heart of the name (in brackets) have nothing to do with this.

[19] Baeyer, Ber., 33, 37714775 (1900).

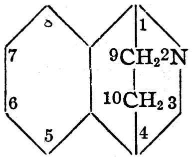
Heterocyclic Systems.—The "Rules for Numbering" extend the Baeyer method to heterocyclic systems, choosing as low numbers as possible for the hetero atoms. Such systems are named conveniently by using the prefixes "aza-," "oxa-," etc., in connection with the Baeyer names for the corresponding carbocyclic forms, as the difficulty about tautomers referred to under Class B (see p. 3084) does not arise. Thus, nortropidine



may be called aza-8-bicyclo[3,2,1]octene-3; or, if it seems desirable to have all such compounds appear together under "Bicyclo-" in an index, it may be called bicyclo[3,2,1]-az-8-octene-3. If the characteristic ending for the names of bases be added, the termination would be changed from "-octene-3" to "-octen-3-ine."

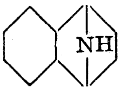
Complex Bridged Systems

Systems Related to Class B.—The "Rules for Numbering" have distinguished as "Class C II" a small class of parent compounds which may be regarded as formed by throwing a bridge or bridges across an ordinary ortho-fused system of Class B (naphthalene, anthracene, quinoline, etc.). These systems, when not too complex, may be suitably named by prefixing the name of the bridge to the name of the corresponding Class B form. Thus, the system



would be named ethyleno[1,4]isoquinoline. It is questionable whether the more complicated members of this class will ever need to be named as parent compounds.[20]

It should be remarked that the plan just proposed does not give to bases names ending in -ine if the nitrogen is in the bridge. For example the system



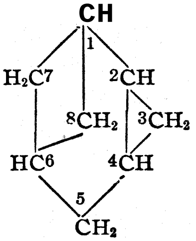
would be imino[1,4]naphthalene. On this account it might be better in such cases to indicate the bridge last and choose the name naphthalen-[1,4]imine.

---

[20] See some of the formulas given under Class C II in This Journal, 47, 559 (1925).

Tricyclo and Tetracyclo Systems (Class C **III**)

These systems are numbered, in the "Rules for Numbering," by a simple extension of the Baeyer method. If these rules are adhered to, names similar to the Baeyer names for bicyclic systems can be given to them, with these differences: (1) the name must now begin "**tricyclo**" (or, rarely, "tetracyclo," etc.) and (2) the additional bridge or bridges must be designated as to number of members and position. This can most simply be done by inserting additional numbers in the middle of the name, with indices to show where the bridge ends are **attached**.[21] For example, the system

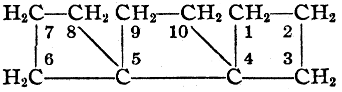


may be called **tricyclo**[4,1,1,$0^{2,4}$]**octane**, the zero denoting that the additional bridge contains no atoms and the "2,4" showing where it is attached. It will now be seen why the *decreasing* order of announcing these numbers was preferred on a previous page (3084).

Heterocyclic systems of this class would be named in exactly the same manner as the simple heterocyclic bridged systems (see p. 3085).

Simple **Spiro** Systems (Class D I)

Simple spiro systems containing one or more spiro atoms can be given names similar to those of the bridged systems. For example, the system



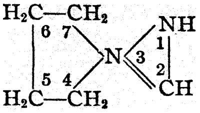
could be called **spiro**[3,0,3,2]**decane**, the figures denoting the numbers of members in the bridges between spiro atoms, in the order in which the "Rules for Numbering" number the system. The number of figures in the brackets is equal to twice the number of spiro atoms present. Perhaps it would be better to say bi- (or di-) **spiro**[3,0,3,2]**decane** in the above case and trispiro- when three spiro atoms are present, and thus make the names still more analogous to those of the Baeyer compounds.[22] An advantage of using simply spiro- in all cases is that these compounds will then all be found in one place in indexes (as may be seen in the indexes to *Chemical Abstracts*).

---

[21] Such indices were proposed by Buchner and Weigand, ***Ber.***, 46,2110–2113 (1913). They are here used in a slightly different and (the writer believes) clearer manner.

[22] See Radulescu, ***Ber.***, 44, 1023–1024 (1911).

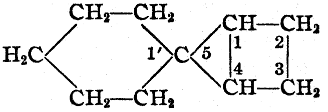
Hetero atoms may be indicated in the same way as recommended for bridged systems. Thus, the system



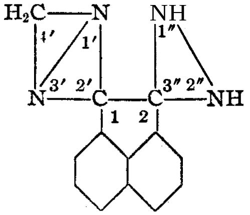
would be called spiro[2,4]diaza-1,3-heptene-2 (or -hepten-2-ine).

Complex Spiro Systems (Class D II)

These systems contain other unions in addition to the spiro unions and are numbered provisionally in the "Rules for Numbering." They may be given corresponding names by juxtaposing the names of the components after the prefix "spiro" and indicating which is the common atom. For example, the system



would be spiro-bicyclo(2,1,0)pentane[5,1′]cyclohexane, while the unusually complex system



would be spiro-acenaphthene[1,2′]bicyclo(1,1,0)diaza-1′,3′-butane[2,3″]-hydrazimethylene. If such a compound should prove of importance as a parent substance a special name should be coined for it, as has been done for fluoran.

Summary

Several general principles are formulated for the correct naming of parent ring systems. The individual classes of ring systems are then considered. The present state of their nomenclature is presented, the more promising methods for forming their names are discussed, and some new proposals are submitted.

THE PREPARATION OF COMPOUNDS OF THE TYPE OF MALACHITE GREEN AND OF PHENOLPHTHALEIN BY MEANS OF THE GRIGNARD REACTION[1]

BY JOSEPH S. CHAMBERLAIN AND MALCOLM F. DULL[2]

RECEIVED JULY 30, 1928 PUBLISHED NOVEMBER 6, 1928

Malachite Green Type

Baeyer and Villiger[3] used the Grignard reaction for preparing *p*-aminotriphenylcarbinol from paminobenzoic acid methyl ester and phenylmagnesium bromide and also from *p*-aminobenzophenone and the same Grignard reagent. At the same time they prepared numerous related compounds, including the dye Malachite Green, which resulted from the reaction between phenylmagnesium bromide and Michler's ketone, 4,4-tetramethyldiaminobenzophenone. Votocek and Matejka[4] prepared alkoxy derivatives of Malachite Green by the reaction between Michler's ketone and magnesium compounds of ring-halogenated phenol ethers and also from the esters of anisic acid by reaction with the Grignard reagent made from p-bromodimethylaniline. Gilman and Schulze[5] made use of the formation of colored products from Michler's ketone as a qualitative test for Grignard reagents.

Thus the preparation of Malachite Green itself by the Grignard reaction is well established, and also the formation of the Grignard reagent from p-bromodimethylaniline. However, the preparation of the latter seems to have been difficult and uncertain for Baeyer and Villiger[3] were unable to obtain it in their efforts to make methyl violet. Sachs and Ehrlich[6] successfully prepared the Grignard reagent from p-bromodimethylaniline by activating the magnesium with ethyl bromide and Baeyer[7] prepared Grignard reagents from o-, *m*- and p-iododimethylaniline by activating the magnesium with iodine. Hurd and Webb[8] prepared and used the Grignard reagent from *p*-bromodimethylaniline in making *p*-dimethylaminophenylmethylcarbinol. The formation of magnesium compounds with halogen derivatives of other tertiary amines was also studied by F. and L. Sachs.[9]

[8] Hurd and Webb, THIS JOURNAL, 49,546 (1927).

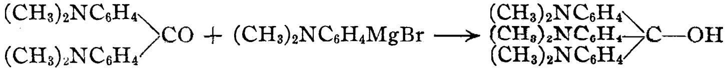
[9] Sachs and Sachs, *Ber.*, 37,3088 (1904).

The first part of the present investigation concerns the preparation of the Grignard reagent from p-bromodimethylaniline, by Sachs and Ehrlich's or Baeyer's method of activating the magnesium, and the reaction of this reagent with Michler's ketone, resulting in the formation of methyl violet, and also the preparation of the Grignard reagent from *p*-bromobenzoic acid and its reaction with Michler's ketone to the formation of chrome green.

Experimental

As a preliminary experiment Malachite Green was prepared in the same manner in which Baeyer and Villiger made it by the reaction of phenylmagnesium bromide on Michler's ketone. The carbinol was obtained in good yield, purified and analyzed. It was also converted into its salts. All of the results identified the product as Malachite Green, thus corroborating the work of Baeyer and Villiger.

Methyl Violet.—This compound, being the hexamethyltriaminotriphenylcarbinol, if possible of preparation by the Grignard reaction as attempted by Baeyer and Villiger, should result from Michler's ketone by reaction of the Grignard reagent obtained from *p*-bromodimethylaniline.



$$\begin{matrix}(CH_3)_2NC_6H_4\\(CH_3)_2NC_6H_4\end{matrix}\Big>CO + (CH_3)_2NC_6H_4MgBr \longrightarrow \begin{matrix}(CH_3)_2NC_6H_4\\(CH_3)_2NC_6H_4\\(CH_3)_2NC_6H_4\end{matrix}\Big>C—OH$$

Michler's ketone Grignard reagent Methyl violet (carbinol)

The p-bromodimethylaniline was prepared and identified, and from it the Grignard reagent was obtained by the following procedure, activating the magnesium by Sachs and Ehrlich's method.

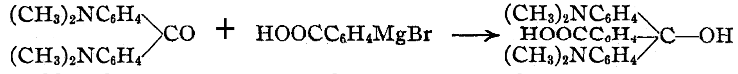
One and three-tenths grams of magnesium turnings was placed in a 150cc. flask and an ethereal solution of 8 g. of ethyl bromide added. The ether used in all cases was specially prepared for use in making Grignard reagents by drying over phosphorus pentoxide, and during reactions was protected from outside moisture by tubes of calcium chloride. The ethyl bromide used was specially purified also.

The flask containing the mixture of magnesium and ethyl bromide was then connected with a reflur condenser carrying a calcium chloride tube at the top. A crystal of iodine was now added to the contents of the flask. After the reaction had continued for three or four minutes, the bulk of the liquid was rapidly decanted and an ethereal solution of 12.5 g. of p-bromodimethylaniline added in its place. The new mixture was then warmed gently on the steam-bath and in a very short time a vigorous reaction began. When the magnesium had all dissolved the contents of the flask were cooled and 15 *g.* of Michler's ketone was added through the condenser tube. The flask was then again warmed for an hour. The ether layer in the flask became deep red in color and a gummy solid was deposited. After cooling, the ether layer was decanted and evaporated. A gummy, almost black mass separated which, in water, yielded an intense violet color. This product was hydrolyzed by boiling with water and after drying yielded 9.0 g. The ether-insoluble product that remained in the flask proved to be unchanged Michler's ketone and amounted to 7.0 g. **A** part of the product obtained from the ether solution was converted into the chloride salt, and also into the double salt of zinc chloride, yielding characteristic products with brilliant turkey bronze coloration. Its water solution gave a deep violet color. The original carbinol was then purified by recrystallization from alcohol and analyzed with the following results.

Anal. Calcd. for $C_{25}H_{31}N_3O$: C, 77.07; H, 8.03; N, 10.79; O, 4.11. Found: C, 77.06; H, 7.65; N, 10.36; O (by diff.) 4.93.

There seems to be no doubt, therefore, that a reactive Grignard reagent may be prepared from p-bromodimethylaniline and that with Michler's ketone it yields methyl violet.

Chrome Green.—This dye, being the p-carboxy derivative of Malachite Green, should result by the Grignard reaction from Michler's ketone and the Grignard reagent obtained from p-bromobenzoic acid.



$$\begin{matrix}(CH_3)_2NC_6H_4 \\ (CH_3)_2NC_6H_4\end{matrix}\!\!>CO + HOOCC_6H_4MgBr \longrightarrow \begin{matrix}(CH_3)_2NC_6H_4 \\ HOOCC_6H_4 \\ (CH_3)_2NC_6H_4\end{matrix}\!\!>C{-}OH$$

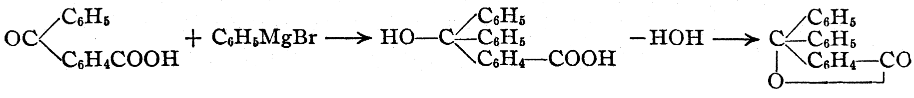
Michler's ketone Grignard reagent from p-bromo-benzoic acid Chrome green (carbinol)

The preparation of the Grignard reagent from p-bromobenzoic acid was unsatisfactory, though various methods of activating the magnesium were tried. It was found, however, that on the addition of Michler's ketone a noticeable sea-green color was produced. The ether solution contained enough of this color product to dye wool mordanted with potassium dichromate (a property of chrome green dye) a permanent sea-green color. It was not possible, however, to obtain a sufficient quantity of this compound to afford identification other than the qualitative one just mentioned.

Phenolphthalein Type

To study the Grignard reaction for the preparation of compounds of the type of phenolphthalein, it was decided to attempt the preparation of phthalophenone (diphenylphthalide) from o-benzoylbenzoic acid.

According to Beilstein [4th ed., Vol. VII, p. 828] the reaction of phenylmagnesium bromide upon esters of this ketone acid results in the formation of o-dibenzoylbenzene. This product is obtained by the reaction of one molecule of the Grignard reagent with the carboxyl carbonyl of the ester. If, however, the phenylmagnesium halide should react with the ketone carbonyl, then phthalophenone should result by the loss of water from the o-carboxytriphenylcarbinol, which would be the direct product of the Grignard reaction.



$$OC\!\!<\!\begin{matrix}C_6H_5 \\ C_6H_4COOH\end{matrix} + C_6H_5MgBr \longrightarrow HO{-}C\!\!<\!\begin{matrix}C_6H_5 \\ C_6H_5 \\ C_6H_4{-}COOH\end{matrix} \quad -HOH \longrightarrow C\!\!<\!\begin{matrix}C_6H_5 \\ C_6H_5 \\ C_6H_4{-}CO\end{matrix}\ (O\text{ bridging C and CO})$$

o-Benzoylbenzoic acid o-Carboxytriphenylcarbinol Phthalophenone

Ostersetzer[10] studied this reaction but was unable to obtain phthalophenone as "only an oily reaction product" resulted. He did, however, ob-

---

[10] Ostersetzer, *Monatsh.*, 34, 795 (1913).

tain methylphenylphthalide, analogous to phthalophenone (diphenylphthalide) by using methylmagnesium iodide instead of phenylmagnesium iodide.

Experimental

A preliminary attempt to effect a reaction between *o*-benzoylbenzoic acid itself and one molecule of phenylmagnesium bromide resulted in failure, practically all of the acid being recovered unchanged. The direct product formed was unquestionably the magnesium salt or the magnesium halide double salt of the acid.

The procedure was then modified by using double molecular quantities of the Grignard reagent. Five and four-tenths grams of magnesium turnings was placed in a one-liter flask, to which was then added 200 cc. of dry ether and 40 g. of bromobenzene. The reaction was started in the usual manner. After it had ceased and the contents of the flask had cooled, an ethereal solution of 20 g. of o-benzoylbenzoic acid was added slowly and with constant shaking. The flask was connected with a reflux condenser and heated for about thirty-six hours. It was then cooled and the ether solution filtered off with suction. After being washed several times with dry ether, the residue was dried over sulfuric acid in a vacuum. When the last traces of ether had been removed, the solid product was treated with about 200 cc. of water containing about 20 cc. of sulfuric acid and kept cool under running water. A rather vigorous reaction took place with the formation of a solid mass of yellow, gummy material. This was treated four times with boiling water in order to remove any traces of unchanged benzoylbenzoic acid. After drying, it was extracted with petroleum ether to remove any bromobenzene. It was then recrystallized three times from hot alcohol.

The compound thus obtained was difficultly soluble in cold alcohol but easily in hot, from which it crystallized in leaflets melting at 115°. This is the melting point of phthalophenone while that of dibenzoylbenzene is 145". It was soluble in ether, benzene, acetone, concentrated sulfuric acid and hot alcoholic alkali, from which latter solution it was reprecipitated by diluting with water and acidifying. It was insoluble in water, petroleum ether, aqueous alkali and concentrated hydrochloric acid. After several careful tests no oxime could be obtained on treating the substance with hydroxylamine, thus indicating that it was not a ketone.

An analysis was made for carbon and hydrogen and the molecular weight was determined by the freezing-point method using benzene as the solvent. The results obtained are as follows.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93; O, 11.18; mol. wt., 286.2. Found: C, 83.99; H, 5.14; O (by diff.) 10.87; mol. wt., 277.5.

As dibenzoylbenzene and phthalophenone are isomers, the above molecular weight determination and analysis would apply equally well to either. The properties, however, as given above do not agree with those given for dibenzoylbenzene, but are those of phthalophenone. It seems reasonable to conclude, therefore, that the product obtained was phthalophenone.

Summary

Grignard reagents were prepared from *p*-bromodimethylaniline and (qualitatively) from p-bromobenzoic acid. These reagents yielded with Michler's ketone dyes of the Malachite Green type, namely, methyl violet and chrome green.

The Grignard reagent, phenylmagnesium bromide, reacts with *o*-benzoylbenzoic acid in the proportion of two molecules to one, with the formation of phthalophenone and not dibenzoylbenzene.

PSEUDO BASES AND THEIR SALTS IN THE ISOXAZOLE SERIES. SECOND PAPER[1]

BY E. P. KOHLER AND N. K. RICHTMYER

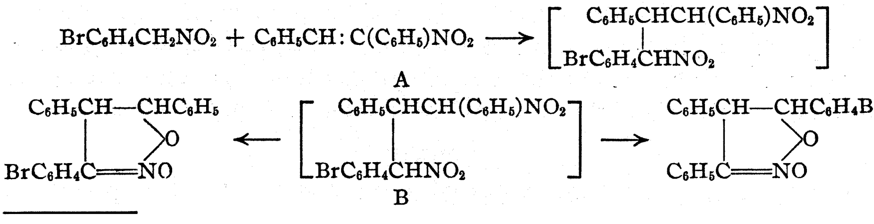
RECEIVED AUGUST 2, 1928 PUBLISHED NOVEMBER 6, 1928

In the first paper[2] it was shown that when the salts that are obtained by methylating triphenyl isoxazole are treated with bases they undergo a series of transformations which can be represented by the sequence

$$\text{Salt} \rightleftharpoons \text{base} \rightleftharpoons \text{pseudo base} \longrightarrow \text{anhydro compound}$$

Owing to the instability of the base and the pseudo base it was possible to isolate only the first and last members of this series, and it was impossible to establish the structure of the pseudo base, the anhydro compound and their derivatives because all of these substances contain three groups which are the same. We have now found that some of these difficulties can be avoided by alkylating with ethyl instead of with methyl sulfate and that most of the others can be overcome by substituting bromophenyl for one of the phenyl groups.

The change from methylation to ethylation presented no complications but the preparation of a substance which differs from triphenyl isoxazole only in having a substituent in one of the phenyl groups proved to be exceedingly troublesome. No isoxazoles of this type are known and no intermediates are available for making them by any of the methods employed in the preparation of triphenyl isoxazole. Since all methods which hold any promise of success are equally likely to give a mixture of isomers we decided to undertake the preparation of the p-bromo compounds by way of the isoxazoline oxides.[3] To this end we condensed p-bromophenyl nitromethane with nitrostilbene. It was to be expected that this condensation would give a mixture of two isoxazoline oxides



$$BrC_6H_4CH_2NO_2 + C_6H_5CH{:}C(C_6H_5)NO_2 \longrightarrow \left[\begin{matrix} C_6H_5CHCH(C_6H_5)NO_2 \\ | \\ BrC_6H_4CHNO_2 \end{matrix}\right]$$

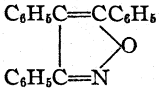
---

[1] In memory of Ira Remsen.

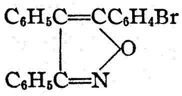
[2] Kohler and Blatt, THIS JOURNAL, 50, **1217 (1928).**

[3] Kohler and Barrett, *ibid.*, 46, 2105 **(1924).**

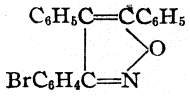
Instead of the two oxides expected we actually obtained three, because some of the nitrostilbene is hydrolyzed and the resulting phenylnitromethane leads to the formation of a small quantity of the unbrominated triphenyl isoxazoline oxide. The separation of this mixture is not feasible; the oxides crystallize indistinctly and since they decompose below the melting point, it is impossible to ascertain whether or not any method of crystallization really results in separation. The mixture of oxides was therefore boiled with alcoholic sodium methylate and thus transformed into a mixture of the corresponding isoxazoles:



I

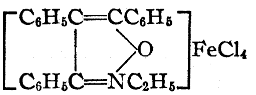


II

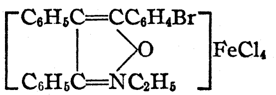


III

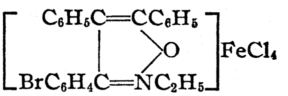
These isoxazoles crystallize fairly well, and they have definite melting points but apparently they are capable of forming mixed crystals in all proportions. The attempt to separate at this stage was, therefore, abandoned. The isoxazoles were ethylated and then transformed into a mixture of ferric chloride salts containing



IV

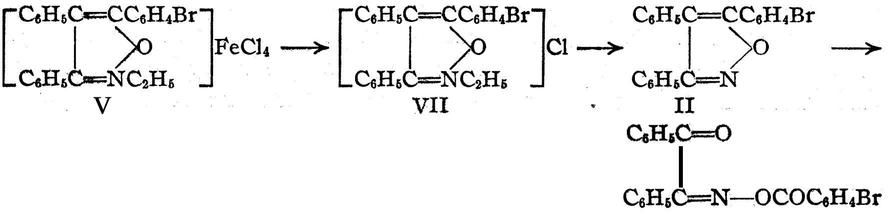


V



VI

By systematic fractional crystallization of this mixture it was possible to isolate one salt which crystallized well from a number of solvents, had a sharp melting point and appeared to be a pure substance. This contained bromine and therefore was either V or VI but inasmuch as the salts are not attacked by ozone it was necessary to convert it into the corresponding isoxazole in order to establish its structure. The isoxazole proved to be 3,4-diphenyl-5-*p*-bromophenyl isoxazole (II) because it formed an ozonide that on hydrolysis gave the p-bromobenzoate of *β*-benzilmonoxime.



V VII II VIII

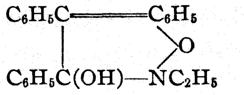
As a result of these operations we now had available for investigation the salt IV, which was easily obtained in a pure condition by ethylation of triphenyl isoxazole, and the salt V which was free from its isomer but—to judge from the analytical results—generally contained a small quantity of the unbrominated compound. We also had a supply of the salt VI which was sufficiently pure for most purposes but always contained appreciable quantities of the unbrominated compound and was not entirely free from its isomer.

These salts are not attacked by ozone, either in water or in organic solvents—a property which serves to distinguish them as well as the corresponding salts with other acids from all the substances into which they can be transformed. They are readily oxidized by permanganate, both when suspended in water and when dissolved in acetone. Since the salt which has the bromophenyl group in the 5-position gives *p*-bromobenzil and benzoic acid, while that in which the same group occupies the 3-position is oxidized to benzil and *p*-bromobenzoic acid, this reaction with permanganate supplies a reliable means for determining the structure of salts of this type.

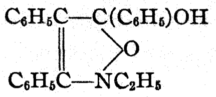
When any one of these salts is added to caustic alkalies in the presence of ether, ferric hydroxide is precipitated and all of the organic matter is immediately found in the ether. Under these conditions, therefore, the change from salt to pseudo base appears to be direct and instantaneous. But when a salt is treated with barely enough cold, saturated sodium bicarbonate to precipitate all of the iron, it yields a clear, colorless, strongly basic solution which contains nothing that can be extracted with ether. This strongly alkaline solution must contain the true base in equilibrium with its carbonates. At low temperatures such solutions remain clear for days but all ultimately become cloudy and deposit the pseudo base and all attempts to concentrate such solutions by evaporation or freezing invariably end in pseudo base. It is not possible, therefore, to isolate any substances corresponding to quaternary ammonium bases; increase in concentration of the hydroxyl ions more than compensates for the effect of lowering the temperature in decreasing the rate of formation of the pseudo bases.

While these pseudo bases are readily formed by the action of alkalies on the salts, they are not easily isolated. It was possible, however, to obtain in pure crystalline form those corresponding to salts IV and V. They are quite insoluble in water, readily soluble in organic solvents. Acids dissolve them slowly but even very dilute acids extract them rapidly and completely from their solutions in organic solvents. Like the pseudo bases derived from unsaturated cyclic amines, they readily form ethers which behave toward acids exactly like the bases themselves.

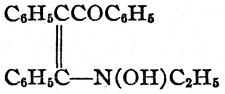
The pseudo bases and their ethers also behave alike toward oxidizing agents. Aqueous permanganate does not attack them but they are rapidly oxidized in acetone, and unlike the salts they are also easily ozonized. All methods of oxidation yield essentially the same products. Thus the pseudo base corresponding to the unbrominated salt IV invariably gives benzoic and acetic acids and benzil; but permanganate also forms variable quantities of acetaldehyde, while ozone gives some nitrogenous compound. The oxidation products, unfortunately, do not distinguish between all possible formulas of the substance. These are



IX



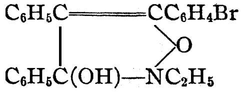
X



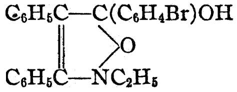
$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \quad \| \\ C_6H_5C{-}N(OH)C_2H_5 \end{array}$$

XI

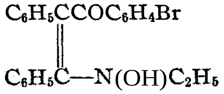
Each of these formulas represents a substance which by a combination of oxidation and hydrolysis could give benzil and benzoic acid. In the case of the pseudo base from the brominated salt V the results are somewhat more helpful. Here the oxidation products are bromobenzil, benzoic and acetic acids, and the possible formulas



XII



XIII



$$\begin{array}{l} C_6H_5CCOC_6H_4Br \\ \quad \| \\ C_6H_5C{-}N(OH)C_2H_5 \end{array}$$

XIV

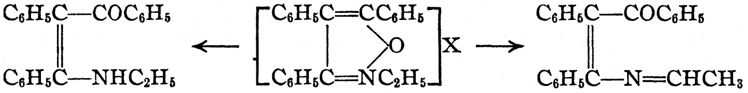
Since the first of these formulas cannot be reconciled with the formation of bromobenzil, this type of formula is definitely excluded for the pseudo bases of the triphenyl isoxazole series.

Between the remaining formulas it is probably impossible to distinguish by chemical methods. Indeed it is not at all improbable that they represent two phases of the same substance which can coexist in solution. Either formula is satisfactory for interpreting the reactions of the pseudo bases but in order to gain an insight into the mechanism by which these substances are formed it is desirable to secure some compound which is formed in a similar manner but has a group less mobile than hydroxyl or methoxyl. With this end in view we treated the chloride with a sulfinate and later with a sulfocyanide but in each case obtained only the corresponding salt. Soluble cyanides formed a cyanogen compound that is not a salt but this proved useless for our purpose because it behaved exactly like the pseudo base and its ether, the cyanogen group disappearing in every reaction.

Since the experiments involving the interaction of soluble salts showed fairly conclusively that it would not be possible to secure the desired type of compound in this manner, it became necessary to resort to metallic derivatives. In a well-conceived series of investigations, Freund[4] showed that the salts of unsaturated cyclic ammonium bases differ much in their behavior toward organic magnesium compounds. Some react very readily; others not at all; but whenever a reaction does occur, the product is always a substance that is constituted like the corresponding pseudo base, the hydrocarbon residue occupying the position of the hydroxyl group.

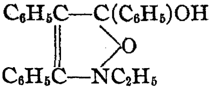
[4] Freund, *Ber.*, 37, 4666 (1904); Freund and Beck, *Ber.*, 37, 4673, 4679 (1904); Freund and Richard, *Ber.*, 42, 1101 (1909); Freund and Bode, *Ber.*, 42, *1746* (1908).

We found that our chloride reacts slowly with methyl magnesium iodide and that the ferric chloride double salt reacts very smoothly both with methyl magnesium iodide and with phenyl magnesium bromide. In each case, however, the reaction is quite different from that described by Freund: chlorine is removed, hydrogen is introduced, and the product is an open chained amine—XV. Still another type of reaction occurs between the chloride and sodium malonic ester in benzene, but here again the product (XVI) does not meet our needs because it is not constituted like the pseudo bases.

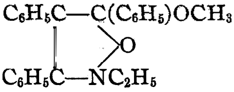


XV XVI

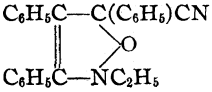
In the absence of definite proof it is necessary to base a choice between the two possible types of formulas for the pseudo bases and the substances constituted like them on circumstantial evidence. Even this is slight. The open chained amine XV, the analogous methyl, and isopropyl compounds, the corresponding unsubstituted amine as well as its more complicated substitution products are all yellow in color while the pseudo base, its ethers and the corresponding cyanogen compound are colorless. This invariable difference would hardly be expected if the difference in structure were not greater than that represented by the possible open chained formula of the pseudo base (XI) and the established formula of the amine (XV). Although this evidence is not conclusive—and could not be tested because we were unable to replace the remaining amino hydrogen in the yellow compounds with anything else—we nevertheless deem it sufficiently significant to make us prefer the cyclic formula for the colorless compounds. We shall therefore represent these substances with the formulas.



X

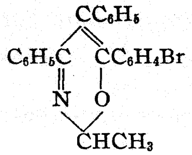


XVII

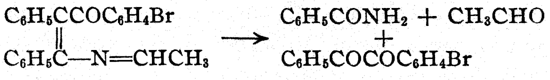


XVIII

All of these colorless compounds differ notably from the corresponding derivatives of pyridine and other similar unsaturated cyclic nitrogen compounds in stability. Above the melting point and in solutions containing traces of a base they lose water, alcohol or hydrocyanic acid and pass into an "anhydro compound." In the earlier paper the structure of these anhydro compounds was left in doubt. It has now been established with certainty by ozonizing the substance that is formed when the brominated pseudo base loses water. The ozonization products—p-bromobenzil, acetaldehyde and benzamide—definitely exclude the cyclic formula XIX and prove that the substance must be constituted like a Schiff base XX.



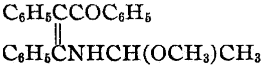
XIX



$$\begin{array}{l} C_6H_5CCOC_6H_4Br \\ \| \\ C_6H_5C{-}N{=}CHCH_3 \end{array} \longrightarrow \begin{array}{c} C_6H_5CONH_2 + CH_3CHO \\ + \\ C_6H_5COCOC_6H_4Br \end{array}$$

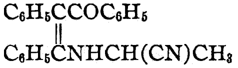
XX XXI

These anhydro compounds are, as would be expected, very actively unsaturated. They combine with alcohols to form alkoxyl compounds that are isomeric with the ethers of the pseudo bases, with hydrocyanic acid to form cyanogen compounds isomeric with those formed from the salts, and with Grignard reagents to form unsaturated secondary amines.



$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \| \\ C_6H_5CNHCH(OCH_3)CH_3 \end{array}$$

XXII



$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \| \\ C_6H_5CNHCH(CN)CH_3 \end{array}$$

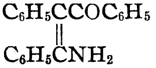
XXIII

$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \| \\ C_6H_5CNHCH(CH_3)_2 \end{array}$$

XXIV

These addition reactions are promoted by bases. Since the ethers and cyanides are sensitive even to traces of base, they show a marked tendency to undergo a rearrangement that ends in yellow amines which constitute the final products of the action of basic reagents on the salts. These amines are always due to secondary reactions but, inasmuch as the changes follow each other in rapid succession, they are easily mistaken for primary products. Thus only the colorless methyl ether (XVII) is formed when slightly less than the equivalent quantity of sodium methylate is added to the chloride in methyl alcohol, but when slightly more than one equivalent is added the sole product is the yellow amino compound XXV.

Another manner in which the active unsaturation of the anhydro compounds manifests itself is in the ease with which they are hydrolyzed. In the presence of traces of acid all of them rapidly pass into the corresponding amines



$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \| \\ C_6H_5CNH_2 \end{array}$$

XXV

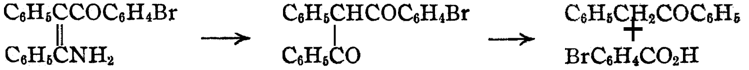
$$\begin{array}{l} C_6H_5CCOC_6H_4Br \\ \| \\ C_6H_5CNH_2 \end{array}$$

XXVI

$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \| \\ BrC_6H_4CNH_2 \end{array}$$

XXVII

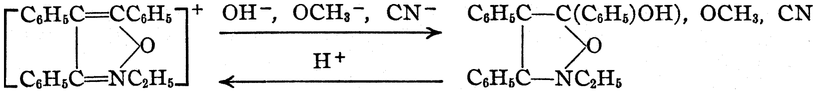
In the presence of more concentrated acid the process does not stop even here but gives first a β-diketone and finally a monoketone and an acid



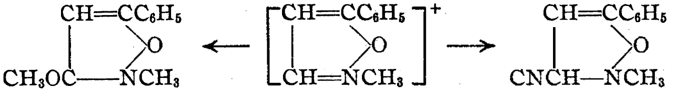
$$\begin{array}{l} C_6H_5CCOC_6H_4Br \\ \| \\ C_6H_5CNH_2 \end{array} \longrightarrow \begin{array}{l} C_6H_5CHCOC_6H_4Br \\ | \\ C_6H_5CO \end{array} \longrightarrow \begin{array}{c} C_6H_5CH_2COC_6H_5 \\ + \\ BrC_6H_4CO_2H \end{array}$$

A survey of these transformations explains the precautions that are necessary for securing the pseudo bases of the isoxazole series. If the ether that is used is not entirely free from alcohol, the base becomes contaminated with its ethyl ether or the corresponding isomeric amino compound. These prevent it from crystallizing promptly. As it tarries in the solution it begins to lose water and form the anhydro compound. If the ethereal solution is carefully protected this may ultimately crystallize, but the solution generally catches a trace of acid from the air, turns yellow and finally ends by depositing an equivalent quantity of the amine, which is stable under these conditions and crystallizes well.

It is difficult to compare our results with those of earlier investigators who have studied other isoxazoles because since no pseudo bases have heretofore been isolated, it is frequently impossible to distinguish between primary and secondary products. In the triphenyl isoxazole series the first step is probably a direct union of ions to form the undissociated pseudo bases, their ethers or cyanides and the process can easily be reversed.



The same process seems to occur in the case of the salts formed from 3-methyl isoxazole,[5] and 3-phenyl isoxazole,[5] for, although owing to the difference in the number of substituents, the final products obtained from these substances are quite different from ours they appear to be formed from the same type of pseudo base. The salts from 5-methyl isoxazole[6] and from 5-phenyl isoxazole,[7] however, must form a different pseudo base, because such final products as $CH_3COCH_2C(CN){=}NCH_3$, $C_6H_5COCH_2C(OCH_3){=}NCH_3$ and $C_6H_5COCH_2C(CN){=}NCH_3$ can come only from substances that are formed by adding the negative ion in the 3-position



The factors that determine the mode of addition of these ions, therefore, appear to be the same as those which determine the mode of addition in reactions that are not usually supposed to involve ions.

Experimental Part

I. Results Obtained with Triphenyl Isoxazole. A. Cyclic Compounds

Three classes of cyclic compounds were investigated: salts, the pseudo base, and substances which are formed by metathetical reactions of the salts but are constituted like the pseudo base. The distinction between these metathetical products and the salts which are isomeric with them was, in all cases, based on the behavior toward ozone. The salts are not attacked by ozone, while all these other cyclic compounds are readily ozonized.

Ethylation, the Ferric Chloride Double Salt, IV.—Ethyl sulfate was added to triphenyl isoxazole by heating a mixture containing 100 g. of the former and 25 g. of the latter at 120° for five hours. In order to decompose the excess of reagent and

---

convert the addition product into a simple salt, the solution was digested on a steam-bath for an hour with 50 cc. of concd. hydrochloric acid diluted with an equal volume of water. The resulting clear solution was cooled, thoroughly extracted with ether and then treated with excess of 1:1 aqueous ferric chloride. This precipitated a pale yellow salt which was washed—first with 1:1 concd. hydrochloric acid and then with ether—and dried to constant weight on a steam-bath; yield 42.0 g. instead of 44.1 g. calculated.

Although the salt was practically pure, it was recrystallized from ethyl bromide, from which it separates in pale yellow plates melting at 165–167°.

Anal. Calcd. for $C_{23}H_{20}ONCl_4Fe$: C, 52.7; H, 3.8; Fe, 10.7. Found: C, 51.9; H, 3.7; Fe, 10.9.

The salt is very soluble in acetone, moderately soluble in ethyl bromide and in glacial acetic acid, sparingly soluble in water and alcohol, insoluble in ether.

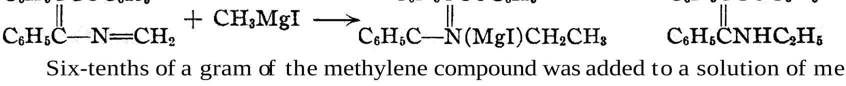
Oxidation.—A current of ozone was passed for six hours through solutions of 2 g. of the salt in water and in ethyl bromide but in each case all of the salt was recovered. A solution of potassium permanganate was then added gradually and in excess to one gram of the salt which was partially dissolved and partially suspended in 50 cc. of water. Each addition of reagent produced a violet colored precipitate—the permanganate—which rapidly turned brown and the odor of acetaldehyde soon became perceptible. On completion of the oxidation the mixture was decolorized with bisulfite and extracted with ether. From the ethereal solution sodium carbonate extracted 0.2 g. of benzoic acid and a trace of acetic acid. The solution was then dried and evaporated. It left 0.31 g. of benzil.

Reaction with Grignard Reagents.—Two g. of the salt was added to a solution of methyl magnesium iodide made from 1 g. of magnesium. The salt reacted at once and the solution became black. It was immediately poured into cracked ice, the ethereal layer separated and the mixed hydroxides extracted with ether until they were free from organic material. The combined ethereal solutions on drying and evaporation deposited a single substance which crystallized in yellow prisms and melted at 118–119°.

Anal. Calcd. for $C_{28}H_{21}ON$: C, 84.4; H, 6.4. Pound: C, 84.5; H, 6.5.

The composition of the product corresponds to that of a substance which has hydrogen in place of the $FeCl_4$ group and the color indicated that it was an open chained compound. It was therefore hydrolyzed. This was accomplished by dissolving 1 g. in 10 cc. of boiling methyl alcohol, adding a few drops of concd. hydrochloric acid to the solution, then diluting it with hot water to incipient cloudiness and setting it aside until it became colorless. The colorless crystalline compound which separated was collected on a filter and identified as phenyl dibenzoyl methane by comparison with a sample on hand. The filtrate was thoroughly extracted with ether and then evaporated to dryness. It left a colorless, hygroscopic hydrochloride that crystallized in needles and melted at 78–79°, the melting point of ethylamine hydrochloride.

Synthesis.—In an earlier paper,[2] it was shown that organic magnesium compounds combine with anhydro compounds to form the magnesium derivatives of unsaturated secondary amines. If, as seemed probable from its hydrolysis products, our yellow compound is a secondary amine of this type, then it should be possible to synthesize it from the anhydro compound described in the earlier paper



$$\begin{array}{l} C_6H_5CCOC_6H_5 \\ \quad \| \\ C_6H_5C{-}N{=}CH_2 \end{array} + CH_3MgI \longrightarrow \begin{array}{l} C_6H_5CCOC_6H_5 \\ \quad \| \\ C_6H_5C{-}N(MgI)CH_2CH_3 \end{array} \quad \begin{array}{l} C_6H_5CCOC_6H_5 \\ \quad \| \\ C_6H_5CNHC_2H_5 \end{array} \qquad XV$$

Six-tenths of a gram of the methylene compound was added to a solution of methyl magnesium iodide containing 0.5 g. of magnesium. The mixture was stirred for fifteen minutes and then decomposed with ice. The ethereal layer gave a product which crystallized in yellow prisms, melted at 117–119° and caused no depression of the melting point of the product from the salt.

Ethyl-1,2-diphenyl-2-benzoyl-vinylamine, XV, is formed with equal ease by the action of methyl magnesium iodide and phenyl magnesium bromide on the ferric chloride double salt. The chloride does not react with phenyl magnesium bromide and it reacts only very slowly with methyl magnesium iodide but it forms the same product as the more soluble ferric chloride double salt.

The Pseudo Base, 2-Ethyl-3,4,5-triphenyl-5-hydroxy Isoxazoline, X.—The pseudo base was obtained in various ways of which the most convenient was as follows. To a solution of 8 g. of sodium hydroxide in 40 cc. of water were added in succession 25 cc. of alcohol-free ether, 50 g. of ice and 8 g. of finely ground ferric chloride double salt. The mixture was shaken for ten minutes, after which the ethereal layer was removed and the aqueous layer extracted a few more times with ether. All ethereal solutions were then combined, dried with sodium sulfate and concentrated under diminished pressure. The result was an oil which solidified when diluted with petroleum ether and rubbed. The yield was 4.5 g. of pseudo base and a residue of base mixed with a small quantity of anhydro compound.

Anal. Calcd. for $C_{23}H_{21}O_2N$: C, 80.5; H, 6.1. Found: C, 80.6; H, 6.4.

The substance is readily soluble in all organic solvents except low-boiling petroleum ether; it is insoluble in water. Unless solid is available for inoculation, it tends to separate from solution as an oil and when this is allowed to remain in contact with the solution it slowly loses water. It is most readily purified by dissolving it in benzene and diluting this solution with petroleum ether. It then crystallizes in colorless prisms. When heated rapidly in a capillary tube it melts with effervescence at about 120".

Oxidation.—The pseudo base does not reduce cold aqueous permanganate. In acetone the permanganate is reduced, slowly at first, then as rapidly as added; the products are the same as those obtained from the salts. A current of ozonized oxygen was passed for two hours through a cold concentrated solution of 2 g. of the pseudo base. It precipitated a pasty ozonide which was decomposed with water. The resulting oily emulsion, on distillation with steam, yielded 0.5 g. of benzoic acid and 1.1 g. of benzil, and it left a small quantity of a red nitrogenous residue.

Salt Formation.—By shaking an ethereal solution of the pseudo base with an inadequate amount of an acid it is possible to get an aqueous solution of the corresponding salt. From such a solution of the chloride, ferric chloride regenerates the double compound, while potassium chlorate precipitates a moderately soluble salt, potassium bromide, and bromine a very sparingly soluble perbromide and potassium permanganate a violet colored permanganate. At low temperatures and in the presence of acid the permanganate persists for a time but ultimately it turns brown and passes into benzil, acetaldehyde, ammonia and potassium benzoate. Its formation accounts for the fact that the salts are oxidized by permanganate while they are not attacked by ozone or chromic acid.

Metallic Derivatives.—Although the pseudo base is insoluble in aqueous alkalies, it is capable of forming easily hydrolyzable metallic derivatives. Thus when a solution of a salt is added to cold concd. sodium hydroxide it first imparts a yellow color to the solution and then, as the quantity is increased, produces an oily yellow precipitate. The color of both oil and solution fades on dilution with water and when the suspension is shaken with ether the oil disappears and both the ethereal and the water layers become colorless. The ether contains only pseudo base, the water only inorganic compounds.

Slightly less than the calculated quantity of powdered sodium was added to a solution of *2* g. of the pseudo base in absolute ether. Hydrogen was evolved and the sodium slowly changed to a lemon yellow, crystalline powder. This was thoroughly washed with ether, dried and analyzed.

Anal. Calcd. for $C_{23}H_{20}O_2NNa$: Na, **6.3.** Found: Na, **6.2, 6.4.**

Reaction **with** Methyl Magnesium Iodide.—A quantitative determination showed that one mole of the pseudo base reacts with **3** moles of methyl magnesium iodide and liberates **2** moles of gas. In accordance with this it was found that the product of the reaction is the same as that formed from the anhydro compound.

The Methyl Ether, **2-Ethyl-3,4,5-triphenyl-5-methoxy** Isoxazoline, **XVII.**—The ethers are easily made by dissolving the pseudo base in alcohols but it is more convenient to prepare them directly from the ferric chloride double salt. Thus the methyl ether was obtained by exactly the same procedure that was employed for making the pseudo base, except that methyl alcohol was substituted for most of the water. Much of the ether crystallized during the operation. This was redissolved by repeated extraction with ether. In order to prevent premature crystallization, a little acetone was added to the ethereal solution, which was then distilled to a small volume. The product was purified by recrystallization from acetone and methyl alcohol; yield 17 g. instead of a possible **18.4** g. from **27** g. of the double salt.

Anal. Calcd. for $C_{24}H_{23}O_2N$: C, **80.7;** H, **6.4.** Found: C, **80.7;** H, **6.5.**

The methyl ether crystallizes in small prisms and melts at 100°. It is readily soluble in acetone, moderately soluble in methyl alcohol and in ether. As would be expected, the ether is more stable than the pseudo base but above 150° it effervesces freely as it loses methyl alcohol and passes into the anhydro compound. It is oxidized by permanganate under the same conditions and in the same manner as the pseudo base and it also gives the same products when it is ozonized. Concentrated aqueous sodium hydroxide does not attack the ether but methyl alcoholic solutions that contain the merest trace of base soon become yellow and ultimately all of the ether is changed into the same yellow methoxyl compound that is formed by adding methyl alcohol to the anhydro compound. Since the ether behaves toward acids exactly like the pseudo base, is stable and is easily made and purified, it constitutes the most convenient intermediate for the preparation of soluble salts.

The Cyanide, **2-Ethyl-3,4,5-triphenyl-5-cyano Isoxazoline, XVIII.**—Dry hydrogen chloride was passed into a cooled solution of **5** g. of the methyl ether in absolute ethyl ether until the precipitation of the crystalline chloride was complete. The chloride was collected on a filter, washed with dry ether and dissolved in water. The slightly acid solution was neutralized and then treated with a solution of **3** g. of sodium cyanide in **10** cc. of water. The resulting paste was extracted with ether, the ethereal solution dried with sodium sulfate, concentrated under diminished pressure and diluted with low-boiling petroleum ether. It deposited the cyanogen compound in colorless prisms which after recrystallization melted at 89°; yield, **4.1** g.

Anal. Calcd. for $C_{24}H_{20}ON_2$: C, **81.8;** H, **5.7.** Found: C, **81.5;** H, **5.9.**

The cyanogen compound behaves toward permanganate, ozone and acids exactly like the methyl ether. At the melting point it loses hydrocyanic acid with effervescence and passes into the anhydro compound. It is exceedingly soluble in organic solvents. The ethereal solution soon smells of hydrocyanic acid and if it is allowed to stand for some time in a closed vessel the cyanide gradually changes into an isomeric compound.

B. The Open Chained Compounds

'She anhydro compound and the substances that are obtained from it by addition or hydrolysis constitute a class of compounds with properties entirely different from those of the cyclic compounds. All of the latter are readily converted into each other and all are also easily transformed into the anhydro compound, but neither the anhydro compound itself nor any of its derivatives or addition products can be changed into one of the cyclic compounds. The distinction between the two classes, therefore, presents no difficulties.

The Anhydro Compound, Ethylidene-α,β-diphenyl-β-benzoyl-vinylamine, $C_6H_5COC(C_6H_5)=C(C_6H_5)N=CHCH_3$.—The anhydro compound is formed from the pseudo base by loss of water, from the methyl ether by loss of alcohol and from the cyanogen compound by loss of hydrocyanic acid. Owing to the ease with which it is hydrolyzed, it is difficult to get a pure product by any procedure. In order to avoid this hydrolysis as far as possible it is important to decompose these substances at the lowest possible temperature, to remove the volatile product as rapidly as possible and to crystallize the residue without undue contact with the air of the laboratory.

Thus 4 g. of the pseudo base was heated at 120° under 3 mm. pressure for ten minutes, at the end of which time effervescence ceased. The residue was dissolved in the minimum quantity of alcohol-free ether, the solution immediately diluted with an equal volume of petroleum ether and cooled in a freezing mixture. It deposited 3.2 g. of yellow needles melting at 105°. After several recrystallizations the melting point rose to 110° but the substance was still quite yellow. Rapid solution in methyl alcohol followed by immediate chilling in a freezing mixture finally gave needles which were almost colorless and melted at 112°.

Anal. Calcd. for $C_{23}H_{19}ON$: C, 84.7; H, 5.8. Found: C, 84.9; H, 5.9.

The anhydro compound is readily soluble in all organic solvents except low-boiling petroleum ether. Although it combines with alcohol it can be recrystallized from methyl alcohol provided that this is entirely free from bases. It reduces permanganate and it is readily ozonized.

α-Methoxyethyl-α,β-diphenyl-β-benzoyl-vinylamine, $C_6H_5COC(C_6H_5)=C(C_6H_5)NHCH(OCH_3)CH_3$.—When the anhydro compound is dissolved in boiling methyl alcohol which contains a trace of base, the solution almost immediately turns yellow and in a comparatively short time a pale yellow addition product begins to crystallize. The same substance is formed with equal rapidity by similar treatment of the cyanogen compound (XVIII) and, more slowly, also from the methyl ether (XVII). It was purified by recrystallization from methyl alcohol, from which it separates in yellow plates melting at 140°. Above the melting point it loses methyl alcohol and reverts to the anhydro compound.

Anal. Calcd. for $C_{24}H_{23}O_2N$: C, 80.7; H, 6.4. Found: C, 80.6; H, 6.5.

α-Cyano-ethyl-α,β-diphenyl-β-benzoyl-vinylamine, $C_6H_5COC(C_6H_5)=C(C_6H_5)NHCH(CN)CH_3$.—When a saturated ethereal solution of the cyanogen compound XVIII was kept in a stoppered flask at the ordinary temperature, it slowly deposited a more sparingly soluble substance which separated in large, very pale yellow prisms which melt at 130°. Like the methoxyl compound it decomposes above the melting point and reverts to the anhydro compound and like it, also, it is easily ozonized and hydrolyzed. With concentrated hydrochloric acid, the products of hydrolysis are phenyl dibenzoyl methane and alanine hydrochloride.

Anal. Calcd. for $C_{24}H_{20}ON_2$: C, 81.8; H, 5.7. Found: C, 82.0; H, 5.7.

Addition of Methyl Magnesium Iodide, *Iso*propyl-α,β-diphenyl-β-benzoyl-vinylamine, XXIV.—The anhydro compound obtained by heating 2.2 g. of the methyl ether to 150° under diminished pressure was added to a solution of methyl magnesium iodide containing one g. of magnesium. The solution became hot and deposited a colorless, crystalline magnesium derivative. This was separated by decanting the supernatant liquid, washed with ether and stirred into cracked ice and ether. The ethereal layer and washings yielded 1.7 g. of a yellow solid which was purified by recrystallization from ether and from methyl alcohol.

Anal. Calcd. for $C_{24}H_{23}ON$: C, 84.5; H, 6.7. Found: C, 84.9; H, 7.3.

The amine is readily soluble in all organic solvents except petroleum ether. It crystallizes in yellow needles and melts at 115°. Its structure was established by hydrolysis. For this purpose a small quantity of concd. hydrochloric acid was added to a solution of 1 g. of the substance in boiling methyl alcohol. The solution was diluted with an equal volume of hot water; then set aside until it was colorless. It deposited phenyl dibenzoyl methane. The filtrate from the diketone was thoroughly extracted with ether and then evaporated to dryness. It left a hydrochloride which after one recrystallization from dry methyl alcohol and anhydrous ether melted at 152–153°. This hydrochloride when treated first with sodium nitrate and then with an alkaline solution of iodine gave iodoform. It is therefore the hydrochloride of *iso*-propylamine.

Hydrolysis of the Anhydro Compound, **α,β-Diphenyl-β-benzoyl-vinylamine, XXV.**—The pure solid anhydro compound is not altered by air but when it is not quite pure or when its solutions are not securely protected against contamination by acids, it is hydrolyzed to the corresponding amine. In petroleum ether this hydrolysis is very slow. It occurs most rapidly when solutions in moist ether are exposed to the air of the laboratory. The product separates as a bright yellow solid. This was purified by recrystallization from acetone and methyl alcohol.

Anal. Calcd. for $C_{21}H_{17}ON$: C, 84.3; H, 5.7. Found: C, 84.2; H, 5.9.

The amine is sparingly soluble in methyl alcohol, moderately soluble in ether and very readily soluble in acetone. It crystallizes in needles and melts at 162°. Its structure was established by ozonization and by hydrolysis.

Ozonization.—A current of ozone was passed for several hours through a solution of the amine in carbon tetrachloride. The ozonide was decomposed with ice, the solvent pumped off and the residue dissolved in ether. After the removal of a small quantity of benzoic acid with sodium carbonate the ethereal solution was dried and allowed to evaporate slowly. It deposited first a white solid which was purified by sublimation and identified as benzamide, and then pale yellow prisms, identified as benzil.

Hydrolysis.—When the anhydro compound is triturated with cold concd. aqueous hydrochloric acid the hydrolysis stops at the amine. In alcohol both the anhydro compound and the amine undergo further hydrolysis. Thus when a drop of concd. hydrochloric acid was added to a solution of 0.6 g. of the amine in methyl alcohol, the color gradually faded and the solution deposited an almost equal quantity of a colorless solid which was identified as phenyl dibenzoyl methane. A similar solution was boiled. It became colorless in a few minutes but gave, in addition to the diketone, methyl benzoate and desoxybenzoin.

Isomeric **Amine.**—In one experiment in which a considerable quantity of crude methylene anhydro compound[8] which had been kept in a vial for several years was recrystallized from ether without protection against the acid in the air, a more sparingly soluble yellow compound made its appearance. This separated from ether in small prisms and melted at 208°.

Anal. Calcd. for $C_{21}H_{17}ON$: C, 84.3; H, 5.7. Found: C, 84.7; H, 5.8.

This new product is isomeric with the amine melting at 162°. It is hydrolyzed

---

[8] Ref. 2, p. 1224

under the same conditions as the lower melting substance and also gives the same products—phenyl dibenzoyl methane and ammonium chloride. It is therefore difficult to comprehend how it can be anything except a geometrical isomer of the lower melting compound. There is, however, one grave objection to this interpretation. When the lower melting amine is treated with standardized methyl magnesium iodide, it consumes two moles of reagent, liberates two moles of gas, and is recovered when the magnesium derivative is decomposed. The higher melting amine likewise dissolves in the reagent but it consumes only one mole of it and it liberates only one mole of gas. It also is recovered when the resulting magnesium compound is decomposed.

Synthesis.—In order to secure more of this isomer we hydrolyzed both the methylene and the ethylidene anhydro compounds in different solvents and under varying conditions. All these attempts ended in the lower melting amine. We therefore turned to synthesis. Amines of this type have been obtained by Claisen,[9] who found that some isoxazoles react with phenyl magnesium bromide to form compounds to which he assigned this structure. We added triphenyl isoxazole to a solution of phenyl magnesium bromide containing 5 equivalents of the reagent. The isoxazole is sparingly soluble and the reaction was extremely slow. After boiling for sixty-four hours the mixture was decomposed in the usual manner. It gave, besides unchanged isoxazole, only the amine melting at 162°.

Although methyl magnesium iodide seldom acts as a reducing agent, we found that it reacts with triphenyl isoxazole much more rapidly than phenyl magnesium bromide. The sole product in this case also was the lower melting amine. This amine was also the only product obtained in an entirely different method of synthesis which started with the nitrile of benzoyl-phenyl-acetic acid: $C_6H_5CH(COC_6H_5)CN \longrightarrow C_6H_5CH(COC_6H_5)C(C_6H_5){=}NMgBr \longrightarrow C_6H_5C(COC_6H_5){=}C(C_6H_5)NH_2$.

II. Experiments with Diphenyl p-Bromophenyl Isoxazoles

As outlined in the introduction, the first step in the preparation of the brominated isoxazoles was the condensation of nitrostilbene and *p*-bromophenyl nitromethane. In the earlier experiments this condensation was conducted in such a manner as to give the best yield of isoxazoline oxides. When it became evident that the separation of the oxides is not feasible, the conditions were changed in order to secure the isoxazoles instead of the oxides. The procedure then was as follows.

A solution of one g. of sodium in 75 cc. of methyl alcohol was added in the course of a few minutes to a boiling solution of 9.0 g. of nitrostilbene and 8.6 g. of bromophenyl nitromethane in the same solvent. After boiling for about five minutes, during which it became filled with a mass of solid oxide, it was treated with sodium methylate from 8 g. of sodium dissolved in 125 cc. of methyl alcohol and boiled for three to four hours. It was then cooled and filtered. The yield of crude washed and dried product melting at 168–171° was 105 g. from 90 g. of nitrostilbene. Recrystallization from ether raised the melting point to 172–173° where it became constant, but ozonization showed that the recrystallized product was a mixture.

Ethylation.—The mixture of isoxazoles was ethylated by exactly the same procedure that had been employed with the unbrominated compound and thus converted into a mixture of ferric chloride double salts This was subjected to fractional recrystallization from ethyl bromide. The least soluble component separated from cold solutions in greenish yellow needles, and from boiling solutions in brown plates or

---

[9] Claisen, Ber., 59, 150 (1926).

tables. Both forms melt at 172–174° and the yellow slowly passes into the brown form if it is allowed to remain in contact with the mother liquor. From 22 g. of the mixed isoxazoles was obtained 34 g. of crude, washed and dried ferric chloride double salts: of this approximately 50% was later isolated in the form of the salt V.

Anal. Calcd. for $C_{23}H_{19}ONBrCl_4Fe$: C, 45.8: H, 3.2; Cl, 23.5 Found: C, 45.7; H, 3.1; Cl, 24.2.

3,4-Diphenyl-5-bromophenyl Isoxazole, II.—In order to locate the bromophenyl group it was necessary to convert the double salt into the isoxazole. To this end an ethereal solution of the corresponding pseudo base was prepared by shaking 8 g. of the powdered double salt with a mixture of 50 cc. of 20% sodium hydroxide, 50 g. of ice and 100 cc. of ether. This etherral solution was repeatedly extracted with small quantities of concd. hydrochloric acid which had been diluted with an equal volume of water until the ether left no residue when evaporated. The combined acid extracts when chilled in a freezing mixture and freed from ether by evaporation in a draught deposited a hydrated chloride in colorless needles. The chloride was collected on a glass filter and partially dried by suction, then transferred to a flask and heated in a rapid current of air. As the temperature rose the chloride melted, lost first water then ethyl chloride, resolidified and finally melted again at about 170°. The product was recrystallized from acetone and methyl alcohol.

Anal. Calcd. for $C_{21}H_{14}ONBr$: C, 67.0; H, 3.7 Found: C, 67.4; H, 3.9.

The isoxazole is readily soluble in acetone, moderately soluble in ether, sparingly soluble in methyl alcohol. It crystallizes in needles and melts at 172–173°, almost exactly the melting point of the mixture of the two isomeric isoxazoles. In open vessels it sublimes freely at its melting point.

Ozonization.—The isoxazole was ozonized in ethyl bromide in the usual manner, the solvent removed under diminished pressure and the pasty residue shaken with ice water for two hours, during which most of it solidified. Solid and oil were then dissolved in ether. From the ethereal solution sodium carbonate extracted only a trace of *p*-bromobenzoic acid. The dried ethereal solution on evaporation deposited small colorless prisms that melted at 145–146°.

Anal. Calcd. for $C_{21}H_{14}O_3NBr$: C, 61.8; H, 3.1. Found: C, 61.6; H, 3.7.

β-Benzilmonoxime-*p*-bromobenzoate, VIII.—The ozonization product was readily hydrolyzed both with acids and with bases. Acids gave mainly benzil, hydroxylamine and *p*-bromobenzoic acid, while sodium methylate formed mainly benzonitrile and methyl *p*-bromobenzoate. In order to determine whether, as is usual in the case of phenylated isoxazoles, ozonization results in a derivative of β-benzil monoxime, the substance was synthesized by shaking 1.7 g. of β-benzil monoxime with 2.3 g. of *p*-bromobenzoyl chloride in 20 cc. of pyridine for two hours. The product melted at 145–146° and a mixture of the two substances melted at the same temperature.

The Pseudo Base, **2-Ethyl-3,4-diphenyl-5-bromophenyl-5-hydroxy** Isoxazoline, XIII.—From the ferric chloride double salt the brominated pseudo base was obtained by the method previously employed for getting its unbrominated analog. It crystallized in colorless prisms and melted with effervescence at about 105°.

Anal. Calcd. for $C_{23}H_{20}O_2NBr$: C, 65.4; H, 4.7. Found: C, 66.0; H, 4.7.

Ozonization.—Two grams of the pseudo base was ozonized in ethyl bromide for two hours. After removing the solvent the pasty residue was boiled with water for a short time, then cooled and dissolved in ether. From the etherral solution sodium carbonate extracted benzoic acid and a very small quantity of *p*-bromobenzoic acid which, like the analysis, indicated that the base was contaminated with a small quantity of the unbrominated compound. The ethereal solution on evaporation deposited pale yellow needles. After repeated recrystallization from petroleum ether containing a few drops of ether these melted at 89–90°.

Anal. Calcd. for $C_{14}H_9O_2Br$: C, 58.1; H, 3.1. Found: C, 58.9; H, 3.4.

p-Bromobenzil, **XXI**, is readily soluble in all organic solvents. It has a pronounced tendency to separate from solution as an oil and consequently is extremely difficult to purify. The analyses show that our sample was contaminated with benzil. Our melting point, therefore, is doubtless a little too low but the fact that the substance readily formed a quinoxaline derivative and was oxidized to equivalent quantities of benzoic and *p*-bromobenzoic acids by alkaline hydrogen peroxide leaves no doubt as to its character.

The **Anhydro** Compound, **Ethylidene-α,β-diphenyl-β-bromobenzoyl-vinylamine, XX.**—The anhydro compound was made like its bromine-free analog. It crystallizes from ether and from methyl alcohol in very pale yellow needles and melts at 102°.

Anal. Calcd. for $C_{23}H_{18}ONBr$: C, 68.3; H, 4.5 Found: C, 68.7; H, 4.7.

Ozonization.—The substance was ozonized in ethyl bromide The products, isolated in the same manner as those from the bromine free compound, were *p*-bromobenzil and benzamide

Hydrolysis. **α,β-Diphenyl-β-bromobenzoyl-vinylamine, XXVI.** Like its bromine-free analog, the anhydro compound is hydrolyzed with the utmost ease to acetaldehyde and a yellow, unsaturated amine. The amine was purified by recrystallization from acetone and methyl alcohol. It is readily soluble in acetone, moderately soluble in ether, sparingly soluble in methyl alcohol. It crystallizes in deep yellow needles and melts at 172°.

Anal. Calcd. for $C_{21}H_{16}ONBr$: C, 66.7; H, 4 2 Found: C, 67.4; H, 4.7.

Summary

This paper contains a description of the isolation of two pseudo bases in the triphenyl isoxazole series, an account of their properties, an opinion as to their structure, and a discussion of the mechanism by which such pseudo bases are formed from their salts.

treated benzal chloride with potassium sulfhydrate. In 1902 Houben and Kesselkaul[5] announced the formation of the acid by the action of carbon disulfide on phenylmagnesium bromide. In 1906 Houben[6] described a series of arylcarbithioic acids.

In this paper is described the preparation of *p*-cymyl-2-carbithioic acid by the action of carbon disulfide on *p*-cymyl-2-magnesium bromide. From this acid various salts and esters were prepared.

The name given to the dithio acid follows the suggestion of Houben. The expression "dithiocarboxylic acid" indicates oxygen as well as sulfur and as there is no oxygen present such a designation should be avoided. The name given is made up of car (carbon), bi (two) and thio (sulfur) and seems to us to be a perfectly good and logical name.

Experimental Part

The Grignard Reagent.—2-Bromo-p-cymene was made by brominating cymene according to the method of Bogert and Tuttle.[7] The portion boiling at 103–105° at 5 mm. was used. Thirty *g.* of clean, dry magnesium turnings was washed with dry ether and covered with 500 cc. of dry ether. Several small crystals of iodine were allowed to dissolve at the bottom. In order to keep the iodine in contact with the magnesium the solution was not stirred while 250 cc. of bromocymene in 25cc. portions was added. The product was a grayish-black, somewhat sirupy liquid. It was decanted from the small residue of magnesium and used in this condition

***p*-Cymyl-2-carbithioic Acid, $C_6H_3CH_3C_3H_7CSSH$.**—The Grignard reagent (the whole amount prepared above) was cooled by a freezing mixture to −10° and then 180 cc. of carbon disulfide was added dropwise and slowly enough to keep the temperature at −10°. This operation took three hours. Air was almost entirely excluded. After stirring had been continued for another hour, the stirring assembly was removed, the flask stoppered and the mixture kept cold by the freezing mixture for twelve hours. The reaction mixture was then poured upon a kilo of ice and hydrochloric acid was added until the liquid was acid to Congo Red. A reddish-orange ether layer separated out on top. This was removed with a separatory funnel. The aqueous layer was extracted three times with 200cc. portions of ether. The ether extracts were then combined and extracted with 150cc. portions of 5% sodium hydroxide solution until the alkali solution assumed only a slight yellow color or none at all. This gives a solution of the sodium salt of the carbithioic acid with some excess of alkali. This solution is used for making other salts. It does not keep well, decomposing in two to three days.

The free acid is obtained by covering the alkaline solution with ether and adding hydrochloric acid until acid to Congo Red. The free acid is then extracted with ether It is a viscous red oil when its ether solution is evaporated in a vacuum. It does not solidify at −15°. It decomposes when an attempt is made to distil it at 2 mm. long before there is any evidence of boiling. The decomposition product is a thick brown oil of disagreeable odor. When the ether solution is allowed to evaporate in the air, a reddish-orange, gummy mass of slightly disagreeable odor remains. In ether solution the acid ranges from purple-red in concentrated solutions to orange in dilute solutions. The acid is fairly stable in ether solution. only slight decomposition being noticed

after five months. The sodium, potassium, barium, strontium and calcium salts are soluble in water. The zinc salt is insoluble.

Zinc **Salt** of Cymylcarbithioic Acid, $(C_6H_3CH_3C_3H_7CSS)_2Zn$.—A solution of **6** *g*. of zinc chloride, 100 cc. of water and 15 cc. of glacial acetic acid was made. To this solution was added the freshly prepared solution of the sodium salt of the carbithioic acid, which contained some excess of sodium hydroxide, until no further precipitation took place. The precipitate was filtered off, dried and dissolved in absolute alcohol. The solution was boiled with animal charcoal and filtered The cooled solution was poured into water, whereupon the zinc salt precipitated. It is an amorphous powder of yellow ochre color, soluble in alcohol, benzene, carbon tetrachloride and acetone but does not crystallize from any of them. It melts at 92°.

Anal. Calcd. for $C_{22}H_{26}S_4Zn$: S, 26.50; C, 54.7; **H,** ***5.38;*** Zn, **13.62.** Found: S, 26.39; C, 56.0; H, **5.43;** Zn, 13.66.

Complex Salts

A number of salts were prepared in which the metal is half saturated with acetic acid and half with cymylcarbithioic acid. A metallic salt in dilute acetic acid solution is added to an aqueous solution of the sodium salt of the carbithioic acid. The precipitate is filtered and washed with a little alcohol to remove traces of resin. These salts dissolve in a number of organic solvents as alcohol, benzene, carbon tetrachloride and acetone, but they do not crystallize from them. The lead salt is brown and melts at 65°. The silver salt is a beautiful orange but it turns black in fifteen minutes. These were not analyzed.

TABLE I

TYPE FORMULA $C_6H_3CH_3C_3H_7CSS\text{-}M\text{-}OCOCH_3$

Salt used	Color	Form	M. p., °C.
Zinc chloride	Yellow	Amorphous	196 decomp.
Copper sulfate	Red-yellow	Amorphous	75 decomp.
Mercuric chloride	Yellow	Amorphous	>300
Cadmium acetate	Yellow	Amorphous	125 decomp.

Methyl Ester of Cymylcarbithioic Acid, $C_6H_3CH_3C_3H_7CSSCH_3$ The ester is prepared by treating the aqueous solution of the sodium salt with dimethyl sulfate until a thick brown oil collects on the surface and a further addition causes no brown color in the aqueous layer. The sulfate is added slowly with stirring The oil is separated, washed with dilute sodium hydroxide, then with water, dried over calcium chloride and distilled in vacuum. It is a sirupy liquid boiling at 167–168° and 8 mm. When pure it is not very disagreeable in odor. In dilute form it smells like a freshly cut turnip. It is quite stable When exposed to the air for three days no change was noticed and it did not change in color in a sealed tube in the sunlight for a week

Anal. Calcd **for** $C_{12}H_{16}S_2$ S, 28.57; C, 64.3 H, 7.148 Found S, 28.77; C, 64.1; H, 7.13.

Ethyl Ester. Liquid boiling at 141–2° and 3 mm.

Anal. Calcd. for $C_{13}H_{18}S_2$: S, 26.97; , 65.5; H, 7.57. Found: S, 26.88; C, 65.1; H, 7.53.

Action of Phenylhydrazine.—An unexpected reaction took place between phenylhydrazine and the carbithioic acid. Small, white plates were obtained, melting sharply at 112°. The substance was insoluble in most organic solvents and evolved hydrogen sulfide when heated with any such solvent. It contains 6.79% N and 16.18% S.

Acid Chloride.—The action of phosphorus pentachloride on the carbithioic acid gave a liquid boiling at 141° and 8 mm. Though its odor was somewhat sharp it gave no typical reaction with ammonia or aniline so doubt remains as to its nature.

Summary

1. *p*-Cymyl-2-carbithioic acid is obtained by the action of carbon disulfide on cymyl-2-magnesium bromide.

2. Its zinc salt was prepared.

. Complex salts of metals with acetic acid and carbithioic acid were obtained. Zinc, copper, mercury and cadmium gave such salts.

4. The methyl and ethyl esters of carbithioic acid were prepared.

5. Reactions (undetermined) took place between the carbithioic acid and phenylhydrazine, also phosphorus pentachloride.

UNSYMMETRICAL ARSENO COMPOUNDS DERIVED FROM PARA-ARSONOPHENYLAMINO-ETHANOL AND PARA-ARSONOPHENYLGLYCINE-AMIDE[1]

BY CHARLES SHATTUCK PALMER AND ERNEST B. KESTER[2]

RECEIVED JUNE 6, 1928 PUBLISHED NOVEMBER 6, 1928

During recent years there has been considerable interest in the attempts to apply *p*-arsonophenylglycine-amide in the form of its monosodium salt, "tryparsamide" (I), to the treatment of diseases of protozoal origin. Especial success has attended its introduction into the treatment of trypanosomiasis,[3] and it has also shown promise in paresis.[4] To a lesser

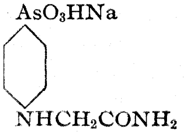
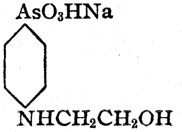
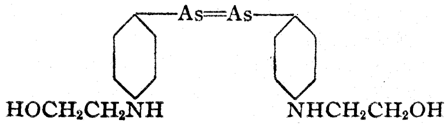
extent the sodium salt (II) of *p*-arsonophenylamino-ethanol[5] has been under investigation. In the usual course of chemo-therapeutic study, when an arsonic acid, $RAsO_3H_2$, has been shown to be valuable, it is reduced to the corresponding arseno compound, RAs=AsR, in order that the effect of both pentavalent and trivalent arsenic may be determined in combination with the same K group. The arseno compound (III) from *p*-arsonophenylamino-ethanol has been made,[6] but it is soluble only in strongly acid solutions and is therefore useless for therapeutic purposes. No arseno compound derived from tryparsamide has been described, but this substance likewise could contain no substitutions which would make possible its dissolving to form a neutral aqueous solution.



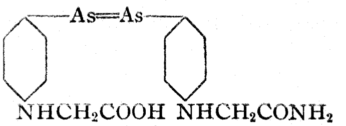
(I)



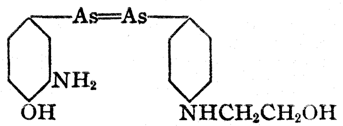
(II)



(III)



(IV)



(V)

In order to obtain water-soluble arseno compounds with phenylglycine-amide and phenylamino-ethanol nuclei, it was decided to prepare unsymmetrical arseno compounds (IV, V) in which one arsenic is attached to either of the above-mentioned groups and the other to a benzene ring containing solubilizing substituents, for example,—$NHCH_2OSOH$, —OH, —$NHCH_2COOH$ and —OCH_2COOH.

Four general methods for preparing unsymmetrical arseno compounds are available. *A*. The action of a primary arsine on a primary arsine oxide or halide[7]

$$RAsH_2 + R'AsCl_2 \longrightarrow 2HCl + RAs{=}AsR'$$
$$RAsH_2 + R'AsO \longrightarrow RAs{=}AsR' + H_2O$$

B. Rearrangement of two symmetrical arseno compounds when warmed in solution to give the unsymmetrical derivative[8]

$$RAs{=}AsR + R'As{=}AsR' \longrightarrow 2RAs{=}AsR'$$

[8] Karrer, *Ber.*, 49, 1649 (1916); German Patent, 293,040; Hart and Payne, J *Am. Pharm. Assoc., 12,* 699 (1923).

C. Simultaneous reduction of two different arsonic acids, arsine oxides or arsine halides or of an arsine oxide with an arsonic acid, etc.[9]

$$RAsO_3H_2 + R'AsO_3H_2 + 8H \longrightarrow RAs{=}AsR' + 6H_2O$$
$$RAsO + R'AsCl_2 + 4H \longrightarrow RAs{=}AsR' + H_2O + 2HCl$$

D. Substitution in only one of the two groups attached to arsenic in a symmetrical arseno compound[10]

$$RAs{=}AsR \longrightarrow RAs{=}AsR'$$

Of the above methods, C was selected for use since it offered a means for preparing unsymmetrical arseno compounds from the readily procurable arsonic acids.

The uniform procedure was the reduction of equimolar solutions of *p*-arsonophenylamino-ethanol or *p*-arsonophenylglycine-amide with some other arsonic acid by means of a reagent specific for the arseno group. Sodium hydrosulfite was not used since it frequently contaminates the reduced product with sulfur-containing impurities. Hypophosphorous acid or stannous chloride are free from this objection and will act at the low temperatures necessary in preparing arseno compounds of complex structure because of their instability. Those derived from *p*-arsonophenylglycine-amide and p-arsonophenylamino-ethanol are particularly sensitive. For example, 4-amino-4'-β-hydroxyethylamino-arsenobenzene (VI), arsenic content, 33.24%, is prepared readily at 5–10°. If, however, the reduction of arsanilic acid and parsonophenylamino-ethanol is carried out at 55–60°, the product contains 61% of arsenic, while at 100° a substance containing 78% of arsenic is formed. As a result, all of the arseno compounds described below (which were derived from *p*-arsonophenylglycine-amide or parsonophenyl-amino-ethanol) had to be made below room temperature.

When *p*-arsonophenylglycine-amide and *p*-arsonophenylglycine were reduced simultaneously with hypophosphorous acid, it was not found possible to obtain the unsymmetrical arseno compound. Instead, a product resulted which from an arsenic analysis seemed to be tetra-arsenobenzene-4-glycine-4'-glycine-amide. Stannous chloride, on the other hand, produced the pure arseno compound, arsenobenzene-4-glycine-4'-glycine-amide (IV).

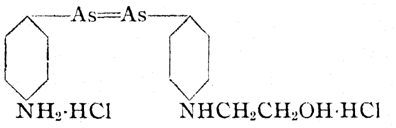
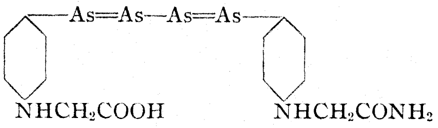
The mechanism of the formation of unsymmetrical arseno compounds is undoubtedly, first, reduction of each arsonic acid to its arseno derivative and, second, rearrangement of the two arseno compounds to the unsymmetrical according to method B above. Thus *p*-arsonophenylamino-ethanol can be reduced with a large excess of hypophosphorous acid in hydrochloric acid to give a solution of *p*-arsenophenylamino-ethanol (III). Within a short time after adding an equimolecular proportion of *p*-arsonophenoxyacetic acid, and an additional quantity of the reducing agent, the unsymmetrical derivative, 4-hydroxyethylamino-arsenobenzene-4′-oxyacetic acid (VIII) begins to precipitate.

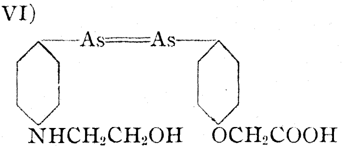
It is not to be inferred, however, that the successive or even simultaneous reduction of two arsonic acids leads invariably to the formation of the unsymmetrical arseno compound. One case, in particular, was encountered in which the two symmetricals predominated in the reaction product, regardless of experimental conditions, namely, in the reduction of phenyl arsonic acid with 3-amino-4-hydroxyphenylarsonic acid.



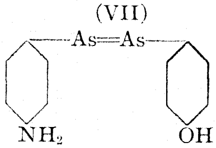
(VI)



(VII)



(VIII)



(IX)

The unsymmetrical compounds described in the experimental part show variety in the choice of conditions and reducing agents. In the earlier experiments where hypophosphorous acid was employed, no catalyst was used. Later work, however, showed that the time element could be shortened from a period of several days to a few minutes by the introduction of a small amount of potassium iodide; but with or without catalyst, in all reductions involving tryparsamide or etharsanol, the temperature needed to be kept under 15°.

The proof that each unsymmetrical arseno compound derived from *p*-arsonophenylglycine-amide or *p*-arsonophenylamino-ethanol and another arsonic acid containing a solubilizing group of an acidic nature, is not a mixture of two symmetrical products, rests on the observation that they are wholly soluble in aqueous alkalies. If any symmetrical arseno compound from p-arsonophenylamino-ethanol or *p*-arsonophenylglycine-amide were present it would remain as a residue insoluble in alkali. Moreover, the products behave as single definite compounds when derivatives such as hydrochlorides or methylenesulfoxylic acids are prepared. In one case, the methylenesulfoxylic acid of the unsymmetrical was produced directly by treatment of the two arsonic acids with formaldehydesulfoxylic acid.

The pharmacological study of several of the compounds described is being carried out by Dr. A. S. Loevenhart at the University of Wisconsin, but is not yet complete.

The toxicity of arseno compounds is a function not alone of the molecular configuration but also of the method of preparation. Contact with air usually increases toxicity, probably because arsine oxides are formed. Hence, in preparing specimens for biological testing, filtrations were performed in carbon dioxide atmosphere. It was found, too, that toxicity could be reduced in the case of compounds having a phenolic function by dissolving in dilute sodium hydroxide and precipitating with carbon dioxide. By this treatment arsine oxides that may have been in the reaction product because of incomplete reduction were left in solution as the sodium salt. After filtering, the base could then be converted to the hydrochloride.

Experimental

Derivatives of p-Arsonophenylamino-ethanol

(1) 4-Amino-4'-p-hydroxyethylamino-arsenobenzene Dihydrochloride **(VI)**.—A solution of a fiftieth mole each of *p*-arsonophenylamino-ethanol and arsanilic acid in 30 cc. of water and 10 cc. of 12 *N* hydrochloric acid was prepared. This was treated with one-half mole of 50% hypophosphorous acid and kept at a temperature below 15° for three days. No precipitate appeared but the clear solution became light yellow in color. Precipitation was brought about by stirring into 100 cc. of cold, 6 *N* hydrochloric acid. The product was granular in character and could be filtered easily in the open air without discoloration due to oxidation. It was washed repeatedly with dilute hydrochloric acid and then triturated in a mortar with 30 cc. of methanol to which had been added 5 cc. of hydrochloric acid (d., 1.19). After filtering again, washing with ether left the compound almost dry; yield, 7 g. or 78%.

This compound does not dissolve in water of itself but merely turns red and gumlike. If, however, a small quantity of hydrochloric acid be added, solution proceeds quickly.

Anal. Subs., 0.1803, 0.1375: 35.35, 26.47 cc. of iodine soln. (1 cc. = 0.001703 g. of As). Calcd. for $C_{14}H_{18}ON_2Cl_2As_2$: As, 33.24. Found: As, 33.39, 32.78. Subs., 0.2231, 0.3721: AgCl, 0.1357, 0.2333. Calcd. for $C_{14}H_{18}ON_2Cl_2As_2$: Cl, 15.72. Found: 15 05, 15.51.

(2) 4-Amino-4'-β-hydroxyethylamino-arsenobenzene-N-methylenesulfoxylic Acid.—Five grams of the preceding compound was dissolved in 50 cc. of water to which had been added 3 cc. of hydrochloric acid (d., 1.19), and a solution of 2.5 g. of sodium formaldehydesulfoxylate in 25 cc of water added. In a few minutes a yellow precipitate began to form. Precipitation was complete in an hour at room temperature. The product was filtered in carbon dioxide and after it had been thoroughly washed with water was dried by washing with methanol and ether. The drying was completed in a vacuum desiccator over sulfuric acid for a period of eighteen hours. The yield was quantitative.

Anal. Subs., 0.1444, 0.1467: 23.80, 24.52 cc. of iodine soln. (1 cc. = 0.001965 g. of As). Calcd. for $C_{15}H_{18}O_3N_2SAs_2$: As, 32.86. Found: As, 32.29, 32.84. Subs., 0.2649, 0.2386: $BaSO_4$, 0.1301, 0.1205. Calcd. for $C_{15}H_{18}O_3N_2SAs_2$: S, 7.03. Found: S, 6.76, 6.94.

(3) **4-Hydroxy-4′-β-hydroxyethylamino-arsenobenzene Hydrochloride.**—The reduction of fiftieth moles of *p*-arsonophenol and *p*-arsonophenylamino-ethanol was carried out in a manner identical with (1). In this case the arseno compound precipitated as formed. Before filtering, 20 cc. of 12 N hydrochloric acid was added and the filtration then performed in a current of carbon dioxide. The product was washed repeatedly with dilute hydrochloric acid and finally with methanol acidified slightly with hydrochloric acid. It was dried in a vacuum over sulfuric acid and caustic soda and amounted to 5 g. of the hydrochloride or 60% of the theoretical. Smaller additional amounts were obtained by allowing the mother liquors to stand in the cold.

This compound is readily soluble in dilute caustic soda, somewhat soluble in methyl alcohol and acetone but only sparingly in dilute hydrochloric acid. Water turns it red and gum-like. An alkaline solution of it heated to boiling speedily clouds and on continued boiling forms a filterable precipitate. This may be the symmetrical *p*-arsenophenylamino-ethanol

Anal. Subs., 0.1200, 0.1843: 24.75, 37.95 cc. of iodine soln. (1 cc. = 0.001758 g. of As). Calcd. for $C_{14}H_{16}O_2NClAs_2$: As, 36.07. Found: As, 36.26, 36.20.

(4) The free base of this compound was prepared by dissolving the hydrochloride in dilute caustic soda and precipitating with carbon dioxide. The precipitate was fairly easily filtered and could be washed rapidly with warm water. It was found to be somewhat soluble in methanol.

Anal. Subs., 0.1410, 0.1067: 28.75, 21.65 cc. iodine soln. (1 cc. = 0.001940 g. of As). Calcd. for $C_{14}H_{15}O_2NAs_2$: As, 39.54. Found: As, 39.56, 39.36. Subs. 1.2678: 7.01 cc. of 0.500 N HCl. Calcd. for $C_{14}H_{15}O_2NAs_2$: N, 3.70. Found: N, 3.87.

(5) **3-Amino-4-hydroxy-4′-β-hydroxyethylamino-arsenobenzene Dihydrochloride (Free Base, V).**—Following the procedure as described under (1), fiftieth moles of 3-amino-4-hydroxyphenylarsonic acid and p-arsonophenylamino-ethanol were reduced to the unsymmetrical arseno compound. Precipitation, however, did not come about spontaneously and it was necessary to stir the reaction mixture into 100 cc. of 12 *N* hydrochloric acid in order to bring it about. The product was purified by dissolving in 66 cc. of water and pouring into an equal volume of 12 *N* hydrochloric acid. After repeating this treatment, the product was filtered, washed with dilute hydrochloric acid, then with a mixture of 50 parts each of methanol and ether and dried in a vacuum over sulfuric acid and caustic soda; yield, 5 g. or 53%. The compound was readily soluble in water or dilute alkali.

Anal. Subs., 0.1964, 0.1188: 37.90, 22.90 cc. of iodine soln. (1 cc. = 0.001671 g. of As). Calcd. for $C_{14}H_{18}O_2N_2Cl_2As_2$: As, 32.10. Found: As, 32.25, 32.21. Subs., 0.1998, 0.2405: AgCl, 0.1214, 0.1477. Calcd. for $C_{14}H_{18}O_2N_2Cl_2As_2$: Cl, 15.18. Found: Cl, 15.03, 15.19.

(6) **3-Amino-4-hydroxy-4′-β-hydroxyethylamino-arsenobenzene-N-methylene-sulfoxylic Acid.**—The procedure for preparing this compound was identical with that of (2). The yield, also, was quantitative.

Anal. Subs., 0.1146, 0.1334: 23.65, 27.35 cc. of iodine soln. (1 cc. = 0.001526 g. of As). Calcd. for $C_{15}H_{18}O_4N_2SAs_2$: As, 31.75. Found: As, 31.49, 31.28. Subs., 0.2130, 0.2178: $BaSO_4$, 0.1057, 0.1115. Calcd. for $C_{15}H_{18}O_4N_2SAs_2$: S, 6.79. Found: S, 6.82, 7.03.

(7) **4-β-Hydroxyethylamino-arsenobenzene-4′-N-glycine Dihydrochloride.**—A solution was prepared of one-hundredth moles each of *p*-arsonophenylamino-ethanol

and *p*-arsonophenylglycine in 20 cc. of hydrochloric acid (d., 1.19) and 30 cc. of water. After cooling to 15°, one-quarter mole of 50% hypophosphorous acid was added and the solution cooled as before. While stirring rapidly, a solution of one gram of potassium iodide in 10 cc. of water was added dropwise. During this process the color of the solution changed first to deep red and back again to a very light yellow. Finally, a heavy yellow precipitate appeared that was filtered and washed with very dilute hydrochloric acid. The product did not darken on exposure to air; yield, 4 g. or 78% of the theoretical. The product was wholly soluble in sodium bicarbonate.

Anal. Subs., 0.1870, 0.1038: 28.15, 15.74 cc. of iodine soln. (1 cc. = 0.001910 g. of As). Calcd. for $C_{16}H_{20}O_3N_2Cl_2As_2$: As, 29.45. Found: As, 28.75, 28.96.

This compound was also prepared by means of stannous chloride.

(8) The free base of this compound was prepared by dissolving 4 g. of the dihydrochloride in 30 cc. of water to which had been added sufficient sodium hydroxide to form the sodium salt. The solution was then stirred into a solution of 10 cc. of acetic acid in 50 cc. of water. The precipitate so formed was decidedly gelatinous and difficult to filter, but the product was rendered practically free from inorganic salts by repeated triturations with warm water, and finally was dried in a vacuum over sulfuric acid.

Anal. Subs., 0.1070, 0.1242: 19.55, 22.65 cc. of iodine soln. (1 cc. = 0.001910 g. of As). Calcd. for $C_{16}H_{18}O_3N_2As_2$: As, 34.37. Found: As, 34.90, 34.83.

(9) **4-β-Hydroxyethylamino-arsenobenzene-4'-oxyacetic Acid (VIII).**—A fiftieth mole of *p*-arsonophenylamino-ethanol was dissolved in a mixture of 10 cc. of hydrochloric acid (d., 1.19) and 30 cc. of water and treated with one-quarter mole of 50% hypophosphorous acid. It was allowed to remain on ice for eighteen hours, after which time the solution had a light yellow color.

A second solution was then made of a fiftieth mole of *p*-arsonophenoxyacetic acid in 25 cc. of hydrochloric acid (d., 1.19) and 10 cc. of water, added to the above, and then a second quarter mole of hypophosphorous acid. The solution, now containing *p*-arsenophenylamino-ethanol and the unreduced *p*-arsonophenoxyacetic acid, was allowed to remain on ice for five days, during which time a yellow precipitate formed. The filtered product was washed repeatedly with warm water, methanol and ether to an almost dry yellow powder; yield, 8 g. or 92% of the theoretical. A sample was found to be completely soluble in sodium bicarbonate solution.

Anal. Subs., 0.1072, 0.2020: 18.85, 35.60 cc. of iodine soln. (1 cc. = 0.001965 g. of As). Calcd. for $C_{16}H_{17}O_4NAs_2$: As, 34.30. Found: As, 34.55, 34.63.

The independent reduction of the *p*-arsonophenylamino-ethanol to the corresponding arseno derivative before the reduction of the *p*-arsonophenoxyacetic acid shows that, as the latter was reduced, there was a rearrangement of the two arseno compounds to give a product composed entirely of the unsymmetrical. The mother liquors in the filtrate were colorless and showed no trace of any *p*-arsenophenylamino-ethanol left in solution.

Derivatives of p-Arsonophenylglycine-amide

(10) **4-Amino-arsenobenzene-4'-N-glycine-amide Dihydrochloride.**—A solution was prepared of one-hundredth moles each of *p*-arsonophenylglycine-amide and arsanilic acid in 30 cc. of hydrochloric acid (d., 1.19) and 10 cc. of water. Twenty grams of crystalline stannous chloride was then dissolved in it portionwise, after which a solution of one gram of potassium iodide in 5 cc. of water was added. A heavy, light yellow precipitate instantly formed. It was readily filtered and washed with dilute hydrochloric acid, after which trituration in a mortar with dilute hydrochloric acid removed

occluded tin salts On filtering again, the cake was washed with dilute hydrochloric acid and methanol and dried in a vacuum over sulfuric acid; yield, 4 g. or 86%. This compound is not appreciably soluble in water and difficultly soluble in warm dilute hydrochloric acid. The latter seems to promote decomposition.

Anal Subs., 0 1043, 0 1244: 17 15, 20.00 cc. of iodine soln. (1 cc. = 0.001940 g. of As) Calcd. for $C_{14}H_{17}ON_3Cl_2As_2$: As, 32 31. Found: As, 31.90, 32.12. Subs., 0 2707, 0 25-10 AgCl, 0.1684, 0.1543. Calcd. for $C_{14}H_{17}ON_3Cl_2As_2$: Cl, 15.28. Found: As, 15 06, 14 97.

(11) **4-Amino-arsenobenzene-4′-glycine-amide-N-dimethylenesulfoxylic Acid.**—Owing to the difficulty encountered in obtaining a solution of the preceding compound, the methylenesulfoxylic acid derivative was produced by reduction of the two arsonic acids with sodium formaldehydesulfoxylate. The subsequent analysis showed that part at least of the product contained only one methylenesulfoxylic acid group.

To a solution of fiftieth moles each of arsanilic acid and *p*-arsonophenylglycine-amide in 30 cc of water and 20 cc. of hydrochloric acid (d., 1.19) was added one-tenth mole of sodium formaldehydesulfoxylate in 50 cc. of water. A yellow precipitate began to form immediately and precipitation continued over a period of several days The product was filtered and washed with cold water, methanol and ether to a dry powder It was then placed in a vacuum desiccator over sulfuric acid; total yield, 2 g. or 18% of the calculated quantity.

Anal. Subs, 0 1072, 0 1042: 17 85, 17 15 cc of iodine soln. (1 cc. = 0.001742 g. of As). Calcd for $C_{16}H_{19}O_5N_3S_2As_2$ As, 27.39. Found: As, 29.01, 28 67. Subs.. 0 2127, 0.1905 $BaSO_4$, 0 1734, 0 1583 Calcd for $C_{16}H_{19}O_5N_3S_2As_2$: S, 11.72. Found: S, 11.20, 11 42.

(12) 4-Hydroxyarsenobenzene-4'-N'-glycine-amide Hydrochloride.—This compound was prepared in a manner similar to (1) from *p*-arsonophenylglycine-amide and p-arsonophenol except that the solvent in this case was a mixture of 30 cc. of water and 25 cc of hydrochloric acid (d., 1 19). The unsymmetrical arseno compound precipitated during reduction and after filtering was washed well with dilute hydrochloric acid, alcohol and ether to an almost dry state. After drying over sulfuric acid in a vacuum desiccator, the product weighed 6 g.. representing a yield of 67%. The analysis seemed to indicate a monohydrate. To confirm this, the free base was prepared.

Anal. Subs., 0.1060, 0.1300: 18.80, 23.15 cc. of iodine soln. (1 cc. = 0.001898 g. of As). Calcd. for $C_{14}H_{15}O_2N_2ClAs_2\cdot H_2O$: As, 33.57. Found: As, 33.98, 33.80. Subs., 0.2409, 0.2225: AgCl, 0 0749, 0.0695. Calcd. for $C_{14}H_{15}O_2N_2ClAs_2\cdot H_2O$: Cl, 7.94. Found: Cl, 7.69, 7.73.

(13) The free base was prepared in a manner similar to (4).

Anal. Subs., 0.1629, 0.1621: 33.75, 33.70 cc. of iodine soln. (1 cc. = 0.001826 g. of As). Calcd. for $C_{14}H_{14}O_2N_2As_2$: As, 38.24. Found: As, 37.83, 37.96. Subs., 0.2254, 0.1891: CO_2, 0.3498, 0.2926; H_2O, 0.0730, 0.0618. Calcd. for $C_{14}H_{14}O_2N_2As_2$: C, 42.87; H, 3.60. Found: C, 42.34, 42.21; H, 3.62, 3.66. Subs., 1.4763: 73.8 cc. of 0.100 N HCl. Calcd. for $C_{14}H_{14}O_2N_2As_2$: N, 7.14. Found: N, 7.00.

(14) 3-Amino-4-hydroxyarsenobenzene-4'-glycine-amide Dihydrochloride.—The reduction was carried out as in the preparation of (7), using hundredth moles of p-arsonophenylglycitie-amide and 3-amino-4-hydroxyphenylarsonic acid in 35 cc. of hydrochloric acid (d., 1.19), 20 cc. of water and one-quarter mole of 50% hypophosphorous acid. When the crude product was fiitered, purification was brought about by dissolving in 50 cc. of water containing enough sodium hydroxide to form the sodium salt and precipitating by stirring into 100 cc. of 6 *N* hydrochloric acid. The filtered product was washed with dilute hydrochloric acid and finally with absolute methanol containing 16% of hydrogen chloride. Drying was completed in a vacuum desiccator; yield, 3.5 g. or 73%. This compound is soluble in water and dilute caustic soda.

Anal. Subs., 0.1015, 0.1493: 16.42, 24.23 cc. of iodine soln. (1 cc. = 0.001940 g. of As). Calcd. for $C_{14}H_{17}O_2N_3Cl_2As_2$: As, 31.23. Found: As, 31.38, 31 48.

(15) The free base of the preceding compound was obtained after the manner of (4) and (13) except that in this case one *g.* of sodium sulfate was dissolved in the solution prior to passing in carbon dioxide, in order to obtain particles of larger size. The filtered product was washed repeatedly with warm water and dried in a vacuum desiccator over sulfuric acid.

Anal. Subs., 0.0959, 0.1079: 18.50, 20.80 cc. of iodine soln. (1 cc. = 0.001910 g. of As). Calcd. for $C_{14}H_{15}O_2N_3As_2$: As, 36.82. Found: As, 36.85, 36.82.

(16) **3-Amino-4-hydroxyarsenobenzene-4′-glycine-amide-N-methylenesulfoxylic** Acid.—The procedure for preparing this derivative of (14) from its parent compound was identical with that of (2) and (6).

Anal. Subs., 0.1380, 0.1878: 22.55, 30.80 cc. of iodine soln. (1 cc. = 0.001910 g. of As). Calcd. for $C_{15}H_{17}O_4N_3SAs_2$: As, 30.90. Found: As, 31.21, 31.32. Subs., 0.4790, 0.2530: $BaSO_4$, 0.2072, 0 1080. Calcd. for $C_{15}H_{17}O_4N_3As_2$: S, 6 61. Found: S, 5.94, 5.86.

(17) **Arsenobenzene-4-N-glycine-4′-N′-glycine-amide** Dihydrochloride (Free Base, IV).—To a mixture of 60 cc. of hydrochloric acid (d., 1.19) and 20 cc. of water was added fiftieth moles of *p*-arsonophenylglycine and *p*-arsonophenylglycine-amide. After warming to dissolve the solid matter and chilling again in an ice-bath, 40 g. of stannous chloride was put in portionwise. The mixture was shaken well until no stannous chloride remained undissolved, following which 2 g. of potassium iodide in a few cc. of water was added. A heavy yellow gum immediately separated. The supernatant liquor was decanted and the gum thoroughly worked with several portions of 6 *N* hydrochloric acid, and finally with oxygen-free water until it had assumed the form of a bright yellow powder. The filtered product was washed with very dilute hydrochloric acid. It was then dissolved in 200 cc. of water containing sufficient caustic soda to make the sodium salt and reprecipitated as a bright yellow, granular powder by stirring into 200 cc. of 6 *N* hydrochloric acid. The product so obtained was washed repeatedly with very dilute hydrochloric acid and dried over sulfuric acid in a vacuum; yield, 5 g. or 48%. It was entirely soluble in sodium bicarbonate solution, and also somewhat soluble in methanol.

Anal. Subs., 0.1251, 0.1806: 18.35, 26.65 cc. of iodine soln. (1 cc. = 0.001965 *g.* of As). Calcd. for $C_{16}H_{19}O_3N_3Cl_2As_2$: As, 28.72. Found: As, 28.82, 29.00. Subs., 0.2943, 0.2475: AgCl, 0.1628, 0.1356. Calcd. for $C_{16}H_{19}O_3N_3Cl_2As_2$: Cl, 13 58. Found: Cl, 13.68, 13.55.

(18) **Tetra-arsenobenzene-4-N-glycine-4′-N′-glycine-amide** Dihydrochloride (Free Base, VII) is formed as follows. A solution of fiftieth moles of *p*-arsonophenylglycine and *p*-arsonophenylglycine-amide was prepared in 25 cc. of hydrochloric acid (d., 1.19) and 30 cc. of water. It was treated with 53 cc. of 50% hypophosphorous acid and allowed to remain at room temperature for several days. There was a gradual color change of the solution from water white to deep red, at which stage precipitation began and yielded 4 g. of product, or 30% of the calculated. It was filtered, washed with dilute hydrochloric acid, methanol and ether and dried in a vacuum over phosphorus pentoxide.

Anal. Subs., 0.2438, 0.1462: 67.00, 40.30 cc of iodine soln. (1 cc. = 0.001664 *g.* of As). Calcd. for $C_{16}H_{19}O_3N_3Cl_2As_4$: As, 44.62. Found: As, 45.73, 45 87.

(19) Arsenobenzene-4-glycine-amide-4'-oxyacetic acid.—Fiftieth moles of *p*-arsonophenylglycine-amide and *p*-arsonophenoxyacetic acid dissolved in **35** cc. of hydrochloric acid (d., **1.19)** and **20** cc. of water were reduced with one-half mole of hypophosphorous acid without catalyst as in (12). After four or five days below **15"** the reaction mixture was warmed to 40° to dissolve any crystals of unreduced *p*-arsonophenoxyacetic acid, the arseno compound immediately filtered and washed repeatedly with water, methanol and ether; yield, 6 g or 67% of the calculated The compound was entirely soluble in alkaline solutions.

Anal. Subs., **0.1087, 0.1058: 18.80, 18.20** cc. of iodine soln. (1 cc. = **0.001965** g. of As). Calcd. for $C_{16}H_{16}O_4N_2As_2$: As, **33.30.** Found: As, **33.99, 33.87.**

Other Unsymmetrical Arseno Compounds

(20) 4-Hydroxyarsenobenzene-4'-glycine Hydrochloride.—The reduction of fiftieth moles of *p*-arsonophenylglycine and *p*-arsonophenol in **30** cc. of water and 25 cc. of hydrochloric acid (d., 1.19) was carried out as in **(19).** It was necessary to keep this solution on ice for five or six days before reduction was complete. The precipitated product was then filtered off, washed with dilute hydrochloric acid and a mixture of fifty parts of methanol and fifty parts of ether, and dried in a vacuum desiccator; yield, 5 g. or 56% Analysis showed it to be a monohydrate (cf 4-hydroxyarsenobenzene-4'-glycine-amide hydrochloride)

Anal. Subs, **0.1079, 0.1891: 18.48, 32.65** cc. of iodine soln. (1 cc. = **0.001965** g. of As). Calcd for $C_{14}H_{13}O_3NClAs_2 \cdot H_2O$: As, 33.57. Found. As, **33.67.** 33.92. Subs., 0.1995, **0.2623**: AgCl, **0.0619, 0.0809.** Calcd for $C_{14}H_{13}O_3NClAs_2 \cdot H_2O$: Cl, 7.94. Found: Cl, 7.68, **7.63.**

(21) 3-Amino-4-hydroxyarsenobenzene-4'-oxyacetic **Acid.**—Fiftieth moles of *p*-arsonophenoxyacetic acid and 3-amino-4-hydroxyphenylarsonic acid were dissolved in an acid mixture similar to **(20)** and reduced with one-half mole of hypaphosphorous acid at a temperature below 15° After eighteen hours, a light yellow precipitate had developed consisting of **3.5** g. of product. Before filtering, the mixture was warmed to 50° to dissolve any unreduced *p*-arsonophenoxyacetic acid The product **was** washed repeatedly with water and ethanol and dried in a vacuum. Warming the mother liquors at 100° for thirty minutes gave an additional crop of **2**.5 g. that **was** entirely free from decomposition products; total yield, 73%.

Anal. Subs., **0.1084, 0.1457: 20.00, 26.95** cc. of iodine soln. (1 cc. = **0.001965** g. of As). Calcd. for $C_{14}H_{13}O_4NAs_2$: As **36.65.** Found. As, **36.25, 36.35.**

(22) 3,4'-Diamino-4-hydroxyarsenobenzene Dihydrochloride.[11]—This compound was prepared like several of those already described but with the use of pyridine to prevent too rapid precipitation. The reaction mixture was made up from fiftieth moles of arsanilic acid and 3-amino-4-hydroxyphenylarsonic acid, **30** cc of water, 40 cc. of pyridine, **10** cc. of hydrochloric acid (d., 1.19) and **53** cc of hypophosphorous acid. The mixture was warmed on a water-bath at 100° for one-half hour and acquired a light reddish tint At this point it was poured into 100 cc. of hydrochloric acid, which caused the reaction product to precipitate. This was redissolved in **100** cc. of water acidified with a few cc of strong hydrochloric acid and reprecipitated by stirring into 100 cc. of 6 *N* hydrochloric acid The compound was filtered and washed with dilute hydrochloric acid, acetone and ether, yield, 5.6 g **or** 65%

Anal. Subs, **0.2270, 0.2287. 46.00, 17.23** cc of iodine soln. **(1** cc. = 0.001742 g. of As). Calcd for $C_{12}H_{14}ON_2Cl_2As_2$: **As,** 35.**44.** Found. **As. 35.30. 35.97.**

---

[11] German Patent, **251,104,**

(23) **4-Amino-4′-hydroxyarsenobenzene Hydrochloride**[12] **(IX).**—To a solution of fiftieth moles of arsanilic acid and *p*-arsonophenol in 30 cc. of hydrochloric acid (d., 1.19) and 10 cc. of water, was added 20 g. of stannous chloride. After shaking until the latter was dissolved, 1 g. of potassium iodide in 5 cc. of water was stirred in and immediately a reddish-yellow precipitate formed. Filtration was performed with some difficulty because the solid matter was very finely divided, and it was finally washed with water, methanol and ether. Five g. of product or 67% of the calculated quantity was obtained. It was found to be completely soluble in caustic soda solution.

Anal. Subs., 0.1106, 0.1683: 32.30, 33.85 cc. of iodine soln. (1 cc. = 0.01905 g. of As). Calcd. for $C_{12}H_{12}ONClAs_2$: As, 40.35. Found: As, 39.61, 39.52.

(24) **3-Amino-4-hydroxyarsenobenzene Hydrochloride.**[13]—Repeated attempts to prepare this compound by simultaneous reduction of 3-amino-4-hydroxyarsenobenzene with phenylarsonic acid resulted in every case in mixtures of the two symmetrical arseno compounds, from which arsenobenzene and 3,3′-diamino-4,4′-dihydroxyarsenobenzene dihydrochloride (arsphenamine) were both isolated and identified.

Summary

1. A series of alkali-soluble unsymmetrical arseno compounds has been prepared by simultaneous reduction of equimolecular proportions of p-arsonophenylglycine-amide and an arsonic acid containing a solubilizing group, or in which solubilizing groups can be easily substituted.

2. A similar series from *p*-arsonophenylamino-ethanol has been prepared.

3. One unsymmetrical tetra-arseno compound, tetra-arsenobenzene-4-glycine-4′-glycine-amide dihydrochloride has been described.

4. Several unsymmetrical arseno compounds containing neither glycine-amide nor amino-ethanol groupings have been prepared in an effort to shed light on the mechanism by which unsymmetrical arseno compounds are formed.

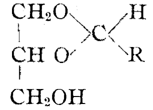
STUDIES ON THE REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XVII. STRUCTURE OF THE ISOMERIC METHYLIDENE GLYCEROLS

BY HAROLD HIBBERT AND NEAL M. CARTER[1]

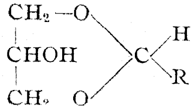
RECEIVED SEPTEMBER 13, 1928 PUBLISHED NOVEMBER 6, 1928

The work described in this paper is an outcome of attempts to investigate the structure and relative proportions of the isomeric cyclic acetals A and B formed when an aldehyde (RCHO) condenses with glycerol

(A)

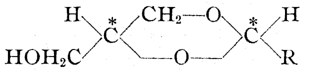


(B)

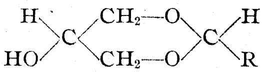


An examination of these two formulas shows that in a five-membered ring of Type I (corresponding to A), due to the presence of two asymmetric

(I)



(II)



carbon atoms(*), the product should be capable of existing in two geometrically isomeric *racemic* forms, while in Type II (corresponding to B), two geometrical isomers are theoretically possible, optical activity being excluded due to pseudo-symmetry.

The complications thus introduced by this considerable number of possible isomeric cyclic acetals make such investigations a matter of considerable difficulty and uncertainty and most probably account for the anomalous results sometimes obtained in the process of purification[3] and the gradual change taking place on standing in the melting points of crystalline derivatives of cyclic acetals.[3]

The view that only the five-membered type of cyclic acetal is formed in such condensations has, unfortunately, been accepted by various investigators. Thus in the recent paper by Yoder[4] dealing with the condensation of chloral and glycerol, the assumption is made that only the five-membered acetal is formed. An investigation by the present authors of this same reaction is in progress and will presumably yield evidence of the simultaneous formation of both the five- and six-membered acetals. In the condensation

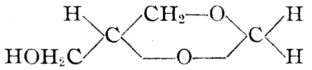
of chloral with glucose the number of theoretically possible isomers (structural, geometrical, optical) capable of existence, is much greater, hence the confusion arising out of the various investigations[5] dealing with this reaction.

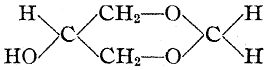
A solution not only of this but also of other problems in carbohydrate and polysaccharide chemistry, will doubtless be found in the further application of the principles enumerated in the series of investigations carried out by Hibhcrt and co-workers during the last eight years in this field, embracing, as they do, a recognition of the important role played by the somewhat neglected, but invaluable and indispensable "Partition Principle" of Arthur Michael[6] as well as of the deductions derivable from a consideration of the nature of the structural, geometrical and optical isomerism involved.[7]

The complications referred to above can be avoided if the study is confined to those acetals (or ketals) where such *geometrical* isomerism is impossible, as, for example, in the case of the isomeric methylidene glycerols,[8] III and IV.

(III)



(IV)



In Type III only one asymmetric carbon atom is present, so that the product should yield a single optically resolvable racemic form, while Type IV is not capable of existing in more than one, non-optically active, modification. The number of possible isomers is thus limited to one representative of each ring system, the five-membered acetal, however, being capable of active resolution.

In view of the relative stability of methylidene glycerol toward hydrolysis,[9] as compared with other acetals[10] and ketals,[11] this cyclic acetal was chosen as the simplest type conforming to the above requirements.

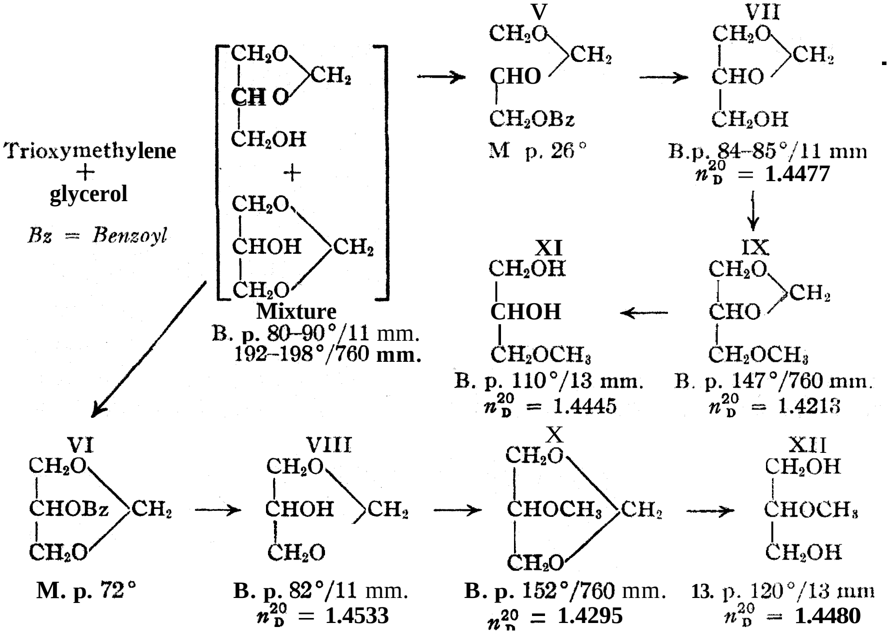
Methylidene glycerol has long been known[12] and the existence of two isomeric benzoates was shown by Schulz and Tollens,[13] who, however, left open the question of their structure. Its properties were further studied by Nef,[9] and Peacock[14] obtained a partial optical resolution of his product which led him to assign to it the structure corresponding to I.

A careful study by the authors of the product formed in the reaction between formaldehyde (trioxymethylene) and glycerol has shown this to consist of the two isomeric cyclic acetals III and IV, which have been separated and identified by the method outlined in the following scheme.



This sharp separation into two isomeric series was rendered possible by the successful isolation of the two pure isomeric benzoates V and VI (as indicated in the experimental part) from which it was then possible to prepare, for the first time, the pure acetals **VII** and **VIII** and the methyl ethers **IX** and X.

These ethers yielded the corresponding α- and β-glycerol methyl ethers on hydrolysis, the identification of the β-derivative being definitely settled by comparison with the pure glycerol β-methyl ether recently isolated in this Laboratory.[15]

Among other attempts to obtain a separation of the isomeric acetals

from the original reaction mixture by means of crystalline derivatives, the *p*-nitrobenzoates were prepared, These crystallize much less readily than the corresponding benzoates and were more difficult to separate. The five membered derivative melted at 135° and its six-membered isomer at 185°.

The Interconversion of 1,2- and 1,1′-Methylidene Glycerols

The mixture of acetals obtained in the original condensation product can only be partially separated into its component isomers by fractional distillation at atmospheric pressure and it was in this connection that the observation was first made of a change in the higher boiling fraction (197–198") on standing for several months into approximately that of the lower (192–193°). It was found later that the unseparated mixture of acetals, on treating with a few bubbles of dry hydrogen chloride gas and allowing to stand for some hours at 100°, always gave, on benzoylation, a greater yield of the benzoate of the 1,1′-acetal than the untreated mixture. On the other hand, after the pure acetals had finally been isolated, treatment of each for thirty minutes at 100" with approximately 0.01% by weight of dry hydrogen chloride showed a large percentage conversion of VII into VIII, as indicated by change in refractive index, while VIII evidenced little, if any, change into VII. In view of this transformation from a 5- to a 6-membered ring under the catalytic influence of small amounts of acid, it was necessary to show that a similar conversion does not take place during the alkaline hydrolysis of the benzoates and the methylation of resulting acetals, also carried out in *alkaline* solution. This was accomplished by first hydrolyzing separate samples of V and VI and then re-benzoylating only after the acetals had first been given an opportunity of undergoing interconversion by heating in presence of alkali. In each case the original benzoate was obtained exclusively, showing that no tendency toward such change exists under these conditions. All subsequent operations with the free acetals were therefore performed in the presence of a small piece of solid potassium carbonate to ensure alkalinity.

Due to the sensitivity toward acid media and the close similarity in chemical properties of the two liquid isomeric acetals, it is difficult to determine, other than qualitatively, the ratio of the two isomers present in the original reaction product. The evidence, however, points to a preponderance of the 5-membered ring in the ratio of approximately 3 to 2.[16]

Experimental Part

Preparation of the Mixture of Isomeric Acetals.—As a result of many preliminary experiments on the preparation of the methylidene acetals,

---

[16] The problem of finding an aldehyde capable of giving crystalline isomeric cyclic acetals has been solved by the use of pnitrobenzaldeliyde and it has been found possible to isolate the theoretical number of isomers in the case of *p*-nitrobenzylidene glycerol derivatives. This work is to appear in the near future.

using the original method of Schulz and Tollens,[13] and also employing several of the catalysts mentioned by Adams and Adkins[17] as being advantageous in acetal formation, the best yields were eventually obtained by the following original method.

An equimolecular mixture of 75 g. of pure glycerol and 26 g. of trioxymethylene was acidified with 2 cc. of concentrated hydrochloric acid, the whole well shaken in a stoppered flask, and then kept at 100° for one and one-half hours with frequent shaking. The resultant clear solution, while still hot but without further heating, was placed under reduced pressure (12 mm.) and the vacuum maintained until no further evolution of water was observed. This removal of water with consequent displacement of the equilibrium: trioxymethylene + glycerol acetal + water, was found materially to improve the yield of acetal. The residual liquid was allowed to stand for another twelve hours at 100° and then distilled under reduced pressure in the presence of the hydrochloric acid. The first drops of acetal commenced to distil at about 90° (10 mm.) and the temperature was then gradually raised until the distillate began to appear viscous, by which time most of the acetal had distilled over. Redistillation from a boiling water-bath yielded 50 g. (63%) of the pure mixed acetals boiling between 80–90° (11 mm.) $n_D^{20} = 1.4497$, the latter value indicating a mixture of approximately 60% of the 1,2- and 40% of the 1,1′-methylidene glycerol.

Conversion of Mixed Acetals into Benzoates.—The mixed acetals may be benzoylated directly, but since for the purpose of this investigation as large a yield as possible of the benzoate (VI) of the 6-membered acetal was desired, advantage was taken of the action of dry hydrogen chloride in bringing about a large conversion of the 1,2- into the 1,1′-acetal. Fifty g. of the isomeric mixed acetals as obtained by direct distillation, b. p. 80–90° (11 mm.), was treated with 0.01% by weight of dry hydrogen chloride and allowed to stand for half an hour at 100°, then cooled and added to 40 g. of pure, dry pyridine. The theoretical quantity (68 g.) of benzoyl chloride was slowly run in from a dropping funnel, with constant shaking, at such a rate that the temperature of the exothermic reaction was kept below 60°. The product was allowed to stand at 20° for forty-eight hours to complete the reaction, dissolved in slightly more than the minimum quantity of ether necessary for solution, washed successively with considerable water, then with very dilute sulfuric acid and finally with dilute sodium bicarbonate solution prior to being dried over fused calcium chloride. After removal of the ether under reduced pressure and cooling, the mixed isomeric benzoates were left as a more or less oily white crystalline paste; yield practically quantitative (95 g.).

Separation of the 1,2-Methylidene Glycerol 1′-Benzoate (V) from the Isomeric 1,1′-Methylidene Glycerol 2-Benzoate (VI).—The above semi-crystalline mass was dissolved in four times its volume of warm ether and cooled to room temperature (18°), when it deposited a network of fine, prismatic needles. These were filtered off by suction but not washed, since they are relatively quite soluble in the solvent at ordinary temperatures. By further cooling the filtrate to 0° a second crop could be filtered off at this temperature. Finally, sufficient solvent was evaporated from the remainder to cause the solution practically to solidify when cooled to −20° with stirring; the cold paste was transferred to a small, previously cooled Büchner funnel and suction applied while the whole was slowly allowed to warm to room temperature. The remaining thin layer of unmelted crystals was added to the two previous crops and the whole allowed to lose any adsorbed ether by standing at a temperature below 15°. Recrystallization from hot ligroin (b. p. 80–90°) gave pure 1,1′-methylidene glycerol 2-

---

[17] Adams and Adkins, THIS JOURNAL, 47, 1361 (1925).

benzoate (VI) in the form of long (1–2 cm) colorless prismatic needles, m. p. 72°, corresponding to the product obtained by Schulz and Tollens.[13] The crystals are very soluble in benzene, and other solvents at 30° and are deposited readily from ether and alcohol as the temperature falls toward 0°; they are insoluble in water and cold ligroin. The yield in the most favorable experiment was approximately 50% of the mixed benzoates.

Anal. Subs., 0.1952: CO_2, 0.4536; H_2O, 0.0988. Calcd. for $C_{11}H_{12}O_4$: C, **63.4; H, 5.81.** Found: C, 63.3; H, 5.66%.

The ethereal solution of the remaining isomeric benzoate (V) contained residual traces of pyridine, which was removed by distillation and the residue then fractionated under reduced pressure.

The main product boiled at 172 175° (15 mm.) and undoubtedly was the "oily benzoate" analyzed by Schulz and Tollens; yield, 45% of total mixed benzoates. On long standing at 0° or by solution in methyl alcohol and cooling to −20°, large, colorless, tabular prisms of 1,2-methylidene glycerol 1'-benzoate (V) melting at 26° and possessing the same solubility relations in organic solvents as the first isomer were eventually obtained, though only with considerable difficulty.

Anal. Subs.. 0.2047: CO_2, 0.4741; H_2O, 0 1061 Calcd. for $C_{11}H_{12}O_4$: C, **63.4;** H, 5.81. Found: C, 63.2; H, 5.52. *Mol. wt* Subs., 0.4117; ethylene bromide, 40 07; ΔT, 0.566°. Mol. wt., calcd : 208 1. Found: 213.

Alkaline Hydrolysis of **1,2-Methylidene** Glycerol 1'-Benzoate (V) to **1,2-Methylidene** Glycerol **(VII).—Forty** g. of V was added to 110 g. of a 20% potassium hydroxide solution and continuously shaken at 75° for ten to fifteen minutes until the oil resulting from the melting of the crystals had dissolved completely to a clear solution. After cooling the solution, the excess of potassium hydroxide was converted into carbonate by passing in carbon dioxide and the solution completely saturated by adding anhydrous potassium carbonate. The resulting liquid acetal (together with some sodium benzoate thrown out of solution) was extracted by repeated shaking with ether and decantation, the sodium benzoate filtered off and the ether solution dried over solid potassium carbonate. After removal of the ether, distillation under reduced pressure in the presence of a small amount of solid potassium carbonate yielded 15 g (75%) of crude product. On redistillation pure 1,2-methylidene glycerol (VII) was obtained; b. p. 84–85° (11 mm.); 104° (28 mm.); 195° (760 mm.); n_D^{20} = 1.4477 d_4^{20} = 1.2113.

Anal. Subs., 0.2061: CO_2, 0.3414; H_2O, 0.1435 Calcd. for $C_4H_8O_3$: C, 46.12; H, 7.75. Found: C, 46.20; H, 7.79. *Mol. wt* Subs., 0.1049, 0.4312: ethylene bromide, 40.77, 40.77; ΔT, 0.250, 0.954°. Mol. wt., 122, 131.

These values indicate some association due to the free hydroxyl group, extrapolation to zero concentration giving a mol. wt. of 107 (theoretical, 104).

The substance is a slightly viscous, colorless, hygroscopic liquid, soluble in all proportions in ether, alcohol, water and warm benzene. When freshly distilled a very slight odor is noticeable which later disappears. Even on prolonged exposure no odor of formaldehyde is developed, hydrolysis only occurring on boiling with dilute acids (hydrochloric acid, etc.). This behavior is in marked contrast to most glycerin acetals.

When the acetal is mixed with 0.01% by weight of dry hydrogen chloride and heated to 100° for twenty minutes, the refractive index (which is practically unchanged immediately after addition of catalyst) rises from 1.4477 to 1.4540 (20°), thus indicating a large conversion to the 1,1'-isomer (VIII) described below.

Alkaline Hydrolysis of **1,1'**-Methylidene Glycerol **2-Benzoate** (VI) to **1,1'-Methylidene** Glycerol **(VIII).—Forty** grams of VI hydrolyzed in the same manner as the above corresponding isomer yielded 12 g. (60%) of 1,1'-methylidene glycerol (VIII). Careful distillation of the resulting product gave a slightly viscous. colorless, hygroscopic liquid; b. p. 82° (11 mm.); 100° (28 mm); 191° (760 mm.); n_D^{20} = 1.4533; d_4^{20} = 1.2266

Anal. Subs, 0.2037: CO_2, 0.3432; H_2O, 0.1416 Calcd. for $C_4H_8O_3$: C, 46.12; H, 7.75. Found: C, 45.95; H, 7.77. *Mol.* wt. Subs., 0.2009, 0.4074, 0.5116; ethylene bromide, 40.44, 40.44, 40.44; Δ*T*, 0.498°, 0.936°, 1.114°. Mol wt., 118, 127, 134. By extrapolation to zero concentration as before, mol. wt. = 107 (theoretical, 104.1).

In odor, solubility in solvents and resistance toward hydrolysis, it closely resembles the 1,2-isomer (VII). On similar treatment with hydrogen chloride, the refractive index, instead of falling as would be expected from a partial conversion into the isomer (VII), gradually rose over a period of twenty-four hours to 1.4583 at 20°, accompanied by discoloration and increase in viscosity, the latter phenomena indicating some more deep-seated change.

Methylation of **1,2-Methylidene** Glycerol (VII).—Ten grams of acetal (VII) was dissolved in 43 g. (3 moles) of methyl iodide and the usual methylation procedure followed by slowly adding 35 g. of dry silver oxide during a period of three hours, the mixture being refluxed and well stirred throughout the addition. After extracting with ether and drying over calcium chloride, fractionation of the resulting liquid yielded 8.5 g. (80%) of crude 1,2-methylidene glycerol 1'-methyl ether (IX), b. p. 145–150° (760 mm.). To remove unchanged acetal, glycerol, etc., this was heated with a globule of metallic sodium for a few minutes at 80°, the product filtered and the filtered liquid re-stilled. The pure methyl ether was then obtained as a colorless, mobile liquid possessing a pleasant, ethereal. odor, soluble in all proportions in ether, alcohol, benzene and water; b. p. 147° (760 mm.); n_D^{20} = 1.4213; d_4^{20} = 1.0788.

Anal. Subs., 0.1988: CO_2, 0.3651; H_2O, 0.1497. Calcd. for $C_5H_{10}O_3$: C, 50.8; H, 8.66. Found: C, 50.1; H, 8.43. *Mol.* wt. Subs., 0.3107; ethylene bromide, 40.50; Δ*T*, 0.741°. Mol. wt., 122 (theoretical, 118.1).

Methylation of **1,1'-Methylidene** Glycerol (VIII).—Ten grams of the acetal was methylated by means of dimethyl sulfate and caustic potash according to the method of Haworth[18] and the resulting methyl ether (X) separated from the reaction mixture by continuous ether extraction over a period of eight hours. Distillation of the extract yielded 6 g. (55%) of crude 1,1'-methylidene glycerol 2-methyl ether, b. p. 150–160° (760 mm).

Purification with metallic sodium as above and redistillation gave a pure product, b. p. 152° (760 mm.); n_D^{20} = 1.4295, and possessing the same appearance, odor and solubilities as the corresponding isomer (IX).

Anal. Subs., 0.2019: CO_2, 0.3731; H_2O, 0.1521. Calcd. for $C_5H_{10}O_3$: C, 50.80; H, 8.56. Found: C, 50.61; H, 8.43. *Mol. wt.* Subs., 0.2115; ethylene bromide, 43.11; Δ*T*, 0.508°. Mol. wt., 114 (theoretical, 118.1).

Acid Hydrolysis of **1,2-Methylidene** Glycerol 1'-Methyl Ether (IX).—Seven grams of the ether was dissolved in an equal volume of water and 6 drops of concentrated hydrochloric acid added. On refluxing for ten minutes at the boiling point, liberation of formaldehyde commenced and after further refluxing for thirty minutes it was allowed to simmer for two to three hours in a small open Erlenmeyer flask until the evolution ceased. Water was added from time to time to replace that lost by evaporation. The hot solution was then neutralized by adding solid lead carbonate, cooled, filtered and subjected to vacuum distillation. The sole product (b. p. 110° at 13 mm.) was readily recognized as glycerol α-methyl ether by its boiling point and refractive index, n_D^{20} = 1.4445;[3] yield, 3 g. (50%).

---

[18] Haworth, *J. Chem. Soc.*, 107, 8 (1915).

Acid Hydrolysis of **1,1′-Methylidene** Glycerol 2-Methyl Ether (X.) Five grams of this ether was hydrolyzed by the same method and yielded 2 g. (45%) of pure glycerol β methyl ether;[15] b. p. 120° (13 mm.); $n_D^{20} = 1.4480$.

The identity was further confirmed by conversion of the product into 1,1′-*p*-nitrobenzylidene glycerol 2-methyl ether and isolation of the two crystalline isomers, m. p. 42 and 47°, respectively.[19]

Summary

1. The possibility of both optical and geometrical isomerism in the structurally isomeric cyclic acetals of glycerol is pointed out.

2. Advantage is taken of the absence of geometrical isomerism in the methylidene glycerols in order to isolate and determine the structure of the two isomers formed by partition of formaldehyde between the 1,2- and 1,1′-hydroxyl groups of glycerol during cyclic acetal formation.

8. The isolation and identification of the two isomeric methylidene glycerols and of certain of their derivatives are described.

4. The interconversion of the ring systems of the two isomeric acetals has been investigated.

MONTREAL, CANADA

NEW BOOKS

A Textbook of Inorganic Chemistry. Volume VI, Part I. Nitrogen. By EDMUND B. R. PRIDEAUX, M.A., B.Sc. (N. Z.), D.Sc. (Lond.), F.I.C., and HERBERT LAMBOURNE, M.A. (Cantab.), M.Sc. (Lond.), F.I.C. J. B. Lippincott Company. Philadelphia, 1928. xxviii + 242 pp. 25 figs. 15.5 X 23 cm.

This volume deals solely with nitrogen, and in view of the present importance and extensive literature on the subject, naturally presents a problem to the authors as to what they shall include in the 231 pages of text allotted to them.

The fourteen chapters include an introductory chapter on the nitrogen atom, the properties of nitrogen, one on ammonia, hydroxylamine, nitrogen and the halogens, oxy-halogen derivatives, hydrides and their derivatives, hyponitrous acid, the oxides of nitrogen, nitrous acid, nitric acid, nitrogen and sulfur and one on the fixation of nitrogen. Some space might have been saved in the chapter on ammonia by a more judicious selection of graphs. For textbook purposes a satisfactory discussion of the synthetic production of ammonia is presented, including a brief reference to the technical features of the process.

The authors' prefatory intention to avoid "undue detail in physical constants and in the minutiae of chemical processes" has been somewhat overlooked by the later inclusion of such data as the tables of the solubility of nitrogen in water, and in sea water, and the listing of five different equations for the specific heat of ammonia at constant pressure. This

---

[19] A full account of this work has been submitted for publication in THIS JOURNAL

oversight, however, is not a serious one and merely attests to the zeal of the authors in making their book "a starting point for research."

The chapter on the fixation of nitrogen, in 26 pages, includes a discussion of the arc process, with a brief historical account of the early developments, and gives the reader some idea of the details of construction of the various furnaces. The section on Synthetic Ammonia includes a discussion of the "Haber" process with a brief discussion of the method of gas preparation and purification. The Claude, Casale and Fauser processes are briefly dealt with, as is also the commercial oxidation of ammonia. Brief mention is made of the Serpek, or aluminum nitride process, the Bucher cyanide process and the cyanamide process. A survey of the nitrogen fixation problem completes the chapter and the book.

As a whole the book is a valuable compilation of information on the chemistry and technology of nitrogen and should be of service to the student and research worker in this field.

H. J. KRASE

Physical Chemistry and Biophysics for Students of Biology and Medicine. By MATTHEW STEEL, Ph.D., Professor of Biological Chemistry, the Long Island College Hospital, Brooklyn, New York. John Wiley and Sons, Inc., New York, 1928. x + 372 pp. 38 figs. 15 × 23.5 cm. Price, $4.00.

Chapters 1 to 4 are entitled, respectively, General Introduction; Nature and Structure of Matter; General Properties of Matter; Energy Transformations in Living Matter. Chapters 3 to 12 contain the usual treatment of elementary physical chemistry. Such recent developments as the theory of Debye and Hückel and Cohn's studies of the physical chemistry of the proteins are unmentioned. Chapter 13, the last, is entitled "Dynamical Physical Chemistry of the Cell."

This book is fairly satisfactory in scope but the treatment of several subjects lacks precision. Thus on p. 106 we learn that when "a mixture is chemically and physically homogeneous, and no abrupt change in its properties results from a change in the proportions of the compounds of the mixture, it is a one-phase system and is termed a solution." However, this appears to be a definition not of solution but of "true solution," for glucose and water form "a homogeneous, one-phase system composed of two different substances, uniformly mixed with each other. Such a system is called a true solution, to distinguish it from heterogeneous mixtures, such as colloidal solutions." This ambiguity is accentuated on p. 108 where smoke in air is given as an illustration of solutions of solids in gases.

"Water as a Solvent" is the title of a paragraph on p. 120. Water has great "power of solution." "All kinds of substances dissolve in it. . . . . The urine, for instance, may have as many as a hundred substances dissolved in it. Among these are. . . adinine, allantoine,. . . tyrocine, . . .;

salts of sodium, . . . iron, carbonic acid, nitrogen, argon;. . . blood form elements and pigments, pus, . . . arsenic, mercury,. . . urorosin, urocromogen. . ." In this one paragraph, in addition to typographical errors, the words *power, substance* and *element* are used in the popular sense and an error of logic is made in illustrating the solvent "power" of water by the solvent "power" of urine.

This lack of precision may also be illustrated by inconsistency in nomenclature. Thus we have on p. 121 "ions of water," and on the same page, "OH-ions of the substrate are substituted for H-ions"; on p. 173, "quantity of H^+ ions and $OH-$ ions"; on p. 189, "$HCl \rightleftarrows H^+ + Cl'$" and "the H+-ion content"; on p. 232, "$Ct' - An' + H'OH' \rightleftarrows H' - An' + Ct' - OH'$", and on page 362, "the (H^+) and (OH^-) concentrations."

Although errors and inconsistencies appear to be rather numerous, it may be said that the plan and scope of the book should make it useful to students of biology who have little time to devote to chemistry and physics.

D. B. DILL

Holzchemie. (The Chemistry of Wood.) BY DR. ERIK HÄGGLUND, Professor of Wood Chemistry at the Academy of Åbo. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 4, Leipzig C 1, Germany, 1928. viii + 275 pp. 33 figs 16 × 23.5 cm. Price, unbound, M 18; bound, M 20

The name of Hagglund needs no introduction to students of wood chemistry. In the Foreword of his present book he calls attention to the lack of publications in the line of wood chemistry. He acknowledges recent American publications, but justifies his own book on the ground that he has drawn for material on a great number of German and Scandinavian investigators, and thus he gives his work a more widespread appeal.

This small but rather comprehensive text is divided into eleven chapters, commencing with a very interesting one on The Texture of Wood. This chapter is illustrated by photographs and diagrams on sections of various types of woody plant structures. The next chapter deals rather briefly with The Physical Attributes of Wood. It is in this chapter that the tremendous amount of work connected with gathering material for the text begins to become apparent. There are in the entire text somewhat over 175 tables and curves representing data either accumulated by the author or taken from other literature in support of one of his contentions.

The third and most elaborate chapter deals with The Constituents of Wood and their Chemical Properties. Therein are studied in some detail the usual. list of wood constituents. The formulas of lignin due to Klason and to Schrauth are presented. Subsequent chapters deal variously with the reactions of wood with acids, sulfites and alkali. The two last chapters treat of The Behavior of Wood Accompanying Storage

(Stratification) and Certain Opposing Reagents, and with The Decomposition of Woods in Nature.

Throughout the text are innumerable references to the literature, much of which is American. There is at the end of the book an eleven-page Author Index to the rich list of references, which, for one interested in this subject, is worth the price of the book, for the author has spared no labor in gathering these references.

As a whole, the text is a fine review of the subject, not adding much that is startlingly new, but organizing and tabulating that which had already been written in such a way as to eliminate much of the usual "dead timber."

R. LYMAN HEINDEL, JK.

Synthese der organischen Arzneimittel. (Synthesis of Organic Medicinals.) By PROFESSOR DR. ERNST WASER, Zürich. Ferdinand Enke, Stuttgart, Germany, 1928. xi + 227 pp. 16.5 X 25.5 cm. Price unbound, M 16; bound, M 18.

This book is an advanced text on the synthetic methods for preparing organic medicinals and is planned by the author as an aid to students in chemistry as well as to those in medicine and pharmaceutical chemistry who desire to become acquainted with this field. The discussion is limited essentially to the methods of preparation. The physical properties of the various drugs are described very briefly and the general physiological action of each is given in a table, classified in one of fourteen different groups, such as drugs exciting the central nervous system, drugs for local anesthesia, etc.

The discussion of the various compounds is under six headings.

(1) Aliphatic Compounds
    (*a*) Hydrocarbons and Halogen Compounds

References from which the information is obtained about the preparation of the drugs are included. Over 250 drugs are listed with their trade names.

The book is copiously supplied with structural formulas which are a great aid to the reader and make it possible to obtain proper information without too much study. All of the methods of preparation or references to all of them for each of the individual drugs are not in every case included; in fact now and again omission of a very important method has been noted. The author has made no attempt to indicate which of the methods described is of the greatest commercial value and frequently more detail is given about a less important method than about a more important one. As a consequence, the student must not be misled into believing that the information which is given is more than of general help in the development of a manufacturing process for any drug.

To the reviewer it seems a pity that the author could not have added to his rather extensive list of drugs a few of the more important ones which have been developed, manufactured and widely distributed in the United States, such as mercurochrome-220, hexylresorcinol and butyn. These are certainly of far more commercial value than a large proportion of those described which find only a very limited use and distribution. It should be mentioned also that the author has omitted a discussion of the therapeutic compounds of arsenic, antimony and mercury.

At the end of the book are appended five useful tables which indicate by means of structural formulas all of the various methods of preparation for novocaine, tyramine, hordenine, suprarenine and hydrastinine.

It is unfortunate that a chapter on the comparative medicinal value of the individual substances in any one class could not have been given but it is clearly recognized how difficult it is to procure this information.

If an occasional statement is overlooked such as that ethylene chlorohydrin is made from ethylene glycol, much valuable chemistry is involved in the book and is presented in a very condensed and readable form. The student, therefore, milt benefit by the study of this book from the purely synthetic organic chemical standpoint at the same time that he is acquiring a knowledge of synthetic drugs.

The book is one which any chemist interested in synthetic drugs should surely have at his disposal.

ROGER ADAMS

The Chemistry of Leather Manufacture. By **JOHN ARTHUR WILSON**, Chief Chemist, A. F. Gallun and Sons Co. (Tanners), Milwaukee, Wisconsin. Volume I, second edition. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 495 pp. 105 figs. 95 plates. 15.5 X 23.5 cm. Price, 610.00

The first English edition of this book appeared early in 1923. Its outstanding merit was instantly recognized as shown by the publication of translations in three foreign languages, the German in 1923, French in 1926 and Russian in 1027. Since the publication of the first edition, scientific knowledge of the fundamentals pertaining to the many materials used and the leathers produced by tanneries has grown enormously, the author himself being one of the most prolific contributors. As a result of the increase in exact information, together with "many and varied suggestions for increasing the scientific value and general usefulness of the book," the author has found it necessary to increase the size of the book to two volumes, each greater in size than the original book.

Volume I consists of 14 chapters including Histology and Chemical Constituents of Skin, Measurements of Acidity and Alkalinity, Physical Chemistry of Proteins, Microörganisms and Enzymes, the Preservation, Disinfection, Soaking, Fleshing, Unhairing, Bating and Pickling of Skins and the practical aspect of Vegetable Tanning Materials as well as their chemistry and evaluation.

The author has acquitted himself well in a difficult task, producing a work so fundamentally chemical that it possesses broad scientific value as well as being the authoritative reference and textbook for the leather and tanning industry.

A NEW EQUATION OF STATE FOR FLUIDS.
II. APPLICATION TO HELIUM, NEON, ARGON, HYDROGEN, NITROGEN, OXYGEN, AIR AND METHANE

BY JAMES A. BEATTIE AND OSCAR C. BRIDGEMAN[1]

RECEIVED MARCH 29, 1928 PUBLISHED DECEMBER 10, 1928

In the preceding paper,[2] the authors proposed an algebraic equation of state whose constants are easily and uniquely determinable from pressure–volume–temperature data, and which can readily be used for evaluating the usual thermodynamic relations. This equation of state is

$$p = \frac{RT\,(1-\epsilon)}{V^2}\,[V+B] - \frac{A}{V^2} \qquad \begin{aligned} A &= A_0\,(1-a/V) \\ B &= B_0\,(1-b/V) \\ \epsilon &= c/VT^3 \end{aligned} \qquad (1)$$

in which R is the gas constant and A_0, a, B_0, b and c are parameters which depend upon the kind of substance under consideration. It was shown that the data on gaseous ethyl ether and carbon dioxide were represented very satisfactorily by an equation of this form. A physical basis for this equation and the details of the method for the evaluation of the constants from the compressibility measurements will shortly be presented elsewhere.

In the present paper are given the results of the application of Equation 1 to the p–V–T data on eight gases extending over the temperature range from −252 to +400°, and to pressures of about 100 to 200 atmospheres. The region of high pressures (1000 atmospheres or over) will be treated later. The data used for the present comparisons have resulted from the investigations of Kamerlingh Onnes and his associates,[3] and of Holborn, Otto and Schultze[4] on helium, neon, argon, hydrogen, nitrogen, oxygen and air; of Bartlett[5] and Verschoyle[6] on hydrogen and

nitrogen; of Witkowski on hydrogen[7] and air;[8] of Smith and Taylor[9] on nitrogen; of Koch[10] and Amagat[11] on air; and of Keyes and Burks[12] on methane.

Within the density range studied, all of the measurements of the above observers were used for the determination of the values of the equation of state constants, and also in the comparisons given in Table II, with the following exceptions: helium, the isotherms below −252° for which the pressures even at large densities are small; argon, the 18.39" isotherm of Onnes and Crommelin; hydrogen, the data of Crommelin and Swallow (Leiden) which could not be correlated with the rest of the field, and the measurements of Verschoyle and Bartlett who made no observations below about 50 atmospheres; nitrogen, the 5 cc. per gram isometric of Smith and Taylor, which is possibly in error; and air, the −130, −135, −140 and −145° isotherms of Witkowski, which show large deviations from the rest of the field.

In order to determine the values of the equation of state constants for a substance, it is necessary to have data in the form of isometrics. Most investigators present their results in the form of isothermals; that is, they list a series of pressure–volume products together with the corresponding pressures (or volumes) for each of several different temperatures. To convert these results into isometrics, the quantity $[pV - RT]$ was calculated for each measurement on a given isothermal. A straight line was passed through the point of zero density (where $[pV - RT]$ is zero) and the highest measured density on the isotherm. Deviations of the observed values from those calculated by the linear equation were plotted against the density on a large scale. By use of the linear equation and the plot, values of $[pV - RT]$ and hence of the pressure (which are considered as the "observed pressures") could be interpolated for a set of evenly spaced densities, the same densities being used at each isotherm. Thus all of the original data were transformed into isometrics by a procedure which smooths with respect to volume; but no attempt was made to smooth for temperature, all of the original isotherms being preserved.

It has long been known[13] that at constant volume the pressure of a gas varies almost linearly with the temperature, and many equations of state which make use of this property have been proposed. The experimental work indicates that the curvature $(\partial^2 p/\partial T^2)_V$ is always negative in the

gas region,[14] but that the isometrics approach linearity as the density decreases, and as the temperature increases.[15] It has been shown that the curvatures of the isometrics of nitrogen,[15] ethyl ether,[16] carbon dioxide,[17] and methane[18] could be represented by introducing into the Keyes[19] equation of state a logarithmic function of the temperature.

The method used for the determination of the values of the constants of the new equation of state can be indicated by rearranging (1) into the form

$$p' = p + \frac{c\psi(V)}{VT^2} = T\psi(V) - \phi(V) \qquad (2)$$

where $\psi(V) = R[V + B]/V^2$ and $\phi(V) = A/V^2$ both being functions of the volume alone. The quantity p' will be called the "corrected pressure." When c is positive, Equation 2 expresses the experimental findings concerning the curvature $(\partial^2 p/\partial T^2)_V$ mentioned above. If the volume and temperature functions used in (2) are satisfactory, there is one value of c which will cause the corrected pressure p' (calculated from p, c, and the volume and temperature functions given) to vary linearly with the temperature for all isometrics; this provides a method for determining c. With a chosen value for this parameter, the corrected pressures are calculated for a representative density; if too small a value of c has been used, all of the curvature is not removed from the corrected isometric, while too large a value causes the curvature of the p', T lines to change sign. Ordinarily two or three approximations are sufficient to select a satisfactory value of c even when correlating different sets of data. This provisional value of c is then verified by a study of the linearity of the corrected isometrics over the entire density field. It is generaliy true that measurements by two different observers give isometrics having different curvatures over the same temperature range; hence the value of c chosen represents a compromise.

From each corrected isometric there is obtained a value of $\psi(V)$ and of $\phi(V)$ which appear as the slope and intercept on the p' axis, respectively, of the linear p', T line. Since $V + B = V^2\,\psi(V)/R$, and $A = V^2\,\phi(V)$, it is possible to calculate a value of B and A for each isometric, and a plot of B against $1/V$ should give a straight line, the slope and intercept

of which are B_0b and B_0, while A should also vary linearly with $1/V$, the slope and intercept being A_0a and A_0. Thus, with the exception of c, all of the adjustable constants appear as the slopes or intercepts of straight lines in which all of the measured data are given weight.

The values of the constants for the gases studied are given in Table I, where for comparison those for ethyl ether and carbon dioxide are included. In the units chosen, R has the same value for all gases, namely, 0.08206, and T_0 was taken as 273.13. It was found necessary to use different values of the constants for the data of Smith and Taylor on nitrogen, which are very consistent among themselves but could not be correlated with the determinations of the other investigators. Therefore, in the Tables, N_2^a applies only to the Smith and Taylor data, while N_2 includes all of the other data; these latter are the accepted constants for nitrogen.

TABLE I

CONSTANTS OR THE EQUATION OF STATE ROR TEN GASES

$p = [RT(1 - \epsilon)]/V^2\,[V + B] - (A/V^2)$. $A = A_0(1 - a/V)$. $B = B_0(1 - b/V)$. $\epsilon = c/VT^3$. R = 0.08206 for all gases. Units: pressures in atmospheres, volumes in liters per mole, temperatures in degrees Kelvin. $T°K = t°C + 273.13$.

[a] Constants for Smith and Taylor's data alone.

In Table II is given a summary of the comparisons of the pressures calculated from the equation of state, using the constants listed in Table I, with the observed pressures. In this comparison the entire measured temperature range is included for all gases, with the few exceptions mentioned above. For some of the gases the entire measured density range at the lower temperatures was not used. This was partly due to the fact that in the low temperature high density region the data were too fragmentary to define the isotherm sufficiently to allow smoothed values of the pressure to be obtained, and partly to the difficulty of correlating this region with the rest of the field due to the large experimental error. In every case all of the isotherms were extended to the maximum density listed in Table II when any data existed.

The second and third columns of Table II give the average deviations in atmospheres and percentage between the observed and calculated

pressures over the complete temperature range and to a density of 5 moles per liter, which corresponds to an Amagat density of approximately 110, that is, 110 times as dense as at 0° and 1 atmosphere. The fourth and fifth columns contain the same information over the total range of temperature and density considered, these ranges being given in the succeeding columns. The last two columns give the number of different investigators whose data were correlated and the total number of points at which comparisons of observed and calculated pressures were made.

In the evaluation of the constants for the gases and in the comparisons given in Table II, the data of all observers on any particular gas were correlated, if possible, since a better average was thus obtained. For this reason the errors between observed and calculated pressures were larger than if separate equations were used for each group of results. It is in general true that the consistency of one set of data taken by the same observer is much greater than the agreement between two different sets. In fact, the deviations shown in Table II would be about halved if separate equations were used for the measurements of each observer. This can be seen from the results on methane, ethyl ether and Smith and Taylor's nitrogen, which are obtained from the work of the individual investigators and, further, the derivation of individual equations for one experimenter's data in the case of some of the other gases has verified this conclusion. The values of the constants obtained from a consideration of all the data were about the mean of those derived from the individual sets of measurements and are thus the best values that can now be assigned to them. In the cases in which the constants were determined from a consideration of the results of several investigators, the deviations between the observed and calculated values can be taken as an approximate estimate of the accuracy of the available data.

Summary

The new equation of state has been applied to the compressibility measurements on helium, neon, argon, hydrogen, oxygen, nitrogen, air and methane, and the values of the constants are given for these gases and for carbon dioxide and ethyl ether. A method is outlined for transforming the experimental pressure–volume–temperature data into isometric form, and a brief description of the procedure for evaluating the constants of the equation of state is given. Comparison of the observed pressures and those calculated from the equation have been made at 1777 points for these ten gases, the average deviation being **0.08** atmosphere or 0.18% over the entire temperature and density range considered. The average deviation is 0.06 atmosphere or 0.16% over the experimental temperature range and to a density of 5 moles per liter (an Amagat density of approximately 110).

THE VOLATILITY WITH STEAM OF WATER-SOLUBLE ORGANIC SUBSTANCES.

BY ARTTURI I. VIRTANEN AND L. PULKKI

RECEIVED MAY 24, 1928 PUBLISHED DECEMBER 10, 1928

Investigations on the determination of volatile fatty acids by means of steam (which from an analytical point of view is a very important mode of procedure) have in many ways explained our opinion as to the quantitative course of distillation by steam and have rendered it possible to express quantitatively in a simple manner the volatility of water-soluble substances with steam. When boiling the diluted solutions of fatty acids a certain percentage of acid is always distilled into a certain quantity of water, this percentage being different in the case of different acids. If there are several acids in the same diluted solution of acid, each acid is distilled independently of the others. Duclaux's[1] well known and purely empiric mode of procedure for the determination of volatile fatty acids is based on these facts. This procedure is, however, complicated and requires definite tables; it also applies only to fatty acids.

Among the investigations, the purpose of which has been to derive simple mathematical formulas in order to follow the course of distillation, should be mentioned Barrel, Thomas and Sidney Young's[2] differential equations,

---

[1] **Duclaux,** *Traité de Microbiologie,* 3,384 (1900); 4,685 (1901).

[2] Barrel, Thomas and Young, *Phil. Mag. and J. of Science, (V)37,* 8 (1894).

which are based upon Brown's[3] work and of a later time upon Richmond's[4] and Wiegner's[5] logarithmical equations, which have evidently been derived independently.

From Brown's equation $dy/dx = ky/x$, where y is the weight of the volatile substance in the liquid and x is the weight of the water in the liquid, Wiegner has derived a simple logarithmical equation

$$\log y = k \log x + 2 - 2k$$

which is very well applicable in practice. If the quantity of water at the beginning of the distillation is denoted by x_1 and at the end by x_2, and the substance to be distilled at the beginning by y_1, and when completed by y_2, we get the following equation

$$\frac{\log y_1 - \log y_2}{\log x_1 - \log x_2} = k$$

k is a constant which according to the above equation is easily calculable from the observations.

k, which we may call the constant of distillation, is a very practical means of indicating the volatility of the substance. If the solution is diluted with regard to the volatile substance to be investigated and if the distillation is made so that the condensation of steam is completely prevented, the value of k is constant for each volatile substance. Now it is impossible in practice completely to prevent the condensation of steam on the walls of the retort, but it may, however, be reduced so much that practically constant values may be obtained for k.

An ordinary steam distillation by blowing steam through the solution is not applicable to quantitative analyses since it is difficult to keep the volume of the solution perfectly constant during the time of distillation and the steam bubbles may be too large in passing through the solution, in which case an exact state of equilibrium between the composition of the steam and the composition of the solution is not obtainable. In practical laboratory work it is in many respects very important to know the volatility of different substances.

First, it is in many cases possible by means of fractional distillation to decide whether the substance is chemically pure or a mixture and thus the purity of the substance can be determined. If many fractions are distilled, k will have the same value in each fraction if the substance under investigation is pure.

Second, it is possible by means of steam distillation to obtain a quantitative analysis of volatile substances, as shown by the determinations mentioned below.

Third, it is possible on the basis of the value of k to decide in advance

---

[3] Brown, *Trans.* Chem. *Soc.*, 1879,550; 49,304 (1880); 517 (1881).

[4] Richmond, *Analyst, 33,* 209, 305 (1907).

[5] **Wiegner,** ***Mitt. Gebiete Lebensmitteluntersuchung Hygiene,*** 10, Fasc. *3/6* **(1919).**

whether a substance can be separated from non-volatile substances by means of distillation, whether in such cases neutral salts must be added or whether it is necessary to use altogether different methods.

Taking all of the above-mentioned circumstances into consideration, it is important that the values of k should be found for all substances volatile with steam and that these values should be stated in the handbooks.

Volatility could be expressed not only by distillation constants but also simply by using the number which indicates the percentage of each substance distilled, when a certain volume (half, for instance) is distilled. By means of these values of semi- or quarter-distillations, it is easy to calculate k and *vice versa.*

In this investigation we have determined the value of k for numerous compounds which represent different groups of substances. For quantitative determinations it is important to know how different circumstances influence the value of k and therefore we have investigated by using certain fatty acids, the influence of some factors on the course of the distillation. At the same time we have made minute distillations with mixtures containing two or three different substances.

The influence of salts upon the distillation of substances by steam has been previously investigated by one of us.[6] With a view to theoretically explaining this question we have made additional investigations, which we shall present in this article.

Methods

In the quantitative distillation by steam the only exact procedure is by the method of boiling. For this purpose the solution of the'substance in water to be investigated is distilled without leading steam through the solution, the volume of the solution thus steadily diminishing. While employing the method of boiling it is important that attention be paid to the size of the vessel used in order to prevent the steam from becoming condensed uselessly. For the same reason the tube which unites the retort with the condenser must be sufficiently large and as low as possible. In our experiments we have used a 300cc. Erlenmeyer flask, the volume of the solution being 200 cc. The dimensions of our apparatus are shown in Fig. 1. It is necessary to be certain that the volume of the flask really is precisely 300 cc.

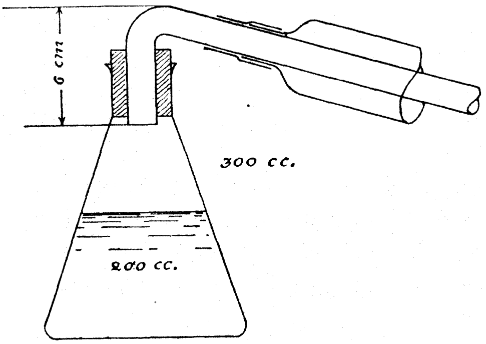

Fig. 1.

The flask was placed upon a network of asbestos and heated by means of an or-

---

[6] Virtanen, *Suomen Kemistiseuran Tiedonantoja (Publications from the Chemical Society of Finland),* **1921,** 9.

dinary Bunsen burner. Calibrated volumetric flasks were used as receivers. The acids were determined by titration with $N/20$ sodium hydroxide, with phenolphthalein as indicator; the amines were determined by $N/10$ sulfuric acid with Congo red as indicator. The determination of other substances will be mentioned separately.

There are several circumstances which influence the course of the distillations of these substances in cases where the constant is very great or on the contrary very small. The concentration of the solution is of great importance even if the solution is very much diluted. (Table I.) According to Duclaux, his method of distillation is applicable up to solutions of 2%. Our determinations show that the differences of concentration in solutions with this dilution have a remarkable influence upon the value of k for a number of substances. The time of distillation, upon which the condensation of steam depends, must also be taken into consideration. Below are given a few examples which show the effects of these factors. (Table II.)

Acetic Acid[a] (Kahlbaum)				0.05	0.0058	1.92	73.5
0.09	0.0150	0.657	36.6	.16	.0181	1.96	74.4
.51	.0843	.657	36.6	.29	.0332	1.99	74.8
				.88	.1000	2.00	75.0
				2.29	.2600	2.02	75.3

[a] The effect of the concentration of acetic acid is very small. For solutions of 2% and for more concentrated solutions, the value of k is almost the same as in the above distillations.

TABLE II

THE INFLUENCE OF THE TIME OF DISTILLATION UPON THE VALUE OF k

The time is that which elapsed in distilling from 200 to 100 cc.

Concn., %	Minutes	k	Semi-dist. value, %	Concn., %	Minutes	k	Semi-dist., value, %
Formic Acid				Propionic Acid			
0.39	59	0.389	23.7	0.12	60	1.239	57.6
.39	125	.325	20.2	.12	75	1.245	57.9
Acetic Acid				Butyric Acid			
0.12	41	0.668	37.0	0.15	36	1.940	73.9
.12	51	.659	36.7	.15	60	1.964	74.4
.12	58	.658	36.6	.15	88	2.035	75.6
.12	78	.641	35.9				
.12	135	.608	34.4				

From the above values of distillation it is evident that the time used for distillation has a remarkable effect upon k, especially with formic and butyric acids. A rapidity of distillation is, in our opinion, most conveniently used when half of 200 cc. is distilled in sixty minutes. In order to obtain identical values the same rate of distillation should always be used.

The Use of Method of Distillation in Analyzing Mixtures of Volatile Substances

The aforesaid experiences concerning the course of distillation as influenced by the concentration and the time used for distillation are facts to be noted in the quantitative analysis of volatile substances. Previous investigators have not paid attention to these facts but have generalized their method for solutions of fatty acids of 2% at most. In all analyses the differences in concentration may in most cases be passed over, but the results in such cases may be comparatively inexact. By taking the conditions of concentration into consideration it is possible to determine the volatile substances with surprising accuracy by using the method of distillation, as is evident from the determinations mentioned below.

Wiegner has suggested, in his valuable investigation in which fractional steam distillation is theoretically treated, a method to be put into use according to which the solution to he investigated, if containing two volatile fatty acids, is first half distilled; an equal quantity of water is then added to the remainder and the solution is again distilled to a semi-volume. For safety's sake this treatment is repeated for the third time. From the first and second distillations equations will be obtained by which the quantities of acids in the solution may be determined. The third equation may be used as control.

As the conditions of concentration always exercise, according to our determinations, a great influence upon the values of k, it is evident that by using this method the first distillation gives values which are different from those of the second. The third distillation can by no means be compared to the first. One of the authors[7] has previously presented a much simpler method for analyzing a solution containing two volatile acids.

Exactly half of the solution, the total quantity of acid in which is known, is distilled and the quantity of acid in the distillate is determined by titration. If the wanted quantities of acids in the solution are A and B and the value of A's semi-distillation is marked with a and that of B's semi-distillation with b, it is possible to determine the quantities of acids by means of one single distillation. The total quantity of acid may be z and the quantity of acid distilled in the semi-volume Z_1. Thus we obtain the following equations

---

[7] Virtanen, *Soc. Scient. Fennica, Comm. Physico-Mathemat.*, **1**, 36 (1923).

$$A + B = z$$

$$\frac{a}{100} A + \frac{b}{100} B = z_1$$

The accuracy of this method is evident from the following example.

Experiment 1.—In 200 cc. there was acetic acid corresponding to 47.4 cc. of $N/20$ acid and propionic acid corresponding to 17.6 cc. of $N/20$ acid. The whole solution thus corresponded to 65.0 cc. of $N/20$ sodium hydroxide. The distillate of 100 cc. used 27.55 cc. of $N/20$ sodium hydroxide. The value of the semi-distillation of acetic acid (A) being 36.6% and that of the propionic acid (P) 57.7%, we obtain the equations $A + P = 65.0$ and $0.366\ A + 0.577\ P = 27.55$, which give $A = 47.2$ cc. of $N/20$ acid and $P = 17.8$ cc. of $N/20$ acid. The error in the acetic acid is −0.4% and that for the propionic acid, +1.1%.

Experiment 2.—In 200 cc. there was 23.6 cc. of $N/20$ acetic acid, 13.7 cc. of $N/20$ propionic acid and 24.0 cc. of $N/20$ butyric acid. Two fractions of 50 cc. were distilled, one of which consumed 18.5 cc. and the other 15.7 cc. of $N/20$ sodium hydroxide. The values of the semi-distillation being 36.6% for acetic acid, 57.7% for propionic acid and 74.0% for butyric acid, and the values of the quarter-distillation being 17.2% for acetic acid, 30.0% for propionic acid and 43.0% for butyric acid, we find the equations $A + P + B = 61.3$, $0.172\ A + 0.3\ P + 0.43\ B = 18.5$ and $0.366\ A + 0.577\ P + 0.74\ B = 34.2$, of which $A = 23.2$ cc. of $N/20$ acid, $P = 14.4$ cc. of $N/20$ acid, and $B = 23.7$ cc. of $N/20$ acid. The error as to the acetic acid is −1.7%; propionic acid, +5.1%; and butyric acid, −1.3%.

The above experiments show that by using the method of distillation it is possible to determine with great accuracy two volatile substances in the same solution when the time of distillation and the effect of the concentrations upon the value of the semi-distillation are taken into consideration. From our determinations it is evident that the best results will be obtained when each component has a value of semi-distillation which corresponds to the total concentration of acids in the solution. Thus, if there are in the solution, for example, 70 cc. of $N/20$ acetic acid and 30 cc. of $N/20$ butyric acid, for each acid the value of semi-distillation which corresponds to the concentration of 100 cc. $N/20$ must be used.

If the solution contains, at the same time, three volatile substances, it is possible to determine them with a comparatively great accuracy as is evident from Experiment 2. If four different substances have to be determined in the same solution, the errors will be very great.

The method of distillation is applicable in general to the determination of volatile substances of which the constant of distillation is not very great. If the value of k exceeds 5, the errors become so great as to render quantitative determinations out of the question.

The volatile acids can be determined according to the method suggested above only in solutions which contain no other substances. Therefore, in analyzing the results of reactions the volatile substances must first be distilled over quantitatively by passing steam through the solution. In the case of a volatile substance which has a low constant of distillation it is advisable to add sodium chloride to the solution so as to promote the distillation (see last section). On the other hand, one must take into account that if there is present in the solution lactic acid, for instance, this also passes over to some extent with steam. In studying cultures of bacteria and similar solutions, it is most advantageous to proceed as follows.

The alcohols, aldehydes, etc., which may be present in the neutral solution are removed by evaporating to half the original volume. The solution is then rendered acid with sulfuric acid and the volatile acids are removed by a current of steam, measured quantities of distillate (200 cc. for example) being collected. If the solution contains such a substance as lactic acid, it, too, passes over after the volatile acids have been removed. The process is stopped when the last two or three distillates contain a constant small quantity of acid. In order to eliminate carbon dioxide, it is necessary to boil the first fraction under an upright reflux condenser. All of the distillates are titrated with barium hydroxide of known strength. The solutions are then united, concentrated in an evaporating dish to small volume and quantitatively transferred to a 250-cc. volumetric flask. The calculated amount of sulfuric acid to react with the barium is added and the flask is filled up to the mark with distilled water. After standing for some time to allow the barium sulfate to settle, 200 cc. of the clear liquid is taken for the analysis. If it is known in advance which acids are present in the solution it is possible to make the quantitative determination as explained above. In order to eliminate the lactic acid which may have distilled together with the others the volatile acids must be expelled quantitatively, by means of steam, from the residue left after 100 cc. has been distilled from the 200 cc. The concentration of the lactic acid is now so low that it does not distil over any more. In this way we determine the amount of volatile acids present in the residue and the calculations can be made according to the method explained above. In order to hasten the volatilization, an excess of sodium chloride must be added to the residue before steam distillation. This addition is absolutely necessary especially when formic acid is present in the solution, since it distils rather poorly from very dilute solutions.

If we do not know what volatile acids are present in the solution, then several fractions, for instance of 10 or 25 cc., must be distilled. From the constants of distillation calculated on a basis of different fractions it is usually possible to judge which acids are present in the solution. Depending on the solution and the acids present we can, of course, use other methods for the qualitative determination of the acids.

Some Constants of Different Organic Substances

In all of the determinations the above-mentioned apparatus was used. From 200 cc. either two fractions of 50 cc. or four fractions of 25 cc. were distilled. In this manner it has been possible to ascertain whether k has the same value in different fractions and, consequently, the substances to be investigated are pure. At the same time the influence of the concentration can be determined.

Organic Acids.—

Acid	Concn., N	k	Semi-dist. value, %	Acid	Concn., N	k	Semi-dist. value, %
Diethylacetic	0.018	4.57	95.4	*o*-Toluic	0.010	0.608	29.7
Chloro-acetic	.036	0.047	3.2	*m*-Toluic	.013	.420	25.2
Phenylacetic	.017	.070	4.8	*p*-Toluic	.009	.378	23.1
Pyruvic	.033	.074	5.0	Anisic	.006	.050	3.4

Acid	Concn., *N*	k	Semi-dist. value, %	Acid	Concn., *N*	k	Semi-dist. value, %
α-Crotonic	.012	.760	41.0	Cinnamic	.010	.102	7.4
Benzoic	.024	.270	17.1	o-Aminobenzoic	.020	.019	1.3
Salicylic	.020	.088	5.9				

Meta and p-aminobenzoic acids and a-, *m*- and *p*-nitrobenzoic acids are not volatile with steam. Levulinic, glycolic and lactic acids are distillable in small quantities but have no constants of distillation. The quantity of distilled acid does not increase in proportion to the concentration. This proves that the said acids are not, in the proper sense of the word, volatile acids. It is possible that anhydrides which are volatile are formed in the distillation.

According as the carbonic chain is prolonged and the solubility diminished, k increases in homologous series notwithstanding the rise of the boiling point. In the aromatic series the a-compounds distil best, then the meta. The *p*-compounds do not distil as well as the others.

Amines.—Many amines are so easily volatile as to be completely distilled by the removal of a half-volume. In these cases out of 200 cc. only *10* cc. was distilled and k was determined accordingly. In these cases an exact value for the constant could not be obtained. The amines were determined by titration with $N/10$ sulfuric acid with Congo Red as indicator.

Amine	Ammonia	Methyl	Ethyl	Propyl	Butyl	Diethyl
B. p.. °C.	−34	−6	+19	+50	+77	+56
Concn., N	0.02	0 02	0.03	0 02	0.02	0.02
k, approx.	13	11	20	30	40	43

An increase of one carbon atom in the homologous series of monovalent aliphatic amines raises the value of k by about 10 units.

Amine	Ethylene di-	Aniline	Methylaniline	Benzyl	Benzyl	a-Naphthyl
Concn., *N*	0.03	0.05	0.03	0.02	0.20	0.01
k	.02	5.51	16	3.27	3.25	1.05
Semi-dist., %	1.4	98.6	...	89.6	89.5	51.7

β-Naphthylamine evaporates copiously but solidifies in the condenser. The value of k could not be determined. In some of the experiments aniline was determined by titration with a solution of $N/10$ sodium nitrite (0°); in other experiments by determining nitrogen by the Kjeldahl method. Methylamine also was determined by the latter method.

Phenols.—

Compound	Phenol	*p*-Chloro-	*p*-Nitro-	m-Nitro-	Thymol
Concn., N	0.10	0.01	0.07	0.06	0.06
k	1.94	1.30	.005	.01	12
Semi-dist., %	74.1	59 *6*	.35	.85	...

Phenol, p-chlorophenol and thymol were determined by titration with a solution of bromine. The nitrophenols could be titrated with $N/20$ sodium hydroxide by using phenolphthalein as indicator.

It is evident from the values given above that chlorine in replacing hydrogen in the benzene ring does not exert a noteworthy influence upon the volatility. On the contrary the nitro-group diminishes the volatility enormously. Of the nitro compounds the m-derivative is distilled better than the para. The influence of the position of the substituent has been proved to be the same in the cases of other substances.

Aldehydes.—The aldehydes were determined by titration with potassium bisulfite and a solution of iodine.

Compound	Formaldehyde	Acetaldehyde	Benzaldehyde	Anisaldehyde
Concn., N	0.03	0.01	0.01	0.01
k	2.6	Above 40	18	**3.1**
Semi-dist., %	83.0	...	...	88.5

Alcohols.—

Alcohol	Methyl	Ethyl
Concn., % by weight	0.05	0.10
k	8.9	12.5

Methyl and ethyl alcohols were determined according to Kuriloff by oxidation with a solution of sulfuric acid and bichromate of potash, which oxidizes ethyl alcohol quantitatively to acetic acid and methyl alcohol to carbon dioxide. The solution to be investigated was heated for three hours at 100° together with an oxidizing solution in a closed pressure flask. The quantity of alcohol was calculated according to the quantity of bichromate used. The precision of the method is 1%.

From these investigations the conclusion is reached that volatility with steam of water-soluble substances depends to a large extent upon the degree of hydration of these substances in solution. The lower members of an homologous series (for example formic acid in the series of fatty acids) are distilled much less easily than the higher members, although from the boiling points the reverse would be expected to be true. Since the value of k in an homologous series shows a regular increment with each added carbon atom (0.6 for fatty acids, 10 for amines), this evidently depends upon the fact that the degree of hydration regularly decreases as the carbon chain is lengthened. This is verified by the diminution in solubility. It is evident then that the effect of neutral salts upon the steam distillation is one of diminution of hydration of the volatile substance. The subject is treated more fully in the following section.

The Effect of Salts upon the Volatility of Substances with Steam

Neutral salts have in general a stimulating effect upon the constant of distillation, the influence of each salt having a different force. The investigations previously made by Virtanen show that the effect of the anions is most important, while that of the cations is much weaker. The influence of the different salts upon the distillation of acetic acid in dilute solution is shown by the curves in Fig. **2**. In distilling acetic acid in a saturated sodium chloride solution a value of $k = 2.3$ is obtained and, consequently, in distilling the semi-volume of the solution a quantity of 80% is distilled (of a pure water solution 36.6%). In the aforesaid investigation it has already been shown that the influence of salts upon the distillation of different acids is different. Fig. **3** indicates the distillation of different acids from a sodium chloride solution. The curves of formic acid and of acetic acid (both entirely soluble in water) are fairly straight lines, while the curves of less soluble acids the solubilities of which are appreciably diminished by the salts, rise more or less.

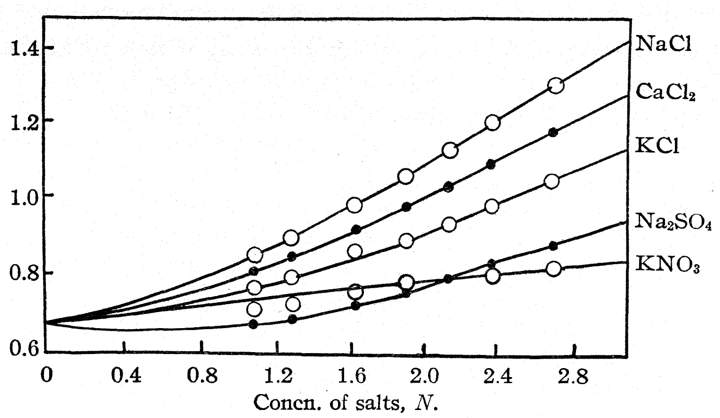

Fig. 2.—The curves indicate the influence of different salts upon the distillation of acetic acid.

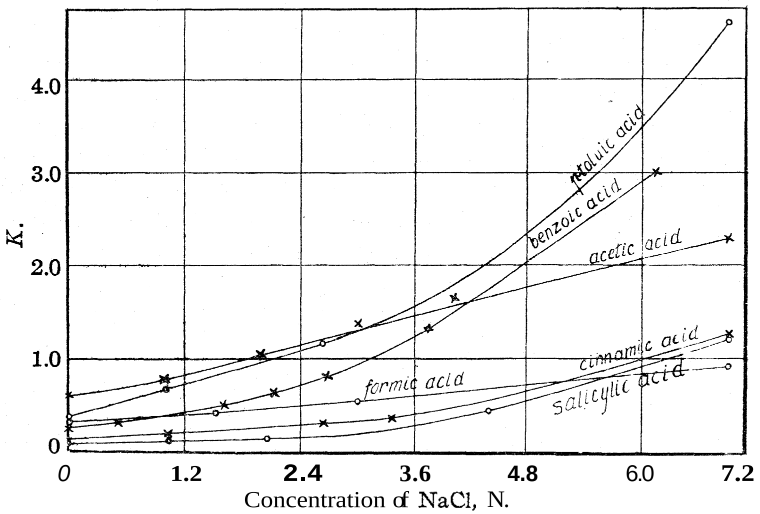

Fig. 3.—Influence of NaCl upon the distillation of some organic acids.

The question as to the real influence of the salts upon the distillation with steam has already been treated by Virtanen in a publication mentioned above. The rise in boiling point produced by the salt does not considerably alter the distillation. This is evident from the fact that several substances which are apt to raise the boiling point as much and even more than sodium chloride do not in a noteworthy degree raise the value of k. For example, the sodium acetate facilitates very little the distillation of acetic acid and glycerin does not in a noteworthy degree change the value of k, not even in a solution of 25%.

The volume mechanically taken up by the salts and the diminution of the quantity of water due thereto are not sufficient to explain the great influence of numerous salts. In 200 cc. of a solution of 1 *N* sodium chloride there are about 196.3 cc. of water at 20°. This small change in the volume of water cannot have much influence upon the value of k.

The only plausible explanation as to the influence of salts is that the salts in being hydrated or, in other words, in uniting themselves more or less firmly with the water molecules, diminish the hydration of the organic substances so that these substances detach themselves from the water molecules. Should this be the case, it is probable that the influence of the salts upon the solubility of volatile substances is, at least to some extent, to be compared to the influence of these salts in the distillation by steam. This appears, in general, to be the case, though unexpected exceptions are to be found, through the parallel determinations of the influence of some salts upon the solubility and upon the distillation of benzoic acid and salicylic acid. Fig. 5 shows the influence of the salts upon the volatility and upon the solubility of benzoic acid.

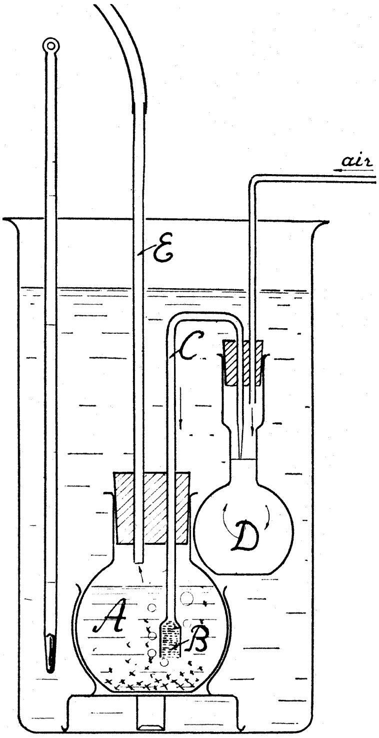

Fig. 4.

The distillation was determined so that out of 200 cc. one fraction of 25 cc. was always distilled. The determinations of solubility were made by using the apparatus shown in Fig. 4. The whole apparatus is submerged in boiling water (100"). The substance to be examined is dissolved in bottle **A.** From this the saturated solution is blown through the glass filter B and pipe C into the **25cc.** volumetric flask (D), from which the solution can be taken for titration. Stirring is effected by means of air flowing in the opposite direction, being forewarmed to 100° in the flask D. The pipe E leads to the vertical condenser, which prevents the water evaporating from the solution in the bottle A.

Of the salts investigated, sodium chloride most diminishes the solubility of benzoic acid. The influence of this salt upon the distillation of benzoic acid is also most effective. Sodium nitrate diminishes the solubility of benzoic acid to a less extent and correspondingly its effect upon the constant of distillation is also small. Sodium sulfate decreases the solubility more than sodium nitrate. In a weaker concentration, up to a normality of 2.5, sodium sulfate diminishes, strangely enough, the distillation of benzoic acid as well as that of other acids. To what this is due is, at present, inexplicable. Fig. 5 shows graphically the effect of sodium chloride, sodium sulfate and sodium nitrate upon the solubility and distillation of benzoic acid.

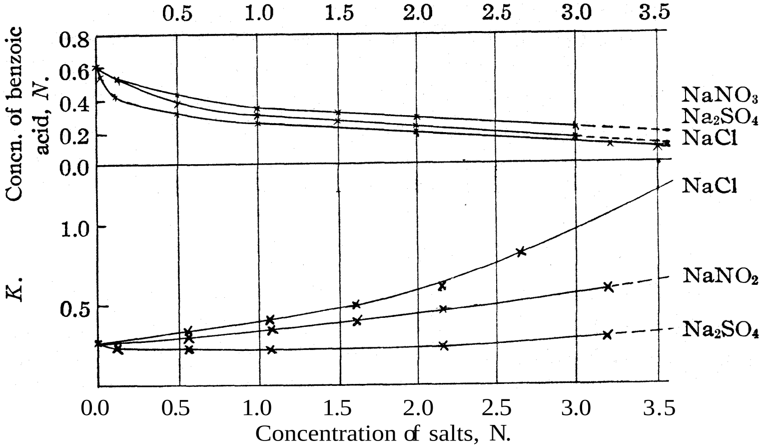

Fig. 5.—The curves in the upper figure indicate graphically the solubility of benzoic acid in NaCl, $NaNO_3$ and Na_2SO_4 solutions of different concentrations. The lower figure shows correspondingly the effect of the same salts upon the values of the distillation constant, k.

The hydration of acids has been shown to diminish at the same time that the degree of dissociation diminishes,[8] and it is to be concluded, accordingly, that the ions hydrate themselves. Since in the series of fatty acids the dissociation of acids diminishes at the same time that the molecular weight augments, it might be supposed that the weaker distillation of the first fatty acids would be due to their greater ionization in the diluted solutions. This opinion is, however, contradicted by the observation that if in the diluted solutions of acetic and formic acids alkaline salts of the same acids are added while the dissociation of acids diminishes to a minimum, the distillation of acids augments much less than through

---

[8] Kendall, Booge and Andrews, THIS JOURNAL, **39**, **2303** (1917).

many other salts. On the contrary, the constant of the distillation of formic acid diminishes somewhat. As the great reduction in the dissociation of acetic and formic acids by no means essentially affects the distillation of these acids by steam, it is evident that it is chiefly through the hydration of the non-dissociated molecules of acids that the acids attach themselves to water.

The tendency of the electrolytes to unite molecules of water to themselves causes changes in the solutions which occur in many different ways. Especially have those changes been investigated which are caused by the neutral salts in the dissolution of the different substances.[9]

Wiegner, Magasanik and Virtanen[10] have investigated the influence of salts upon the adsorption of fatty acid by bone-charcoal and have found that the absorption becomes more effective, for example, through the influence of sodium chloride. We can in general find a great analogy in the influence of salts upon the distillation and adsorption of fatty acids. This is quite natural, for the detachment of acids from water through the influence of salts is the reason why acids escape more easily in steam and why they attach themselves more easily to adsorbent substances.

We will later on enlarge upon the question as to the distillation by steam of substances soluble in water and on the influence of salts.

Summary

The steam distillation of substances soluble in water and passing over with steam gives a possibility of determining whether the substance to be examined is pure or contains other substances belonging to the same group, for instance homologs. As a quantitative means of expression for the distillation of a substance with steam, either the distillation constant, k, or half-distillation, or one-fourth distillation value, respectively, can be employed.

By means of steam distillation volatile substances can be determined according to a very simple method. This mode of determination has been developed very accurately in this study. If there are in the same solution two substances belonging to the same group (for example, organic acids), they can be determined by means of a single fraction with considerable accuracy. If there are three substances, then the determination may be made by means of two fractions. The time of distillation and the variations of concentration in solutions have an appreciable effect on the course of distillation. If the volatility of the substance is so great that the value of the distillation constant k is above 5, the steam distillation cannot easily be used for the quantitative determination of the substance.

[9] Geffken, *Z. physik. Chem.*, 49, 257 (1904); Euler, *ibid.*, 49, 303 (1909); Rothmund, *ibid.*, 40, 611 (1902).

[10] Wiegner, Magasanik and Virtanen, *Kolloid-Z.*, 28, 51 (1921).

Distillation constants have been determined for many organic substances belonging to different groups. In homologous series the value of k increases with the lengthening of the carbon chain. This is obviously due to the decline in hydration as the molecular weight increases.

The effect of salts upon the steam distillation is powerful. Among the salts studied sodium chloride has in the greatest degree raised the value of k. The influence of anions is obviously much more intense than that of cations.

The effect of the salts upon the distillation of different substances is variable (Fig. **3**). The curves indicating the dependency of k on salt concentration rise rather rectilinearly for those substances which dissolve indefinitely in salt solutions, while for those substances which do not dissolve indefinitely in water and which in part separate from water through the effect of salts, k rises with the increase in salt concentration so powerfully that the curve arches strongly upward.

The promoting effect of salts upon distillation is obviously due to the fact that they diminish the hydration of the substance, especially of undissociated molecules. The promoting effect of salts upon distillation can to a great extent be turned to advantage in distinguishing volatile from non-volatile compounds.

A NEW EQUATION OF STATE FOR FLUIDS. III. THE NORMAL DENSITIES AND THE COMPRESSIBILITIES OF SEVERAL GASES AT 0°

BY JAMES A. BEATTIE AND OSCAR C. BRIDGEMAN[1]

RECEIVED JUNE 8, 1928 PUBLISHED DECEMBER 10, 1928

The compressibility of gases at 0° and at pressures up to one atmosphere is of great importance in the determination of the atomic weights of the inert gases from density measurements and for the calculation of the normal densities of those gases whose molecular weights can be determined by chemical analysis. The experimental evaluation of the ratio of the pressure–volume product at 0" and at one atmosphere, p_1V_1, to the product at zero pressure, p_0V_0, is difficult, and it is believed that this ratio can be obtained for any gas for which there are extensive p–V–T data with as great an accuracy from the equation of state.

The relations between these quantities are given by the equations

$$p_0V_0/p_1V_1 = 1 + \lambda \tag{1}$$

$$p_0V_0 = (m/M)\ RT_0 \tag{2}$$

$$d_n = \frac{m}{V_1} = \frac{M(1 + \lambda)}{RT_0} \tag{3}$$

---

[1] **National Research Fellow in Chemistry.**

where λ is a constant for a given gas, M is its molecular weight, R is the gas constant per mole and T_0 is the value of 0° on the Kelvin scale. In Equation I the ratio p_0V_0/p_1V_1 can refer to any quantity of gas, but in Equation **2** the product p_0V_0 is taken for m grams. Combination of these relations leads to Equation **3,** in which d_n is the normal density of the gas, that is, the weight in grams of one liter of the gas at 0° and one atmosphere pressure.

Thus if RT_0 is known and a value of λ is available, the molecular weight of the gas can be calculated from the normal density. If, on the other hand, the molecular weight has been determined by chemical means, the normal density can be calculated.

Recently the authors have proposed a new equation of state[2]

$$p = \frac{RT\,(1-\epsilon)}{V^2}\,[V+B] - \frac{A}{V^2}$$

$$A = A_0(1 - a/V). \quad B = B_0(1 - b/V). \quad \epsilon = c/VT^3 \qquad (4)$$

in which R is the gas constant and A_0, a, B_0, b and c are constants for each gas.

The values of these constants have been determined[3] for the ten gases helium, neon, argon, hydrogen, nitrogen, oxygen, air, carbon dioxide, methane and ether. The equation was found to reproduce the experimental pressure–volume–temperature data over wide ranges of temperature and density very satisfactorily. In the present article advantage is taken of this correlation to compute the values of p_0V_0/p_1V_1 and hence of λ for the nine of the above substances which are gases at 0° and one atmosphere; and then by use of Equation **3** to calculate the normal density of those gases for which the molecular weight can be determined by chemical means, and also to compute the molecular weights from the best values of the normal densities.

When working at constant temperature, it is more convenient to transform the Equation of state 4 into the virial form

$$\begin{aligned} pV &= RT + \beta/V + \gamma/V^2 + \delta/V^3 \\ \beta &= RTB_0 - A_0 - Rc/T^2 \\ \gamma &= -RTB_0b + A_0a - RB_0c/T^2 \\ \delta &= RB_0bc/T^2 \end{aligned} \qquad (5)$$

For the gases under consideration at 0° and one atmosphere, the term δ/V^3 is negligible, and on the average γ/V^2 affects the calculated value of p_1V_1 by one part in 300,000, while β/V contributes one part in 600. In the least favorable case—carbon dioxide—these last two terms are about three times as large. Thus if β is known to only 1%, the uncertainty introduced into p_1V_1 is on the average 0.002%, while for carbon dioxide it is 0.007%.

[3] Beattie *and* Bridgeman, *ibid.*, 50, 3133 **(1928).**

In the determination of the equation of state constants from the pressure–volume–temperature data, the values of R and T_0 used were 0.08206 and 273.13 in units of international atmospheres for pressure, liters per mole for volume, and degrees Kelvin for temperature.[4] These give 22.4131 for RT_0, which is in good agreement with the value 22.4133 recently found by Baxter and Starkweather,[5] based on their determinations of the density of oxygen.

In Table I are listed the values at 0° of the parameters β, γ and δ calculated from the equation of state constants by means of the relations (5). It should be noted that these values are based on the correlation of the pressure–volume–temperature data of different investigators for each gas, over the whole temperature range and a wide density range, thus tending to eliminate both constant and accidental errors.

TABLE I

VIRIAL COEFFICIENTS AT 0° COMPUTED FROM THE EQUATION OF STATE

R = 0.08206; T_0 = 273.13; RT_0 = 22.4131 (g = 980.665). Units: international atmospheres, liters per mole, degrees Kelvin.

Gas	β	$\gamma \times 10^3$	$\delta \times 10^6$	Gas	β	$\gamma \times 10^3$	$\delta \times 10^6$

N_2	− .25974	40.669	− 16.1	Air	−0.31547	34.303	− 24.2

N* denotes values of the constants obtained from a consideration of the data of Smith and Taylor alone.

In Table II are given the details of the calculation of the ratio p_0V_0/p_1V_1 from the coefficients of Table I, by means of the relation

$$\frac{p_0V_0}{p_1V_1} = \frac{RT_0}{RT_0 + \beta/V_1 + \gamma/V_1^2 + \delta/V_1^3} = 1 + \lambda \qquad (6)$$

In the second column of this table are listed values of $p_1V_1 - RT_0$, that is, $\beta/V_1 + \gamma/V_1^2 + \delta/V_1^3$, which indicates the magnitude of the quantity which is obtained from the equation of state. In the third are given values of p_1V_1 calculated by use of Equation 5. Since the volume is contained implicitly in this relation, the perfect gas value, 22.41, was assumed for the first approximation. The convergence was very rapid, the next approximation giving the final value of p_1V_1. In the last two columns are listed the values of λ calculated from Equation 6 and those

---

[4] This value of R is used in the "International Critical Tables" and was derived by Keyes, *Amer.* SoG. *Refrig. Eng J.*, *8*, 505 (1922); the value of T_0 was determined by Buckingham, *Bull. Bureau Standards*, 3, 237 (1907), and has been used for many years in this Laboratory.

[5] Baxter and Starkweather, *Proc.* Nat. *Acad. Sci.*, 10, 479 (1924); *ibid.*, 12, 699 (1926), give the value 22.4144 using 980.616 for *g*, and this was reduced to the international gravity, 980.665.

selected by Pickering.[6] It should be noted that the variations of the measured values obtained by different observers are large.

[a] Observed values are those given in "International Critical Tables," Vol. III, p. 3.

The values of λ calculated from the equation of state can be used to compute the normal density of those gases whose molecular weights can be determined by chemical means. The method of carrying out the calculation is evident from a consideration of Equation **3** and the results are given in Table III. The atomic weights given in "International Critical Tables," Vol. I, were used, and the resultant weights of a normal liter are compared with those selected by Blanchard and Pickering.[7]

the measured values of Baxter and Starkweather (reduced to g = 980.665), and the selected values of Blanchard and Pickering (which only in the case of helium and oxygen include a consideration of the measurements of the former) are used in the computation of the molecular weights of the various gases. The results are compared with the values given in the "International Critical Tables," Vol. I. For those gases whose molecular weights can be determined by chemical analysis, this comparison is given as an indication of the consistency of the measured normal density and calculated X, with the molecular weight. The agreement in general is excellent.

[a] B. and P. = Blanchard and Pickering; B. and S. = Raxter and Starkweather.

The calculated values of X depend only on the equation of state constants of the various gases and the value of RT_0, and small errors in the latter evidently tend to cancel. The deviations between the observed and calculated values of X and of the normal densities and molecular weights shown in Tables II to IV are well within the variations between the determinations of different observers except for the gas oxygen. Thus, for instance, Moles[9] gives 1.25062 as the normal density of nitrogen, while the review of the normal densities of gases given by Blanchard and Pickering shows a rather wide variation in the experimental determinations. In the case of oxygen, however, the value of λ calculated from the equation of state seems to be too large, which gives too large a value for the normal density. The equation of state of oxygen reproduces the experimental compressibility data quite satisfactorily in the neighborhood of 0°. Moreover, since the values of λ calculated for other gases from the equation of state agree well with the experimental values, it seems reasonable to assume

---

[9] Moles, *Gazz chim. ital.*, 56, 915 (1926). The value was reduced to g = 980.665,

that the discrepancy in the case of oxygen is due to an inconsistency between the compressibility and the normal density data.

The value of λ and the weight of a normal liter have been determined experimentally for carbon monoxide and nitrous oxide, but the compressibility data on these gases are too fragmentary to allow of the evaluation of their equation of state constants. Langmuir[10] has pointed out that the physical properties of CO and N_2O are very similar to those of N_2 and CO_2, respectively. He has postulated that the external arrangements of the electrons are the same in CO and N_2, and in N_2O and CO_2; and thus in each pair the electrical fields are quite similar. The constants of the equation of state are probably due largely to the external electrical fields and hence the constants of CO and N_2O should be close to those of N_2 and CO_2. In Table V the experimentally determined values of λ and of the weight of a normal liter of CO and N_2O selected by Blanchard and Pickering[7] are compared with those calculated from the equation of state, using the values of the constants of N_2 and CO_2, respectively. The agreement is good and indicates that at moderate pressures and at temperatures which are not too near the critical temperature, the thermodynamic properties of CO and N_2O can be calculated by use of the equation of state constants for N_2 and CO_2.

TABLE V

COMPARISON OF OBSERVED AND CALCULATED VALUES OF λ AND OF THE WEIGHT OF A NORMAL LITER OF CO AND N_2O

Gas	Mol. wt., I. C. T.	$\lambda \times 10^3$ (calcd.)	$\lambda \times 10^3$ (obs.)	Wt. of liter (calcd.)	Wt. of liter (obs.)
CO	28.000	+0.51	+0.5	1.2499	1.250_4
N_2O	44.016	+6.82	+7.4	1.9772	1.977_8

Calculated values are obtained by use of the equation of state constants for N_2 and CO_2, the isosteres of CO and N_2O. Observed values are those given in "International Critical Tables."

Summary

The equation of state proposed by the authors is used to calculate values of the ratio at 0° of the pV products at one atmosphere and at zero pressure for several gases, and a brief discussion is given concerning the merits of this particular method and its accuracy. These ratios are then employed to compute the weights of a normal liter of hydrogen, oxygen, nitrogen, carbon dioxide and methane, whose molecular weights can be determined by chemical means, and a good agreement is obtained with accepted values. The molecular weights of the gases named above and of helium, neon, argon and air are calculated from the normal densities, and the agreement with the "International Critical Tables" values is very good. The agreement obtained in these calculations indicates that the

---

[10] Langmuir, THIS JOURNAL, 41, 868, 1543 (1919).

equation of state extrapolates to low pressures with a high degree of accuracy.

The values at 0° of the ratio of the pV product at one atmosphere to that at zero pressure, and the weights of a normal liter of CO and N_2O are calculated from their molecular weights and the values of the constants of the equation of state of their isosteres, namely N_2 and CO_2. The agreement with the observed values is very good, and indicates that for many thermodynamic calculations the constants of N_2 and CO_2 can be used for CO and N_2O, respectively.

THE IONIC CONCENTRATIONS AND ACTIVITY COEFFICIENTS OF WEAK ELECTROLYTES IN CERTAIN SALT SOLUTIONS

BY HERBERT S. HARNED AND ROBERT A. ROBINSON[1]

RECEIVED JUNE 15, 1928 PUBLISHED DECEMBER 10, 1928

The electromotive forces of cells of the types

$$Ag \mid AgX \mid HX(m_0),\ MX(m) \mid H_2 \mid HX(m_0) \mid AgX \mid Ag$$

and

$$H_2 \mid MOH(m_0),\ MX(m) \mid M_xHg \mid MOH(m_0) \mid H_2$$

have proved very useful in determining the activity coefficients of some strong acids and hydroxides in certain salt solutions.[2] In the cases so far considered, this method has been applied to the class of strong acids and hydroxides. The question naturally arises as to whether measurements of this kind cannot be extended so as to determine the activity coefficients of weak acids and hydroxides in salt solutions of varying strengths as well as the hydrogen and hydroxyl ion concentrations of weak acids and hydroxides in these solutions.

It is the purpose of this study to show that this information may be acquired by measurements of cells without liquid junction potentials. Furthermore, this result can be accomplished with cells which contain easily reproducible electrodes such as the hydrogen and silver–silver chloride electrodes. The limitations of the method are for the most part experimental and depend on the difficulty of obtaining the reversible electro-

motive force of the hydrogen electrode in solutions containing hydrogen or hydroxyl ion at very low concentrations and salts at high concentrations.

This opens up a wide field for investigation, since we shall be able to study the effect of the powerful fields of electrolytic solutions upon the characteristic potentials of the organic cations and anions, and make preliminary attempts to parallel this property with the ion constitution. Further, these results may be compared with results obtained from catalytic data by Harned and Hawkins[3] and the values of the ionic activity coefficients of water in salt solutions.[4,2i,j]

Outline of the Method

The activity coefficient of a weak electrolyte may be defined in two ways. Assuming that the activity product, a_Ca_A, of the ions of a uni-univalent weak electrolyte has been determined, wc may define an activity coefficient by either

$$\text{(a)} \quad \gamma = \sqrt{\frac{a_Ca_A}{m_Cm_A}} \quad \text{or} \quad \text{(b)} \quad \gamma = \sqrt{\frac{a_Ca_A}{m_+m_-}}$$

In (a) m_C and m_A are the stoichiometrical molalities of the ion groups of the electrolyte which would be computed in just the same way as in the case of a strong electrolyte. Thus, in a solution of $HAc(m_1) + NaAc(m_2)$, m_C equals m_1 and m_A equals $(m_1 + m_2)$, and in a solution of $HAc(m_1) + NaCl(m_2)$, m_C equals m_A equals m_1.

In (b), m_+ and m_- are the true molal concentrations of the ionic species. It is the second of these quantities which is the subject of the present study. In fact, the second is the more important since this quantity is directly comparable to the activity coefficients of strong electrolytes and to the potentials of ionic solutions in general.

In the first place, we shall consider the determination of the activity coefficients of a weak acid in a salt solution. Let us consider the simple cells

$$H_2 \mid HAc(m_1),\ MX(m_2) \mid AgX \mid Ag \qquad (1)$$
$$H_2 \mid HX(m_0),\ MX(m_3) \mid AgX \mid Ag \qquad (2)$$

where HAc is a weak acid and HX is a strong acid. Subtract (2) from (1) and obtain

$$Ag \mid AgX \mid HX(m_0),\ MX(m_3) \mid H_2 \mid HAc(m_1),\ MX(m_2) \mid AgX \mid Ag \qquad (3)$$

The cell reaction of **(3)** represents the transfer of HX from the solution containing HX to the solution containing HAc. The electromotive force of **(3)** is therefore given by

$$\mathbf{E} = \mathbf{0.05915}\,\log \frac{\gamma_{H(2)}\gamma_{X(2)}\,m_0(m_3 + m_0)}{\gamma_{H(1)}\gamma_{X(1)}\,m_Hm_0} \qquad (4)$$

where $\gamma_{H(2)}\gamma_{X(2)}$ is the activity coefficient product of the ions in the solution

---

[3] Harned **and** Hawkins, THIS JOURNAL, **50, 85** (1928).

[4] Harned, *ibid.*, **47, 930 (1925).**

containing HX only and $\gamma_{H(1)}\gamma_{X(1)}$ the same in the solution containing HAc; m_H is the stoichiometrical molality of the hydrogen ion.

We shall now consider the conditions under which $\gamma_{H(1)}\gamma_{X(1)}$ may be taken equal to $\gamma_{H(2)}\gamma_{X(2)}$. Throughout this discussion, let it be understood that the total ionic strengths of the two solutions are equal. Thus,

$$m_3 + m_0 = m_H + m_2$$

Assume that the molality of the weak acid is low enough so that the presence of the undissociated molecule of the acid causes no appreciable change in $\gamma_{H(1)}\gamma_{X(1)}$. It has been shown for mixtures of strong electrolytes of these types that a constant total molality of the ions

$$\log \gamma_{HX} = \alpha m_{HX} + \log \gamma_0 \qquad (5)$$

where α is a constant, γ_{HX} equals $\sqrt{\gamma_H\gamma_X}$ and γ_0 equals γ_{HX} when m_{HX} equals zero.[2d,1] The values of the constants α for the different salt solutions are such that γ_{HX} practically becomes independent of the acid concentration in solutions containing less than 0.01 M HX. This is illustrated in Fig. 1 in which γ_{HCl} in a potassium chloride solution is plotted against the logarithm of the acid concentration. The total concentration of the acid and the salt is 3 M. Thus at concentrations below 0.01 M hydrochloric acid, the plot becomes parallel to the abscissa. To be exact, at 0.01 M, γ_{HCl} equals 0.860, and at 0.001 M it equals 0.859, corresponding to a difference of less than 0.1 mv. Thus, if $m_{H(1)}$ and m_0 are 0.01 M or less, $\gamma_{H(1)}\gamma_{Cl(1)}$ may be taken equal to $\gamma_{H(2)}\gamma_{Cl(2)}$ without introducing an error greater than the experimental. Equation 4 becomes

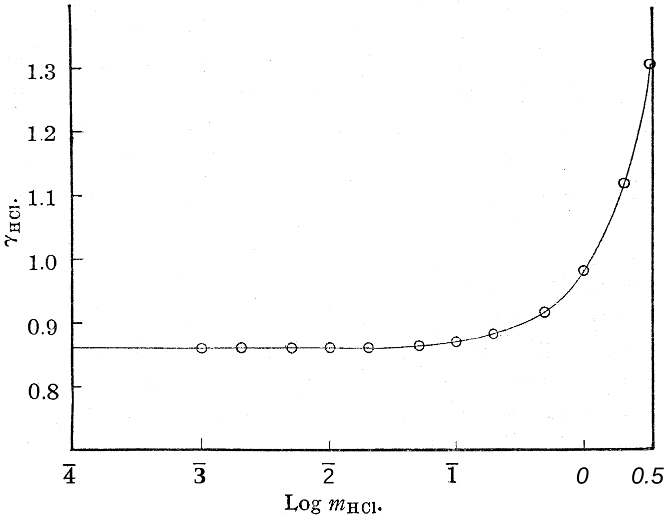

Fig. 1.—γ–log m plot of hydrochloric acid in potassium chloride solutions at a constant total molality of 3.

$$E = 0.05915 \log \frac{m_0(m_0 + m_3)}{m_H m_2} \tag{6}$$

and since m_0, m_2 and m_3 are known, m_H may be computed.

After having computed m_H by Equation 4 or Equation 6, the calculation of $\gamma_H\gamma_{Ac}/\gamma_{HAc}$ becomes a simple matter since the thermodynamic equation for the dissociation of HAc is

$$K = \frac{\gamma_H\gamma_{Ac}}{\gamma_{HAc}} \frac{m_H^2}{m_1 - m_H} \tag{7}$$

and K, m_1 and m_H are known.

That exactly similar considerations will apply to the determination of the activity coefficient products of weak hydroxides in salt solutions from measurements of cells of the type

$$H_2 \mid MOH(m_0),\ MX(m_3) \mid M_xHg \mid BOH(m_1),\ MX(m_2) \mid H_2 \tag{3a}$$

where MOH is a strong and BOH a weak hydroxide, may readily be shown.

For this case, the equation corresponding to Equation 4 will **be**

$$E = 0.05915 \log \frac{\gamma_{M(2)}\gamma_{OH(2)}\ m_0(m_3 + m_0)\ a_{H_2O(1)}}{\gamma_{M(1)}\gamma_{OH(1)}\ m_{OH}\ m_2\ a_{H_2O(2)}} \tag{4a}$$

where the subscript (2) refers to the solution containing the strong, and (1) to that containing the weak hydroxide. Since the ratio of the activity of water in the two solutions will be unity, and since for low concentrations of the weak base we may take the activity coefficient ratio in the two solutions as unity, we obtain

$$E = 0.05915 \log \frac{m_0(m_3 + m_0)}{m_{OH}\ m_2} \tag{6a}$$

which corresponds to Equation 6.

In many cases it may be simpler from the point of view of experiment to measure cells with salt bridges such as

$H_2 \mid HX(m_0),\ MX(m_3) \mid$ sat. KCl $\mid HAc(m_1),\ MX(m_2) \mid H_2$
$H_2 \mid MOH(m_0),\ MX(m_3) \mid$ sat. KCl $\mid BOH(m_1),\ MX(m_2) \mid$ *Ha*

In the case of the latter cells, the difference in the two liquid junction potentials will be very small provided that the hydrogen-ion concentrations in the first and the hydroxyl-ion concentrations in the second are the same on both sides of the salt bridge. If we apply the above considerations to these cells, then at small concentrations of HAc and BOH (not above 0.5 M), the electromotive force is a measure of the ratio of the hydrogen or hydroxyl-ion concentrations in the two electrode compartments.

So far we have assumed that the concentration of the undissociated molecule, HAc, is so low that it has only a negligible effect on $\gamma_{H(1)}\ \gamma_{X(1)}$. At higher concentrations of HAc, the absolute value of $\gamma_{H(1)}\ \gamma_{X(1)}$ relative to pure aqueous solution will increase with increasing concentration of the undissociated molecule. Thus, Harned and Fleysher[5] have found that

---

[5] Harned and Fleysher, THIS JOURNAL, 47, 82 (1925).

$\gamma_H\gamma_{Cl}$ in a 0.01 M acid solution in water increases 3 1 times its initial value on the addition of 25 mole per cent. of ethyl alcohol. From the nature of the plot of their results, the presence of 0.1 M ethyl alcohol would cause an increase of somewhat less than 0.5% in $\gamma_{H(1)}\gamma_{X(1)}$. Consequently, Equation 6 is only exactly valid at zero concentration of HAc, but is valid to within less than 1.2% for solutions containing 0.2 M HAc or less, if we presume that the effect of undissociated acetic acid upon the activity coefficient is not greater than that of ethyl alcohol. Equation 6 will be strictly valid in the case of the cells

$$\mathrm{Ag} \mid \mathrm{AgCl} \mid \mathrm{HX}(m_0),\ \mathrm{M}(m_4),\ \mathrm{MX}(m_3) \mid H_2 \mid \mathrm{HAc}(m_1),\ \mathrm{MX}(m_2) \mid \mathrm{AgCl} \mid \mathrm{Ag}$$

provided that **M** is an undissociated molecule at a concentration $m_4 = (m_1 - m_H)$ which produces the same effect on $\gamma_{H(1)}\gamma_{X(1)}$ as does the undissociated acetic acid.

Since the present study contains extensive determinations of $\gamma_H\gamma_{Ac}/\gamma_{HAc}$ and $\gamma_B\gamma_{OH}/\gamma_{BOH}$ in aqueous solutions, we have not thoroughly investigated the above effect at this time. We have, however, obtained a few series of results with acetic acid at high concentrations in sodium chloride solutions which we shall use to illustrate the magnitude of this effect.

Part 1. The Ionic Concentrations and Activity Coefficients of Acetic Acid in Salt Solutions

Experimental Results and Method of Numerical Calculation.—The cells measured were of the type

$$\mathrm{H_2} \mid \mathrm{HAc}(m_1),\ \mathrm{MX}(m_2) \mid \mathrm{AgCl} \mid \mathrm{Ag} \qquad (8)$$

Extended series of measurements of cells containing 0.1, 0.2, 0.5, 1.0, 5.0 and 10 M acetic acid were made in each of which sodium chloride was varied over a concentration range of 0.02 to 3 M. Further, a series of determinations of cells containing acetic acid at a concentration of 0 2 M and potassium, lithium and barium chlorides of varying strengths was made, as well as a series of cells with 0.1 M acetic acid and potassium chloride. The acetic acid and salts were of a high grade of purity. The potassium and sodium salts were dried at a suitable temperature, barium chloride was used in the form of the dihydrate and the lithium chloride solutions were made by dilution of an analyzed concentrated solution.

The silver–silver chloride electrodes were of the spiral type. The silver oxide paste was heated at 500° on the platinum spiral. No electrolytic silver was deposited on the spiral previous to this operation. Electrodes made in this way have the same potential as those made by the Noyes and Ellis method.

The hydrogen electrodes were of the usual platinum foil type and were found to give reproducible results in all cases except those of the cells containing 0.1 M acetic acid. In the latter case, with cells containing either sodium or potassium chlorides, it was found impossible to obtain electromotive forces corresponding to reasonable values of the activity coefficient of acetic acid unless the platinum foils were coated with an extremely thin film of platinum black. With this additional precaution, potential readings were obtained which are thought to be reasonably close to the correct ones, but a high degree of accuracy is not claimed. This source of error is in accord with the experiments of Harned.[2d] He found that in solutions containing hydrochloric acid and sodium or potassium chlorides (of constant total molality) the hydrogen electrode as usually prepared was unreliable at acid concentrations below 0.002 M to 0.005 M. He showed that very thinly coated electrodes improved the situation but did not completely eliminate the error when the salt to acid ratio was very high. Our observations agreed with his, since the error was found to be the greater. the higher the salt concentrations.

In the cells containing acetic acid at 0.2 M or higher, the reproducibility was approximately ±0.2 mv. if the salt concentrations were at 0.05 M or higher. Attempts were made to obtain results in solutions of 0.02 M salt but they were successful in only a few cases.

Instead of comparing the electromotive force of the cell containing acetic acid with that of the cell containing hydrochloric acid in salt solution of the same total molality according to the Scheme **3** and Equation 4 it was found more convenient to proceed as follows.

If the cell

$$Ag \mid AgCl \mid HCl(m_0),\ MCl(m_3) \mid H_2 \mid HCl(0.01) \mid AgCl \mid Ag \tag{9}$$

be subtracted from **(3)** for the case where X equals chlorine, the cell

$$Ag \mid AgCl \mid HCl(0.01) \mid H_2 \mid HAc(m_1),\ MCl(m_2) \mid AgCl \mid Ag \tag{10}$$

is obtained. But this cell is also obtained by subtracting

$$H_2 \mid HCl(0.01) \mid AgCl \mid Ag \tag{11}$$

from the cells measured, namely

$$H_2 \mid HAc(m_1),\ MCl(m_2) \mid AgCl \mid Ag \tag{12}$$

Let E' equal the electromotive force of cells (12)[2g,i] and 0.4644 be the electromotive force of (11), then

$$E' - 0.4644 = 0.05915 \log \frac{(0.902)^2(0.01)^2}{\gamma_{H(1)}\gamma_{X(1)}\, m_H m_2} \tag{13}$$

if 0.902 be taken as the activity coefficient of hydrochloric acid in water at 0.01 M. Equation 13 reduces to

$$E' - 0.2225 = -0.05915 \log \gamma_{H(1)}\gamma_{Cl(1)}\, m_H m_2 \tag{14}$$

Neglecting for the present any correction involving the change in solvent caused by the presence of undissociated acetic acid, we let $\gamma_{H(1)}\gamma_{Cl(1)}$ equal $\gamma_{H(2)}\gamma_{Cl(2)}$, which latter data were obtained from cells of the type (2) containing hydrochloric acid and a chloride.

The experimental data as well as the calculated hydrogen-ion concentrations and activity coefficients are given in Table I; m_1 is the molal concentration of the acetic acid, m_2 the molal concentration of added salt and E' the measured values of the electromotive forces, The values of $\gamma_{H(2)}\gamma_{Cl(2)}$ or $\gamma_{H(1)}\gamma_{Cl(1)}$ were read off plots of the data taken from the tables of Harned and Åkerlöf.[2k] m_H is the hydrogen or acetate-ion concentration calculated by Equation 14. The next column gives the values of $\sqrt{\gamma_A}$ computed by Equation 8 from the values of m_H. The value employed for the dissociation constant of acetic acid[6] was 1.85×10^{-5}. All measurements were made at 25°. Since m_H was unknown in the most dilute solutions,

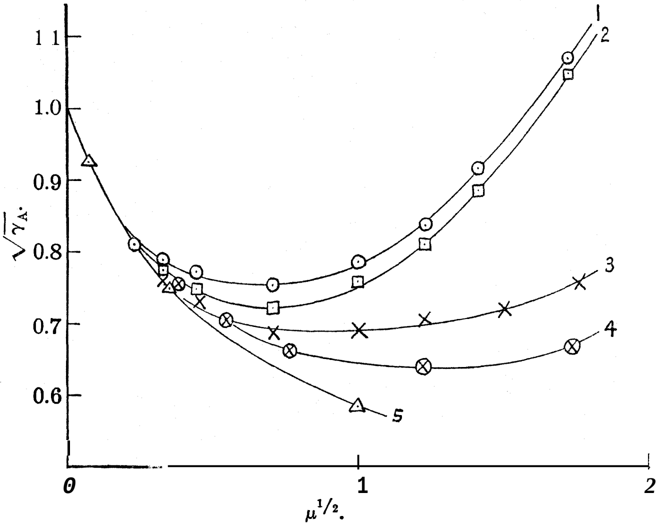
and therefore the total molality was unknown, γ_{HCl} or $\gamma_{H(1)}\gamma_{Cl(1)}$ was obtained approximately by trial and a first rough value of m_H determined. From this a more accurate value of the total ionic molality was computed and a more accurate value of γ_{HCl} was obtained; m_H could then be calculated with certainty.

It was found necessary to determine γ_{HCl} in 0.01 *M* hydrochloric acid–barium chloride mixtures by means of cells of type (2). These are included in the table and will be found to agree excellently with some recent values of Randall and Breckenridge.[2m]

Discussion of the Properties of the Acetic Acid–Salt Systems

(a) General Considerations.—From the data in Table I, it is obvious from the behavior of m_H that in all cases the first addition of salt increases the dissociation of the acid. As the concentration of the added salt increases this dissociation reaches a maximum, and in the more concentrated solutions decreases with increasing salt concentration. On the other hand, γ_A decreases, passes through a minimum and then increases upon the addition of the salt. This latter behavior is in accord with that of all strong acids in salt solutions, of the ionic activity coefficient product of water in salt solutions, and of the ionic activity coefficient of the mono- and dichloro-acetic acids as computed from catalytic data.

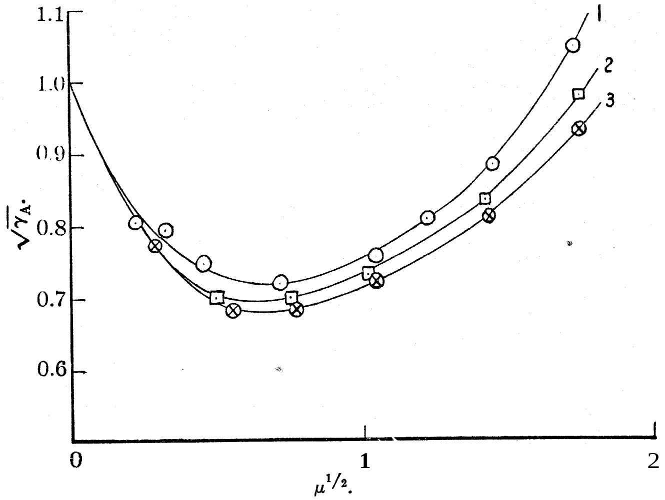


1, KCl; 2, NaCl; 3, LiCl; 4, $BaCl_2$; 5, Debye and Hückel theory.

Fig. 2.—The ionic activity coefficients of 0.2 M acetic acid in salt solutions.

Figure 2 contains plots of $\sqrt{\gamma_A}$ in the four salt solutions against the square root of the ionic strength, $\mu^{1/2}$. These were obtained from the cells containing 0.2 *M* acetic acid. Since for the present we have neglected the effect of the change in solvent due to the presence of the undissociated molecule, these results for $\sqrt{\gamma_A}$ may all be low to the extent of approximately 0.5%. Exactly the same order and approximately the same arrangement of results is obtained as was found by Harned[4,7] in the case of the ion activity coefficient of water, of strong hydroxides in the corresponding chloride solutions, of formic acid in salt solutions, and by Harned and Hawkins[3] in the case of the mono- and dichloro-acetic acids in halide solutions.

In Fig. 3, the values of $\sqrt{\gamma_A}$ for acetic acid and dichloro-acetic acid in potassium and sodium chloride solutions are plotted. Since in the case of the dichloro-acetic acid a greater curvature appears at the lower concentration, it would seem that its activity coefficient should always lie below that of the acetic acid. The values of γ_A have therefore been taken as calculated by Harned and Hawkins. The value of γ_A of monochloro-acetic acid in sodium chloride solutions is also given. Thus, in aqueous salt solutions, it would appear that γ_A decreases as the chlorine substitution increases up to the formation of dichloro-acetic acid. The plots in the upper part of Pig. 4 show the effect of change of concentration of the acetic acid on the activity coefficients relative to unity at infinite dilution of the pure aqueous solutions and calculated according to Equation 14. It is interesting to note that the upper four plots are parallel.



1, CH_3COOH; 2, $CH_2ClCOOH$; 3, $CHCl_2COOH$.

Fig. 3.—The ionic activity coefficients of acetic, mono- and dichloro-acetic acids in sodium chloride solutions.

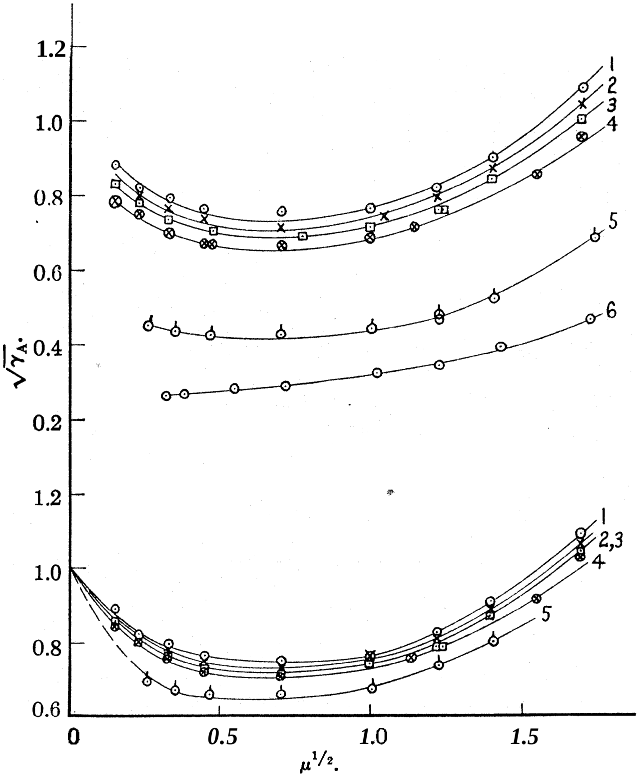
As previously pointed out, Equation 6 is not valid in the case where considerable concentrations of undissociated acetic acid are present and, therefore, to compute the activity coefficients relative to unity at infinite dilution for each separate solvent, cells equivalent to those represented by (8) are necessary. Equation 14 would be valid in the form

---

[7] Harned, THIS JOURNAL, 49, 1 (1927).

$$\begin{aligned} E' - 0.2225 &= -0.05915 \log \gamma'_{\mathrm{H}(1)}\gamma'_{\mathrm{Cl}(1)}\, m_{\mathrm{H}} m_2 \\ &= -0.05915 \log \gamma_{\mathrm{H}(1)}\gamma_{\mathrm{Cl}(1)}\, m_{\mathrm{H}} m_2 - 0.05915 \log \frac{\gamma'_{\mathrm{H}(1)}\gamma'_{\mathrm{Cl}(1)}}{\gamma_{\mathrm{H}(1)}\gamma_{\mathrm{Cl}(1)}} \qquad (14a) \end{aligned}$$

where $\gamma'_{(\mathrm{H}1)}\gamma'_{\mathrm{Cl}(1)}$ is the activity coefficient of hydrochloric acid in a solution containing the acetic acid and salt relative to $\gamma_{\mathrm{H}(1)}\gamma_{\mathrm{Cl}(1)}$ in the salt solution in pure water. The second member on the right is, therefore, the correction term for the electromotive force E which will take into account the change in solvent.



1, 0.1 *M*; 2, 0.2 *M*; 3, 0.5 *M*; 4, 1.0 *M*; 5, 5.4 *M*; 6, 10.2 *M*.

Fig. 4.—The ionic activity coefficients of acetic acid at different molalities, *M*, in sodium chloride solutions.

To correct for this change in solvent, we have used a method which, although approximate, yields results of the right magnitude and illustrates the effect of the correction. We make the assumption that up to 5.4 M concentration the effect of the undissociated acetic acid on the activity coefficient of the hydrochloric acid is the same as that of ethyl alcohol. Further, owing to the parallel nature of the plots in Fig. 4, we assume that at a given acetic-acid concentration the correction is independent of the salt concentration. To this end we have plotted the electromotive forces of the cells

$$H_2 \mid HCl(0.01) \mid AgCl \mid Ag$$

in water and water–alcohol mixtures against the mole per cent. of alcohol, and have read off this plot the changes in electromotive forces produced by the addition of 0.1, 0.2, 0.5, 1 and 5.4 M alcohol. These were found to be 0.1, 0.3, 0.8, 1.9 and 10.7 millivolts, respectively. These corrections, which correspond to the second member on the right of Equation 14a, we have added to E'. Subsequently, m_H was recalculated and $\sqrt{\gamma_A}$ computed by Equation 7. The corrected results are given in the last columns of Table I, and the corrected values of $\sqrt{\gamma_A}$ are plotted in the lower part of Fig. 4. It is obvious upon inspection of these curves that this correction brings the curves much closer together. The distribution is also what is to be expected from the change in the dielectric constant produced by the addition of the undissociated acid.

Since acetic acid has a dielectric constant lower than that of water, the value of the ionic activity coefficient product of the acid relative to unity in infinite dilution in a given solvent will decrease with increasing acetic-acid concentration. The extent of the variation may be calculated approximately in the case of dilute solutions by the equation

$$\frac{\log \sqrt{\gamma_{A(1)}}}{\log \sqrt{\gamma_{A(2)}}} = \left(\frac{D_2}{D_1}\right)^{3/2} \qquad (14b)$$

derivable from the Debye and Hückel theory. This calculation requires a knowledge of the dielectric constants of acetic acid–water mixtures. These data are not available, although we find that the dielectric constant of pure acetic acid is 9.7.[8] Assuming that the dielectric constant of acetic-acid–water mixtures varies in the same way as that of alcohol–water mixtures, and taking the dielectric constant of pure water as 81, we obtain 80, 78, 75 and 58 for the dielectric constants of 0.2, 0.5, 1 and 5.4 M acetic-acid solutions, respectively. We now select a concentration (0.3μ) at which $\sqrt{\gamma_A}$ equals 0.800 in pure water. Substituting the values of the above dielectric constants in Equation 14b, we obtain the values of $\sqrt{\gamma_A}$ in the different solvents which are given in the third line of Table II. These may be compared with the values read off the curves in the lower part of Fig. 4, which are given in the second line.

---

[8] Francke, Wied. Ann., 50, 163 (1893).

These results show that the procedure which we have adopted and which is necessarily an approximation, gives results of the correct order of magnitude and illustrate very well the influence of the various factors which come into force when the nature of the solvent medium is altered.

Part 2. The Ionic Concentrations and Activity Coefficients of Ammonia and its Methyl Derivatives in Salt Solutions

Experimental

As this investigation is intended as a preliminary survey of the possibilities of determining the activity coefficients of weak electrolytes in salt solutions rather than a very accurate determination of such activity coefficients, it was considered advisable to employ cells with liquid junctions, rather than cells of the type (3a), in the determination of the activity coefficients of the weak hydroxides. Cells of the type (3a) can undoubtedly be used for the accurate determination of these activity coefficients (provided that there is no reaction between the amalgam and the cation of the base), but cells of the type

$$H_2 \mid MOH(m_0),\ MX(m_2) \underset{A}{\mid} MX(m_2) \mid AgCl \mid Ag \mid AgCl \mid MX(m_2) \underset{B}{\mid} BOH(m_1),\ MX(m_2) \mid H_2 \qquad (15)$$

obtained by difference of the half-cells

$$H_2 \mid MOH(m_0),\ MX(m_2) \mid MX(m_2) \mid AgCl \mid Ag \qquad (16)$$

$$H_2 \mid BOH(m_1),\ MX(m_2) \mid MX(m_2) \mid AgCl \mid Ag \qquad (17)$$

which can be constructed with greater ease and rapidity, probably give quite accurate results.[9]

Cells of this type were therefore constructed, in which MOH was sodium hydroxide at a concentration of 0.01 M and MX was sodium chloride at concentrations varying between 0.02 and 3.0 M. Five bases were used, as follows: ammonia, mono-, di- and trimethylamines, and tetramethyl ammonium hydroxide. BOH therefore represents one of these hydroxides in a sodium chloride solution of the same concentration as that in the left half of the cell (15). Junction between these two solutions was made by means of silver–silver chloride electrodes in solutions of sodium chloride at the same concentration as in the hydroxide solutions. In practice the two halves of the cell were measured separately.

In this case two liquid junctions are encountered, at A and B. Virtually, however, this reduces to one liquid junction, namely, that at the boundary

$$NaOH(m_0),\ NaCl(m_2) \mid BOH(m_1),\ NaCl(m_2) \qquad (18)$$

When the concentration of the sodium chloride is great compared with that of the hydroxide, the liquid junction potential must be very small

---

[9] *Note that we have made* $(m_0 + m_2)$ *equal* to $(m_{OH} + m_2)$ *so that the* ionic *strengths* in *each are* **equal.**

and, indeed, negligible. Even in the lowest sodium-chloride concentrations which were used (0.02 M), the liquid junction potential must be very small, since we endeavored to work with concentrations of the weak hydroxide such that its hydroxyl-ion concentration was around 0.01 *M*, that is, nearly that of the sodium hydroxide in the left half of cell (15).

The mono- and dimethylamines were used at a concentration of approximately 0.2 M. The ammonia was 0.5 M, giving a hydroxyl-ion concentration of about 0.005 M. Trimethylamine was used at 0.2 M, giving a hydroxyl-ion concentration of between 0.005 M and 0.01 M. Tetramethylammonium hydroxide was used at 0.01 M, since we were able to show that in all probability it belongs to the class of "completely dissociated" electrolytes.

Two difficulties were encountered. In the first place, preliminary measurements of sodium-chloride solutions of sodium hydroxide at low concentrations of the latter (0.0025 M) showed that the hydrogen electrode would not give accurate potentials at this concentration of hydroxyl ion. This is in accordance with our experience with the hydrogen electrode in acetic-acid solution, as previously described.

Secondly, in the 0.02 *M* and 0.05 *M* sodium-chloride solutions of ammonia and trimethylamine, difficulty was experienced in determining the potentials accurately. This is probably due to one of two causes. (1) Diminution of the salt concentration lowers the hydroxyl-ion concentration. It may be, therefore, that in the above two salt concentrations we are approaching the limit of the hydroxyl-ion concentration at which the hydrogen electrode will work efficiently. (2) The liquid junction according to the scheme (18) will probably no longer be of negligible magnitude if the sodium-hydroxide concentration is 0.01 *M* and the hydroxyl-ion concentration of the weak hydroxide is approximately 0.005 M. As the salt concentration increases, most of the ionic transference is due to the sodium and chloride ions, and therefore it is likely that for solutions of concentrations 0.1 M sodium chloride and greater, the liquid junction potential may be neglected with safety. We have therefore omitted measurements in 0.02 M and 0.05 M sodium-chloride solutions of ammonia and trimethylamine.

Cells were also measured containing potassium chloride and either ammonia or methylamine against cells containing 0.01 *M* potassium hydroxide in potassium chloride solutions, and also similar series with lithium chloride as salt.

The electrodes were of the type already described. Measurements were made at 25°. The liquid junctions were of the static type, a capillary tube containing the hydroxide–salt solution being dipped into a cup containing the pure salt solution.

Calculation of Results

Table III gives the electromotive forces of the half-cells (16) and (17) measured, that is, cells containing 0.01 M sodium, potassium or lithium hydroxides in the respective salt solutions,-the five hydroxides in sodium-chloride solution, and ammonia and methylamine in potassium- and lithium-chloride solutions.

.5	.9371	.9208	.9528				

Considerations similar to those which led to Equation 4 will show that the electromotive forces of the cells (15) are given by

$$E = 0.05915 \log \frac{\gamma_{H(2)}\gamma_{X(2)}\ C_{H(2)}\ m_2}{\gamma_{H(1)}\gamma_{X(1)}\ C_{H(w)}\ m_2} = 0.05915 \log \frac{\gamma_{OH(1)}\gamma_{X(2)}\ a_{H_2O(2)}\ m_2 m_{OH}}{\gamma_{OH(2)}\gamma_{X(1)}\ a_{H_2O(1)}\ m_2 m_0} \quad (19)$$

Since the concentrations of BOH have been taken low enough to render the dielectric constant correction negligible, the activity and activity coefficient ratios may again be taken as unity. Equation 19 becomes

$$E = 0.05915 \log \frac{m_{OH}}{m_0} \quad (20)$$

which is comparable to Equation 6. We can therefore calculate m_{OH}

from a knowledge of the difference of the two half-cells (16) and (17), one containing the strong base and the other the weak base. Table IV contains the hydroxyl-ion concentrations of the weak hydroxides in sodium, potassium and lithium-chloride solutions, calculated by Equation 20.

$\gamma_B\gamma_{OH}/\gamma_{BOH}$ or γ_R may be computed from m_{OH} by

$$K = \frac{\gamma_B\gamma_{OH}}{\gamma_{BOH}} \frac{m_{OH}^2}{m_1 - m_{OH}} \tag{21}$$

employing the law of mass action in a manner identical with that previously used in the case of acetic acid (compare Equation 8).

In the case of ammonia,[10] the dissociation constant was taken to be 1.85×10^{-5}. In the case of mono- and dimethylamines, it was assumed that in 0.02 M sodium-chloride solution, the value of $\sqrt{\gamma_B\gamma_{OH}/\gamma_{BOH}}$ or $\sqrt{\gamma_R}$ was equal to the activity coefficient of sodium hydroxide in this concentration of sodium chloride, that is, 0.830. On this assumption a value of K was calculated. In the case of trimethylamine, as the variation of $\sqrt{\gamma_R}$ with the sodium-chloride concentration was very similar to the corresponding variation of $\sqrt{\gamma_R}$ in the case of dimethylamine, we assumed that the values of $\sqrt{\gamma_R}$ for these two bases are identical at a sodium chlor-

[10] Lundén, *J. chim.* phys., 5, 574 (1907); Noyes, Kato and Sosman, *Z. physik. Chem.*, 73, 1 (1910).

ide concentration of 0.1 M, that is, 0.709. It is to be realized that the choice of a reference point for the calculation of K is a somewhat arbitrary matter, and therefore the values of K used in the calculation of $\sqrt{\gamma_R}$ are to be considered tentative and subject to revision should more accurate values be forthcoming.

Table V contains the values of K calculated in the above manner, compared with the values obtained by Bredig from conductivity measurements.[11]

TABLE V

DISSOCIATION CONSTANTS OF AMINES AT 25°

Base	Present authors	Bredig
Monomethylamine	4.42×10^{-4}	5.0×10^{-4}
Dimethylamine	5.12×10^{-4}	7.4×10^{-4}
Trimethylamine	5.27×10^{-5}	7.4×10^{-5}

Using these values of K, $\sqrt{\gamma_R}$ was calculated and these values are given in Table VI.

Discussion of the Properties of the Hydroxide–Salt Systems

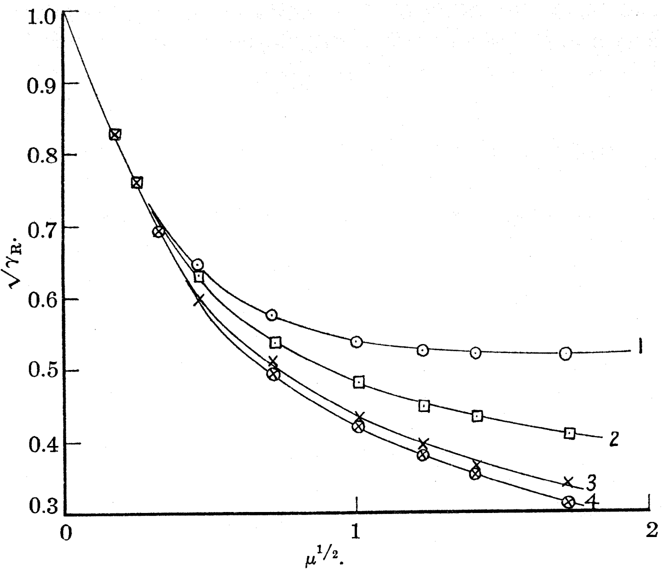
In Fig. 5 the activity coefficients of four bases in sodium chloride solutions are plotted against $\mu^{1/2}$. It appears that as substitution of the am-

---

[11] Bredig, Z. *physik. Chem.*, 13, 191 (1894).

monium ion by the methyl groups occurs, lower values for the activity coefficients are obtained. This is in accord with our results on acetic acid and the chloro-substituted acetic acids. The results are of the expected order of magnitude but no great accuracy can be claimed, particularly in the dilute solutions where errors due to small liquid junction potentials are possible.

That the order of the salt effects corresponds to that of acetic acid in the simple halide solutions is shown by the plots in Fig. 6.



1, NH_4OH; 2, CH_3NH_3OH; 3, $(CH_3)_2NH_2OH$; 4, $(CH_3)_3NHOH$.

Fig. 5.—The ionic activity coefficients of ammonia and amines in sodium chloride solutions.

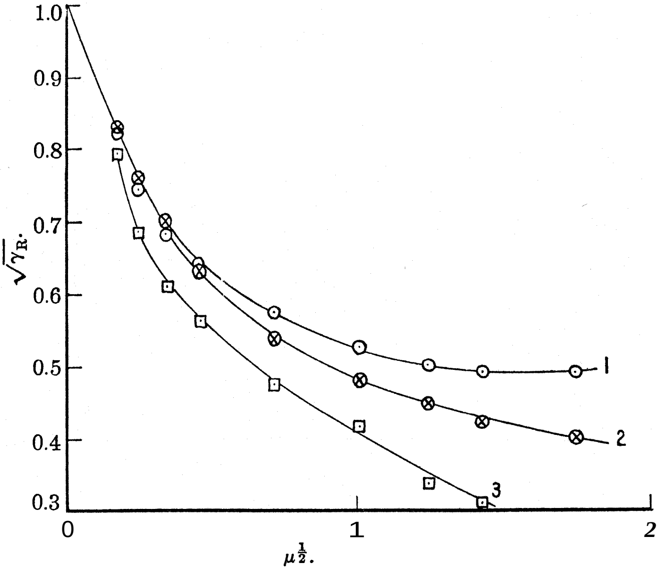
The activity coefficients of tetramethylammonium hydroxide cannot be determined by this method but it is of very great interest to note that our measurements show that, in the presence of sodium chloride, this hydroxide is more highly dissociated than sodium hydroxide. The ratios of hydroxyl-ion molalities, $m_{OH(T)}/m_{OH(NaOH)}$, at the various salt concentrations computed by Equation 20, are given in Table VII.

TABLE VII

HYDROXYL-ION CONCENTRATION RATIOS OF TETRAMETHYLAMMONIUM HYDROXIDE TO SODIUM HYDROXIDE IN SODIUM-CHLORIDE SOLUTIONS

Salt concn.	0.1	0.2	0.5	1.0	1.5	2.0	3.0
$m_{OH(T)}/m_{OH(NaOH)}$	0.988	1.012	1.052	1.048	1.060	1.052	1.048

Since the stoichiometrical concentrations of the hydroxides were both 0.01 M, the liquid junction potential must indeed be small at 0.1 M salt concentration, and certainly negligible at high salt concentrations. Thus, at 0.5 M sodium chloride and higher the amine is between 4.8 and 6% more strongly dissociated than the sodium hydroxide. At 0.1 M salt, it appears to be somewhat less dissociated. Since the amine possesses a high dissociation constant, the addition of salt would increase its dissociation somewhat due to the decrease in γ_R. If γ_R decreases more rapidly than $\gamma_{Na}\gamma_{OH}$ upon salt addition, and if sodium hydroxide is not completely dissociated, we may account for this observation. That sodium and lithium hydroxides are probably not dissociated to the extent of the halides of the alkali metals has already been pointed out by Harned.[12]



1, KCl; 2, NaCl; 3, LiCl.

Fig. 6.—The ionic activity coefficient of methylamine in potassium, sodium and lithium chloride solutions.

We desire to take this opportunity of expressing our thanks to the Commonwealth Fund for the grant of a Fellowship, which has made this joint contribution possible.

General Considerations and Summary

1. A method has been discussed whereby the activity coefficients and dissociation of weak acids and bases in salt solutions may be computed from the electromotive forces of cells without liquid junctions containing easily reproducible electrodes.

2. This method has been employed to obtain the activity coefficient of

---

[12] Harned, *Z. physik. Chem.*, **117**, 1 (1925).

acetic acid in potassium, sodium, lithium- and barium-chloride solutions. In this case, the cells employed were

$$H_2 \mid HX(m_0),\ MX(m_3) \mid AgX \mid Ag$$
$$H_2 \mid HAc(m_1),\ MX(m_2) \mid AgX \mid Ag$$

Measurements of the second type have been made.

3. A modified method employing cells with negligible liquid junction potentials was employed for the determination of the activity coefficients of the bases. In this case, the cells measured were

$$H_2 \mid MOH(m_0),\ MX(m_2) \mid MX(m_2) \mid AgX \mid Ag$$
$$H_2 \mid BOH(m_1),\ MX(m_2) \mid MX(m_2) \mid AgX \mid Ag$$

where MOH is a strong and BOH a weak hydroxide.

4. The dissociation constant of a weak electrolyte in a given solvent or in salt solutions in this solvent, is given by $K = (C_C C_A/C_{CA})(\gamma_C \gamma_A/\gamma_{CA}) = K_c\gamma^2$. When the electrolyte is at infinite dilution so that γ^2 equals unity, K equals K,. Thus, ***K*** is a constant which measures the dissociation of the weak electrolyte in the pure solvent. γ^2 is a measure of the effect of the presence of the attractive and repulsive forces of the electrical field produced by the addition of the salts on the electrical potentials of the ions of the weak electrolyte. K_c is an absolute measure of the dissociation of the weak electrolyte under varying conditions of salt concentration. Although the change of K_c upon salt addition depends upon the variation of γ^2, its absolute value does not. This is shown clearly by the behavior of the methyl derivatives of ammonia. Thus, K_c increases in the order ammonia, tri-, mono-, dimethylamine, whereas, at a given salt concentration, γ^2 increases in the order tri-, di-, monomethylamine, ammonia.

5. We may generalize our results of the specific relative salt actions by the following brief rules. *A.* The ionic activity coefficients of acetic, mono- and dichloro-acetic acids are less in the solution of a given strength of that salt which possesses the higher activity coefficient in pure water. B. The same is true for ammonia and monomethylamine. It seems highly probable that it would also be the case for di- and trimethylamine. This order agrees with that found for the ionic activity coefficients of water, and is the reverse of the order found for the activity coefficients of halide acids in salt solutions.

6. Our results show that a 0.01 M solution of tetramethylammonium hydroxide containing 0.1 M sodium chloride has a slightly lower hydroxyl-ion concentration than that of an identical salt solution containing sodium hydroxide. At higher salt concentrations, however, sodium hydroxide is about 6% less dissociated.

7. The effect of the change in the solvent caused by large quantities of the undissociated molecules has been discussed, and approximately computed.

8. The method here employed, as well as the results, should prove very useful for studying salt effects in organic and biological media. It is far more sound from a kinetic or a thermodynamic point of view than the usual method which employs single electrodes and ordinary salt bridges.

THE FORMATION OF OZONE BY CATHODE RAYS

BY ABRAHAM LINCOLN MARSHALL

RECEIVED JUNE 23, 1928 PUBLISHED DECEMBER 10, 1928

The purpose of this investigation was to secure quantitative data on a supposedly simple reaction, the production of ozone from oxygen under the influence of high velocity electrons, which could be used in the interpretation of more complicated reactions. It has been found, however, due to the secondary decomposition of the ozone formed, that an analysis of the results is far from simple. The cathode ray tube recently described by Coolidge[1] was used, which allows one to obtain an intense source of very high velocity electrons. The various controllable variables, such as duration of exposure, average velocity and number of electrons, size and shape of the reaction chamber, were studied separately.

Not much work has been reported in the literature on the chemical effects of high velocity electrons in gaseous systems. Kriiger and Moeller[2] have studied the formation of ozone with very low intensity, low velocity electrons and their work has been subsequently very materially amplified by Kriiger and Utesch.[3] The latter worked with a hot cathode tube as a source of electrons and used an aluminum foil, 0.011 to 0.005 mm. thick, supported on a brass plate containing 65 holes 0.8 mm. in diameter as a window through which they obtained electrons from their tube. The source of voltage was a 500-cycle, high voltage transformer with a single kenotron rectifier giving peak voltages up to 60 kv. The largest current used in the tube was 0.4 milliampere. With a tube current of 3×10^{-4} ampere, 4.5×10^{-5} ampere was incident on the aluminum foil and of this 2.0×10^{-6} ampere passed through into the reaction chamber. The maximum amount of energy entering the reaction vessel in any experiment was estimated to be 0.12 watt. In one set of experiments a vessel containing two condenser plates placed 26 mm. apart was fastened to the window end of the tube. The plates were 4×2.5 cm. The diameter of the cathode ray beam at the window was 19 mm. and the authors be-

---

lieve that none of the primary electrons hit the condenser plates. With the tube operating, and oxygen at atmospheric pressure in the cell, voltage was applied to the condenser plates. At about 3000 volts, saturation current was reached and this current was taken as a measure of the intensity of ionization. The amount of ozone formed with the tube operating under the same conditions was determined and it was then possible to calculate the ratio of the number of molecules of ozone formed to the number of ions formed. The values obtained for this ratio range from 12 to 40. Any uncertainty in this value comes from the measurement of the saturation current, and in view of the importance of the value of this ratio in developing the theory of these reactions the measurements should be further substantiated. In their experiments oxygen was circulated through the reaction vessel at varying rates up to 15 liters per hour, and it was found that the amount of ozone formed increased up to a circulation of 10 liters per hour and then remained roughly constant. From the results it was calculated that 6–11% of the energy put into the gas was used to form ozone, from 2–4% caused ionization and the remainder heated up the gas. Their conclusion was that the formation of ozone by cathode rays was not connected with ionization of oxygen but with activation. The larger fraction of the energy absorbed from the electron stream was taken up in small amounts which produce excited oxygen molecules and these subsequently react to form ozone.

Experimental Method

The cathode ray tube was operated from a 200-kv. transformer which in turn was fed from a 1:1 transformer having a secondary insulated for 100 kv. As the case of the high voltage transformer was insulated from ground and connected to its primary and to the middle of the secondary, this method of operation enabled one to ground the anode end of the tube.[4] Since the cathode ray tube only imposes a half-wave load on the line, the inverse or non-useful voltage would normally be higher than the useful. This imposes an unnecessary strain on the tube and high voltage transformer and renders difficult a measurement of the voltage usefully employed. To obviate this difficulty, the wave form is distorted on the low voltage side of the transformer by connecting a half-wave load to the line, in the form of a mercury arc, on that half of the wave not used by the cathode ray tube. This load is made much greater than that of the tube and thus causes the inverse voltage to fall below the useful Voltage was measnred by means of a regulation sphere gap using the standard tables of the A. I. E. E. lor calibration. A large ballast resistance was placed in the primary circuit of the 1:1 transformer which was connected to a 550-volt, 60-cycle supply. The ballast resistance limited the energy input if for any reason the high voltage insulation broke down.

The tube used was modified slightly from that described by Coolidge, to enable one to fasten the reaction vessel directly to the anode arm of the tube. An invar ring one inch wide was brazed onto the end of the invar sleeve which constitutes part of the anode structure of the tube. The cell was fastened to a similar ring and the two were

---

[4] **Ref. 1*a*, p. 707.**

clamped together with a rubber gasket between them. This made a gas-tight joint which could be easily assembled and aided greatly in all subsequent manipulation.

The bulb of the tube was **30.5** cm. in diameter and the tube was 89 cm., overall length. **A** detailed description of this particular type of tube which is the best available at present for operation in air has been given by Coolidge.[1b]

The tube and high voltage source were placed in a lead house having 1/8" to 1/4" thick walls and very thick lead glass windows. This gave complete protection from both x-rays and high voltage; the former was very necessary in an investigation of this nature where the tube was to be operated almost continuously. A remote control device was inserted in the power line supplying the high voltage transformer. Safety switches were placed on all the doors of the house so that it was impossible to come in contact with the high voltage circuit when the power was on. The filament of the cathode ray tube was operated from a storage battery in order to obtain **very** steady discharge currents. To avoid corona losses the battery was placed in an iron box having all the corners and edges rounded and the high voltage leads, which were kept very short, were made of **2**" brass tubing with 4" spheres placed at all right angle bends.

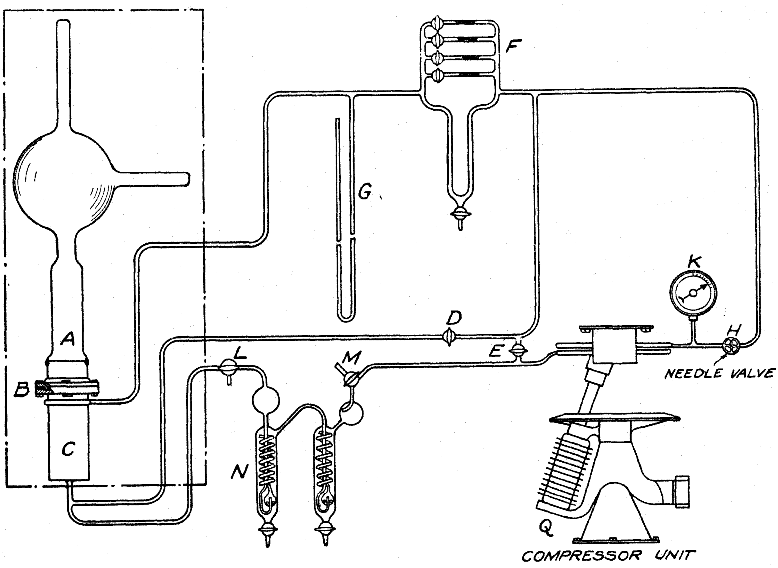

Fig. 1.

The window material employed was **resistal**,[1b] which is an alloy consisting of 18 parts by weight of chromium, **3** parts of silicon, **0.2** of carbon, 4–3.8 of iron and **35** of nickel. The window thickness varied from 0.50–0.57 of a mil.

A cooling coil of copper was soldered around the metal sleeve of the anode through which water was circulated. With this cooling it was possible to operate the tube continuously at 180 kv. and 1 milliampere.

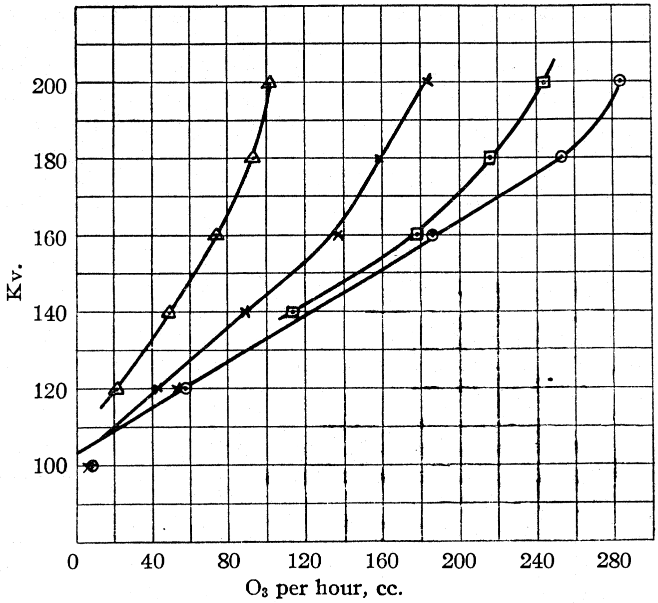
A closed system, illustrated in Fig. 1, was used at first and pure oxygen made by the electrolysis of a solution of potassium hydroxide was circulated by means of a compressor **Q.** The compressor unit was designed by J. G. deRemer and is described in the *Proc. Am. Soc.* Mech. *Eng.* for **1926.** It operated on the principle of Archimedes' screw using mercury as the compressing fluid. The pump is of all steel construction and contains no stuffing-boxes, so that there is no opportunity for oxygen to be contaminated with grease or to leak from the system. The oxygen always contained traces of mercury vapor coming from the mercury in the pump and water vapor from the gas scrubbers. The high pressure side of the unit was kept at 39 lbs. above atmospheric by means of the needle valve H, the pressure being measured on the gage K. The maximum rate of flow from the compressor was 1200 liters per hour measured at one atmosphere pressure. The rate of flow through the cell C was measured on the flowmeter F and controlled by means of the by-pass D. In this it was possible to vary the rate of flow through the reaction vessel from 20 to 1200 liters per hour and keep the pressure in the cell C always at one atmosphere. After being exposed in the reaction vessel the oxygen was passed through two scrubbing bottles, N, to remove any ozone formed. These scrubbers contained an alkaline solution of potassium iodide (50 g. KI, 25 g. KOH, per liter) and ozone could not be detected in the effluent gases when circulating at 1200 liters per hour. The full flow of gas from the compressor was sent through the scrubbers in order to minimize as much as possible any momentary pressure inequalities in the system due to the method of flow through the goose-neck of the scrubber and thus ensure a steady flow of gas through the reaction vessel. After an experiment the stopcock at E was opened and then L and M were opened to the atmosphere. The solution was removed from N and replaced; pure oxygen was bubbled through to displace the air and then the wash bottles were reconnected to the system for the next experiment. These operations required from five to ten minutes so that it was quite feasible to make a large number of experiments in a day with a single filling of the whole system.

Experimental Results

Surface Effects.—A series of experiments was made to determine whether an extension of the surface exposed in the glass reaction vessel had any effect on the amount of ozone formed. A cell 87 mm. in diameter and 20 mm. long was filled with loosely packed glass wool which came in contact with the tube window. The presence of the glass wool modified greatly the method of flow of the oxygen in the cell and tended to form pockets where the gas would be moving slowly. In ten minutes with circulation at the rate of 1200 liters per hour, 180 kv. and 1 milliampere, 11.2 *cc.* of ozone was formed. Blank experiments without glass wool gave 21.3 and 18.7 cc. in the same time interval. The glass wool was then replaced and 10.7 cc. of ozone was formed. A number of experiments were also performed with a cell 250mm. long filled loosely with glass wool to within 50 mm. of the tube window. About 35 cc. of ozone was formed in both this experiment and the control without glass wool. A fine network of tungsten wire was used to fill the cell and this apparently produced only a very minor effect.

In order to determine whether the "resistal" window was exercising an effect on the course of the reaction, it was completely covered with a sheet of mica 0.5 mil thick which was kept in close contact with the window by a brass ring. Three consecutive experiments with oxygen circulating at 1200 liters per hour, 200 kv. and 1 milliampere gave 39.2, 38.9 and 38.1 cc. of ozone in a ten-minute interval, while a blank without the mica gave 40.4 cc. of ozone.

The nature of these results indicates that the amount of ozone formed is almost entirely independent of the nature or extent of surface exposed during raying, and the ozonization of oxygen by cathode rays is a homogeneous gas phase reaction. This does not mean, of course, that there are no complications introduced by the walls due to reflection of primary and emission of secondary electrons during bombardment.



Cell length: △, 5 mm.; ×, 24 mm.; ⊡, 56 mm.; ⊙, 247 mm. Tube current, 1 milliampere. Pressure, 1 atmosphere. Rate of circulation, 1200 liters per hour.

Fig. 2.

Variation in Yield with Voltage and Cell Length.—The results given in Table I for three different cells show in part the reproducibility of the results for a given set of conditions and are tabulated to show how the yield varies with the voltage applied to the tube. The rate of circulation was 1200 liters per hour with a tube current of 1 milliampere.

TABLE I

OZONE FORMED PER HOUR, CC.

Kv. (max.) applied	Cell length, cm.		
	10	25	2
200	(257,264, 261) 261	282	177
180	(239,234, 232) 235	242	161
160	183	198	137
140	120	132	99
120	57.8	70	49.7
100	12.7	11.4	10.7

Air was used in the 10-cm. cell in one experiment at 180 kv. and 177 cc. of ozone was formed as compared with **235** cc. with pure oxygen. The above results were all with glass cells. Fig. 2 illustrates the results of a more detailed study with copper reaction vessels varying in length from 5 to 247 mm. Copper cells were used wherever possible in all subsequent work since the glass did not stand up well under the intense bombardment and would often crack badly after only short use. In Fig. **3** the yield for a given voltage is shown as a function of the cell length. These results are for **1** milliampere tube current and oxygen circulating at 1200 liters per hour.

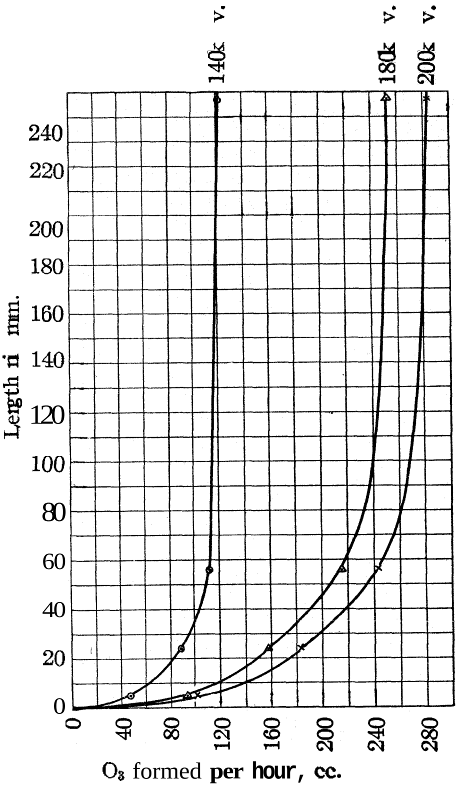


Fig. 3.

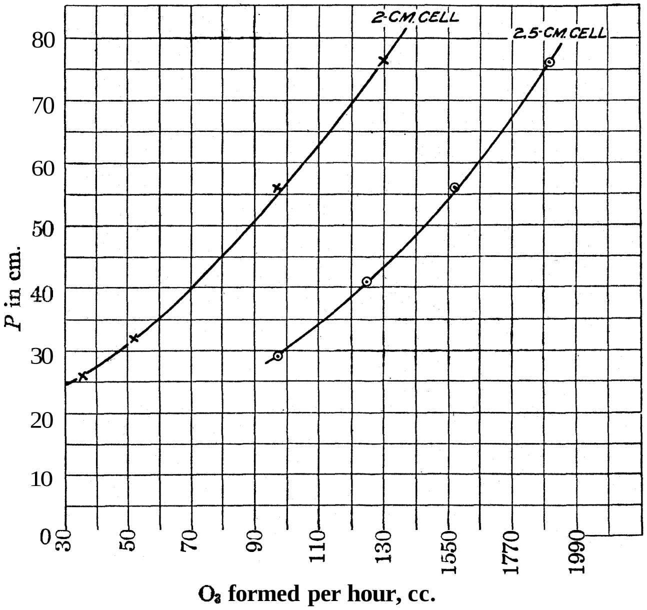
Pressure Variable.—Experiments were made with two cells on the effect on the yield of varying the oxygen pressure. The tube was operated at 180 kv., **1** milliampere and oxygen circulated at the rate of 655 liters per hour, the volume circulated being measured at the pressure under consideration. Fig. 4 illustrates the results obtained; the relationship is not a linear one and shows that at high pressures the yield for a given cell becomes independent of pressure.

Rate of Flow.—In connection with the investigation of the effect of varying the rate of flow of oxygen through the cell, a large number of preliminary experiments were made while determining the best method of carrying out the experiments. From studying these results, a purely empirical result was discovered, namely, that there appeared to be an approximately linear relationship between the logarithm of the rate of flow and the yield of ozone for a given time of raying. At low tube currents this relationship appeared to be very real over the whole range of circulation employed but deviations became large at higher currents. Fig. 5 illustrates the general trend of all these results. So far no theoretical significance has been obtained for this relationship, but it proved quite useful in the early stages of the experimental work in detecting gross errors in results obtained. A similar result was obtained when the tube current was varied.

The yield for a given rate of circulation is a linear function of the logarithm of the tube current.

In the experiments using the mercury compressor, it was noticed that a film of mercuric oxide deposited on the walls of the tubing leading away from the reaction chamber. The mercury could be removed from the gas stream by circulating through a trap immersed in carbon dioxide–ether mush. It was found that the yield of ozone was about 1 cc. greater in a fifteen minute period when the mercury was removed. Calculation showed that about 0.8 cc. of mercury vapor measured at N.T.P. would pass through the system in this period and apparently it was all oxidized.

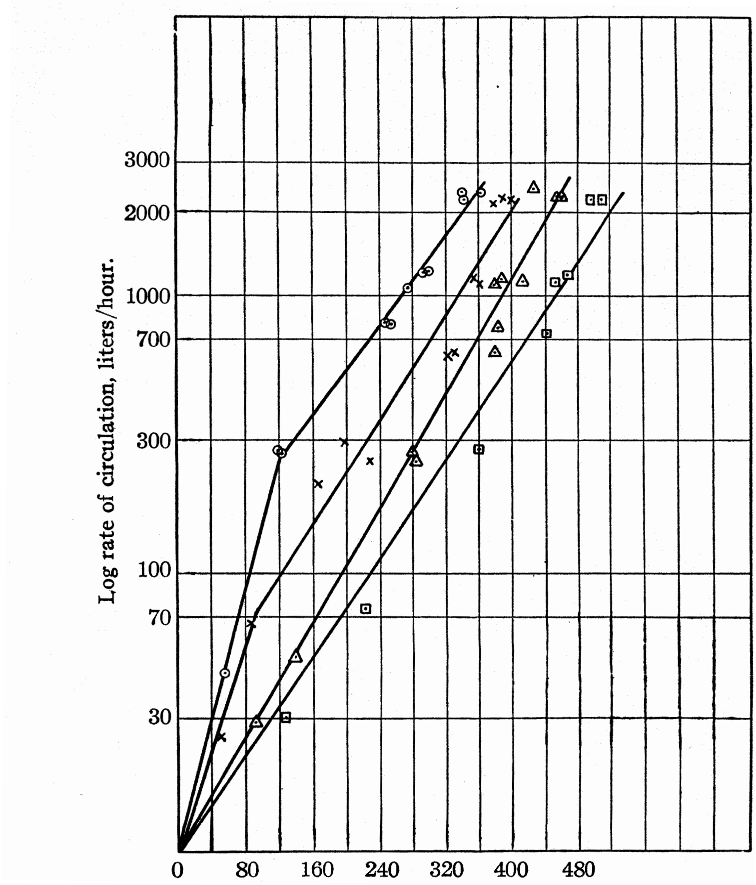


180 kv., 1 milliampere. Rate of circulation, 655 liters per hour.

Fig. 4.

At about this stage in the work a number of experiments were made with the electrolytic oxygen which we have on tap throughout the laboratory. This contains small quantities of hydrogen, nitrogen and water vapor with a trace of carbon dioxide. It was found that the results obtained with this supply of oxygen agreed very well indeed with those obtained from the specially purified gas used previously. All subsequent experiments were therefore made with oxygen from the line. In order to be able to pass oxygen through the system at rates of flow up to 2400 liters per hour and discharge the effluent gas into the atmosphere, it was necessary to operate in the cell at pressures above one atmosphere, and all subsequent experiments were carried out at a pressure of about 91 cm. of mercury.

Several thousand experiments were made with two sizes of cell, namely, 162 cc. and 1520 cc. at various currents, voltages and rates of circulation in order to obtain reliable data for quantitative treatment. The results for the 1520-cc. cell are given in Table II for a tube voltage of 180 kv. and varying currents. Each figure is the average of 4 to 5 experiments and the various experiments were made in random order to detect any source of error that might creep in during the course of a series of experiments.



Volume of cell, 162 cc.; voltage, 180 kv.; pressure, 91 cm.; current, ⊙, 1.00 ma.; ×, 0.50 ma.; △, 0.20 ma.; ⊡, 0.10 ma.

Fig. 5.

In treating these results, it will be more convenient to deal in terms of concentration of ozone and time of exposure rather than rate of flow and amount of ozone formed and these are calculated in the third and fourth columns of the table. In order to make this transformation, the assumption is made that the concentration of ozone is uniform in the cell as the gas passes through. This may be approximately correct at high rates of passage where the flow through the cell is turbulent and the gas is stirred up very rapidly. At lower rates of circulation, however, the concentration

may vary greatly from point to point through the cell. The entering gas contains no ozone and meets the highest electron density at the window of the tube. At the exit the ozone concentration is high and the rate of production much lower. The concentration should be much more uniform in a short cell than in a long one. The time is taken as the average time that a molecule is present in the cell; if there is any tendency to form pockets in the cell when the gas is moving more slowly, the calculated time will be incorrect and again the factor will be more important at the slower rates of flow.

$$t \text{ in seconds} = \frac{3600 \times \text{volume of cell in liters}}{\text{rate of flow in liters/hour}}$$

where *t* is time of exposure.

Some of the results which have been obtained are presented graphically in Figs. 6, 7 and 8. One at once observes that the rate of increase of concentration with time is decreasing rapidly and that a steady state is soon reached. The concentration of ozone in the steady state is about 1 molecule of ozone to 1700 of oxygen. At first sight it did not appear probable that ozone at such a low concentration was being decomposed as fast as it was formed and an alternative explanation was advanced: an intermediate product is formed initially by the cathode rays and is able to break down in two ways—either reverting to oxygen or forming ozone. A study of the reaction between hydrogen and oxygen, however, gave definite evidence in support of the instability of ozone at this low concentration. This will be reported in a subsequent paper.

Warburg[5] and Warburg and Leithauser[6] have studied the rate of formation of ozone in the silent discharge by both static and dynamic methods. In this case also the rate of formation of ozone falls off rapidly with in-

creased time of exposure. Table II illustrates some of the results which they obtained with a glass ozonizer having electrodes 1.4 mm. apart and operating on 50 cycles with a current of 1.15 milliamperes. The pressure was 764 mm. and the temperature 19.5°.

TABLE III

PRODUCTION OF OZONE BY SILENT DISCHARGE

Concn. O_3, mml./liter	341	513	660	689	907	1176	1381	1514	1785
O_3, cc. at N.T.P. per ma./hr. obs.	204	202	195	193	186	175	172	168	159
O_3, cc. at N.T.P. per ma./hr. calcd.	207	202	197	196	189	180	173	168	159

The calculated yield of ozone at zero concentration was 218 cc. per milliampere hour and the concentration of ozone in the steady state which was obtained by a separate experiment in a static system was 3720 micromoles per liter. The striking part of these results as compared with those obtained with cathode rays is the much greater concentrations of ozone obtained. In this case one molecule in twelve is converted to ozone in the steady state, where with cathode rays the concentration was one in seventeen hundred. There is a very marked increase indeed in the stability of ozone in silent discharge as compared with the cathode ray stream.

They have discussed their results theoretically on the basis of an equation involving both formation and decomposition of ozone and have obtained good quantitative agreement with experiment. The amount of ozone formed in time dt is proportional to the current I and to the oxygen concentration. The amount of ozone decomposed is taken as proportional to the current and the ozone concentration

$$\frac{\mathrm{d}(n_{O_3})}{\mathrm{d}t} = I(k_1c_{O_2} - k_2c_{O_3})$$

where n_{O_3} is the number of molecules of ozone formed in time dt. If there is no ozone present the rate of formation is given by

$$\frac{\mathrm{d}(n_{O_3})}{\mathrm{d}t} = k_1Ic_{O_2}$$

and the amount of ozone formed per ampere hour is

$$A^0 = \frac{\mathrm{d}(n_{O_3})}{Idt} = k_1c'_{O_2}$$

where c'_{O_2} is the initial concentration of oxygen and $c'_{O_2} - c_{O_2} = 3/2c_{O_3}$.

$$\frac{\mathrm{d}(n_{O_3})}{Idt} = A_0 - k_1(c'_{O_2} - c_{O_2}) - k_2c_{O_3}$$

The concentration of ozone in the steady state is given by

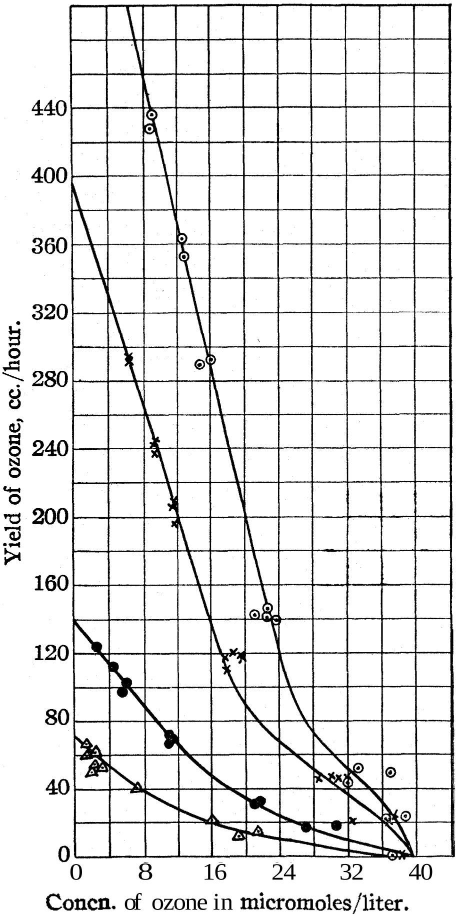
$$Ao = (3/2\,k_1 + k_2)c'_{O_3}$$

Hence the concentration in the steady state is independent within certain limits at least of the current. The current strength determines the velocity at which equilibrium is attained, but not the equilibrium concentration.

$$A = \frac{\mathrm{d}(n_{O_3})}{I\mathrm{d}t} = A_0 - k_1(c'_{O_2} - c_{O_2}) - k_2c_{O_3}$$
$$= A_0 1 - \left\{\frac{c_{O_3}}{A_0}(3/2\ k_1 + k_2)\right\}$$
$$= A_0\left(1 - \frac{c_{O_3}}{c'_{O_3}}\right)$$

A_0 and A are the moles of ozone formed per ampere hour at $t = 0$ and $t = t$.

From this result, it is evident that the yield of ozone should be a linear function of the concentration of ozone in the gas. The results given in Table II and Figs. 6, 7 and 8 and also others obtained with 130 kv. applied to the tube have been treated in this way in Figs. 9–12. One notices at once that at the higher concentrations of ozone, which represent experimentally the slower rates of flow, the linear relationship breaks down and the yield approaches zero



180 kv., 1520 cc. volume. ⊙, 1.00 ma.; **X, 0.50 ma.; ●, 0.20 ma.**; △, 0.10 ma.

Fig. 10.

more slowly than predicted. This may be due in part to the fact that the values calculated for the concentration are much more inaccurate at the higher concentrations. These portions of the curve have not been treated theoretically since the variation in concentration of ozone throughout the cell is unknown and the radiation density is so far from uniform.

There are two methods available for determining the maximum yield of ozone for a given voltage and tube current. One can draw tangents to the curves in Figs. 5 and 8 at zero time. These give a measure of the actual rate of ozone production when none is present to be decomposed. The other method is to extrapolate the straight lines of Figs. 9–12 to zero concentration of ozone.

The results obtained by the use of these two methods with the data given in Fig. 7 are tabulated in Table IV.

The result for 0.50 milliampere is apparently too large; the discrepancy was not noticed at the time and it has not been possible to recheck this value. When one attempts to draw tangents to the curves at the origin one soon realizes that the results in Cols. 2 and 3 are well within the experimental error and that the extrapolation method is more likely to give a reliable result.

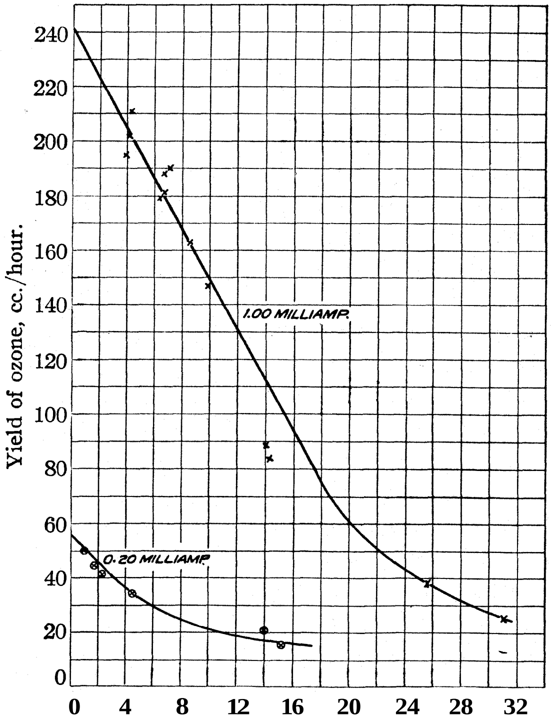
1.00	392	407	407
0.50	202	215	430
.20	91	92	460
.10	49	49	490
.05	24	24	480

The rate of formation of ozone, expressed in micromoles per second, for various times of exposure has been plotted in Fig. 13 as a function of the tube current. For zero time the rate is a linear function of the tube current within the experimental error, but for all actual experiments it deviates from this ideal result due to secondary decomposition of ozone, the deviation being greater the longer the time of exposure and the greater the electron density.



Concn. of ozone in micromoles/liter.
130 kv., 162 *cc.* volume.
Fig. 12.

A series of experiments was carried out with a large spherical reaction vessel of twelve liters capacity in an attempt to find out what additional effect would be obtained by allowing the electrons to scatter laterally; it was also hoped to obtain more exact data on the concentration of ozone in the steady state. The results are given in Table VI; the voltage used was 180 kv. and the current 0.80 milliampere.

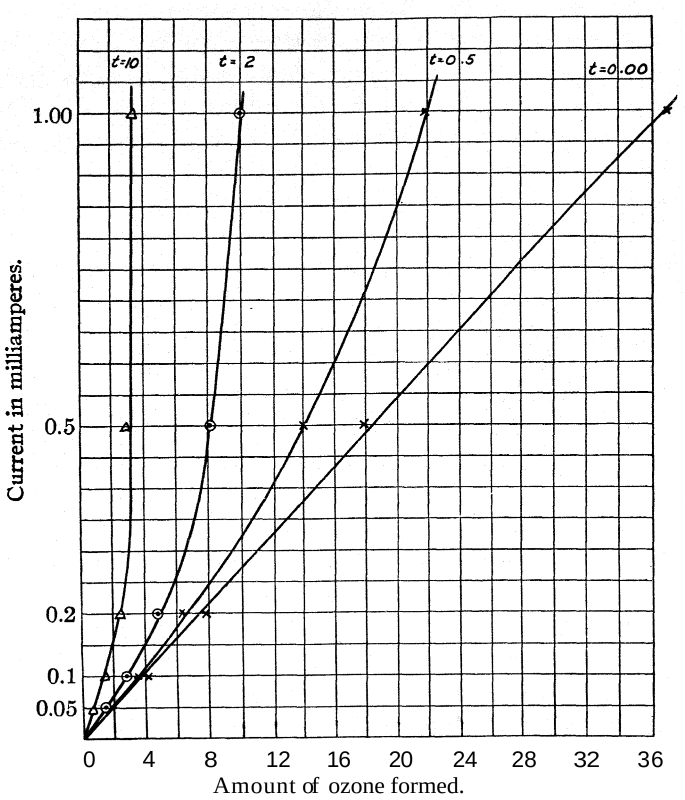


Fig. 13.—All calculated on the basis of one second.

TABLE VI

FORMATION OF OZONE WITH 12-LITER VESSEL

Rate of circulation	O_3 formed per hour, cc.	Time, sec.	Concn. of ozone, micromoles/-liter	$c \times 10^6$ (corr.)

Static	..	300	21.5	..
Static	..	600	26.4	..
Static	..	900	26.4	
Static	..	1800	26.4	

The calculated concentrations given in Col. 4 are too large, due to the experimental conditions. The oxygen in this case is passing through a vessel of 12 liters capacity. After the exposure the vessel is still filled with partially rayed oxygen, which, however, has been rayed during the period of the exposure; the amount of gas rayed is thus greater than that passing through the cell during the duration of the experiment. In the case where oxygen was circulating at 75 liters per hour one knows from the static experiments that the ozone concentration is 26.4×10^{-6} mole per liter and this enables one to calculate the actual concentration in all the experiments. When these results are plotted with the ozone yield as a function of its concentration and extrapolated to zero concentration, the maximum yield is found to be 660 cc. per hour for 0.8 milliampere or 825 cc. per hour per milliampere. This result is to be compared with the value of 640–700 cc. of ozone obtained with the cylindrical cell of 1520-cc. volume and 410490 cc. obtained with the 162-cc. cell. It appears that approximately half of the energy in the electron stream can be expended in a cell 26 mm. deep and 89 mm. in diameter as measured by its ability to produce ozone. Of course, there is considerable reflection of electrons from the walls of the cell, which helps to increase the yield, and the fraction might be much lower if the walls were completely transparent to electrons.

Experiments with an Applied Electric Field

In discussing the work of Krüger and Utesch, the main criticism was launched against their method of determining ionization. If their result is valid and there are as many as 40 molecules of ozone formed per ion, then the conclusions of Lind[7] on the mechanism of these reaction is incorrect. The ozonization of oxygen is a reaction which proceeds with a free energy increase and it would be impossible for one ion to initiate a chain of reactions producing many molecules of ozone. An attempt was made to see if it is possible to obtain saturation currents under somewhat similar experimental conditions to those used by Kriiger and Utesch. A copper plate with a slit 1 cm. wide by 5 cm. long was fastened over the window of the tube. This permitted about 20% of those electrons to enter the gas which would have entered in the absence of the shield. Two condenser plates 6 cm. X 8 cm. were placed in the reaction vessel so that they were symmetrically mounted with respect to the slit. The upper edges of the plates were 3 cm. distant from the window of the tube. They were placed either 2.4 cm. or 6.3 cm. apart.

A 10-kw., 60,000-volt DC outfit consisting of transformer, full wave rectifier and condensers was used as a source of voltage; the mid-point of the condenser bank was grounded so that the voltage drop between the window and each of the plates in the reaction vessel was the same.

---

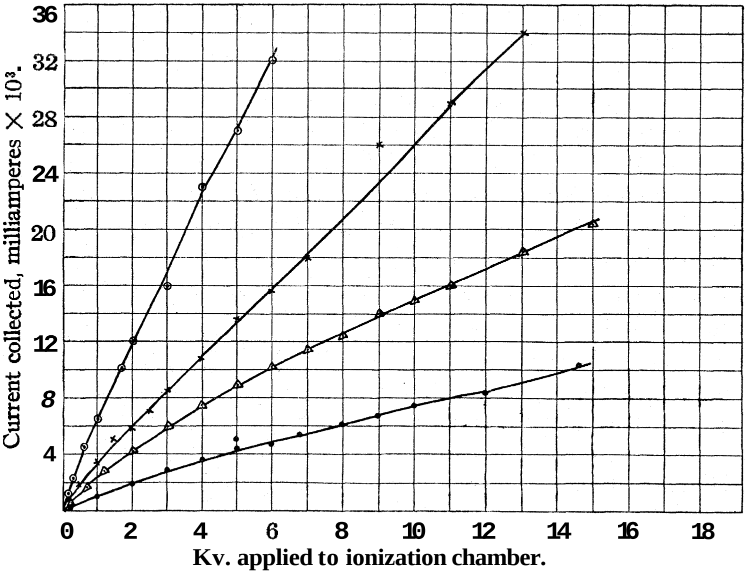
[7] Lind, "Chemical Effects of Alpha Particles," The Chemical Catalog Co., Inc., New York, 1928.

Experiments were first made with and without the field applied, circulating oxygen through the cell and determining the amount of ozone formed. With 180 kv. and 0.50 milliampere, two experiments without applied field gave 46.5 and 55.5 cc. of ozone formed per hour. With the plates 5 cm. apart, 16 kv. applied and a current of 1.3 milliamperes flowing in the ionization chamber, 69 cc. of ozone was formed. With the plates 2 cm. apart, 16 kv. applied and 2.6 milliamperes flowing, 205 cc. of ozone was formed.

A second set of experiments was made with much lower power. The tube was operated at 106 kv. with a current of 0.10 milliampere. A blank experiment without applied field gave 1.6 cc. of ozone formed per hour. With the electrodes 2 cm. apart and 16 kv. applied, a current of 0.11–0.14 milliampere was collected and 3.4 cc. of ozone was formed. The electrodes were than placed 5 cm. apart, 24.5 kv. applied, the same current collected and the same yield obtained. When a voltage gradient as high as 8 kv. per cm. is applied, it is evident that a considerable increase in ionization is obtained, as measured by ozone production; about 3000 volts per cm. is the highest which can be used without causing an increase in the ozone yield. In terms of saturation current phenomena, 3000 volts per cm. should produce saturation and higher voltage should cause increased ionization due to the kinetic energy of the ions becoming sufficient to ionize the gas molecules by impact.

Kriiger and Utesch estimated that the maximum current which they had entering their reaction chamber was 2×10^{-6} ampere. The yields of ozone reported in their experiments where ionization was studied varied from 0.3 to 66 cc. of ozone per hour. These are of the same magnitude as those reported above. In Fig. 14 the currents collected in the ionization chamber are plotted as a function of the applied voltage. There is no indication whatever of a saturation current; the curves in some cases were continued up to 40 kv. and were perfectly continuous. In one case with 0.010 milliampere, the yield of ozone would have been of the order of 0.10–0.20 cc. per hour. With 83 kv. applied to the tube, the current collected at 15 kv. was less than 0.0001 milliampere; at 90 kv. applied to the cathode ray tube, it amounted to 0.0013 milliampere, but here also there was no indication of saturation being attained.

The experiments reported above differ, however, in one respect from those of Kriiger and Utesch; they used 500-cycle power to operate their cathode ray tube while 60-cycle power was used in this investigation. It is difficult to see how this could affect the current collected in the ionization chamber. The average velocities of the electrons were approximately the same in the two cases. In order to be certain that the absence of a saturation current was not due to some ionization being produced outside the region of the applied field from which an increasing number of ions was drawn as the field increased, the ionization chamber was re-designed. The copper plate over the window of the tube was covered with mica, the condenser plates were moved up in the cell until their upper edges touched this mica and they were enclosed in a mica box. In this way all the ionization occurred in the space between the plates. Within the experimental error, the results were the same as those already described. These results render the values for the ratio of molecules produced to ions collected, as reported by Krüger and Utesch, very doubtful and the real value for this quantity will remain an open question until a more reliable method is devised for measuring the rate of ion production at high intensities of ionization.



Tube current—with plates 2.4 cm. apart: ⊙, 0.10 ma.; X, 0.03 ma.; △, 0.01 ma.—with plates 6.3 cm. apart: ●, 0.01 ma.

Fig. 14.

Summary

A cathode ray tube installation has been described which can be conveniently used for studying the effects of high velocity electrons on pure and mixed gases.

The tube can be operated continuously with a current of 0.0010 ampere and 200 kv.

A detailed study has been made of the ozonization of oxygen. The reaction has been shown to occur wholly in the gas phase and to be uninfluenced by the nature of the walls of the containing vessel.

Fifty per cent. of the reaction takes place in a volume within 2 cm. of the tube window, although the cathode rays have a range of 20 cm. under these conditions. This corresponds to the roughly exponential manner in which the energy of the beam falls off as one proceeds away from the window of the tube.

Ozone is both formed and decomposed under the influence of cathode rays. With continued raying a steady state is reached with an ozone concentration of 1 molecule to 1700 of oxygen. This concentration is independent of the tube current. This value compares with the concentration of 1 in 12 obtained with the silent discharge. Cathode rays have a much greater decomposing action than the silent discharge.

The maximum yield of ozone is 825 cc. of gas, measured under standard conditions and obtained with a tube current of 0.0010 ampere at 180 kv.

It has not been possible to check the results of Krüger and Utesch, who determined the amount of ionization by a saturation current method. Saturation was never observed in any of the experiments—the current in the ionization chamber increasing regularly as the applied field increased.

COMBINATION OF HYDROGEN AND OXYGEN UNDER THE INFLUENCE OF CATHODE RAYS

BY ABRAHAM LINCOLN MARSHALL

RECEIVED JUNE 23, 1928 PUBLISHED DECEMBER 10, 1928

The reaction between hydrogen and oxygen presented itself as the simplest oxidation reaction occurring in the gas phase which could be investigated. Hinshelwood and Thompson[1] have shown that it is possible to study a homogeneous thermal reaction between these substances in the range 550–600° with velocities increasing in rate up to explosions. It is well known that when flames of hydrogen and oxygen impinge on a cold surface hydrogen peroxide can be detected as one of the products of reaction. Marshall[2] has found that in the case of the photochemical reaction sensitized by mercury vapor the reaction proceeds by way of the peroxide stage and that this product can be obtained in the pure state. Scheuer[3] has studied the combination of hydrogen and oxygen (electrolytic gas) under the influence of α-particles and in all cases reported hydrogen peroxide as one of the products of the reaction, amounting in one case to 16% of the combined hydrogen.

In a previous paper[4] on the ozonization of oxygen the cathode ray tube

installation and general technique for high voltage work was described. One point, however, which is important for the technical success of this investigation was not mentioned, namely, the temperature of the window during the operation. Coolidge[6] reports a few measurements on window temperature during operation; with 200 kv. and 0.6 milliampere, the window reached 132° in five seconds, and with 1.3 milliamperes it reached 340° in ten seconds. Mixtures of hydrogen and oxygen explode when heated to about 600° so that one is strictly limited as to the amount of energy one can use for successful operation by the temperature of the window. If the filament does not give a uniform distribution of energy over the focal area, it is quite possible for a very small area to be receiving considerably more than its quota of electrons and to form a hot spot on the window. During the early part of the investigation, the tube was operated at 180 kv. and 1 milliampere, and on several occasions, due to a slight increase in current, disastrous explosions occurred. The system was finally operated at 180 kv. and 0.80 milliampere and was stabilized by means of a very sensitive relay connected in the grounded side of the high voltage line. This relay opened the remote control in the power line supplying the transformers when the tube current rose to 0.90–1.00 milliampere. During several months' work it functioned on a number of occasions and no further troubles were experienced from this source.

The reacting gases were taken from the high pressure supply lines of electrolytic hydrogen and oxygen available in the Laboratory and were used without further purification. It was possible to obtain rates of flow up to 1500 liters per hour of each gas. They were circulated through a cylindrical glass cell 3½″ in diameter by 10″ long. In all the experiments the pressure was kept at 91 cm. of mercury. The effluent gases were analyzed for hydrogen peroxide, water vapor and ozone. In order to make this analysis, it was necessary to dry the gases as completely as possible before use. It was found that the use of liquid-air traps for this purpose was entirely ineffective; the moisture was frozen out in the trap in the form of snow which would then be blown out of the trap, due to the high rate of gas passage. The most effective drying agent was found to be concentrated sulfuric acid. Two large gas scrubbing bottles of the type used in the previous investigation for absorbing ozone were connected in series and filled with sulfuric acid. The first scrubber did practically all of the work even at the fastest rates of flow, the purpose of the second being to remove that water vapor which the first could not absorb, due to an increase in its aqueous tension brought about by dilution and heating. It was found after some time that a slight mist of sulfuric acid was being carried over from the scrubbers, which deposited on the walls of the reaction chamber and gave rise to erratic analytical results by absorbing

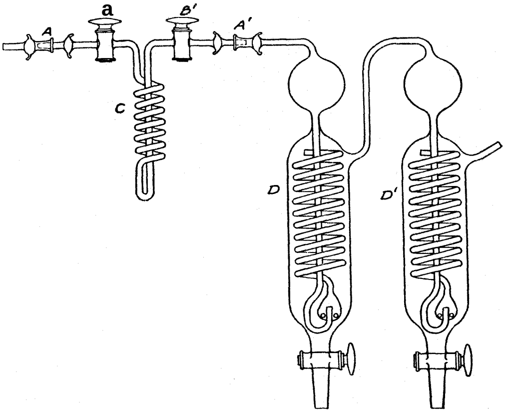
---

[5] Coolidge, *J. Franklin Inst.,* **December, 1926.**

some of the peroxide and water vapor formed in the reaction chamber. A long column of powdered potassium hydroxide was then introduced into the system and a plug of absorbent cotton, which was dehydrated by warming gently and passing a current of dry gas. Separate drying trains were used in each gas line. With this system it was possible to pass gas at 1500 liters per hour and collect less than 1 mg. of material in a liquid-air trap in the exit line over a fifteen minute period. This amount was within the experimental error of the analytical method used.

Method of Analysis

The gas mixture from the reaction vessel was led through a glass coil, C, in Fig. **1,** which was immersed in a carbon &oxide–ether mush to freeze out the hydrogen peroxide and water vapor formed during the reaction. The gas, before it entered the gas scrubbers D and D', was then passed through another spiral, not shown in the figure, which was immersed in warm water. D contained distilled water to absorb any peroxide not caught in C, and D′ alkaline potassium iodide to absorb ozone. The coil C was connected to the rest of the apparatus by means of two ground-glass joints, **A** and **A'.** After an experiment, the trap was disconnected at A and A' and while still in the cooling mixture, dry air was passed slowly through it to remove the hydrogen and oxygen. The stopcocks B and B' were then closed, the male parts of the ground joints carefully wiped free from grease and the coil warmed up to room temperature and dried in a blast of compressed air. The coil was then carefully wiped with a linen cloth and weighed. The coil weighed about **180 g.** and was balanced to the nearest milligram. During a series of experiments, the weight of the coil might drift **10–15** mg. but it was always found possible to check its weight to within one milligram when it was merely chilled, allowed to warm up and dried. It was absolutely necessary to displace the hydrogen and oxygen before weighing and to make sure that the coil was properly chilled before closing the stopcocks.



Pig. 1.

TABLE I

PROOF THAT RATIO H_2O_2/H_2O IS UNCHANGED BY PASSAGE THROUGH TRAP

Rate of circulation, **1400** liters/hour of H_2; **240** liters/hour of O_2

Coil 1		Coil 2			
Weight incr., g.	KMnO₄, cc.	**Weight incr., g.**	KMnO₄, cc.	**Ratio weight**	**Ratio titer**
0.089	27.6	0.011	1.3	8.1	21.2
.033	24.8	.002	2.0	16.5	12.4
Rate of circulation, **450** liters/hour of H_2; 60 liters/hour of O_2					
0.069	14.7	0.026	6.8	2.65	2.16
.034	14.3	.018	7.5	1.89	1.91
.030	13.9	.016	7.4	1.87	1.88

After weighing, the coil was washed out and the peroxide collected titrated with standard permanganate solution; any peroxide collected in D was then added and the total titer obtained. It was found that practically all of the material collected in Coil C was caught in the first two turns; however, some of this was blown through the coil in the form of snow and this was collected in D. From a knowledge of the two titers and the weight of material caught in C, it was possible to calculate the total amount of peroxide and water vapor formed. The physical properties of these two substances are almost identical and thus the ratio of peroxide to water in the coil was the same as that in the scrubber. To be certain of this point, a few experiments were made using a second coil; it was shown that the ratio of materials in Coil 2 was the same as in Coil 1. These results are tabulated in Table I.

The second experiment and the last two are the most reliable and in these it is easy to see that the ratios are the same within experimental error, which proves the desired point as only a small fraction of the material caught in the trap is peroxide.

Having obtained a reliable method of analysis, a study was next made of the effect of adding a small amount of water vapor on the yield of hydrogen peroxide. The results justify the conclusion that peroxide formation does not proceed *via* water vapor. Hydrogen, from an electrolytic generator producing 12.5 liters per hour, was passed through a water saturator at 22° and then led into the dry gas stream on its way to the reaction vessel. The gases were streaming at the rate of 1400 liters per hour of hydrogen and 240 liters per hour of oxygen. In blank experiments about 0.045 g. of water was collected in the coil in 15 minutes; with the tube operating the total material collected averaged 0.081 g., whereas without the water added 0.033 g. were collected. This latter consisted of approximately 85% hydrogen peroxide, so that the addition of the saturator has increased the water vapor concentration about ten-fold. The average of 6 experiments without water addition gave 41.2 cc. of hydrogen peroxide formed in fifteen minutes and the same amount was formed in the presence of the added water vapor.

Several series of experiments were performed using approximately the same concentrations of hydrogen and oxygen throughout the series but varying the rate of circulation. The results given in Table II are taken from the earlier part of the work and are not so reliable as those in Table III, which, however, are for a different concentration.

TABLE II

VARIATION IN REACTION PRODUCTS WITH RATE OF FLOW

Rate of circulation, liters per hour		Product formed in one hour, cc.			
H_2	O_2	H_2O_2	H_2O	O_3	$H_2O_2 + H_2O$
1400	240	116.8	166.0	13.6	282.8
800	120	100.8	188.8	11.2	289.6
1400	240	115.2	164.4	..	279.6
450	60	83.2	218.8	8.0	302.0
800	120	97.2	211.2	..	308.4
1400	240	114.0	167.6	..	281.6

Each set of values is the average of 4 or 5 experiments and while the peroxide determinations are easily reproducible, those for the water vapor in some cases show considerable divergences, typical sets of data being 44.7, 46.2, 37.0, 36.6 and 55.2, 46.0, 41.4, 46.2. This, however, is to be expected, since all the errors of the analysis are placed on the water vapor value, which is obtained by a difference method.

The second half of Table III gives a résumé of all the data obtained for a single set of conditions and is typical of all the results to be reported in this paper.

TABLE III

VARIATION IN REACTION PRODUCTS WITH RATE OF FLOW

Rate of circulation, liters per hour		Product formed in one hour, cc.			
H_2	O_2	H_2O_2	H_2O	O_3	$H_2O_2 + H_2O$
1450	1280	214.0	293.6	108.4	507.6
865	780	198.4	304.4	103.2	502.8
345	300	153.6	353.6	70.0	507.2
865	780	214.0	313.2	122.0	
		212.0	360.0	122.4	
		187.6	306.8	91.6	
		192.0	272.8	92.0	
		174.6	302.4	71.2	
		206.4	316.8	121.6	
		193.1	254.8	92.4	
		193.9	284.2	96.0	
		212.2	327.8	118.8	

It will be noted that the yield of peroxide for a given concentration of hydrogen and oxygen decreases as the rate of flow is decreased. There is a roughly linear relation between the concentration decreases and the water vapor increases, the sum of the two remaining constant. This means that at the lower rates of flow where the concentration of the products is higher, some of the peroxide is decomposed forming water vapor. The total amount of reaction for a given energy input is constant and hence the sum of the peroxide plus water vapor formed is independent of the rate of flow. This is the best proof available that both peroxide and ozone are decomposed as well as formed by high velocity electrons. The amount of water vapor primarily formed by the radiation is constant, independent of the rate of circulation, and the observed increases at lower rates of flow are due to secondary decomposition of hydrogen peroxide.

Influence of Changing Concentrations

Another very interesting study in an investigation of this kind is the kinetics of the reaction. Five different concentrations were used and the gases were circulated at the fastest rate available in an attempt to avoid as much decomposition of hydrogen peroxide as possible. About twenty experiments were made at each concentration and the extreme values of the peroxide and ozone determinations did not vary more than (±)5% from the mean and, in most cases, agreed much closer than this; in the case of the water vapor determinations, the extremes were (±)18% in a few cases with most of the values coming within better than 10% of the mean. The results are given in Table IV.

TABLE IV

VARIATION IN REACTION PRODUCTS WITH CONCENTRATION

Rate of flow, liters per hour		Product formed in one hour, cc.			
H_2	O_2	H_2O_2	H_2O	O_3	$H_2O_2 + H_2O$
1450	300	173	128	24	301
865	1500	167	428	152	595
1450	780	199	211	68	410
345	2000	99	528	256	627
1450	1280	197	269	105	466

These results can be compared with those obtained by Lind[6] raying similar mixtures in a static system with α-particles. Lind gives values for

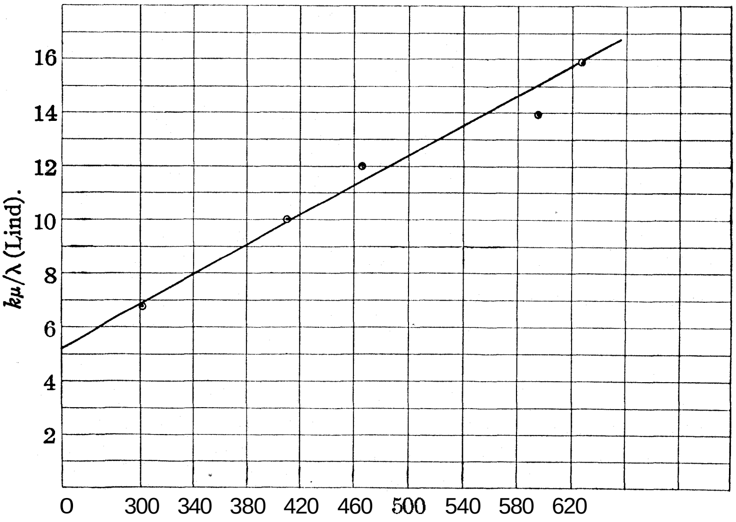


Fig. 2.

$k\mu/\lambda$, the velocity constant obtained with α-particles, for a number of concentrations of hydrogen and oxygen. These velocity constants are all reduced to values for a cell of given volume and plotted as a function of the concentration. This reduction is possible since Lind has shown that the velocity constant varies inversely as the square of the diameter of the sphere in which the reaction is proceeding. From the smoothed curve of

---

[6] Lind, THIS JOURNAL, **41**, 543 (1919).

the reaction velocity–concentration diagram, values are read off corresponding to the concentrations used in this investigation. In Lind's experiments in a static system, the final product would be water vapor with only traces of peroxide and ozone; hence the sum of the peroxide and water vapor formed in a given time in the cathode ray experiments should be proportional to Lind's reaction velocity constant if the mechanism in the two cases is similar. The comparison is given in Fig. 2 and it is seen that any discrepancies lie well within the limits of experimental error in the two investigations.

The rate of peroxide formation is very insensitive to changes in concentration; at 15% hydrogen it has dropped to half the maximum value and at 83% hydrogen it has decreased 13% from the maximum. The rates of formation of water vapor and ozone seem to parallel one another very closely as evidenced by Fig. 3, which shows that over the range investigated the relationship is almost linear. We know that with pure oxygen the curve must return to zero amount of water vapor formed, so that it is possible to guess the result in the concentration region not investigated. This seems to indicate that the mechanisms responsible for water vapor and ozone formation are closely connected and quite different from that which produces hydrogen peroxide.

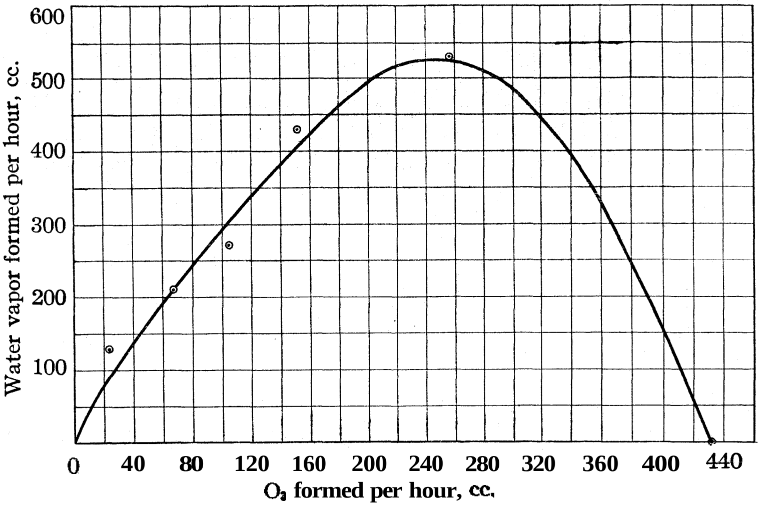

Fig. 3.

Summary

A method has been developed for analyzing gas mixtures containing small quantities of hydrogen peroxide, water vapor and ozone.

In the reaction between hydrogen and oxygen under the influence of cathode rays, it has been shown that peroxide, water vapor and ozone are formed as primary products.

A kinetic study at varying concentrations of hydrogen and oxygen shows that the rate of peroxide formation is almost independent of concentration, whereas the rate of water vapor formation varies over a five-fold range, and ozone over a ten-fold range.

The rates of formation of ozone and water vapor parallel one another very closely at all the concentrations studied, suggesting that the same primary mechanism is responsible for the formation of both.

The gross rate of reaction parallels that observed by Lind for the same reaction under the influence of a-particles.

THE CATALYTIC DECOMPOSITION OF HYDROGEN PEROXIDE IN AN ACID CHLORINE–CHLORIDE SOLUTION. II. AN INTERPRETATION OF THE RATE MEASUREMENTS IN CONCENTRATED SOLUTION

BY ROBERT LIVINGSTON

RECEIVED JUNE 29, 1928 PUBLISHED DECEMBER 10, 1928

The velocity of decomposition of hydrogen peroxide in an acid chlorine–chloride solution can be represented, with approximate accuracy, by the following equation[1]

$$v = \chi(H_2O_2)(H^+)(Cl^-)f^2_{HCl} \qquad (1)$$

where χ is a constant (0.00010) and f_{HCl} is the activity coefficient of hydrochloric acid. In dilute solutions the equation apparently represents the experimental data within the limits of error; in more concentrated solutions the value of χ decreases systematically to a value of 0.00005 at an ionic strength of 5μ. Equation 1 may be considered as a simplified form of the general reaction velocity equation, presented by J. N. Brönsted.[2] The exact form of the Bronsted equation for this reaction is

$$v = K\,H_2O_2(H^+)(Cl^-)f^2_{HCl} \cdot f_{H_2O_2}/f_x \qquad (2)$$

where f_x is the activity coefficient of the "reaction complex," ($H_2O_2 \cdot HCl$). If we assume that $f_{H_2O_2}/f_x$, the ratio of the activity coefficients of two neutral molecules, is equal to unity, Equation 2 reduces to the form of Equation 1.

It has been demonstrated, both on theoretical[3] and on experimental[4]

[1] Livingston and Bray, THIS JOURNAL, 47,2069 (1925); 48,405 (1926).

[2] (a) Bronsted, *Z. physik. Chem.*, 102, 169 (1922); (b) "The Velocity of Ionic Reactions," Columbia Press, 1927.

[3] Debye and McAuley, *Physik. Z.*, 26, 22 (1925).

[4] A review of existing data has been recently presented by Randall and Failey, *Chem. Reviews*, 4,271,285 (1927). This summary demonstrates that the formula holds

grounds, that the variation of the activity coefficient of a non-electrolyte in an aqueous salt solution may be represented by an equation of the following form

$$\log f_0/\mu = k \tag{3}$$

where f_0 is the activity coefficient of the non-electrolyte and k is a constant the value of which depends upon the properties of the salt and the non-electrolyte present.

Since both hydrogen peroxide and the reaction complex are neutral molecules, we may write

$$\log (f_{H_2O_2}/f_x) = \mu(k_{H_2O_2} - k_x) = \mu k' \tag{3a}$$

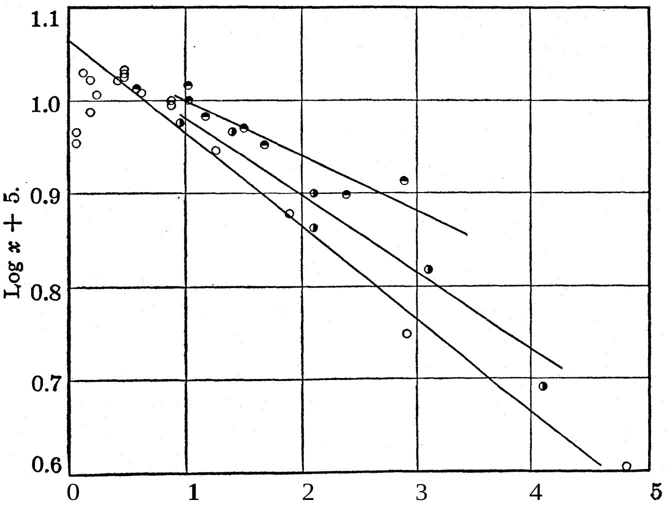
Substituting this relation in Equation 2, we obtain

$$v = K(H_2O_2)(H^+)(Cl^-)f^2_{HCl} \cdot 10^{\mu k'} \tag{4}$$

or

$$\log K = \log \chi - \mu k' \tag{4a}$$

We may test this relation by plotting log χ against μ. Such a plot is given in Fig. 1. The data are taken from Table I of reference 1. The points, representing experiments performed in hydrochloric acid solutions, fall on a straight line within the limits of experimental error. The experi-



Ionic strength.

Fig. 1.—The velocity of decomposition of hydrogen peroxide in an acid chlorine–chloride solution.

---

with reasonable accuracy for all of the non-electrolytes investigated, even at high ionic strengths. Linderström-Lang, *Compt. rend. trav. lab. Carlsberg*, **15**, No. 4 (1924), measured the solubilities of quinone, hydroquinone, succinic acid and boric acid in the presence of varying concentrations of a number of different salts, and found that the ratio of the logarithm of the activity coefficient of the non-electrolyte to the equivalent concentration of the salt was practically constant.

ments at the lowest concentrations show a negative departure of 10 to 20%; however, this is probably due to experimental error, since the absolute values of these rates are very small.[5] The experiments performed in mixtures of hydrochloric acid and perchloric acid or sodium chloride may be also represented by straight lines the slopes of which differ from that determined by the experiments in hydrochloric acid. At the higher concentrations these mixtures may be regarded as practically pure solutions of perchloric acid or of sodium chloride, and therefore we should expect the straight line relation to hold. Unfortunately the experiments were not planned to illustrate this effect and several of the experiments at low ionic strength were performed in mixtures containing relatively large amounts of hydrochloric acid. The values of the ionic strength given are based upon concentrations expressed in moles per liter rather than in molality.[6]

An additional test of Equation 4 may be made by combining the rate measurements (that is, values of χ) with experimentally determined values of $f_{H_2O_2}$. If the reaction complex has properties similar to those of a stable neutral molecule, we may expect that

$$\log f_x = \log (K/\chi) f_{H_2O_2} = \mu k_x \qquad (5)$$

The Activity of Hydrogen Peroxide in Sodium Chloride and Sodium Sulfate Solutions[7]

The activity of hydrogen peroxide in aqueous salt solutions can be readily determined by "partition" experments with a suitable immiscible solvent. A variety of organic solvents have been investigated;[8] of these iso-amyl alcohol is probably best adapted to the purpose.[9]

The following *experimental procedure* was adopted. The aqueous peroxide solution, containing a known amount of salt (weighed out as anhydrous material), was made up in a glass-stoppered cylinder and placed in a 25° thermostat to attain thermal equilibrium. After an hour or more a definite amount of iso-amyl alcohol (also at 25°) was added to the aqueous solution. The cylinder was then shaken vigorously until the two phases formed a fine emulsion and then returned to the thermostat and allowed to remain for two hours. At the end of this time the two phases had separated into clear, apparently homogeneous layers and samples were withdrawn for analysis.[10]

[6] Compare footnote 4.

[7] These experiments were performed at the University of California in 1925.

[8] See Walter and Lewis, THIS JOURNAL, **38,** 633 (1916).

[9] (a) H. Calvert, *Z. physik.* Chem., **38,** 512 (1901); **(b)** A. Joyner, Z. *anorg. Chem*, **77,** 103 (1912).

[10] The experiments of Joyner (ref. 9b) indicate that the partition equilibrium is attained very rapidly.

Materials.—The salts were purified by repeated crystallization of the "C. P." materials. The stock hydrogen peroxide solution was made by diluting "perhydrol." The iso-amyl alcohol was purified by twice distilling "C. P." material in an all-glass still, discarding the first and last fractions.

In the presence of *iso*-amyl alcohol, hydrogen peroxide cannot be titrated with permanganate solution.[9a] After a number of preliminary experiments, the following analytical procedure was adopted. To determine the aqueous solution: add the sample (2 cc.) to *a* glass-stoppered flask containing 50 cc. of distilled water, 1 cc. of concentrated sulfuric acid and 4 g. of potassium iodide, allow to stand for thirty minutes and titrate the resulting iodine with thiosulfate to a starch end-point. To determine the alcohol solution: add the sample (10 cc.) to a glass-stoppered flask containing 200 cc. of distilled water, 4 cc. of concentrated sulfuric acid and 4 g. of potassium iodide, allow to stand for thirty minutes and titrate with thiosulfate, shaking frequently, until the yellow color disappears from the floating droplets of alcohol.[11] These methods give results reproducible within 0.5%. The method for the aqueous solution was shown to give results identical with those obtained by direct titration with permanganate in the absence of the alcohol.

Samples of the alcohol (upper) layer were withdrawn and measured with an ordinary pipet. Samples of the aqueous layer were obtained by introducing a sealed glass tube into the solution, breaking the thin glass seal[12] against the bottom of the vessel and forcing a sample of the lower layer out by air pressure.

Results and Calculations.—The experiments of Joyner[9b] at 0° and of Calvert[9a] at 25° demonstrate that the activity of hydrogen peroxide in aqueous solution is practically independent of its concentration for concentrations between 0.10 and 2.0 M. In light of these results, all of our experiments were performed with hydrogen peroxide solutions of about 1.5 M. The results of the partition experiments are summarized in Table I. The concentration of the added salt, in moles per liter, is given in the second column; the mean value of the distribution constant, D, in the third; and the number of separate experiments, upon which the mean value was based, in the fourth column.

TABLE I

[11] As was pointed out by Calvert (ref. 9a), it is impossible to obtain a starch iodine color in the presence of the alcohol phase. He overcame this difficulty by adding sufficient water at 55" to render the titration mixture homogeneous.

[12] Compare Abbott and Bray, THIS JOURNAL, 31, 738 (1909).

The values of $f_{H_2O_2}$ listed in the fifth column are based upon the assumption that the value for pure aqueous solution is unity.[13] In these computations we have used a value of 6.95 for the distribution coefficient between alcohol and pure water; this is an average of the value presented here (6.87) and that given by Calvert (7.03).

We would predict from Equation 3 that $\log f_{H_2O_2}/\mu$,[14] given in the last column, should have a constant value. While the observed trend may be real,[15] it is also possible that it is due to an error in the average value chosen for the distribution coefficient with pure aqueous solutions. The trend could be eliminated by choosing a value 2% higher.

The Measured Velocity and the Activity of Hydrogen Peroxide.—By combining values of $f_{H_2O_2}$ with velocity measurements which were performed in sodium chloride solution, we may test the validity of Equation 5. The results of such a comparison are summarized in Table II. The first five columns are taken from Table I, ref. 1. The values of $f_{H_2O_2}$, Col. 6, were interpolated from Table I. In computing k_x, Col. 7, K was obtained by extrapolating χ to infinite dilution (Fig. 1) and has a value of 11.7×10^{-9}

TABLE II

INTERPRETATION OF THE REACTION VELOCITY IN SODIUM CHLORIDE SOLUTIONS

No.	(HCl)	(NaCl)	μ	$\chi \times 10^5$	$f_{H_2O_2}$	$\frac{\chi}{f_{H_2O_2}} \times 10^5$	k_x	a_{H_2O}	$K'_a \times 10^5$
1	0.444	0.50	0.94	9 5	0.92	10.3	0.059	0.97	11.3
2	.444	1.00	1.44	9.3	.89	10.5	.033	.95	12.2
3	.098	2.00	2.10	7.3	.85	8.6	.064	.93	10.7
4	.222	1.89	2.11	8.0	.85	9.4	.045	.93	11.7
5	.098	3.00	3.10	6.6	.80	8.25	.049	.89	11.7
6	.098	4.00	4.10	4.9	.75	6.55	.062	.85	10.8

While there is considerable erratic variation in the values of k_x, there is no apparent trend. This may be considered as definite evidence in support of Equation 5. It follows from this that when due allowance is made for the variation of the activity coefficients of the neutral molecules involved, the rate of decomposition of hydrogen peroxide in acid chlorine-chloride solutions at ionic strengths between 0.1 and 4.0 is accurately represented by the Bronsted formula, and that it is unnecessary in this case to make allowance for any change in the nature of the solvent.[16] It is interesting to note that k_x has a value typical of normal non-electro-

---

[13] For a discussion of factors, presumably negligible in this case, which can affect the accuracy of activity determinations based upon distribution measurements, see Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Company, Inc., New York, 1923, p. 262.

[14] Here, as in the rate measurements, the values of the ionic strength are based upon concentrations expressed in moles per liter rather than in moles per 1000 g. of water.

[15] Compare the data recorded by Randall and Failey, ref. 4.

[16] See Bronsted, *Z. physik. Chem.*, 115, 359–363 (1925).

lytes[3] and unlike $k_{H_2O_2}$ is positive in sign; that is, the fugacity of the complex is increased by the addition of salts.

It is also possible to interpret these data in terms of the "activity rate" theory.[17] According to this theory the reaction velocity is proportional to the product of the activities of the components, and the velocity equation is

$$v = K_a a_{H_2O_2} a_{H^+} a_{Cl^-} \qquad (6)$$

However, the data of Col. 7, Table II, demonstrate that K_a $(= \chi / f_{H_2O_2})$ is not a constant. It was suggested by G. N. Lewis[18] that the departure from constancy of K_a might be due to the solvent entering directly into the reaction. As is demonstrated by the data in the last column of Table II, we may obtain an empirical fit if we introduce[19] $a^3_{H_2O}$ into Equation 6. This corresponds to the assumption that three molecules of water take part in the reaction.[20] It is, unfortunately, not possible to determine $a_{H_2O_2}$ in the presence of hydrochloric acid by the distribution method used, both because of the decomposition of hydrogen peroxide in hydrochloric acid and because of the solubility of the acid in *iso*-amyl alcohol. In order to give K' a constant value of about 11.7×10^{-5} for the measurements in concentrated hydrochloric acid, we must assume that hydrochloric acid and sodium chloride have about the same effect on the activity of hydrogen peroxide. However, if this is done, the experiments in dilute solution exhibit a departure which is apparently too great to be attributed entirely to experimental error. Therefore, in spite of the constancy of K' for the measurements in sodium chloride solutions, it seems improbable that the modified form of the "activity rate" theory represents the facts.

A Discussion of Two Analogous Reactions.—The velocity of the decomposition of hydrogen peroxide in a bromine–bromide solution[21] and the velocity of rearrangement of chloro-acetylaminobenzene in an acid chloride solution[22] can be represented by laws analogous to the law determined for the decomposition of hydrogen peroxide in an acid chlorine–chloride solution.

---

[17] See for example Harned and Seltz, THIS JOURNAL, 44, 1476 (1922).

[18] Private communication.

[19] The values of a_{H_2O} given in Table II were computed from the values of γ_{NaCl} presented by Lewis and Randall, ref. 13, p. 351.

[20] It is not at all improbable that water does enter into the reaction, although there is, of course, no *a priori* reason for selecting the third or indeed any positive power. It is a suggestive fact that Walton and Jones, THIS JOURNAL, 38, 1955 (1916), find that certain hydrogen peroxide decomposition reactions occurring in non-aqueous solvents are of second order.

[21] (a) Bray and Livingston, THIS JOURNAL, 45, 1251 (1923); (b) Livingston and Bray, *ibid.*, 45, 2048 (1923); (c) Livingston, *ibid.*, 48, 53 (1926).

[22] (a) Rivett, *Z. physik. Chem.*, 82, 201; 85, 113 (1913); (b) Harned and Seltz, THIS JOURNAL, 44, 1480 (1922); (c) Åkerlöf, Medd. K. Vetenskafisakad. *Nobelinstitut*, 6, No. 2 (1922); (d) Soper, J. Phys. *Chem.*, 31, 1192 (1927).

The decomposition of hydrogen peroxide in acid bromine–bromide solutions has been studied chiefly at ionic strengths less than unity. Under these conditions its velocity may be represented with fair accuracy by the following equation.

$$v = \chi_{\mathrm{HBr}}(\mathrm{H_2O_2})(\mathrm{H^+})(\mathrm{Br^-})f^2_{\mathrm{HBr}} \qquad (7)$$

However, an examination of the data shows that there is apparently a systematic decrease in the value of χ_{HBr} with increasing ionic strength. A plot of log χ against μ shows that the data are consistent with an equation analogous to Equation 4. The measurements performed in hydrobromic acid solutions (at ionic strengths between 0.01 and 0.4) indicate a value of about -0.07 for k'. The experiments performed in solutions containing potassium bromide and sulfuric acid (at ionic strengths[23] between 0.05 and **4.3)** exhibit considerable erratic variation but are consistent with a value of about -0.04 for k'.

The velocity of rearrangement of chloro-acetylaminobenzene was measured by Rivett[22a] in solutions of hydrochloric acid up to one molal and in solutions containing 0.25 M hydrochloric acid and one of a number of different chlorides (as well as sulfuric acid) at a variety of concentrations up to an ionic strength of about 4. More recently Harned[22b] has repeated Rivett's measurements in hydrochloric acid solutions. Åkerlöf[22c] measured the rate in solutions containing 0.25 M hydrochloric acid and aluminum chloride at concentrations up to 2 N. It has been demonstrated that the rate-determining step in the reaction is $\mathrm{C_6H_5{\cdot}NHClAc + H^+ + Cl^- \longrightarrow X}$. This mechanism should lead to a rate equation similar to Equation 4, and therefore the plot of log $[k/(\mathrm{H^+})(\mathrm{Cl^-})f^2_{\mathrm{HCl}}]$ (where k is the first order constant) against μ should be a straight line. We may use the measurements of Harned[24] to obtain approximate values of f_{HCl} in alkali chloride solutions. The experimental values for alkali chloride solutions fall approximately on straight lines with slopes of about -0.09; but these lines do not appear to extrapolate to the same point in dilute solution. Rivett's experiments in pure hydrochloric acid give a straight line with a slope of 0.06; the values of Harned and Seltz are practically constant, but show a slope of about -0.01 if recent values[25] of f_{HCl} are used. These apparent inconsistencies are probably due to a factor which has been discussed by

---

[23] Based upon concentrations expressed in moles per liter rather than in molality. This probably introduces a considerable error in the more concentrated solutions. See note b, Table II, ref. 20. As has already been stated (ref. 21c, p. 55), the values of χ_{HBr} measured in KBr–sulfuric acid solutions are consistently 10% higher than those measured in hydrobromic acid solutions, or in solutions containing HBr and metallic bromides. This difference must be due to some unknown difference in experimental conditions.

[24] Harned, THIS JOURNAL, 42, 1808 (1920); also Harned and Brumbaugh, *ibid.*, 44, 2729 (1922).

[25] Randall and Young, *ibid.*, 50, 989 (1928).

Soper.[22d] He has shown that there are two possible products of the reaction, one of which is an oxidizing agent, and that, therefore, the iodimetrically measured rate is always less than the actual rate. This effect is greatest when $a_{H^+} \times a_{Cl^-}$ is small. A correction for this factor would raise all of the values of k for dilute solution experiments, especially those performed in dilute hydrochloric acid solutions. If proper allowance were made for this factor and the correct values of f_{HCl} were employed, it is very probable that the velocity could be accurately expressed in terms of an equation similar to Equation 4.

In conclusion we may state that for the type of reaction considered here,[26] Bronsted's equation is sufficient to represent the reaction velocity measurements at all concentrations investigated. Taken in conjunction with the success of the theory in interpreting the results of velocity measurements for widely different types of reactions in dilute solutions,[27] this constitutes strong empirical evidence for the general validity of the Bronsted hypothesis as applied to reactions in aqueous solution. The application of the theory to other types of reactions in concentrated solutions will be considered in another paper.

Acknowledgment should be made to Professor W. C. Bray and to Professor F. H. MacDougall for their kind interest and criticism.

Summary

1. The Bronsted reaction velocity equation has been combined with the Debye and McAuley equation for the activity of non-electrolytes to obtain an expression for the rate of decomposition of hydrogen peroxide in acid chlorine–chloride solutions

$$v = K\,(H_2O_2)(H^+)(Cl^-)f^2_{HCl} \cdot 10^{\mu k}$$

It has been shown that this expression is in agreement with the experimental material.

2. The activity of hydrogen peroxide in sodium chloride and sodium sulfate solutions has been determined by distribution measurements. These results have been used to test a prediction based upon the reaction velocity theory.

3. Some discussion of the velocity measurements of two analogous reactions has been presented.

THE ETHYL ACETATE EQUILIBRIUM

BY R. C. CANTELO AND R. D. BILLINGER

RECEIVED JUNE 30,1928 PUBLISHED DECEMBER 10, 1928

When the system ethyl alcohol, acetic acid, ethyl acetate and water has reached a state of equilibrium for a given temperature and pressure, this equilibrium state is expressed by the chemical equation $C_2H_5OH + HAc \quad C_2H_5Ac + H_2O$.

For a virtual change from equilibrium $dZ = 0$, where Z is the thermodynamic potential, and since $dZ = \Sigma\mu dm$, where μ = specific chemical potential and m = mass of component, we may write: $\bar{\mu}_1 + \bar{\mu}_2 = \bar{\mu}_3 + \bar{\mu}_4$, where $\bar{\mu}_1$, $\bar{\mu}_2$, - - - are the molecular chemical potentials respectively of ethyl alcohol, acetic acid, - - -.

Now for each of the four substances constituting the system we have an equation of the form $\bar{\mu}_1 - \bar{\mu}_{1,0} = RT \ln a_1$, where a_1 is the thermodynamic concentration or activity of the component in the system, $a_{1,0}$ for the standard state being arbitrarily placed equal to 1. It is then a simple matter to derive the mass action expression for equilibrium, namely, $K_a = a_3a_4/a_1a_2$. Now it is quite possible that a change in the thermodynamic environment may change the value of one or more of the chemical potentials of the substances involved, and such changes in chemical potential will result in a change in the value of K_a, the equilibrium constant.

In the present investigation we have sought to change the thermodynamic environment by using in place of water alone solutions of the salts sodium chloride, sodium thiocyanate and sodium iodide. These salts form a Hofmeister series as follows: $\overline{CNS}$ $\overline{I}$ $\overline{Cl}$, as regards their relative effects in retarding gelation, that is, in lowering the temperature of gelation. The relative effects of these salts are of interest, therefore, with respect to the water equilibrium. Bancroft[1] considers liquid water to be an equilibrium mixture of hydrol and polyhydrol, the latter being a polymerized form of the former. He ascribes the greater peptizing action of potassium iodide over potassium chloride on gelation in water to the water equilibrium being shifted in the direction of more hydrol, the peptizing agent.

Schlesinger[2] investigated the influence of $LiCl$, $NaCl$, KCl and $CaCl_2$ on the ethyl acetate equilibrium at 100°, and found that the equilibrium was shifted, owing to the presence of these salts. He found that with $NaCl$, $LiCl$ and $CaCl_2$, his equilibrium constant could be calculated from the linear equation, $K = 3045 - 21.217\,C$, C being the salt concentration in milliequivalents per mole of water.

[2] Schlesinger, *Ber.*, 59B, 1965 (1926).

Experimental Method

Weighed quantities of acetic acid, ethyl alcohol and water or salt solution were mixed together in a weighed flask. From this mixture small glass tubes were filled and sealed by means of a blast lamp. The tubes were weighed before and after filling to obtain the weight of sample taken.

The method of filling the tubes was to fit up the weighed flask as a wash bottle with a capillary jet; then by means of a current of air, dried by passing through calcium chloride, it was possible to force the liquid into the small tubes.

The acetic acid, ethyl alcohol and neutral salts used were all c. p. chemicals which were tested for impurities. The acid contained 99.39% of acetic acid by weight and the alcohol 95.75% by weight. The salts were all thoroughly dried before using.

The sealed tubes were placed in a bath of carbon tetrachloride which was kept refluxing by a simple heater. The heater consisted of a 100-watt incandescent lamp in a can insulated with sheet asbestos. By this arrangement it was possible to keep the tubes containing the esterification mixture at a temperature of 78°.

Esterification in the absence of a mineral acid catalyst is slow, even at this temperature, and it was necessary to continue the heating for from thirty to forty days. Then from time to time a tube was taken from the bath, cooled in ice, the capillary end broken and the contents placed in ice cold, freshly boiled water. The mixture was transferred to a volumetric flask and an aliquot portion taken for titration against standard barium hydroxide solution. By means of the titration value the concentration of acetic acid was known in the resulting mixture, and from the known initial concentrations it was possible to calculate the concentration of all four constituents in the equilibrium mixture. Concentrations were figured in terms of millimoles of the constituents and the equilibrium constant K_E was then expressed as

$$K_E = \frac{\text{Millimoles of } CH_3COOC_2H_5 \text{ X Millimoles of } H_2O}{\text{Millimoles of } CH_3COOH \text{ X Millimoles of } C_2H_5OH}$$

When several successive samples gave approximately equal values of K_E, the equilibrium was assumed to have been reached.

TABLE I

ESTERIFICATION WITH NO ADDED SALT

Run	Sample	K_E	Av. K_E	Concn., init.	CH_3-COOH final	Concn. init.	C_2H_5OH, final	Concn. init.	H_2O, final	Concn. CH_3-$COOC_2H_5$, final

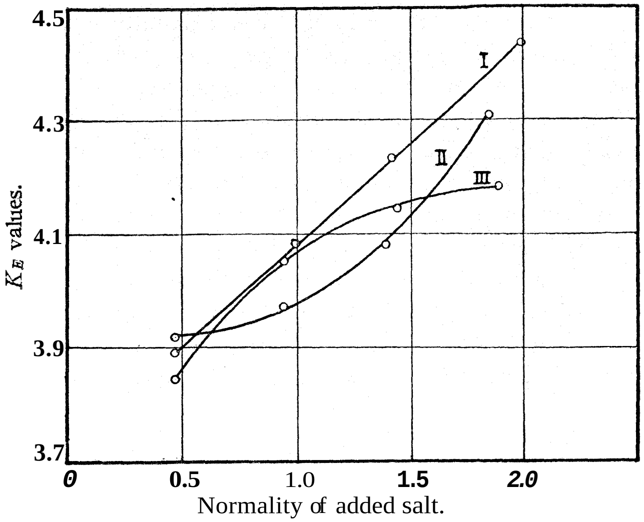
Discussion of Results

Tables II, III and IV, and Fig. 1 show that K_E increases with increasing salt concentrations. When sodium chloride is the added salt, the equilibrium constant is a linear function of the concentration of the salt, but the effect of sodium iodide and sodium thiocyanate is more complicated. Each salt appears to have its own specific effect and work at present in progress in this Laboratory seems to indicate that one salt at least depresses the equilibrium constant below the value 3.7. Further work is evidently necessary before our values may be explained, and work is now in progress with a view to determining the relative chemical potentials of the components in the system with and without the addition of salts. It may be pointed out, however, that the Hofmeister series does not appear to hold for the order of the effects upon the equilibrium constant at 78°.



I, Curve for K_E values with NaCl; II, curve for K_E **values with** NaCNS; III, curve for K_E values with NaI.

Fig. 1.

Summary

The ethyl acetate equilibrium depends upon the equality of the sum of the chemical potentials of the ethyl alcohol and acetic acid to the sum of the chemical potentials of the ethyl acetate and water. Any change in thermodynamic environment may change the value of one or more of these potentials, thereby giving a new value for the equilibrium constant.

The equilibrium constant in the absence of salts for this system has been measured and found to be equal to 3.7.

The equilibrium constant in the presence of salts has been measured and found to increase with the concentration of the salt in the water solution used in place of water alone. With sodium chloride as added salt, the equilibrium constant increases linearly with the concentration of sodium chloride. With sodium thiocyanate and sodium iodide, the effect is more complicated.

The order of the effects of the anions upon the equilibrium constant is not that of a Hofmeister series.

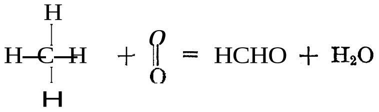
OXIDATION OF METHANE WITH NITROGEN PEROXIDE

BY PER K. FROLICH, P. J. HARRINGTON AND ALDEN H. WAITT

RECEIVED JULY 2, 1928 PUBLISHED DECEMBER 10, 1928

The products ordinarily formed in the direct oxidation of methane are carbon dioxide, carbon monoxide and water. According to Bone's hydroxylation theory, however, the reaction proceeds stepwise with methanol, formaldehyde and formic acid as the intermediate products of oxidation.[1] Although it has been possible to isolate formaldehyde by carefully controlled partial oxidation of methane, nevertheless, no success has been met with in trying to produce methanol by the same procedure. This is supposedly due to the fact that the alcohol is so much more readily oxidized than the hydrocarbon, thus making successive quantities of oxygen attack the initially formed methanol molecules in preference to the remaining methane. Hence methanol is never permitted to build up to concentrations sufficient for its detection. The same reasoning holds for formaldehyde, which, however, represents a further step in the oxidation and therefore is less difficult to isolate when the oxygen concentration is kept low. In normal combustion, however, with a high concentration of oxygen and high temperature, reaction proceeds beyond the formaldehyde stage, with the resulting formation of the ultimate products, carbon monoxide and dioxide.

If this line of reasoning be correct, it should be possible to isolate the intermediately formed alcohol if the process could be carried out under such conditions that the available oxygen, present in only limited concentration, could be consumed by the methane molecules almost instantaneously, avoiding any further reoxidation. It would seem that this could be accomplished by bringing a mixture of nitrogen peroxide with an excess of methane up to reaction temperature, followed by rapid cooling to stabilize the oxidation products against thermal decomposition. Since nitrogen peroxide is capable of liberating 1 atom of oxygen, the tendency for further oxidation of the initially formed methanol would be materially reduced.[2] With elementary oxygen, on the other hand, the conditions seem less favorable in that the consumption of two atoms of oxygen is more probable



$$\mathrm{CH_4} + \mathrm{O{=}O} = \mathrm{HCHO} + \mathrm{H_2O}$$

---

[1] Bone, "Coal and its Scientific Uses," p. 176.

[2] There is, of course, a further possibility of direct reaction of nitrogen peroxide with methane, and from such intermediate substances the final oxidation products may result.

Attempts to isolate intermediate products by oxidation of methane with nitrogen peroxide have already been reported on by Bailey,[3] who found that formaldehyde was produced at a minimum reaction temperature of 450° when a mixture of the two gases was passed through a heated porcelain tube. Bibb[4] has claimed the production of valuable oxidation products from methane by a similar procedure, except that he employed the nitrogen peroxide merely as a gas phase catalyst, limiting its concentration to 2%.

In the present investigation a minimum reaction temperature below 450° with production of methanol was sought, using more than 2% of nitrogen peroxide as an oxidizing agent and various surface catalysts.

Experimental Procedure

In the apparatus, which was made entirely of Pyrex glass, nitrogen peroxide was generated from copper and fuming nitric acid, dried and then liquefied in a bulb surrounded by melting ice. Carefully metered and measured natural gas containing 98.3% of methane was slowly bubbled through the peroxide and saturated with it at 0°. Measured methane was then added to adjust the percentage of peroxide in the mixture to that desired and the gases were passed through a reaction chamber 14 cm. long and of 2.8 sq. cm. in free cross section. A central tube extending through the entire length of the reactor held a thermocouple with a movable weld. The chamber was externally heated by a coil of resistance ribbon. Following the chamber, liquid product was removed through a condenser to a cooled bulb, while the gases were scrubbed and discarded. For the recovery of the nitrogen oxides, oxidation and absorption in sulfuric acid worked successfully.

Samples of liquid product were fractionated and the specific gravity, acidity and formaldehyde content found. With the aid of exit gas analyses, material balances were made and minimum reaction temperatures were investigated. Variations in the minimum reaction temperature and in the quantity and quality of product with variation in rates of gas flow (from 8 to 45 liters per hour) and percentage of nitrogen peroxide in the inlet gas mixture (from 8 to 35%) were studied, as well as the effects of pumice, platinized asbestos, vanadium pentoxide, nickel wire and hopcalite as catalysts.

Results

The results of a series of experiments made with an open chamber and with the chamber filled with pumice granules are given in Table I. Despite great difficulties in the measurement of the corrosive gases and in gas and liquid analyses, the material balances were satisfactory.

The minimum temperature was taken as the point above which the gases issued colorless from the reaction chamber, and below which they came out colored brown by nitrogen peroxide, the absence of color being taken as evidence of reduction of the peroxide as a result of reaction with methane. From the data for the open chamber, it will be noted that the minimum reaction temperature varies both with the rate of gas flow and the ratio of nitrogen peroxide. As shown in Fig. 1, the temperature registered by the thermocouple increases linearly with the rate of flow,

being higher with greater concentrations of nitrogen peroxide. This shows the combined effect of radiation from the electric heating wire, which obviously is at a higher temperature the higher the rate of gas flow through the chamber, and of the heat liberated by the reaction. By extrapolating to zero rate of flow, however, the minimum reaction temperature for the open tube is determined as about 430°.

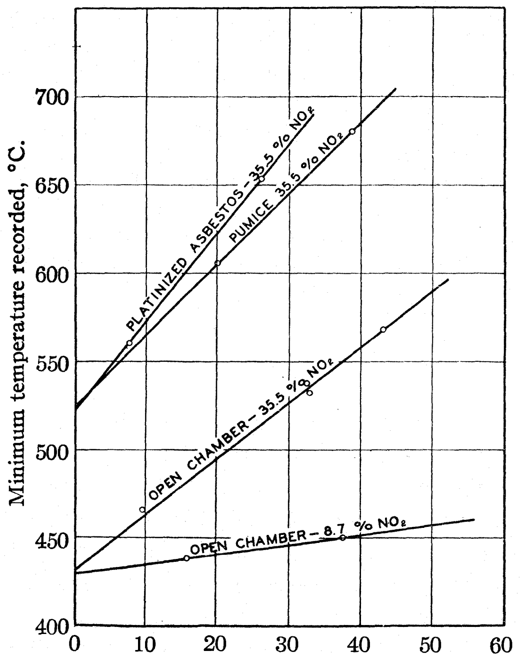

Fig. 1.

The liquid products collected in the condenser contained varying amounts of nitric and, probably, nitrous acid, usually corresponding to a normality of the order of one. Careful fractionations of the liquid products failed to reveal any methanol and only indefinite and small fractions indicating formic acid were obtained. No information could be obtained from the literature in regard to the problem of distinguishing formic acid from mixtures of nitric and nitrous acids, and after many futile attempts the effort to positively identify formic acid was finally abandoned. The conversion of entering methane to formaldehyde varied roughly between 1 and 3.5%, as shown in Table I. In general, the lower the minimum reaction temperature the better the yield of formaldehyde. From a comparison of the data for the various experiments it follows that a low rate of flow with a gas mixture containing a low concentration of nitrogen peroxide results in the highest ratio of formaldehyde to carbon monoxide and dioxide. The formation of these latter compounds, representing further stages of oxidation, is quite considerable. Even in the best experiments the ratio of formaldehyde to carbon monoxide and dioxide, figured on a methane basis, is less than 1:3. Although it might have been possible to improve the formaldehyde yield, such attempts were beyond the scope of this work.

As would be expected, a high yield of formaldehyde on the basis of methane reacting coincides with a low carbon dioxide production, both being characteristic of mild oxidation of the methane molecule.

The loss of nitrogen peroxide by complete decomposition to elementary nitrogen is small, being of the order of magnitude of 1% per passage through the reactor.

In addition to the runs recorded in Table I some fifty experiments were made, mostly with pumice and other contact substances.[6] In the case of catalysts, the reaction temperature was invariably higher than with the open chamber, other conditions being the same, due to localization of the reaction and the formation of a hot spot, as detected by the movable thermocouple. Curves for pumice and platinized asbestos are given in Fig. 1. Vanadium pentoxide gave temperatures in the same region, while a nickel wire introduced into the chamber brought the temperature up by another hundred degrees. The only exception was hopcalite, which gave reaction at approximately the same temperature as the open chamber.

An interesting point is the possibility of reaction between the higher hydrocarbons, present in small amounts, and liquid nitrogen peroxide to form acetic acid. After each run the remainder of the nitrogen peroxide was allowed to evaporate and in almost every case there appeared a residue of several cubic centimeters of a clear, yellow-tinged liquid. This material undoubtedly contained nitric acid and dissolved oxides of nitrogen, but upon careful qualitative analysis it gave a pronounced odor of acetic acid, which apparently was present in considerable quantity.

Conclusions

The fact that methanol is not detected among the products of reaction does not necessarily imply that the alcohol is not formed in methane oxidation. Quite the contrary, methanol seems to be a logical intermediate compound when methane is oxidized with nitrogen peroxide, which splits off only one atom of oxygen per molecule. The failure of the alcohol to appear among the final products can hardly be due solely to further oxidation to formaldehyde, for, as is outlined in the introduction, it is

---

[5] Cooper and Fasce, *Ind. Eng. Chem.*, 20, 420 (1928).

[6] A. H. Waitt, M. I. T. "Thesis," 1926; P. J. Harrington, M. I. T. "Thesis," 1927.

improbable that all the initially formed methanol molecules would be brought in contact with a second molecule of nitrogen peroxide. It is far more reasonable to believe that the high temperature of operation is responsible for thermal decomposition of the alcohol. While methanol is perfectly stable with respect to carbon monoxide and hydrogen at room temperature, it has been pointed out by Lewis and Frolich[7] that the equilibrium constant changes rapidly with temperature, leaving less than 2% of methanol in an equilibrium mixture at 300°. At the temperatures in question, 430° and above, it may therefore be expected that the initially formed methanol decomposes quantitatively into carbon monoxide and hydrogen. Furthermore, the heat of reaction undoubtedly raises the temperature of the alcohol molecules formed to a level above that recorded by the thermocouple as the average for the entire gas mixture. The high content of carbon monoxide and hydrogen in the off-gases may well account for such thermal decomposition of intermediately formed methanol.[8] Instead of decreasing the temperature of reaction, catalysts make the conditions less favorable to the stabilization of methanol by causing a temperature increase and hence even the yield of formaldehyde goes down in the presence of catalysts.

Summary

1. The minimum reaction temperature for the oxidation of methane with nitrogen peroxide is about 430° in an open Pyrex tube. The presence of catalysts results in higher temperatures due to the formation of a hot spot.

2. Methanol cannot be detected among the products of reaction. It is surmised that the alcohol is formed intermediately but decomposes into carbon monoxide and hydrogen, rather than being quantitatively reoxidized.

3. Formaldehyde is formed in good quantities, the maximum yield observed corresponding to somewhat less than one-quarter of the methane reacting. Formaldehyde production is favored by conditions which tend to lower the reaction temperature. These conditions are: low nitrogen peroxide concentration, slow rate of flow and absence of contact surfaces. The accompanying losses of nitrogen peroxide by decomposition to elementary nitrogen are small.

4. The presence of formic acid, as indicated by fractionation of the liquid condensate, could not be verified by direct analysis, due to the disturbing influence of the relatively high concentrations of nitric and nitrous acids.

---

[7] Lewis and Frolich, Ind. Eng. *Chem.,* **20,285** (1928).

[8] It is assumed that the low hydrogen concentration in the last experiment in Table I is due to an analytical error.

5. Attention is called to the possible formation of acetic acid by reaction in the cold of liquid nitrogen peroxide with small amounts of higher hydrocarbons present in the methane.

SYMMETRICAL AND ANTISYMMETRICAL HYDROGEN AND THE THIRD LAW OF THERMODYNAMICS. THERMAL EQUILIBRIUM AND THE TRIPLE POINT PRESSURE

BY W. F. GIAUQUE AND H. L. JOHNSTON

RECEIVED JULY 10, 1928 PUBLISHED DECEMBER 10, 1928

The suggestion of Heisenberg[1] that hydrogen and other homopolar molecules exist in two forms, symmetrical and antisymmetrical, offers the most satisfactory explanation for the alternating intensity observed in the band spectra of these substances. This suggestion has been used by Dennison[2] to explain the heat capacity of hydrogen gas over the low temperature range in which it is taking up its rotational degrees of freedom. Dennison's theoretical curve is the first one of a large number offered by various authors which has agreed with the experimental heat capacity data within the limit of error.

A physical conception of symmetry and antisymmetry in the hydrogen molecule arises from the assumption of nuclei which may spin on their own axes. When the two spinning protons oppose each other, the molecule is symmetrical; when their angular momentum is additive, it is antisymmetrical. The statistical weight of the latter variety is increased by the factor three, since a total spin of $j = 1$, one-half unit for each proton, is assumed, and the *a priori* probability p is as usual taken equal to $(2j + 1)$. The symmetrical form takes up only the even rotation states $j = 0, 2, 4, 6, \ldots\ldots,$ while the antisymmetrical assumes the rotation states $j = 1, 3, 5 \ldots\ldots$

In order to explain the heat capacity of hydrogen, Dennison found it necessary to assume that the transitions between symmetrical and antisymmetrical states are so rare that they do not occur appreciably during the experimental determination of heat capacity. Dennison's assumptions are supported by the band spectra data and interpretation of Hori.[3] Birge[4] has shown that Hori's data lead to a value of 0.480×10^{-40} g. cm.^{2} for the moment of inertia of the hydrogen molecule in its normal state. Hori gave 0.467×10^{-40} as the value which the molecule would have if it lost its last half unit of vibration. This latter value should not be used

for heat capacity calculations. Dennison found 0.464×10^{-40} from the heat capacity data available to him. Cornish and Eastman[5] found 0.475×10^{-40} from their own heat capacity measurements previously to the calculation of Birge. Condon[6] has found from a purely theoretical calculation of the hydrogen molecule problem that 0.426×10^{-40} is a rough value of the moment of inertia and is definitely a lower limit. This would be increased to 0.44×10^{-40} g. cm.^{2} when one-half unit of vibration in the normal state is considered.

Shortly after the publication of Dennison's paper, Dr. E. U. Condon communicated with this Laboratory in the hope that experimental work on the heat capacity of hydrogen gas carried out by Cornish and Eastman[5] might be extended to include a very direct test of Dennison's idea. Condon's suggestion was based on the assumption that hydrogen gas, kept at the temperature of liquid air for sufficient time, might be expected to change from about one-fourth symmetrical to nearly all symmetrical. Subsequent determination of the heat capacity would, if the transition occurred, show a markedly different heat capacity, as may be seen from the computations in Dennison's paper. Unfortunately, the apparatus of Cornish and Eastman had been completely dismantled shortly before the arrival of Condon's letter. However, in connection with the study of the entropies of gases being carried out in this Laboratory, we have apparatus in which it is a comparatively easy matter to measure the vapor pressure of hydrogen. Also, the problem of keeping a considerable quantity of hydrogen gas at the temperature of liquid air for a long period presented little difficulty since large quantities of liquid air are always kept on hand. It seemed worth while to measure the vapor pressure of hydrogen which had been kept at a low temperature for a considerable period of time. The mean life of the transition has been estimated by Heisenberg at about three weeks. Condon suggested that two or three months at liquid air temperature might be expected to produce a considerable change.

Apparatus.—A steel container holding about ten moles of gas at a pressure of seventy-five atmospheres and a temperature of about 85°K. was filled with pure hydrogen, prepared by electrolysis and purified by means of a nickel catalyst until the oxygen present by diffusion was reduced to about 0.01%. The container was suspended in a Pyrex glass Dewar tube by means of a steel capillary tubing of very small bore and 45 cm. long which served as an inlet and outlet for the gas. The Dewar tube was approximately 90 cm. long and 11 cm. inside diameter. The liquid air required was about four liters every two days.

The vapor pressure measurements were carried out in the apparatus previously used by Giauque, Johnston and Kelley[7] for measurements of the vapor pressure of hydrogen and of oxygen. The description of this apparatus has been given by Giauque and

Wiebe.[8] The hydrogen was withdrawn from the container through a sensitive needle valve.

Vapor Pressure of Hydrogen.—It was thought desirable to measure the vapor pressure of ordinary hydrogen shortly before making the measurements on the material which had been kept cold, so this was done. While it seemed improbable that the process of crystallization would in any way affect the relative amounts of symmetrical and antisymmetrical molecules, this was investigated by measuring the vapor pressure of the liquid both before and after solidification. The measurements, made at 53.7 cm. pressure, agreed to better than 0.01". The triple point pressure of the ordinary hydrogen measured on May 1, 1928, was 5.383 international cm., while the reading on the gold resistance thermometer was 83.417 ohms.

The special hydrogen was kept at the temperature of liquid air from October 19,1927, to May 3, 1928, a total of 197 days. In order to introduce the hydrogen into the apparatus, it was necessary to pass through a section of tubing at room temperature. The rate of transfer of the gas was such that it was kept at room temperature for approximately fifteen seconds. It was immediately obvious during the course of the observations that any difference which might exist was extremely small, so further efforts were concentrated on the triple point pressure.

The measurements on the special hydrogen are given in Table I. In the first column, the approximate percentage of the material melted is given. It will be noticed that the pressure was higher when a large amount of liquid was present. The reason appeared to be superheating of the liquid

near the surface, due to heat leak from above. The last two observations listed in Table I were designed to decide this question. With most of the material melted, a measurement was made; then with no other change the heat leak was increased about 150% by raising the temperature of the surroundings a few degrees. The next measurement showed the expected increase in pressure. It appears to be very difficult to avoid a slight superheating of the hydrogen and we suspect that the deviations of various previous observers may be due largely to this effect. The heavy gold walls of the container with the interior gold vanes were apparently unable to prevent a surface heating effect of the order of one-hundredth of a degree necessary to explain the increase in pressure. For this reason we have not considered any measurements where more than half of the hydrogen was melted and take the triple point pressure of the special hydrogen as 5.34 cm.

The surface heating effect made it desirable to repeat the measurements on ordinary hydrogen with greater care, especially since we had not recorded the percentage melted in that case. The results of these measurements are given in Table II. The third and fourth measurements were designed to demonstrate the surface heating in a second manner. With about 85% of the material melted, some of the hydrogen was evaporated from the surface by means of a pump. A reading taken immediately after this agreed with the previous results, but on standing for fifteen minutes the pressure had risen to a considerably higher value.

TABLE II

TRIPLE POINT PRESSURE OF ORDINARY HYDROGEN

May 30, 1928

Percentage melted	Pressure, international cm. of Hg	Resistance thermometer, ohms
<1	5.391	83 417
15	5.394	....
Melted 85% and evaporated some by reduced pressure		
85	5.390	83.417
Fifteen minutes after the surface evaporation		
85	5.440	....
Accepted values	5.39	83.417

The value previously obtained by Giauque, Johnston and Kelley[7] was 5.37 cm. The present determinations of 5.38 and 5.39 cm. seem to indicate that the triple point pressure of ordinary hydrogen is 5.38 ± 0.01 cm. This is in good agreement with the 5.382 cm. value of Onnes and Braak[9] and the 5.38 cm. value of Simon and Lange.[10] Henning[11] has recently ob-

---

[11] Henning, *ibid.*, 40, 775 (1926).

tained a value of 5.486 cm. as a result of four experiments varying from 5.480 to 5.495 cm. The 5.34 cm. value of the triple point pressure of the special hydrogen is lower than any value obtained for ordinary hydrogen. The 0.005-ohm difference on the resistance thermometer, which is not very sensitive at this temperature, indicates that the triple point temperature of the special hydrogen was 0.04" lower than that of ordinary hydrogen. We do not feel that we can claim with certainty that a difference exists but the apparent difference is beyond the limit of any error of which we are aware. The greater part of the hydrogen remains and is being kept cold. We hope to make further observations on its properties at a considerably later date.

The Entropy Effect Due to Symmetrical and Antisymmetrical Hydrogen

Heisenberg[1] in suggesting the presence of more than one kind of hydrogen mentioned an effect on the entropy as a consequence. Fowler[12] has recently considered the manner in which the statistical calculation of the entropy of hydrogen gas must be modified by the recognition of the two forms. However, in making this same calculation we are unable to arrive at the same result. It appears that Fowler's calculation amounts to having considered the entropy of symmetrical and of antisymmetrical hydrogen individually, but has omitted the entropy of mixing of the two. We cannot be sure from his statements that this has not been done intentionally, but, if so, we can see no reason for it.

We consider the matter as follows. Let us assume that the ratio of symmetrical to antisymmetrical molecules is one to three and that the gas has been cooled to a temperature at which it is acting in the manner of a monatomic gas. The statistical weight-of the symmetrical variety is unity while the weight of the antisymmetrical molecules is nine; that is, one-quarter of the gas consists of one kind of molecules and the other three-quarters is divided between nine varieties which arise from the consideration that the unit of momentum of the combined nuclei gives rise to three orientations which are themselves distributed between the three additional orientations arising from the molecular rotation which the antisymmetrical variety retains in its lowest rotation state. The entropy of such a mixture should exceed the entropy of a monatomic gas merely by the entropy of mixing of the ten varieties. Therefore, $AS = -{}^1/_4\, R \ln {}^1/_4 - {}^3/_4\, R \ln {}^1/_{12} = 4.39$ cal./deg. per mole. Thus 4.39 E. U. must be added to the value obtained from the Sackur equation. Fowler found ${}^3/_2\, R \ln 3 = 3.27$ E. U.

The assumption of an exact one-to-three ratio between the two forms of hydrogen is open to question on two grounds: first, the true equilibrium at room temperature would favor the symmetrical form by several per

---

[12] **Fowler,** *Proc. Roy. Soc.*, 118A, *52 (1928).*

cent. if the various rotational energy levels represent the only energy differences between the two forms; second, it is not known that there is not an energy difference between the two forms in addition to that accompanying the rotation change. The alternating lines of the band spectra fall in a smooth series, showing as would be expected that the molecular dimensions are not appreciably different; however, this does not, in itself, eliminate the possibility of a sufficient energy of transition to modify the one-to-three ratio considerably. The band spectra intensity determinations are not very accurate. Dennison's[2] limits of 1:3.5 and 1:2.7 obtained from the heat capacity data are the best experimental indication that the coupling energy is small. The entropy effect corresponding to the above limits is 4.45 E. U. and 4.34 E. U., respectively. Therefore, if Dennison's interpretation of the behavior of hydrogen is correct, we must add 4.38 ± 0.06 cal./deg. per mole to the entropy as given by the Sackur equation or by the ordinary application of the third law.

It has long been generally recognized that the entropy of hydrogen, as given by the direct application of the third law of thermodynamics in the ordinary manner, is lower than the value obtained indirectly from this law. Fowler notes that his 3.27 E. U. increase is rather too large an addition. We agree with this and our calculated amount of 4.39 E. U. is no improvement from this point of view. The only apparent alternative to assuming the non-existence of antisymmetrical hydrogen is to adopt the suggestion of Fowler that the products of reactions in which hydrogen is consumed must also have the antisymmetrical property.

Fowler calls attention to the failure of the Nernst heat theorem for such a substance as hydrogen, but states that the theorem would be true in this case if true equilibrium were attained since there is but one form of the symmetrical state. This question of true equilibrium between the various molecular species of a pure substance was the principal point which led Lewis and Gibson[13] to question the Nernst heat theorem and to make a restatement of the entropy principle which they have called the third law of thermodynamics. We believe that true equilibrium in any system must lead to an ordered crystalline state at the absolute zero of temperature and it is only to this perfect crystalline state, "lacking any sort of randomness," that Lewis and Gibson have assigned zero entropy.

We should like to call attention to a point that has apparently not previously been recognized, namely, that true equilibrium, even in a solution of isotopes, would, in the absence of any specific effect due to nuclear differences, lead to complete separation of the various components at the absolute zero, as may be shown by the thermodynamic equation[14]

---

[13] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances." McGraw-Hill Book Co., New York, 1923, Chapter XXXI.

[14] **Ref. 13,** page 244.

$$\frac{dN_1}{dh} = \left(\frac{W\overline{V}_1}{V}\right) - W_1\frac{N_1g}{RT}$$

obtained for a perfect solution. h is the height, g the acceleration of gravity; W and V the molal mass and volume, respectively, of the solution, and N_1, W_1 and $\overline{V}_1$ the mole fraction, molal mass and partial molal volume, respectively, of component one. The existence of some specific force due to nuclear differences would, of course, in itself, suffice to eliminate randomness either by separation into phases or specific combination as the temperature approached the absolute zero. The above-described processes are, of course, experimentally unrealizable, but we wish to clearly distinguish between the truth of the third law of thermodynamics and our experimental difficulties in using it directly.

It is becoming apparent that there are, perhaps, many substances in which the attainment of equilibrium is so slow as to interfere with the practical application of the third law without recognition of sources of entropy which do not appear from the measurement of heat capacity alone.

The entropy effect due to orientations arising from unbalanced angular momentum of electronic systems has been discussed by Schottky,[15] and by one of us.[16]

In the case of this large group of substances, the practical difficulty in obtaining the entropy from heat capacity measurements alone may be due not only to lack of equilibrium but to the fact that transformation to a single orientation by existing magnetic and electrical fields would occur at temperatures below those experimentally practicable. The behavior of pure antisymmetrical hydrogen, could it be obtained, would be analogous to the above case.

Summary

The triple point pressure of ordinary hydrogen has been found to be 5.38 ± 0.01 cm.

The triple point pressure of hydrogen which had been kept at the temperature of liquid air for 197 days was 5.34 cm. The difference between the two values is small, but we know of no source of experimental error that would account for it.

The experiment was carried out to obtain information concerning the existence of symmetrical and antisymmetrical hydrogen and the extremely slow transition rate believed to exist between the two forms. No large difference in pressure was anticipated. We have regarded the experiment as one that could give evidence for but not against the existence of the two forms.

---

[15] Schottky, *Physik. Z.*, 22, 1 (1921); 23, 9 (1922).

[16] Giauque, This Journal, 49, 1870 (1927).

It has been calculated that the entropy effect due to the existence of the two forms of hydrogen would be 4.39 ± 0.06 cal./deg. per mole. This amount must be added to that given by the Sackur equation or to that given by the ordinary application of the third law of thermodynamics. It does not appear possible to reconcile this addition with third law data unless a similar consideration, not necessarily leading to the same amount, is applied to molecules containing hydrogen. These effects may be expected in many, if not most, of the other elements.

We believe that any system approaches zero entropy as the absolute zero of temperature is approached when true equilibrium exists in the distribution of energy between such energy states as are actually occupied by the system. As a particular example, the cooling of a solution of isotopes is considered. Our conclusions are in complete agreement with the third law of thermodynamics as stated by Lewis and Gibson, although we recognize additional difficulties in the application of this law.

We wish to emphasize the distinction between the exactness of the third law of thermodynamics and our experimental inadequacy in using it directly.

EQUILIBRIUM BETWEEN ALUMINUM CARBIDE AND NITROGEN AT HIGH TEMPERATURES

BY C. H. PRESCOTT, JR.[1] AND W. B. HINCKE

RECEIVED JULY 17,1928 PUBLISHED DECEMBER 10, 1928

Plan of the Investigation

The present work is a continuation of a program of research in the field of high-temperature equilibria involving the extension of our previous methods to cover a region of very low pressures. Measurements have been made of equilibrium pressures from 0.0016 mm. to 0.017 mm. at temperatures from 1774°K. to 1909°K. The McLeod gages now in use would cover the range up to 5 mm. The manometer technique previously devised has been used at pressures from 3 cm. to 2.3 atmospheres and at temperatures up to 2500°K. So the combined methods seem applicable to pressures differing by a factor of a million and at temperatures from 1000°K. to 2500°K. The most significant region probably lies above 1500°K. where more conventional technique is inapplicable.

The subject of the present work is the equilibrium of the system aluminum carbide, nitrogen, aluminum nitride and carbon. The equilibrium pressure of nitrogen may be approximately predicted by combining the

---

[1] National Research Fellow in Chemistry.

results of Fraenkel[2] on the system aluminum oxide, carbon, nitrogen, aluminum nitride, with those of our own experiments on the system aluminum oxide, carbon, aluminum carbide and carbon monoxide.[3] These values have been verified by the present experiments. According to Fichter and Oesterheld[4] the sublimation of aluminum nitride accompanied by decomposition begins at 1870° under about 14 mm. of nitrogen. The chemistry of aluminum nitride has been thoroughly reviewed by Krase, Thompson and Yee.[5]

This investigation was aided financially from a grant made to Professor A. A. Noyes by the Carnegie Institution of Washington.

Apparatus and Procedure

The temperature measurements were made with an optical pyrometer. The details and corrections have already been described.[6]

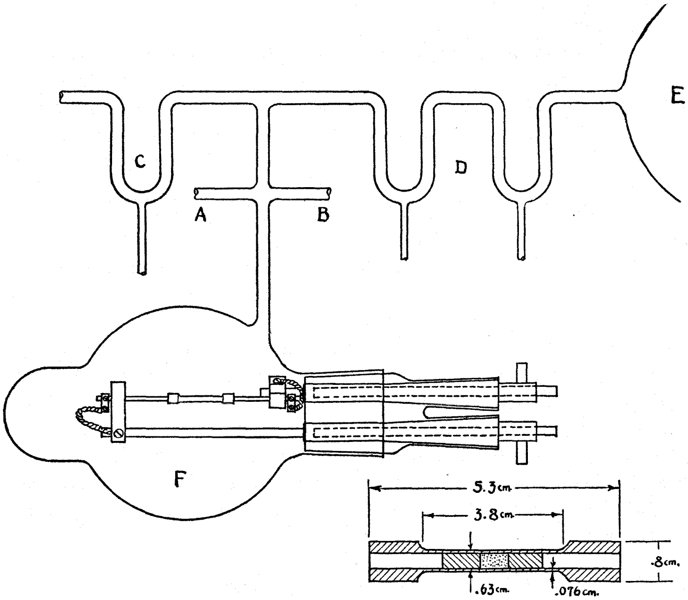

Fig. 1.—Apparatus for low pressure equilibria.

The furnace, shown in Fig. 1, was a tube of Acheson graphite 5.3 cm. long, 0.8 cm. in diameter at the ends, and 0.53 cm. in the central section for a length of 3.8 cm., with a 0.076 cm. wall. In the preliminary experiments a smaller furnace was used whose center was 0.032 cm. in diameter with a 0.04 cm. wall. A pellet of compressed aluminum and graphite powder about 0.4 cm. long was held in the center of the furnace by graphite

plugs. In the later experiments a groove was cut on either side of the center centimeter of the furnace to equalize the temperature gradient.

This furnace was supported horizontally on tungsten rods pressed into its ends, which rested on steel guides clamped to water-cooled copper leads. Electrical connection was made by flexible copper wire fastened to steel clamps on the ends of the tungsten rods. The outer ends of the water-cooled leads were tapered to fit ground-glass seals in a Pyrex plug which in turn was ground to fit a 1-liter Pyrex flask. Seals were made with Dennison's banker's specie sealing wax. A plane glass window was waxed to the end of a **2.5-cm.** tube which projected 16 cm. from the side of the flask, as the flask itself became clouded with a mirror of metallic aluminum. This was developed from apparatus used in preliminary studies on zirconium oxide and carbon.[7]

The flask (F) was connected through a mercury cut-off (C) to a single-stage mercury diffusion pump backed by a Hyvac oil pump. Two mercury cut-offs (D) connected to a 3-liter flask (E) which served as a nitrogen reservoir. Small amounts of nitrogen were introduced by alternately opening the two cut-offs. Tube A led to a Toepler pump which withdrew samples of gas for analysis.[8] Tube B led to two McLeod gages with a combined range from 10^{-4} to 5 mm. Their volumes were as small as possible, 50 and 7 cc., to minimize dead space.

In the procedure finally adopted the whole apparatus was evacuated and the furnace run for a moment at 1500°K. to drive off a part of the adsorbed gases. Hydrogen was next introduced to one atmosphere and the furnace run at 1880°K. for one hour. This baked off the remaining gases, formed the aluminum carbide and partially sintered it, reducing the amount of metallic aluminum which vaporized later. It also helped bake out the Pyrex flask. The apparatus was next evacuated and filled to 6 cm. of nitrogen and the furnace run at 1880°K. for from thirty minutes to three hours to change some of the carbide to nitride. It was again evacuated and a stream of tap water turned on at the top of the flask which completely enveloped it and kept it cold while equilibrium measurements were taken. After this treatment the evolved gases were from 97 to 101% nitrogen as compared to 10% without the stream of water. The gases evolved from the walls were chiefly hydrogen and carbon monoxide. The carbon monoxide probably came from water vapor which reacted with the carbon furnace. The hydrogen was too much in proportion to be accounted for in this way unless the water vapor also reacted with the aluminum on the walls.

For the preliminary baking the current was drawn from a 1-kw. transformer. During the measurements it was drawn from a storage battery. To maintain the larger size of furnace at 1880°K. required 100 amps. at 10 volts, though most of the power was lost in the leads.

The Equilibrium Measurements

The reacting material was in each case a pellet of Baker's analyzed metallic aluminum and Acheson graphite, each ground to pass 200 mesh, and mixed in proportions to form Al_4C_3 with a 10% excess of carbon to reduce any oxide which might be in the finely divided aluminum.

In the first significant experiment such a pellet was run for an hour at 1880°K. in one atmosphere of nitrogen. It was then removed and tested for combined nitrogen. A sample was digested in sodium hydroxide and vapors caught in 0.02 N hydrochloric acid as in a standard

---

[8] Prescott, *ibid.*, **50**, **3237** (1928).

Kjeldahl determination. Further samples were run under reduced pressures of nitrogen down to 1 mm. All showed a considerable proportion of combined nitrogen.

The first equilibrium measurements were made on small furnaces with no cooling water on the flask. Ten times as much interfering gases were evolved as of the nitrogen under consideration. At each temperature several runs were made of an hour's duration, starting each at a different pressure of nitrogen. The final nitrogen pressure was obtained by an analysis of the gases. From the several values of the change of pressure it was possible roughly to interpolate for the equilibrium pressure. The values obtained with two different furnaces are plotted as points in triangles in Fig. 2, a graph where one scale is proportional to the logarithm of the equilibrium pressure in millimeters, and the other is proportional to the reciprocal temperature. A blank run, however, indicated that some nitrogen was also evolved from an empty furnace, of the same order of magnitude as the former pressure changes, so the results are rather dubious. To get sufficient material the pellets were made about 0.6 cm. long and at the conclusion of each series little aluminum remained except at the ends of the original pellet, a region probably at lower temperature than the maximum temperature where the pyrometer was sighted. In view of such uncertainties these measurements are of little weight in comparison with later determinations under better conditions.

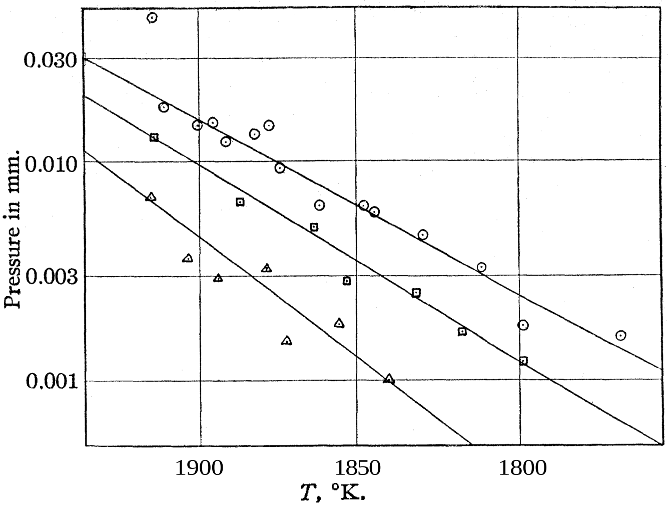

Fig. 2.—Preliminary and final results. Log P, $= 12.772 - 27697/T$.

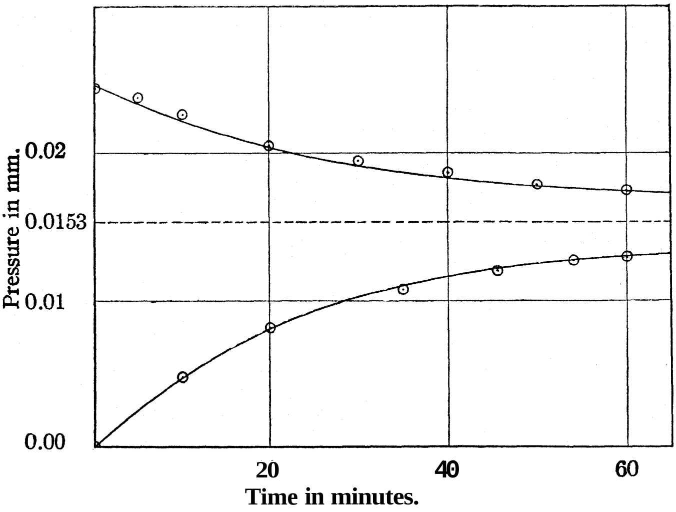
The next measurements were a series of runs on a single large furnace after preliminary baking in hydrogen and with cooling water on the flask.

The interfering gases dropped to a few per cent. and it was possible at once to follow the changes in nitrogen pressure on the McLeod gages, so that two runs of one hour each were sufficient to determine an equilibrium pressure. The results are plotted as points in squares in Fig. 2. It was noticed in assembling that the contact between one tungsten rod and the furnace was quite loose. It was also noticed that this contact ran rather hotter than the other. Unfortunately the pyrometer was still sighted at the maximum of temperature, which, due to the unsymmetrical heating, probably did not coincide with the geometrical center of the furnace where the charge was located. The discrepancy between these and the later results would be equivalent to a temperature error of 36°.



Pig. 3.

With the next furnace the loose contact was eliminated and in two later furnaces grooves were cut to equalize the temperature gradient along the middle portion of the furnace. The pyrometer was sighted at the geometrical center where the charge was definitely located. Fig. 3 is a typical example of two runs which determined an equilibrium pressure. The furnace was run for ten minutes on the pumps. The mercury cut-off C was then released and the pressure rose as shown in the lower curve of the figure. After an hour the current was turned off and the gas pumped off for analysis.[8] Cut-off C was (Fig. 1) lowered and the flask evacuated. It was again raised and nitrogen introduced from the reservoir E to twice the final pressure of the previous run. The furnace was then run for an hour, the pressure falling as shown in the upper curve of the figure. This gas was also pumped off for analysis. In this case both contained 98.5% nitrogen. The two final pressures were corrected and their average taken as the equilibrium pressure: 0.0150 mm. at 1895°K. The broken line on the figure is the average of the uncorrected pressures. The equilibrium values obtained from these three furnaces are plotted as points in circles in Fig. 2 and also in Fig. 4 by themselves.

Anomalous results were obtained from two furnaces in cases where mercury was spilled into the furnace flask before the baking in nitrogen. Nitrogen was evolved at pressures up to one-half millimeter. In the one case which was thoroughly studied reverse rates were at first obtained above this pressure, but later no absorption of nitrogen occurred. Upon removal and analysis of the pellet the nitrogen content was found to be just slightly less than that corresponding to the formation of AlN. This indicated the absence of any aluminum compound higher in nitrogen content. On keeping mercury out of the furnace flask no further trouble resulted. The formation of a nitride of mercury is improbable, so the effect is probably due to adsorption on the finely divided material which distilled around. This gave off gas during the runs, the absorption of nitrogen going on until all of the aluminum carbide present was converted to nitride. It should be noted that mercury vapor was always present at about 10^{-3} mm. from the various traps and gages but never figured in any of the McLeod gage readings of gas pressure.

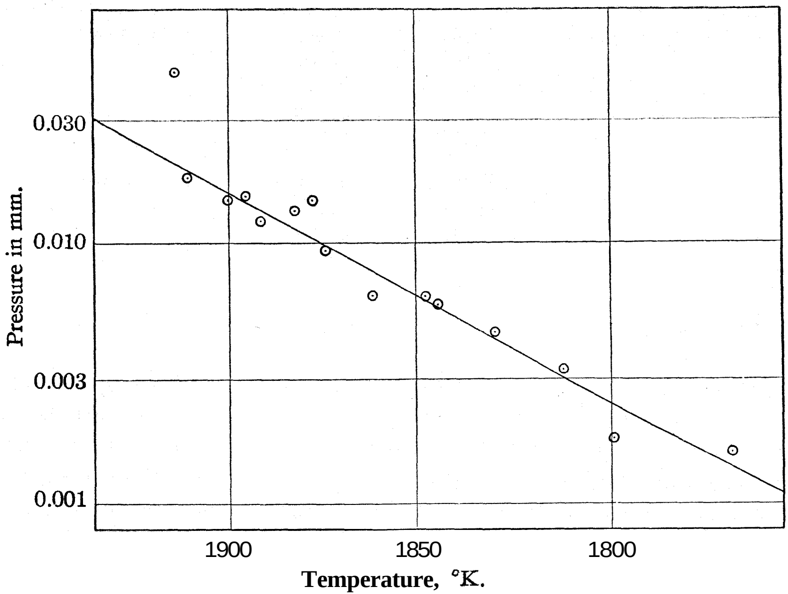


Fig. 4.—$4AlN + 3C = Al_4C_3 + 2N_2$. $\log P_{mm.} = 12.772 - 27697/T$.

Results of the Measurements

The most certain and reproducible results are those plotted in Fig. 4.

The same data are recorded in Table I, together with the duration of the initial baking in nitrogen.

TABLE I

EQUILIBRIUM PRESSURES AND TEMPERATURES

Furnace	Detn.	Temp., °K.	Press., mm.	Time of nitrification
A	1	1895	0.01503	145 minutes
	2	1874	.00954	
	3	1850	.00622	
	4	1829	.00458	
	5	1877	.01453	
B	1	1884	.01334	60 minutes
	2	1845	.00582	
	3	1813	.00325	
	4	1774	.00158	
	5[a]	1915	.0455

	4	1799	.00176	
	5	1862	.00612	

[a] Discarded.

According to the times of nitrification furnace A should have had the highest nitrogen content and C the lowest. This accords with the fact that the final determinations on furnaces A and B fell high, and on furnace C low, although the initial determinations are in very excellent agreement. As material volatilized from the pellet, either carbide or nitride would tend to be exhausted as both were appreciably volatile. The trend of the equilibrium pressures might indicate a slight dependence on concentration effects due to mutual solubility of the solid phases, but is more probably a dynamic effect depending on the methods of measurement. In a true equilibrium state forward and reverse reaction velocities must be equal, and both will occur simultaneously at the same solid interface. When an observable reaction occurs, however, the interface will spread into the reacting material, so the area of the interface and the net over-all velocity of reaction will depend to some extent on the mass of the reacting material. This dependence will decrease the closer approach is made to equilibrium conditions, but will always influence equilibrium measurements derived from the interpolation of finite velocities of reaction, particularly when materials become exhausted.

This might be a valid reason for rejecting such a determination as B 5, the last of its series. A least-square solution of the data in Table I gave a probable error corresponding to an 18% deviation in the pressure. On account of its large deviation the point B 5 could be rejected in accordance with established principles from the laws of probability.[9] A least square solution of the remaining data for the constants of the linear relation shown in Fig. 4 gave the result where log p is the common logarithm of the pressure in millimeters and T the absolute temperature

$$\text{Log } p_{\text{mm.}} = 12.772 - 27697/T$$

Or for the pressure in atmospheres

$$\text{Log } p_{\text{atm.}} = 9.891 - 27697/T$$

with a probable error corresponding to an 11% deviation in the pressure, which is equivalent to 5.8° in the temperature measurements.

In reading pressures, particularly with a McLeod gage, the errors to be expected will be roughly proportional to the pressure, so the weights of observations will be most nearly equal when expressed on a logarithmic scale. Also, in matching light intensities, by Weber's law a difference in visual sensation corresponds to a change in the logarithm of the energy intensity. By the Wien radiation law

$$\frac{1}{T} - \frac{1}{T'} = \frac{\lambda \ln \epsilon}{c_2}$$

Here ϵ would correspond to the ratio of intensities, the logarithm of the ratio of intensities being proportional to the difference in the reciprocal temperature. So the weights of observations should be most nearly equal in the scale adopted, that of the logarithm of the pressure against the reciprocal temperature. Also, since the van't Hoff equation predicts a linear relation for small changes of the heat of reaction, this is the most convenient scale for the adjustment of observations.

$$2.303 \log K = -\frac{AH}{RT} + \text{const.}$$

Thermodynamic Calculations

The equation expressing the chemical reaction involved is

$$4AlN + 3C = Al_4C_3 + 2N2$$

We may now proceed to calculate the free-energy increase (AF) and the heat-content increase (ΔH) attending this reaction when the nitrogen pressure is one atmosphere.

The value of AF may be derived from the equilibrium pressure p by the familiar thermodynamic equation $AFo = -RT$ In K, where $K = p^2$. From the determination of the equilibrium pressure p tabulated in Table I, we thus obtained the values given in Table II.

From the expressions for $\log_{10} p$ derived in the same section we similarly obtain the relations, AFo = 253,630 − 90.58 T, and ΔH = 253,630 calories. At 1875°K. the equilibrium pressure is 0.0100 mm. and the free-energy change is 83,800 calories.

TABLE II

FREE-ENERGY INCREASE ATTENDING THE REACTION

Temp., T, °K.	1909	1901	1895	1891	1884	1877	1874
AF°, cal.	81150	82150	81700	83100	82100	81200	84100
Temp., T, °K.	1862	1850	1845	1829	1813	1799	1774
$\Delta F°$, cal.	86900	86300	86500	87500	89100	92800	92400

The molal heat capacities, (C_p), of graphite and nitrogen were taken from Lewis and Randall,[10] and those for aluminum carbide and nitride estimated from Kopp's law according to the scheme given in Noyes and Sherrill,[11] taking the atomic heat of nitrogen as 2.9, the mean of carbon and oxygen.

For C $C_p = 1.1 + 0.0048T - 0.0000012T^2$
For N_2 $C_p = 6.50 + 0.0010T$
For Al_4C_3 $C_p = 30.2$
Por AlN $C_p = 9.1$

From the above-mentioned heat of reaction and the value of the free-energy change at 1875°K., the following equations are obtained and from them by extrapolation the following values at room temperature

$$AH = 260{,}954 + 3.5T - 0.0062T^2 + 0.0000012T^3$$
$$\Delta F° = 260{,}954 - 3.5T \ln T + 0.0062T^2 - 0.0000006T^3 - 77.621T$$
$$\Delta H_{298} = 261{,}478 \text{ cal.} \qquad \Delta F°_{298} = 232{,}406 \text{ cal.}$$

From these values and the values for the formation of aluminum carbide given by Prescott and Hincke[12] values may be calculated for the formation of aluminum nitride from its elements.

$$2N_2 + Al_4C_3 = 4AlN + 3C \qquad \Delta H_{298} = -261{,}478 \qquad \Delta F°_{298} = -232{,}406$$
$$4Al + 3C = Al_4C_3 \qquad = -60{,}260 \qquad = -53{,}240$$
$$Al + {}^1/_2N_2 = AlN \qquad = -80{,}434 \qquad = -71{,}411$$

By combining equations for the oxide–carbide equilibrium[i2] with those for the carbide–nitride equilibrium given above, the following relations are obtained for the reaction involving the simultaneous reduction and nitrification of aluminum oxide

$$Al_2O_3 + 3C + N_2 = 2AlN + 3CO$$
$$\log K = 14.74 - 27743T \qquad K = p^3_{CO}/p_{N_2}$$
$$AF° = 127{,}065 - 67.5T \qquad AH = 127{,}065 \text{ cal.}$$
$$AH = 138{,}178 + 3.5T - 0.0062T^2 + 0.0000012T^3$$
$$AF° = 138{,}178 - 3.5T \ln T + 0.0062T^2 - 0.0000006T^3 - 56.385T$$
$$\Delta H_{298} = 138{,}711 \text{ cal.} \qquad \Delta F°_{298} = 115{,}947 \text{ cal.}$$

From the above equation the values of the equilibrium constant at 1500 and 1600° are, respectively, 0.123 and 0.851. For a total pressure of one

[12] Prescott and Hincke, THIS JOURNAL, **49**, 2753 (1927).

atmosphere the fraction of carbon monoxide in an equilibrium mixture would be 41.6 and 66.0%. These values are on the upper limits which Fraenkel[2] assigned from his study of this reaction: 25 – 40% at 1500° and 50 – 65% at 1600°.

Summary

Apparatus has been devised and methods have been extended for the study of chemical equilibria at incandescent temperatures at pressures of 0.01 mm. Determinations were made for the reaction $4A1N + 3C = Al_4C_3 + 2N_2$. The increases in free energy and heat content that would attend this reaction between 1775°K. and 1910°K. at one atmosphere pressure were found to be those given by the equations $AF^o = 253,630 - 90.58T$, and $\Delta H =$ 253,630 cal. At 1875°K. the equilibrium pressure is 0.0100 mm. and the free-energy change is 83,800 calories.

Calculations have been made for the reaction $Al_2O_3 + 3C + N_2 = 2A1N + 3CO$. The corresponding equations are $AF^o = 127,065 - 67.51"$ and A H = 127,065 cal, These values are in agreement with the observations of Fraenkel on this reaction.

APPARATUS FOR MICRO GAS ANALYSIS

BY C. H. PRESCOTT, JR.[1]

RECEIVED JULY 17, 1928 PUBLISHED DECEMBER 10, 1928

In connection with measurements on the equilibrium between aluminum carbide and nitrogen[2] it was necessary to analyze quite small quantities of gas to determine the partial pressure of nitrogen. Langmuir[3] has briefly described methods by which quantities of gas as small as one cubic millimeter at atmospheric pressure may be subjected to quantitative analysis. The author has seen this apparatus through the courtesy of Dr. Langmuir and recalls that the methods consisted in treating very small volumes of gas with aqueous reagents at atmospheric pressure.

In the present technique the gases are handled at low pressure over mercury using solid reagents. The volumes are of reasonable size and no gases need be introduced but those actually undergoing analysis. The methods would seem capable of a sensitivity at least as great as that indicated by Langmuir, though this has not been necessary for our present work. The apparatus was developed during one phase of the work on

---

[1] National Research Fellow in Chemistry.

[2] Prescott and Hincke, THIS JOURNAL, 50,3228 (1928).

[3] Langmuir, *ibid.*, 40, 1378 (1918); *Ind.* Eng. *Chem.*, 20, 333 (1928).

zirconium oxide and carbon,[4] but was not used till recently for quantitative measurements.

The apparatus was designed to operate on samples whose volumes would be a third of a cubic centimeter or less at one atmosphere, and to determine carbon dioxide, carbon monoxide, hydrogen and nitrogen. The pressure in the absorption tubes usually started at less than two millimeters. The carbon dioxide was absorbed in soda lime; the carbon monoxide and hydrogen were oxidized by copper oxide at 250° and the water absorbed in phosphorus pentoxide; the carbon monoxide, now dioxide, was absorbed in soda lime, leaving the nitrogen. After each absorption the gas was collected and compressed to one of a series of graduations in a capillary pipet and the pressure measured on a comparison tube as in a pressure reading on a McLeod gage. The time necessary for each absorption and collection for measurement was about an hour. As only nitrogen was significant for our purposes and the soda lime absorbed both carbon dioxide and water, only one absorption was necessary in a routine analysis.

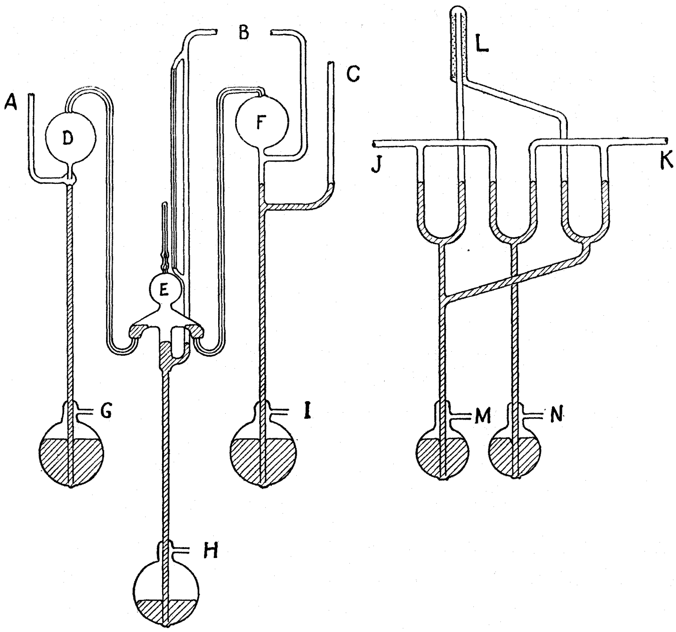

Fig. 1.—Gas analysis apparatus.

The arrangement of apparatus is shown in Fig. 1. The tube A is connected to the apparatus containing at low pressure the gas to be analyzed. A mercury diffusion pump is connected to C. The absorption train is inserted at B, one element of which is shown at the side. Suction is applied

---

[4] Prescott, THIS JOURNAL, 48, 2534 (1926).

to H, I, M, N, etc., withdrawing the mercury from all the cut-offs, and the pipet and absorption train are evacuated to 10^{-4} mm. through the tube C. The suction is then released and by applying compressed air at G the Toepler pump D drives a sample of gas into the pipet E. The sample is compressed into the capillary by applying pressure at H, and its pressure–volume product measured. Suction is next applied at H, allowing the gas to flow up the comparison tube and through the absorption train to the pump F. The pump is operated by applying pressure at I and the gas circulated by pumping back into E. The contraction and expansion of volume resulting helps to clear the dead space in E. The suction at H is then released and the gas pumped back into the pipet and measured. The absorption tubes are each located as at I, and connected in series by the tubes J and K, etc. To pass the gas through a tube, suction is applied at M, withdrawing the mercury below the two cut-offs. To by-pass the gas around a tube suction is applied at N, releasing the suction at M. To clear the apparatus all the cut-offs are lowered as before and the gas escapes through C.

One absorption tube (L) contained $^1/_3$ g. of copper oxide, which was calculated to be sufficient for several thousand analyses. The next contained 1.2 g. of soda lime and the last about 0.6 g. of phosphorus pentoxide mixed with powdered pumice stone. These were baked in *vacuo* to the softening point of the Pyrex glass to drive off adsorbed gases. No gas could then be pumped off the copper oxide or soda-lime when they were cold. A little could be obtained from the phosphorus pentoxide and pumice stone. By circulating until there was no further absorption, it was determined that twenty cycles of the pump was sufficient. Fifteen cycles sufficed to recover the unabsorbed gas.

On several samples of pure nitrogen initial and final readings checked to the same scale division (0.3%). Absorption of hydrogen and carbon monoxide were practically complete. Analyses were made on two known mixtures of carbon monoxide and nitrogen. The composition was initially determined from pressures measured in the rest of the apparatus with a McLeod gage. A small correction was made for 0.23% nitrogen in the carbon monoxide. The results of the analyses are shown in Table I. The

TABLE I

RESULTS OF GAS ANALYSES

THE DECOMPOSITION OF FORMIC ACID BY SULFURIC ACID. II[1]

BY ERNEST R. SCHIERZ AND HENRY T. WARD

RECEIVED JULY 23, 1928 PUBLISHED DECEMBER 10, 1928

Introduction

In a previous paper by one of the authors[2] it was found that the velocity of decomposition of formic acid in sulfuric acid showed some irregularities when the concentration of sulfuric acid was 91.8%. Knietsch[3] found that specific conductance, melting point and viscosity do not increase continuously on progressive dilution of sulfuric acid. Abnormal values for these properties occur in the range of concentration 92–93.5%.

The present investigation was undertaken to determine the velocity constants for the rate of decomposition of formic acid for various concentrations of sulfuric acid from 85–97% at temperatures of 15, 25, 35 and 45° and to observe whether the irregularity referred to above existed at other concentrations.

Experimental Part

Preparation and Purification of Materials.—The formic acid and the sulfuric acid were prepared by the same methods as those previously used. The formic acid distilled at 25.0–25.5° at 37-38 mm.; $d^{20} = 1.220$; refractive index (Abbé) $n_D^{20} = 1.3708$ and melted at 8°.

Apparatus.—The apparatus used was modified to a slight extent only. The measuring burets were of 100-cc. capacity so that it would not be necessary to use a smaller amount of formic acid. The volume of carbon monoxide evolved from 0.07 cc. of formic acid was about 63 cc. at 45° and the prevailing average pressure 585 mm.

The Effect of Water on the Decomposition of Formic Acid by Sulfuric Acid.—The effect of water on the velocity of the reaction was determined by proceeding in the same manner as in the previous investigation, using like amounts of reagents. The results are summarized in Table I. In

[3] Knietsch, Ber., 34, 4089 (1901).

order to conserve space, the values of 0.4343 K, the velocity constants calculated from the equation for unimolecular reaction, were each multiplied by SO^3 and entered in the table as K_s. The table contains some

TABLE I

DECOMPOSITION OF FORMIC ACID BY SULFURIC ACID WITH VARIOUS CONCENTRATIONS OF SULFURIC ACID AT SEVERAL TEMPERATURES

	K_s			
H_2SO_4, %	15°	25°	35°	45°
96.69	28.5	91.5	312 (300)*	810 (975)*
94.40	10.4	33.5	106	280 (330)*
92.78	5.1	16.6	53.5	159
91.49	2.7	8.9	28.7	86.2
89.53	1.2*	4.0	13.1	41.4
85.52	0.24*	0.78*	2.5	7.8

values which have been obtained by graphical extrapolation. According to Rice[4] the graphical representation of the logarithm of velocity constants plotted against reciprocal of absolute temperature, for each concentration of sulfuric acid, should be a straight line or nearly so. In cases where the reaction was too slow to measure, extrapolated values, indicated by an asterisk, are inserted in the table; where the velocity was very great (more than half of the total volume of carbon monoxide, 51 cc., being evolved in the first fifteen seconds), both determined and extrapolated values are given.

The values from Table I are shown graphically in Fig. 1. It will be seen that for like concentrations of sulfuric acid the effect of small amounts of water becomes more marked as the temperature at which decomposition occurs increases. For the addition of 1% of water to the sulfuric acid (diluting from 93 to 92%) in the decomposition of formic acid, the constant changes from 19 to 12 (obtained from interpolation on Fig. 1) at 25" and from 175 to 113 at 45°.

The Effect of Temperature on the Reaction.—The temperature coefficients for 10° intervals have been calculated from the velocity constants at the various temperatures for all of the concentrations of sulfuric acid used. The effect of temperature is summarized in Table II. It will be seen that in general these values decrease as the velocity of reaction increases and that the irregularity found by Schierz[2] has not been found at these concentrations.

The values for E (critical increment) calculated from the integrated form of the simple Arrhenius[5] equation for various temperature intervals are shown in Table II.

TABLE II

TEMPERATURE COEFFICIENTS AND VALUES OR E FOR THE DECOMPOSITION OR FORMIC ACID BY VARIOUS CONCENTRATIONS OF SULFURIC ACID

H_2SO_4, %	K_{25}/K_{15}	E (calcd.)	K_{35}/K_{25}	E (calcd.)	K_{45}/K_{35}	E (calcd.)
96.69	322	19,920	3.27	21,600	325	22,900
94.40	3.22	19,920	3.17	21,420	3.12	22,200
92.78	3.25	20,080	3.22	21,350	2.98	21,300
91.49	3.29	20,310	3.23	21,400	3.10	22,080
89.53	3.33	20,500	3.28	21,650	3.16	22,410
85.52	3.3	20,900	3.2	21,210	3.12	22,200

An examination of these values shows that they are all very nearly the same for any one temperature interval and that there is a general tendency to increase but slightly with increase in temperature. This constancy is in agreement with the work of Essex and Gelormini[6] and Daniels and Johnston,' who conclude that for isolated reactions the critical increment is independent of the temperature.

Conclusions

The results of this investigation, in which the reaction was allowed to proceed at higher temperatures for the more concentrated sulfuric acid, indicate that under these conditions also the role of sulfuric acid is primarily that of a dehydrating agent.

The curves (Fig. 1) show that the change in velocity constant as a function of the percentage composition of sulfuric acid is continuous.

Lichty[8] found the same relation to obtain in his study of the decomposition of oxalic acid by sulfuric acid.

The value of the velocity constant obtained by Schierz for concentration 91.8% (at which the irregularity was noticed) falls on the curve for 25°.

Summary

1. The velocity of decomposition of formic acid by sulfuric acid has

[7] Daniels and Johnston, *ibid.*, 43, 53 (1921).

[8] Lichty, J. Phys. Chem., 11,225 (1914).

been measured using the following concentrations of sulfuric acid: 85.52, 89.53, 91.49, 92.78, 94.40 and 96.69% at 15, 25, 35 and 45°.

2, The temperature coefficients have been given. They decrease in magnitude as the velocity constant increases.

3. The values for E (critical increment) have been calculated and found to be nearly equal for all concentrations at the temperature intervals 25°/15°, 35°/25° and 45°/35°.

4. For equal concentrations of sulfuric acid, the effect of small quantities of water becomes more marked with increase in temperature.

5. No irregularities in velocity constants or temperature coefficients were observed in the temperatures and concentrations studied.

THE USE OF POTASSIUM IODATE IN BACK TITRATION FOR THE DETERMINATION OF THE HYPOCHLORITE CONTENT OF SOLUTIONS

BY JOHN R. LEWIS AND R. F. KLOCKOW

RECEIVED AUGUST 2, 1928 PUBLISHED DECEMBER 10, 1928

Volumetric iodate methods for the analysis of a variety of substances have been collected and published by Jamieson.[1] While searching the literature for methods of analyzing sodium hypochlorite solutions, it occurred to the authors that potassium iodate may also be used here. When a standard arsenite, thiosulfate or iodide solution was used in excess to reduce the hypochlorite, it was found that the excess could be determined by titration with potassium iodate according to the method described by Jamieson for the determination of hydrogen peroxide.

Method I (Sodium Arsenite Method).—To a known excess of standard arsenite is added a measured volume of hypochlorite. The unoxidized excess is then titrated with 0.1 N iodate in the presence of at least 12% hydrochloric acid. The results are accurate in the presence of small amounts of nitrate or chlorate.

Method **II** (Sodium Thiosulfate Method).—This method is based upon the fact that sodium hypochlorite oxidizes sodium thiosulfate to sulfate in an acid solution.[2] The titration mixture should be cooled in an ice-bath before adding the iodate. It makes no difference whether the hypochlorite is added to the acid or neutral solution of the thiosulfate. Results are not concordant in the presence of chlorate.

Method III (Iodide Method).—In this method the hypochlorite is reduced with potassium iodide. The mixture should be cooled in ice water before titrating with iodate. Chlorate interferes.

THE GASEOUS EXPLOSIVE REACTION AT CONSTANT PRESSURE. THE EFFECT OF INERT GASES[1]

BY F. W. STEVENS

RECEIVED AUGUST 3, 1928 PUBLISHED DECEMBER 10, 1928

Thermodynamics

The effect of inert gases upon the thermodynamic equilibrium of gaseous explosive reactions has received extended consideration from Nernst and his pupils,[2] who employed in their investigations a spherical bomb of constant volume with central ignition. This series of studies extended to temperatures of over 3000" Abs. and formed part of the most extensive investigation of gaseous reactions involving the equilibrium products of combustion, carbon dioxide and water vapor that has yet been carried out. "No other chemical equilibrium has so far been investigated by so many methods which can also be controlled at the same time by thermodynamic calculations. . . . A specially high value must be attached to explosion methods since by suitable variations of the experimental conditions it enables both the specific heats and the equilibrium to be determined."[3]

[3] Nernst, "Theoretical Chemistry," Macmillan Company, New York, 10th ed., 1923, p. 783.

The accuracy of explosion methods as employed by the investigators mentioned depends upon the favorable symmetry automatically assumed by the gross mechanism of the gaseous explosive reaction. The sharply localized zone of explosive reaction originating at the spark gap at the center of the spherical bomb is propagated in all directions from this point, as are also the sound and impulse waves resulting from it. Thus the zone of explosive reaction marked by flame and the disturbances and their reflections resulting from it, maintain during the reaction positions symmetrical with the spherical bomb. The equilibrium products of combustion thus remain enclosed within an expanding spherical shell of flame and are thereby protected as well as may be from heat losses due to the walls of the container till the end of the reaction and the attainment of maximum pressure. The maximum pressure of the equilibrium products filling the bomb at the instant the reaction is completed, corresponds to the equilibrium constant of the reaction

$$K = \frac{[A']^{n'_1}\,[B']^{n'_2}\,[C']^{n'_3}\ldots}{[A]^{n_1}\,[B]^{n_2}\,[C]^{n_3}\,\ldots.} \qquad (1)$$

Pier[4] has shown that the deviation from this constant due to the presence of an inert gas permits the specific heat of that gas to be determined at reaction temperature; and Siegel[5] has shown that from a knowledge of the pressure of the bomb and the reaction constant the degree of dissociation of combustion products may be found. For example, in the case of the trimolecular explosive reaction, $2CO + O_2 \qquad 2CO_2$, Equation 1 may be written for constant volume conditions

$$K = \frac{[CO]^2\,[O_2]}{[CO_2]^2} \qquad (2)$$

and if x is the degree of dissociation of carbon dioxide, then

$$K = \frac{[CO]^2\,[O_2]}{[CO_2]^2} = \frac{P}{2RT} \times \frac{x^3}{(1-x)^2\left(1+\frac{x}{2}\right)} \qquad (3)$$

In a previous communication[6] a simple device was described that was found to function as a bomb of constant pressure; it thus provides the complement to the bomb of constant volume referred to above. It expresses the initial and final condition of the explosive reaction in terms of volume at constant pressure instead of pressure at constant volume. The thermodynamic relation between the two forms of device is expressed in the equation of state, $pv = nRT$.

Besides the advantages attending the use of constant pressure methods as applied to'thermodynamic studies of gaseous explosive reactions, the experimental procedure in the use of the constant pressure bomb has the

---

[4] Ref. 2 a, p. 538.

[5] Ref. 2 g, p. 654.

[6] Stevens, THIS JOURNAL, 48, 1896 (1926).

advantage of being unusually simple and direct. The labor and care necessary in evacuating and recharging a bomb of constant volume and of securing constant initial pressures and temperatures in the operations are tedious and time consuming. In the use of the constant pressure device and method these difficulties are practically eliminated. It is not difficult, using this device, to secure fifteen or twenty reaction records, giving initial and final volumes at constant pressure, within an hour. By securing so large a number of observations there is the advantage of using average results in computations.

The term volume here used in connection with the constant pressure bomb does not refer, as it does in the case of the constant volume bomb, to the actual volume of the temporary soap film container. The symmetry of form and movement automatically assumed by the reaction zone in the case of a homogeneous mixture of explosive gases fired from a point and under conditions of constant pressure, offers a much more accurate way of determining initial and final volumes involved in the transformation. The zone of explosive reaction originating at a point within a homogeneous mixture of explosive gases maintained at a constant pressure advances in all directions from this point at a constant linear speed. It thus forms an expanding spherical shell of flame that remains concentric with the point of ignition till the end of the reaction. This sphere of reaction products enclosed by the reaction zone is thus protected as well as may be from heat losses during the reaction, due to conduction and convection. By reference to Fig. 1 it will be seen that the initial volume of active gases whose transformation is photographically followed by the method used, is the volume of an ideal sphere 2r determined by the horizontal diameter of the container passing through the point of ignition and not the actual volume of the container itself, for this is never a sphere. The final volume is this initial volume transformed at a uniform linear rate into the sphere of equilibrium reaction products, $2r'$. The continuous volume changes during this reaction are recorded photographically together with time intervals of a calibrated fork.

The final volume represented by r'—as does the final pressure in the case of a constant volume bomb—corresponds to the equilibrium constant, K, of the reaction (Equation 1). Likewise the other thermodynamic relations characteristic of the reaction at constant volume conditions are expressible for conditions of constant pressure.

The conditions that determine uniform flame movement in a gaseous explosive reaction, whether for the slower reaction rates or for the more rapid rates of the Berthelot explosive wave, are a homogeneous mixture of the explosive gases and a constant pressure; for under these conditions only is it possible for the mass movement of the active gases and for their concentrations to remain constant during the reaction.

Kinetics

The photographic record (Fig. 1) of the gross mechanism and progress of the reaction at constant pressure, upon which equal time intervals have been impressed, is a time–volume record of the reaction and hence may provide some general information as to the kinetics of the gaseous explosive transformation.

If the rate of movement of the zone of explosive reaction is to be connected in any way with the rate of molecular transformation and hence with the rate of energy liberation, it is obvious that its rate should be determined relative to the active gases it is transforming and not relative to space. And it should likewise be recognized that unless the method employed makes it possible to follow the composition and concentrations of the active gases which the zone of explosive reaction is entering, a kinetic relation connecting the movement of the reaction zone with the composition and concentration of the explosive gases could hardly be expected to result from its use.

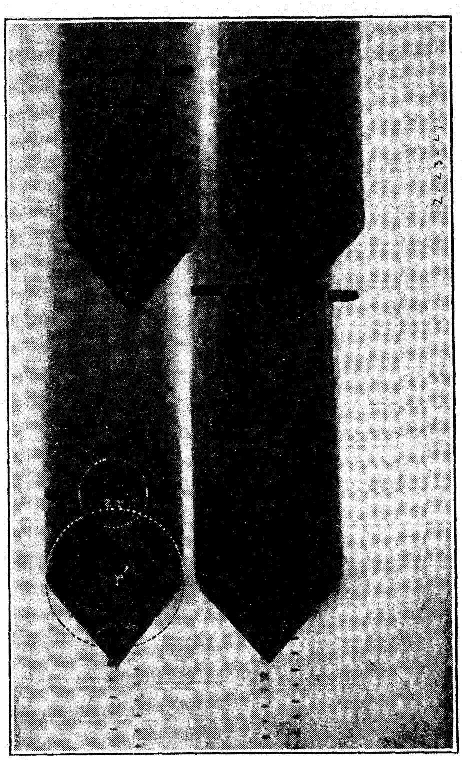

Fig. 1.—A reproduction of a photographic time–volume record of four gaseous explosions at constant pressure. $2r$ gives the dimensions of the sphere of initial active gases considered. $2r'$ the dimensions of the sphere of its reaction products at the instant the reaction is completed. Equal time intervals are recorded on the photographic film during the reaction process.

An examination of a great number of records similar to that reproduced in Fig. 1, obtained with different active gases at different concentration ratios, has shown that at constant pressure the rate of movement, s, of the zone of reaction, measured relative to the active gases, is constant and is proportional to the product of the initial concentrations (partial pressures) of those gases

$$s = k_1[A]^{n_1}\,[B]^{n_2}\,[C]^{n_3}\ldots. \qquad (4)$$

In this expression k_1 is a proportionality factor. The bracketed symbols represent initial concentrations or initial partial pressures of the active gases; their product expresses their impact probability, Γ; s is the linear rate of propagation of the reaction zone measured relative to the active gases it is entering.

It was of interest to examine the effect of inert gases on the rate of propagation of the zone of reaction in the light of the statistical relation expressed in (4) and by a method suggested by that employed by the investigators mentioned in determining the effect of inert gases upon the thermodynamic equilibrium. It is the purpose of this paper to record the results obtained in this endeavor.

Experimental Procedure

From the photographic figures of the progress of the reaction it will be seen that the constant rate of flame movement, s', in space may be determined at any instant during the transformation. It is equal to the radius, r'_i, at any instant divided by the time interval between ignition and the attainment of r'_i

$$s' = \frac{r'_i}{t} \tag{5}$$

But this is not the rate at which the flame is entering the gases. The rate, s, at which the flame is entering the gases may be found for the case of a spherical shell of flame expanding at uniform rate s' as follows.

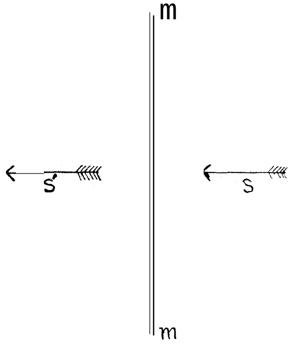

Fig. 2.

Let m, m, Fig. 2, be an element of the flame surface held at rest by the uniform flow s of the active gases against it; then s will be the rate at which the reaction zone enters the gases and s' will be the rate at which the transformed gases leave the flame area. If ρ and ρ' are the initial and final densities of the gases then from the equality of masses

$$\rho s = \rho' s' \tag{6}$$

For the case of the initial and final spheres in the reaction, we also have from the equality of masses

$$\frac{4\pi\rho r^3}{3} = \frac{4\pi\rho' r'^3}{3} \tag{7}$$

hence,

$$\frac{s}{r^3} = \frac{s'}{r'^3} \tag{8}$$

$$s = s' \frac{r^3}{r'^3} \tag{9}$$

For a test of these relations the gaseous explosive reaction at water vapor saturation

$$2CO + O_2 \rightleftharpoons 2CO_2 \tag{10}$$

was selected. For this special case Equation 4 may be written

$$s = k_1[CO]^2\,[O_2] \tag{11}$$

Including Equation 5

$$s = s' \frac{r^3}{r'^3} = k_1[\mathrm{CO}]^2\,[\mathrm{O_2}] \tag{12}$$

and

$$k_1 = \frac{r^3}{r'^2 t\,[\mathrm{CO}]^2\,[\mathrm{O_2}]} \tag{13}$$

Since the sum of the partial pressures of the gaseous components present in the reaction at pressure p must equal p, Equation 11 may be written for atmospheric pressure

$$s = k_1[\mathrm{CO}]^2\,[1 - \mathrm{CO}] \tag{14}$$

without designating the composition of the term [1–CO] further than to indicate that the sum of the partial pressures of its components remains the same as the partial pressure of the component $[\mathrm{O_2}]$ in Equation 11; and that under the same circumstances the products $[\mathrm{CO}]^2\,[\mathrm{O_2}]$ and $[\mathrm{CO}^2]$ [1–CO]'represent the same impact probability, Γ, though not the same proportion, k_1, of effective impacts nor the same potential energy. In case the component [1–CO] is made up of the fraction a of the active gas $\mathrm{O_2}$ and the fraction 1–a of some inactive gas, the partial pressure of the component [1–CO] may be expressed as

$$[1 - \mathrm{CO}] = \underset{\text{active}}{[1 - \mathrm{CO}]a} + \underset{\textbf{inert}}{[1 - \mathrm{CO}](1 - a)} \tag{15}$$

Equation 11 may then be written

$$s = k_1[\mathrm{CO}]^2\,[1 - \mathrm{CO}]a + k_1\,[\mathrm{CO}]^2\,[1 - \mathrm{CO}]\,(1 - a) \tag{16}$$

If, now, all of the impacts involving the inert gas are futile and the possible effect of its various physical properties, as specific heat, heat conductivity, etc., on the course of a thermal reaction be disregarded, then the last term in the above expression may be neglected and the effect on reaction probability of replacing the fraction $(1 - a)$ of an active gas by an inactive one be written

$$s = k_1[\mathrm{CO}]^2\,[1 - \mathrm{CO}]a \tag{17}$$

This expression takes into account the effect of the remaining active components only, and this is the major effect to be expected; but while the inert gas introduced may take no part in the molecular transformation, its presence in the zone of explosive reaction and in the active gases adjacent to it would naturally affect the heat distribution in that region. The effect of different inert gases upon the thermodynamic equilibrium is not the same; a quantitative estimate of their different effects permits their specific heats to be determined under the conditions resulting from the explosive reaction of the active gases. It might therefore be expected that the presence of inert gases in the zone of reaction would likewise have different effects upon the propagation of the reaction zone due to their individual characteristics.

In carrying out the observations the experiments were so arranged that the explosive transformation of the same partial pressures of the active gases, carbon monoxide and oxygen, could be observed on the same partial pressure of each of the inert gases used—and this over the entire range of mixture ratios of the gases that would ignite. The inert gases made use of were helium, argon, nitrogen and carbon dioxide. In the table below some of the physical properties of the gases involved in the transformations studied are set down. The values given for heat conductivity are taken from Taylor's "Treatise on Physical Chemistry," Vol. I, p. 92. The values for molecular heats are from Partington and Schilling, "Specific Heats of Gases."

Table I

Molecular Heats and Heat Conductivities of Gases Referred to in this Paper

Gas	He	A	N_2	O_2	CO.	CO_2
Mol. heat	5.07	5.07	6.90	6.90	6.90	9.0
Heat conductivity	336.0	39.0	56.6	57.0	54.2	33.7

Table II, below, gives results obtained for the $CO - O_2$ explosive reaction when no inert gas is present.

					Av. k_1	691

The results given in the above table may be expressed in graphic form by plotting the values of s as ordinates and either the corresponding partial pressures—shown in Fig. 3—or the corresponding values of $\Gamma = [CO]^2 [O_2]$, shown in Fig. 4 as abscissas. The method followed in Fig. **3** is the more familiar and will be used in expressing the results that follow. In Fig. **3** the observed values of $s = s'(r^3/r'^3)$ are represented by solid circles. Theoretical values of s, $s = k_1 [CO]^2 [O_2]$, are represented by open circles connected by a continuous line. This curve will be reproduced as a convenient reference in the other coordinate figures indicating the effect of inert gases on the CO — O_2 explosive reaction.

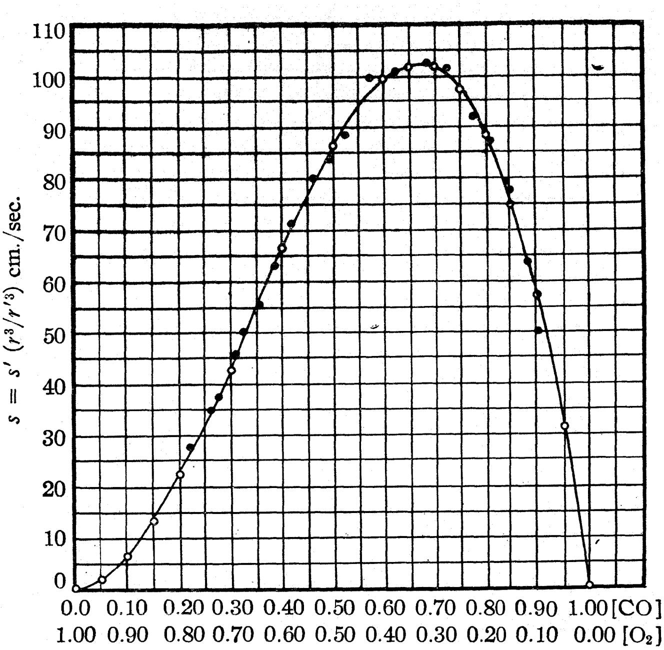

Fig. **3** shows the relation between the linear rate of propagation, s, of the zone of reaction, measured relative to the explosive gases, and the partial pressures of the gases, [CO] and [O_2], in the explosive mixture. The solid circles represent observed values, $s = s'(r^3/r'^3)$. The open circles and continuous line represent calculated values of $s = k[CO]^2 [O_2]$.

In Table III there are given the experimental results obtained when 10% of the component [1 — CO] consists of the inert gas A. These results are represented graphically in Fig. 5 by the mark $\vee$. The upper continuous curve in this figure gives velocity values of the reaction zone when no inert gas is present. The lower curve, indicated also by a continuous line, corresponds to Equation 17, s = 691 $[CO]^2$ [1 — CO] 0.9, for the case where 10% of the component [1 — CO] consists of an inert gas—

the possible effect of its physical properties being disregarded. There is also plotted on this figure the experimental values found when 10% of the component [1 − CO] consisted of nitrogen, marked X on the figure, carbon dioxide, marked ■, and helium marked A.

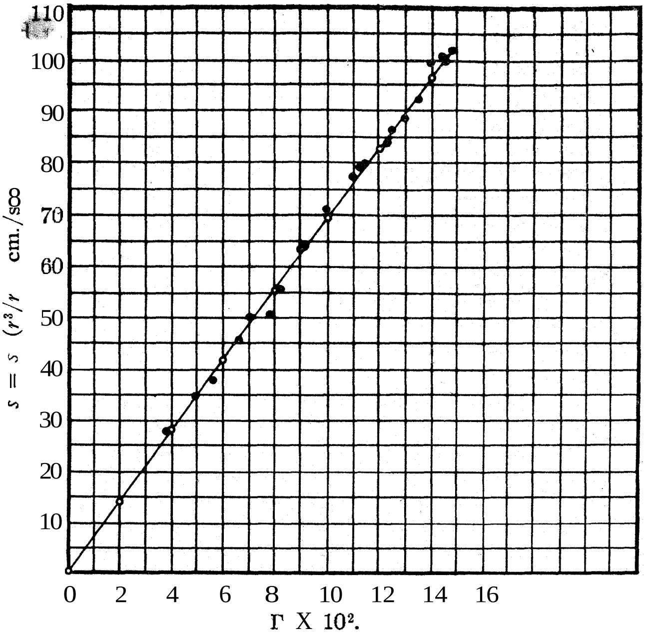

Fig. 4 **shows the relation between the linear rate of propagation of the reaction zone, *s*, and impact probability, Γ.**

Table IV gives the experimental results when 20% of the component [1 − CO] was made up of the inert gas nitrogen. The observed values are indicated in the coordinate Fig. 6 by the mark ×. The upper continuous curve in this figure again represents velocity values of the reaction zone when no inert gas is present. The lower continuous curve in this figure corresponds to Equation 17, $s = 691\ [CO]^2\ [1 - CO]\ 0.8$. The observed results when the inert gas used was helium instead of nitrogen are represented by the mark A; when the inert gas was argon, by the mark V, and when the inert gas was carbon dioxide, by the mark **I**.

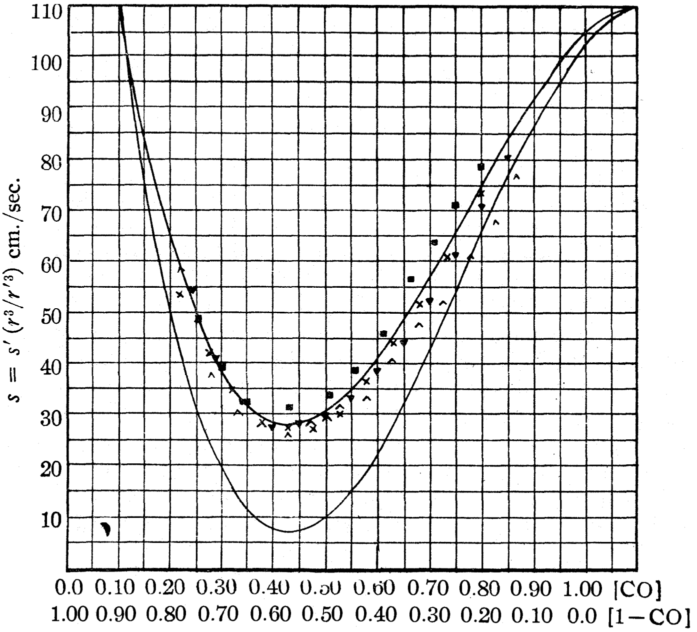

Fig. 6.—The upper continuous curve gives velocity values of the reaction zone when no inert gas is present. The lower continuous curve corresponds to the equation, $s = 691[CO]^2[1 - CO]0.8$; observed results when the inert gas present was N_2 are indicated by the mark X, when the inert gas was He, by the mark ▲, A, by the mark V, CO_2, by the mark ■.

In Table V are given the experimental results obtained for $s = s'\ r^3/r'^3$ when 40% of the component [1−CO] consisted of the inert gas helium. In Fig. 7 these results are shown graphically together with results obtained when the other inert gases were used in the same proportion. The marks employed to designate the s-values of the different inert gases in this figure are the same as those previously given.

From these results it may be seen that when small amounts (partial pressures) of different inert gases are present in the explosive mixture, not much difference in their individual effects is to be noticed; their different physical properties do not mask the effect of the active gases; but as the relative amounts (partial pressures) of the different inert gases become greater, a difference in their effect on the same $CO-O_2$ reaction becomes apparent. This is to be seen in the results given in Table V and shown in Fig. 7. The observed s-values not only diverge more widely from values indicated by Equation 17; they also differ characteristically from each other. It is further to be noticed that this divergence in each case is the greater, the greater the amount (partial pressure) is of the inert gas in the mixture. In Col. 4 of Table V is given the partial pressure of helium in each mixture ratio of [CO] and [1 − CO]. In Col. 8 of this table are given the corresponding values of $k_1 = s/\Gamma$. The values of k_1 in this

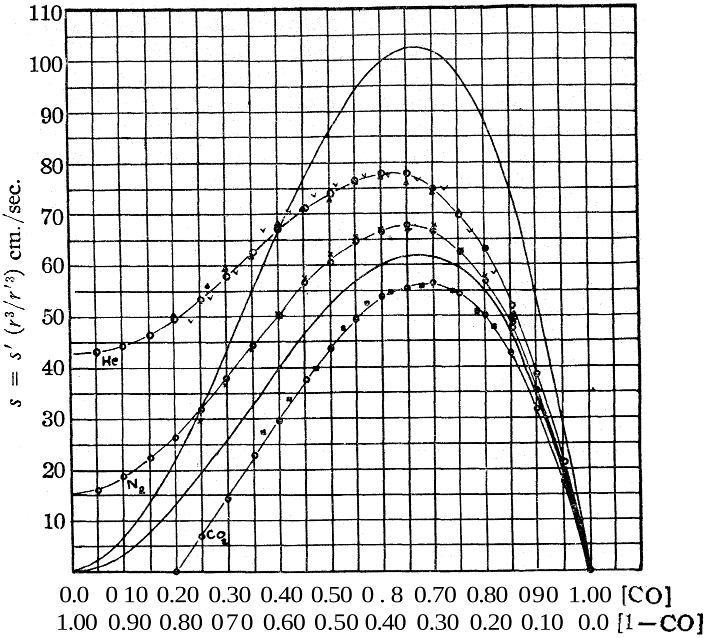

Fig. 7.—The upper continuous curve gives velocity values of the reaction zone when no inert gas is present. The lower continuous curve, without other marks, corresponds to the equation $s = 691 [CO]^2[1 - CO]$ 0 6, where 40% of the component [1 − CO] is made up of an inert gas whose effect upon the reaction rate is disregarded. Observed values when 40% of the component [1 − CO] consisted of A are marked V. Like values for N_2 are marked ×, He, ▲, and CO_2, ■. The curves in this figure marked He, N_2 and CO_2 shown by open circles and continuous lines correspond to Equation 18 when the experimental values for β found for the inert gases are introduced.

column, according to the assumption made in Equation 17, should be constant and equal to 415. The values of k~are seen to be far from constant in this case and only approach the theoretical value for no effect of an inert gas as the partial pressure of helium in the mixture decreases. The highest value of k_1 is seen to correspond to the greatest amount of helium in the explosive mixture and vice *versa.*

It was conceived that the relationship shown in the table between the values of helium and k_1 could be due to characteristic physical properties, whatever they might be, of the inert gas present in the mixture and that the magnitude of their different effects upon the $CO - O_2$ reaction might be directly proportional to the partial pressure of the inert gas in the mixture, that is

$$s = s' \frac{r^3}{r'^3} k_1 [CO]^2 [1 - CO] a + \beta [G_i] \tag{18}$$

where $[G_i]$ is the partial pressure of the inert gas. The observed results were examined for this relationship. The last column of Table V gives the estimated value of β for each mixture ratio of [CO] and [1−CO] that would ignite

$$\beta = \frac{s - k_1 a [CO]^2 [1 - CO]}{[He]} \tag{19}$$

When the average value of β so found, 109, is substituted in Equation 18 the curve represented by open circles and a continuous line, marked He in Fig. 7, is determined. In a similar way it was found that the value for

β for each of the other inert gases used was also a fair constant. Its value for 40% of N_2 in this reaction is 41, for CO_2, **−41.8** and for A, **112.**

In carrying out the experimental work involved in these studies, the inert gases helium, nitrogen and carbon dioxide were first employed. **A** comparison of the results obtained with these gases indicated that their effect upon the $CO - O_2$ reaction was of an order roughly paralleling the order of their heat conductivities, but following also the order of their molecular heats. It was therefore desirable to compare the effects of the two monatomic inert gases, helium and argon, having the same molecular heat but very different heat conductivities. A sample of argon was later obtained and the comparison made. The results indicate that the sample of argon used has practically the same effect on the rate of propagation of the reaction zone in the $CO - O_2$ explosive reaction as the inert gas helium. These two gases being monatomic have the same molecular heat independent of temperature, but the heat conductivity of helium is **8.6** times that of argon.

The mixture ratio for maximum flame velocity for the conditions expressed by Equations 14 and 17 is that given by position 0.667 in the coördinate figures; but for Equation **18** this position will be displaced to the left according to the positive magnitude of the last term, and to the right according to its negative magnitude. This may be seen in the results given in Fig. 7. It is also of interest to note that it might be possible to have a mixture of two inert gases whose individual effects upon the rate of propagation of the reaction zone were in opposite sense and balanced each other. For such a case the last term in Equation 18 would be negligible. The conclusion could be drawn from a special case of this kind that the rate of propagation of the zone of reaction is proportional to the product of the concentrations of the active components as in the case of the pure gases $CO–O_2$. This conclusion might also seem warranted from experimental results obtained when the inert gas is present in the explosive mixture in comparatively small quantities as shown in Figs. 5 and **6** and for all results where the value of [CO] is large and the partial pressure of the inert gas small. It was therefore essential in carrying out the investigation to determine in each case the effect of the same partial pressure of each of the inert gases on the same mixture ratio of [CO] and [1−CO], and this over the entire range of mixture ratios that would ignite. In Fig. 7 the results of this procedure when 40% of the component [1−CO] consists of an inert gas is shown for the inert gases helium, argon, nitrogen and carbon dioxide.

The writer desires to express here his gratitude to the National Advisory Committee for Aeronautics for interest, encouragement and support extended him during an investigation of gaseous explosive reactions. This report deals with the effect of inert gases on the reaction.

Summary

1. Attention is called to previous investigations of gaseous explosive reactions carried out under constant volume conditions, where the effect of inert gases on the thermodynamic equilibrium was determined. The advantage of constant pressure methods over those of constant volume as applied to studies of the gaseous explosive reaction is pointed out and the possibility of realizing for this purpose a constant pressure bomb mentioned.

2. The application of constant pressure methods to the study of gaseous explosive reactions made possible by the use of a transparent constant pressure bomb, led to the discovery of an interesting kinetic relation connecting the rate of propagation of the zone of explosive reaction within the active gases, with the initial concentrations of those gases

$$s = k_1[A]^{n_1}\ [B]^{n_2}\ [C]^{n_3}\ldots.$$

3. By a method analogous to that followed in determining the effect of inert gases on the equilibrium constant K, the present paper records an attempt to determine their kinetic effect upon the expression given above. It is found that this effect on the $CO - O_2$ reaction for the inert gases investigated, helium, argon, nitrogen and carbon dioxide, may be expressed as

$$s = k_1[A]^{n_1}\ [B]^{n_2}\ [C]^{n_3}\ldots. + \beta[G_i]$$

where $[G_i]$ represents the initial concentration of the inert gas in the mixture.

4. An example of the utility of the constant pressure bomb for the study of the kinetics of the gaseous explosive reaction is offered in the results given in the present paper.

THE EQUILIBRIUM OF SILVER OXIDE AND SILVER CHLORIDE WITH AQUEOUS POTASSIUM CHLORIDE AND POTASSIUM HYDROXIDE

BY ROY F. NEWTON

RECEIVED AUGUST 6, 1928 PUBLISHED DECEMBER 10, 1928

Lewis and Randall,[1] in one of their calculations of the free energy of formation of water, have made use of Noyes and Kohr's[2] measurements on the equilibrium between silver oxide, silver chloride, potassium hydroxide, potassium chloride and water. They point out that it would be much simpler to use the dissociation of silver oxide into silver and oxygen, and the electromotive force of a silver–silver oxide electrode against the hydrogen electrode, but that the silver–silver oxide electrode is quite variable

---

[1] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Company, New York, 1923, p. 482.

[2] Noyes and Kohr, *Z. physik. Chem.*, 42, 336 (1902).

and leads to results quite different from those obtained by other sets of reactions. However, Noyes and Kohr's results are not very consistent and it seemed worth while to redetermine the equilibrium between silver oxide, silver chloride, potassium hydroxide, potassium chloride and water.

Materials

Silver oxide was prepared (*a*) by precipitation at room temperature of dilute solutions of barium hydroxide and silver nitrate, (*b*) by heating precipitate (*a*) for several hours at 300°, (c) by precipitating from nearly boiling solutions of the above reagents, (d) by addition of silver nitrate to boiling sodium hydroxide solution and boiling the precipitate in excess sodium hydroxide solution and (*e*) by precipitation from the silver ammonia complex hydroxide by vacuum distillation of the ammonia. Preparation (*e*) was made to see if silver oxide so prepared showed evidence of greater stability than the samples precipitated in the more usual ways. On the contrary, as judged by the concentration ratio of chloride to hydroxide in equilibrium with it in presence of water and silver chloride, it behaved as if it were less stable, or more soluble, than the other four preparations, and for this reason little work was done with it.

The silver chloride was prepared by mixing moderately dilute solutions of silver nitrate and hydrochloric acid and washing thoroughly by decantation. The silver chloride was prepared and stored in a dark room, was kept in a moist condition and did not darken.

The water used was distilled and made free of carbon dioxide by prolonged passage of carbon dioxide-free air. The potassium chloride was a c. p. grade recrystallized and fused. The potassium hydroxide was sometimes made from electrolytically prepared potassium amalgam, and sometimes by precipitating c. p. potassium hydroxide with excess barium hydroxide, filtering and removing the excess barium hydroxide by addition of the required quantity of potassium sulfate as determined by analysis. The potassium sulfate was a recrystallized c. p. product. The sulfuric acid was standardized by titration with weighed quantities of recrystallized borax, using methyl yellow (dimethylamino-azobenzene) as indicator.[3] The hundredth normal silver sulfate solution was standardized against recrystallized fused potassium chloride by electrometric titration as described later.

Procedure

Varying proportions of silver oxide and silver chloride were put into 250-cc. ground-glass-stoppered Pyrex Erlenmeyer flasks, the desired quantities of potassium hydroxide, potassium chloride and water added, and the samples were then rotated in a 25.00 ± 0.02° thermostat for periods varying from several hours to three days. The equilibrium was approached from both sides. No consistent differences were observed. Samples consisting of most of the liquid contents of the flasks were filtered from them, using filters made by sealing disks of alundum into Pyrex glass tubes. First portions of ten to twenty cubic centimeters were rejected to avoid error due to possible selective adsorption. The flasks and filters remained in the thermostat during the filtrations. Potassium hydroxide was determined by titration of the entire samples (about 200 cc.) with 0.5 N sulfuric acid, using phenolphthalein as indicator. The solution was then

---

[3] Kolthoff, THIS JOURNAL, 48, 1447 **(1926).**

carefully evaporated to small bulk and titrated electrometrically with 0.01 N silver sulfate solution, using a silver–silver chloride electrode and connecting to a saturated potassium sulfate–mercurous sulfate–mercury electrode. Standardizations of the silver sulfate were made by titrating weighed quantities of potassium chloride mixed with amounts of potassium sulfate comparable with those encountered in the analyses. While steady potentials were obtained only slowly, and the titrations were tedious, the end-points were definite, the standardizations were reproducible and since the samples were practically identical in composition and concentration with the solutions titrated during standardization, systematic errors in the analyses are not to be expected.

17	b	.0531	.000481	.00906	
18	c	.0536	.000485	.00905	
Average for solutions approx. 0.05 molal				.00897	.00897
Final weighted mean				.00903	.00893
Mean of Noyes and Kohr's results				.00937	.00930

The activity ratios were calculated by multiplying the corresponding concentration ratios by $\gamma^2_{KCl}/\gamma^2_{KOH}$, where γ is chosen to correspond to the *total* ion concentration.[4]

It may be noted that while individual samples are variable, the samples prepared in different ways do not differ significantly from one another, and while the general average is somewhat below the values of Noyes and

---

[4] Ref. 1, p. 362. The individual ion activity coefficients, p. 382, have been derived in the same way, but the values have been so rounded that the difference in activity coefficients of Cl^- and of OH^- in 0.1 molal solution have been exaggerated from barely over 1 to 2%.

Kohr, they probably agree within the limits of error, considering the individual variability, which is characteristic of the results both of Noyes and Kohr, and of the author. While the difference of the equilibrium ratio from that of Noyes and Kohr does not justify a recalculation of the free energy of water based in part on this equilibrium, it may be noted that the free energy calculated from the above results agrees with that obtained by other methods somewhat better than that calculated from the results of Noyes and Kohr.

Summary

The equilibrium of AgCl, Ag_2O, KOH, KCl and H_2O, previously studied by Noyes and Kohr, has been redetermined, using Ag_2O prepared in a variety of ways, and determining the chloride by electrometric titration. While the individual values are somewhat variable, the method of preparation has no significant effect on the equilibrium ratio of chloride and hydroxide. Within experimental error the equilibrium ratio is the same in 0.05 molal solution as in 0.1 molal solution.

A HIGHLY ACCURATE METHOD FOR THE ANALYSIS OF UREA

BY MILLICENT TAYLOR

RECEIVED AUGUST 6, 1928 PUBLISHED DECEMBER 10, 1928

There are many problems in physical and colloid chemistry which require for their experimental solution the use of a reference substance capable of analysis to a high degree of accuracy. Such a reference substance must also be chemically inert and a non-conductor of electricity. These problems include methods of indirect analysis, determination of solvation by the method of ultrafiltration[1] and the determination of the hydration of the ions by measurement of the displacement of the reference substance during electrolysis, as suggested by Nernst in 1900. In Washburn's[2] well-known work on this latter subject, only one substance, raffinose, was considered to possess the requisite properties and it is subject to the drawback that a highly sensitive polarimeter of a type not generally accessible is required to estimate it.

The high molecular weight of raffinose is also a disadvantage. The decimolar solution contains more than 50 g. to the liter, a quantity sufficient to cause considerable increase in the viscosity of the solution and consequently to affect the migration velocities of the ions. Also, it is

---

[1] McBain and Jenkins, *J. Chem. Soc.*, 121, 2325 (1922).

[2] Washburn, THIS JOURNAL, 31, 322 (1909); Washburn and Millard, *ibid.*, 37, 694 (1915).

conceivable, in view of Coehn's[3] observation of the Tyndall cone in sucrose solution and of his statement that sucrose moves in the electric field, that the large molecules of raffinose may tend to become colloidal and to adsorb charged ions in the presence of a considerable quantity of electrolyte. Thus doubt is thrown on the value of raffinose as a reference substance in migration experiments.

The possibility of using urea for this purpose does not appear to have been considered, yet it has properties which render it almost ideal for the purpose. Its equivalent weight is low, it is easy to obtain pure and its aqueous solution is stable at room temperature in the absence of ferments. Moreover, its basic dissociation constant,[4] $[CO(NH_2)_2H][OH]/[CO(NH_2)_2HOH]$, at 25° is 1.5×10^{-14}, the conductivity of its solution is approximately equal to that of water and the effect of its presence in potassium chloride solution is merely a slight lowering of the conductivity, which can be accounted for by the increased viscosity of the solution.

It only remained to find a suitably accurate method of estimating it in solution. A search through the literature revealed the fact that no method has afforded results which would establish an accuracy exceeding 1% of the urea present. The method favored by physiologists at the present time consists in the fermentation of urea by urease[5,6] in the presence of potassium dihydrogen phosphate and subsequent liberation and distillation of the ammonia formed. This method appears to be satisfactory for small quantities of physiological fluids for which an accuracy of 1% is sufficient, but it presents difficulties when a degree of accuracy of the order of 0.1% is desired. As is well known, the removal of the last traces of ammonia by boiling and aerating an aqueous alkaline solution is a matter of some uncertainty, even when no colloidal organic matter is present to induce frothing and bumping. In distilling off the ammonia produced by urease fermentation, the frothing is very marked and, though it can be decreased to some extent by the addition of wax or oil, the escape of ammonia is checked and the titration of the excess of acid in the absorber is rendered less accurate, owing to the fact that a small quantity of the wax distils over with the steam and removes the indicator from the aqueous layer. A further drawback is the long boiling required for the complete expulsion of the ammonia from the mixture, resulting in the extreme and variable dilution of the acid in the absorption flask.

In view of these disadvantages, it was decided to revert to the method of Benedict and Gephart,[7] which depends on the hydrolysis of urea by acid

---

[7] Benedict and Gephart, THIS JOURNAL, 30, 1760 (1908).

under a pressure of four atmospheres. The authors state that the results obtained with pure urea solutions leave no doubt that the urea is completely hydrolyzed. The one experiment quoted consists in the hydrolysis of 5 cc. of a *2.5%* urea solution which yielded 0.0575 g. of nitrogen, whereas the theoretical yield is 0.0583 g., an experimental deficit of more than 1% of the total urea. Wolf and Osterberg,[8] using the same method and a 2% solution of urea, also obtain values lower than the theoretical by 1%. It is obvious that these investigators, having in view the composition of physiological fluids, are not concerned with accuracy exceeding 1%.

Experiments by the writer with larger quantities of urea than those used by Benedict and Gephart have indicated that for the purpose of estimating urea unmixed with other hydrolyzable nitrogen compounds, the autoclave method gives a high degree of accuracy. This accuracy depends on the facts that the reaction goes to completion in the presence of very slight excess of hydrochloric acid, and that the acid does not vaporize under the conditions in the autoclave. Thus the distillation with soda can be avoided by mixing a known quantity of standard acid with a known quantity of the solution to be analyzed and directly titrating the excess of acid with dilute soda. By making the excess of acid small, the effect of any slight error in the concentration of the soda becomes insignificant, and consequently the possible accuracy of estimation of the urea depends only on the accuracy of weighing out the urea and acid solutions concerned, and on the accuracy of making up the hydrochloric acid solution.

Experimental

The digestion is carried out in a 500-cc. stoppered conical flask made of Pyrex glass or silica and provided with an exit tube of an inverted U-shape sealed in near the top of the flask. The flask is weighed and the urea solution and standard acid are pipetted (see p. 3264) into it, the weight being noted after each addition. A Pyrex test-tube containing a little water into which the side tube dips acts as scrubber to the escaping carbon dioxide. The latter is absorbed by the distilled water in the autoclave, to which a few cc. of soda solution has been added. This precaution renders unnecessary any subsequent aeration or boiling of the reaction mixture for the expulsion of carbon dioxide.

The flask and scrubber tube are covered with tinfoil in the autoclave and after displacing all the air, heating for half an hour under two atmospheres, and for four hours under four atmospheres, the apparatus is allowed to cool. The autoclave is then opened, the glass stopper of the flask is removed, and replaced by a rubber bung carrying a tube, by means of which the water in the scrubber tube is sucked back and the scrubber tube rinsed several times into the flask. The titration is carried out in the presence of two drops of 0.02% methyl red indicator.

In the experiments described below, the standard hydrochloric acid was prepared by the distillation method of Hulett and Bonner,[9] and the soda was standardized against the acid to three tints of the indicator, giving three different concentrations of the soda of which the extremes differed by less than 0.02%. Thus it was unnecessary always to titrate the soda to the same tint.

---

[8] Wolf and Osterberg, THIS JOURNAL, 31,425 (1909).

[9] Hulett and Bonner, *ibid.*, 31,390 (1909).

The first experiments were carried out volumetrically using calibrated instruments; the later ones gravimetrically, using weight burets. The results are corrected for the buoyancy of the air.

The solutions of urea and hydrochloric acid contained about 0.2 and 0.4 equivalents per liter, respectively, and each experiment was carried out with about 50 cc. of urea solution. The soda solution used for back titration was about 0.2 N. The urea was Kahlbaum's purest material, m. p. 132.2–133.2°, which had been kept in a desiccator for some days before use. Results are recorded in Tables I to III.

In the experiments recorded in Table I, the urea was hydrolyzed by ordinary concentrated hydrochloric acid and the ammonia estimated by distillation with soda and absorption by standard hydrochloric acid. In each of these two experiments, 50.28 cc. of 0.22509 N urea was digested with 5 cc. of pure concentrated acid.

TABLE I

RESULTS OF EXPERIMENTS

Expt.	HCl concn. in abs., *N*	HCl soln., cc.	Concn. of soda	Vol. of soda, cc.	Equiv. of urea per liter of soln. Found	Taken
1	0.51606	25.03	0.21790	7.41	0.23478	0.22508
2	.41671	30.03	.13591	8.87	.22490	.22508
				Mean =	.22484	

In the second set of experiments (Table 11), 50.28 cc. of the same urea solution was digested each time with varying quantities of 0.41671 N hydrochloric acid and titrated directly with 0.13584 N soda.

TABLE II

RESULTS OF EXPERIMENTS

Expt.	Acid, cc.	Soda, cc.	Equiv. of urea per liter of soln. Found	Taken
3	50.28	71.00	0.22489	0.22508
4	50.28	71.02	.22482	.22508
5	30.03	8.94	22474	,22508
		Mean =	22482	

The method was then applied gravimetrically to determine the concentration of three urea solutions, A, B and C, each of unknown concentration but approximately 0.2 N_w. In all cases, 0.40756 N_w hydrochloric acid was used. The results are recorded in Table III.

Of all the solutions analyzed only one failed to give concordant results. In this case one sample of the urea solution was poured, not pipetted, into the digestion flask, and though excess of hydrochloric acid was added, the water in the scrubber tube became alkaline. The sample of the solution which was pipetted in the usual way was found to contain 0.20147 gram equivalents of urea per 1000 g. of solution, while the second sample gave only 0.20103 gram equivalents, a deficit of 0.2%. It seems probable

that urea is rapidly hydrolyzed by water alone at the autoclave temperature of 150° and, consequently, since it is not convenient to shake up the mixture in the digestion flask, some of the ammonia escaped combination with acid.

With this exception, the extreme divergence between any values for the same solution is 0.05%, and if those results which were obtained gravimetrically and by the use of only slight excess of acid are considered exclusively, the agreement throughout is within 0.02%.

No special precaution other than the use of calibrated weights has been observed and it is probable that using more dilute solutions of acid and alkali, and titrating to a larger number of intermediate indicator tints, a considerably higher degree of accuracy could be obtained. The difference of 0.12% shown in Table I between the urea weighed out and that obtained by analysis is undoubtedly real, owing to the fact that no extreme precautions were taken to dry and purify the urea. The method is now being employed in this Laboratory in experiments on the hydration of the ions, and is found to be extremely convenient owing to the short time required for actual manipulation, the ease of removal of the ammonium chloride and to the fact that the process is at no stage precarious.

Summary

Urea is an excellent reference substance for use in physico-chemical and colloidal problems, being a non-electrolyte of low equivalent weight and chemically indifferent. A simple method of analysis whereby it is converted into ammonium chloride and carbon dioxide is described. The accuracy obtained is at least 0.02% of the urea used.

THE PARTITION COEFFICIENT IN THE FRACTIONAL CRYSTALLIZATION OF RADIUM–BARIUM BROMIDE SOLUTIONS[1]

BY ZACHARY T. WALTER WITH HERMAN SCHLUNDT

RECEIVED AUGUST 20, 1928 PUBLISHED DECEMBER 10. 1928

The latter stages in the preparation of a pure radium salt have usually been carried out by the fractional crystallization of a radium–barium chloride or bromide solution. From a consideration of the alkaline earth group of the periodic table, the general trend of the solubilities of radium salts may be safely predicted. True to expectation, the solubilities of radium bromide,[2] chloride, sulfate[3] and chromate[4] have been found to be less than the corresponding barium compounds and this factor has been generally quoted to account for the enrichment of radium in the crystalline phase. Furthermore, since the solubility of the alkaline earth hydroxides increases with increasing atomic weight, the radium in this instance should remain in the mother liquor. McCoy[5] has satisfactorily demonstrated this prediction.

At least two other theories have been advanced to explain the mechanism of the enrichment of radium in the crystalline phase. One of these theories,[6] advanced by Germann, would explain the phenomenon on the basis of adsorption. The other theory stated by Doerner and Hoskins would explain the mechanism of the enrichment of the crystalline phase as one in which radium atoms replace barium atoms in isomorphous crystals of the barium salt.

Further, irrespective of any theory, at least three different equations have been proposed to explain the regularities observed in the enrichment of radium by the process of fractional crystallization or precipitation.

The experimental part of this paper will present some evidence to test the validity of the respective equations and will include a new procedure by means of which the crystals separated are more completely freed from the mother liquor.

Experimental

(A) Source of Material.—The source material which was used in these experiments consisted of a sample of purified barium chloride, 250 g.,

---

which contained approximately a total of 26×10^{-5} g. of radium element. This material had previously been used in radioactive researches at the University of Missouri. Before its use in this study it was converted to radium–barium bromide by first making radium–barium carbonate. This carbonate was then treated with hydrobromic acid and the pure crystals of radium–barium bromide were obtained upon the evaporation of the hydrobromic acid solution.

(B) Method of Treatment.—The purified radium–barium bromide was taken into solution and the solution made up to exactly one thousand grams. This solution was then analyzed for both its radium and its barium content. The radium in the solution was determined by the emanation method in carefully calibrated electroscopes. The barium in the solution was determined by the sulfate method. This solution throughout this paper is called the stock solution.

(C) Method of Growth and Separation of Crystals.—A suitable quantity of this stock solution was weighed into a fused quartz evaporating dish. The solution was then evaporated on the water-bath until it was saturated. The crystals were then grown from the solution by removal of water with slow evaporation, the process requiring two to four hours depending upon the quantity of crystals removed from the solution. During the separation of the crystals the solution was continuously stirred. When the desired quantity of crystals had been separated, the dish was weighed and the loss of weight during evaporation was obtained. A sample of mother liquor was next decanted from the liquor above the crystals, weighed and made up to 1000 g. for analysis for radium content.

The next step in the process consisted in the complete removal of all mother liquor from the crystals. The usual plant process at this point is merely to decant all of the mother liquor that can be conveniently poured from the crystals, thus leaving them wet with impoverished liquor. The procedure used in this investigation was to centrifuge the crystals in a hand centrifuge. The manner in which the crystals were completely separated from the mother liquor is considered to be the distinctive feature of this work, for in previously reported papers this point had not been given sufficient attention. The dry crystals were finally weighed as the hydrate, $Ra–BaBr_2 \cdot 2H_2O$.

Now from the previously determined content of the stock solution and from the values of the radium content of the mother liquor and quantity of barium bromide separated, the value for K, the partition constant, may easily be obtained.

(D) Data Expressed in Terms of Doerner and Hoskins' Equation.—In Table I all of the information necessary for the calculation of the partition constant, K as defined by Doerner and Hoskins, is given. The equation given by them is as follows: $K = (\log y/a)/(\log n/b)$, where y is the total radium (element) remaining in the mother liquor left after fractionation and separation of crystals; a equals the quantity of radium (element) in the sample of stock solution used in the fractionation; n represents the quantity of anhydrous radium–barium bromide remaining in the mother liquor after fractionation; b is the quantity of anhydrous barium bromide in the sample of stock solution fractionated. All weights are expressed in grams.

(E) Data Expressed in Terms of the Equation of Chlopin and Nikitin.[7]—Another equation has been developed by Chlopin and Nikitin in which a relation is expressed between the concentration of radium per unit volume of crystals separated and the concentration per unit volume of mother liquor. Chlopin and Nikitin state that none of the equations previously given expresses very closely the experimental results. The equation favored by Chlopin and Nikitin is modeled after the Nernst–Berthelot distribution or partition equation. In this equation, K, the partition coefficient, has a somewhat different meaning than is usually given to it. Here it is the ratio of the concentration of radium per unit volume of crystals separated to the concentration of radium per unit volume of mother liquor. The equation follows: $XS_1/m = K(1 - X)S_0/q$. X is the fraction of radium in the crystals separated; $1 - X$, fraction of radium remaining in mother liquor; S_0, density of mother liquor, 1.63; S_1, density of the crystals separated, 3.58; m is the weight of the crystals separated; and q is the weight of the mother liquor remaining after fractionation.

In order to apply the equation of Chlopin and Nikitin to our experimental results, it was necessary to determine the density of the mother liquor and thus calculate the volume of the solution obtained after the crystals were removed. The value used for the density of barium bromide crystals (hydrate) was taken from "International Critical Tables." The

(F) Data Expressed in Terms of Schlundt's Exponential Equations.[8] The calculation of the values of K, the partition constant, as given in Schlundt's exponential equation is comparatively simple. The equation is, $Q_1 = Q_0e^{-Kp}$, where p is the fraction of the crystals separated, K is the distribution or partition coefficient; e is the natural log base; Q_1 is the fraction of radium remaining in mother liquor, and Q_0, the initial quantity of radium, may here be taken as unity. The values of K as calculated by this equation are given in Table III.

TABLE III

EXPERIMENTAL RESULTS IN TERMS OF EXPONENTIAL EQUATION

Expt.	Crystals sepd., %	Q_1	K	Expt.	Crystals sepd., %	Q_1	K

2	885	.664	4.60	8	35.79	076	7.19
3	10.98	.479	6.70	9	45.25	.050	6.62
4	17.55	.252	7.86	10	45.75	.023	8.24
5	18.12	294	6.74	11	54.59	.023	6.91
6	24.55	.193	6.70				

Discussion

From an examination of the experimental tables it will be noticed that the Chlopin-Nikitin equation definitely does not express a true partition coefficient, for the values of K increase as larger fractions of the crystals are removed from the stock solution. It will also be noticed that, while the values for the partition coefficient as expressed by the Doerner-Hoskins equation and the Schlundt exponential equation do not coincide, they do express a fairly exact relation between the radium in the crystals separated

---

[8] Herman Schlundt, "Mesothorium," Technical Paper 265, U. S. Bureau of Mines, 1922.

and the salt remaining in the mother liquor. The average value for the partition constant, K, Schlundt equation, is 6.66, while the Doerner and Hoskins constant is 5.64. The corresponding values for the distribution of radium in other systems using the Doerner-Hoskins equation are: for the radium–barium sulfate system K is equal to about 1.8; for the radium–barium chloride system K is equal to 2.74.[9] It is evident that of these three systems the radium–barium bromide system gives by far the most efficient enrichment of radium by fractional crystallization, and indeed it has been found so in practice, but these results show that it can be made more than twice as efficient as the chloride system.

Summary

1. The theories which attempt to explain the mechanism of fractional crystallization are outlined.
2. Three equations are cited to show the mathematical expressions advanced in the literature to represent the partition of radium salts between mother liquor and crystals separated in the process of fractionation.
3. A method of completely freeing the crystals from mother liquor by use of a centrifuge is described.
4. The average value for the partition coefficient in the Schlundt equation was found to be 6.66.
5. The average value for the partition coefficient in Doerner and Hoskins' equation was found to be 5.6.
6. Both the Schlundt and the Doerner-Hoskins equations seem to express equally well the partition relation, namely, that in the process of fractionation the distribution of radium between crystals and mother liquor takes place continuously in constant ratio.

THE CHEMICAL EFFECTS OF CATHODE RAYS ON OXYGEN, AIR, NITRIC OXIDE ARD CARBON DIOXIDE

BY WARREN F. BUSSE AND FARRINGTON DANIELS

RECEIVED AUGUST 27, 1928 PUBLISHED DECEMBER 10, 1928

The problem of chemical reaction can be studied to advantage through ionic gas phase reactions. The most important progress in this field has been made by Lind,[1] using α-particles, but large quantities of radium are necessary for measurable quantities of chemical products. The limitations are even more severe for β- and γ-rays, and Errera and Henri[2] obtained traces of material only after exposures of about fifty hours to the β- and γ-rays from 500 mg. of radium.

The electrical discharge offers another method for producing ionization and chemical reaction in gases but the phenomena are complicated. In this Laboratory the effect of the electrodes has been studied first by increasing the electrode area[3] and then by reducing it to a minimum.[4] Attempts were made, also, to study reactions brought about by electron bombardment in the absence of electrodes.[5]

Krueger and Utesch[6] studied the formation of ozone by Lenard rays in a small apparatus and reported 20 to 40 molecules of ozone for each ion pair.

The development of the Coolidge cathode ray tube[7] marks an important advance in this field for it is now possible to pass electrons at a high voltage through a window and into a reaction chamber to give a sufficient quantity of product for chemical analysis. The authors are greatly indebted to Dr. W. D. Coolidge of the General Electric Company for the cathode ray tube used in this work.

In this communication a series of gas reactions is reported, comprising the action of cathode rays on oxygen, air, nitric oxide and carbon dioxide. The extent of each reaction was determined by chemical analysis. It was impossible to measure directly the number of ions formed in the gas and the M/N ratios (that is, number of molecules $\div$ number of pairs of ions) could not be determined, but the yields were computed in terms of the number of molecules per electron passing through the cathode ray tube,

giving what may be called an M/C ratio. This ratio was then compared for a given reaction under different conditions, and for different reactions under the same conditions. This M/C ratio was often of the order of one hundred times the M/N ratio.

Apparatus

The Coolidge cathode ray tube is shown at "a" in Fig. 1 and it has been described in detail by Dr. Coolidge." The cathode end is similar to that of the Coolidge x-ray tube with a heated tungsten filament in the focusing cup. The electrons travel from the filament under a high potential gradient to the anode and pass through the thin nickel window (0.0012 cm. thick). The window is supported by a grid so that it can stand a full atmosphere's pressure. A copper tube protects the glass of the anode arm from the electrons. An invar tube holding the grid is sealed to the tube by a metal-to-glass seal.

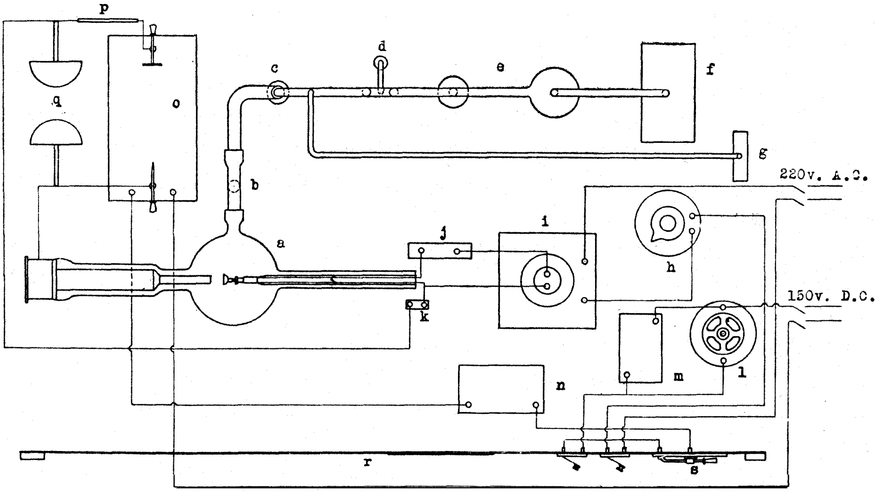

Fig. 1.—Schematic diagram of apparatus for Coolidge electron tube.

The tube was evacuated with a mercury pump, e, backed by an oil pump, f, and a liquid-air trap, c, was used to prevent diffusion of mercury vapor into the tube. A vacuum of less than 10^{-6} mm. could be obtained, but when the tube was operating the pressure increased to about 3×10^{-5} mm. The McLeod gage is shown at g.

The coustruction of the tube is such that potentials up to 200,000 volts can be applied to its terminals and a space current of several milliamperes can be sent through the tube if it is operated intermittently.

A Weston induction coil, o, capable of giving a heavy spark of over 50 cm. between dull points was used as the source of the high voltage. It was operated on direct current with a mercury turbine interrupter, 1, giving about sixty breaks per second. The voltage was determined from the sparking distance between 25-cm. brass hemispheres, q, using the tables of Peeks for spheres of this size.

The filament current was supplied by a step down insulation transformer, i. The space current or electron emission was regulated with an adjustable self-inductance,

---

[8] Peek, "Dielectric Phenomena at High Voltage," 1921, p. 90.

h, in the primary circuit of the filament current transformer. The space current was measured with a calibrated ammeter, k, having a range from 0 to 2 milliamperes.

The heat generated in the window was so great that the current could be turned on only about onc-fourth of the time, and an automobile timer, n, was used as an intermittent contact in the circuit of the primary.

A lead screen, r, 2 by 1.5 meters and 3 mm. thick, protected the operator from the x-rays. A window of lead glass 6 mm. thick, permitted a view of the apparatus and readings of the meter were taken with the aid of a telescope.

A condenser, m; a charcoal tube, b; a resistance, p and an ammeter, j, for the filament current made up the rest of the equipment.

Since there was danger of corroding the nickel window- of the cathode ray tube with the gases used in the experiments, the reaction cellswere not attached to the cathode-ray tube. This arrangement had the disadvantage that the electrons had to pass through two windows and a short air space but it made the manipulation of the cells much easier and increased the life of the nickel window. Only two windows have been necessary while the tube has been in practically constant use for two years. The reaction cells were made of soft glass tubes 7 5 cm. in diameter and of two lengths, 22 and 34 cm. Side arms with stopcocks were provided for sweeping out the gases One end of the cell was sealed off and the other end was closed with a thin window of cellophane (a commercial product of cellulose xanthate), aluminum or mica. The cellophane ancl the aluminum were 0.02 mm. thick and the mica was 0.01 mm. thick. The windows were attached with the help of paraffin and a brass ring. None of the windows reduced the range of the electrons in air more than a few centimeters and the slight differences in the absorption of the different windows did not affect the results appreciably.

Range and Absorption of Cathode Rays

The maximum range of the cathode rays was determined by the red fluorescence of lime, which could be distinguished from the weak green fluorescence caused by x-rays. Fig. 2 shows the relation of the maximum range of the voltage. By extrapolating back to zero range, one finds that it takes 70 kilovolts (peak voltage) to take the electrons through a nickel window 0.013 mm. thick. Application of Thomson's[9] formula, $V_0^2 - V_x^2 = bx$, gives a value of 3.85×10^{12} for the absorption coefficient, b, for nickel. In this formula V_0 is the voltage at the start of the path and V_x is the velocity of the electron expressed in volts after the electron has traversed the distance, x. Dividing this caefflcient by the density of nickel, a value of 4.32×10^{11} is obtained for the mass absorption coefficient of the nickel window and this value is very close to the mass absorption coefficient obtained by Terrill[10] for aluminum, copper and gold.

The maximum voltage as determined by the spark gap was used in these computations since it determines the maximum range of the electrons.

Although the maximum range for 185 kv. electrons was found to be about 50 cm., the number of electrons which reach this distance is very

---

[9] J. J. Thomson, "The Conduction of Electricity Through Gases," University Press, Cambridge, 1911, p. 378.

[10] Terrill, *Phys. Rev.*, 22, 101 (1923).

small. The velocity of electrons falls off in such a manner that the decrease in the fourth power of the velocities is proportional to the distance, but the number of electrons crossing a unit area decreases exponentially with the distance at a rapid rate. Accordingly it is possible to use reaction cells shorter than 50 cm. Experiments showed that for *short* exposures there was no detectable difference in the yields with reaction cells of 22 cm. or 34 cm.

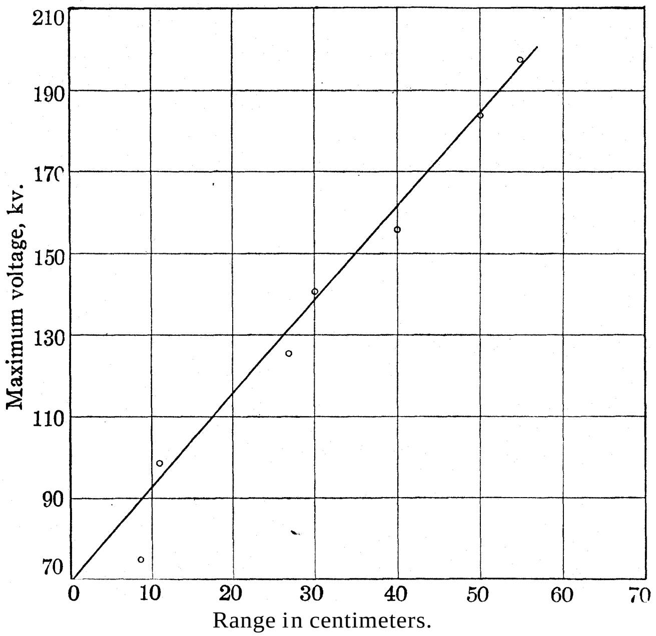

Fig. 2.—Range of electrons as measured by the fluorescence of lime in total darkness.

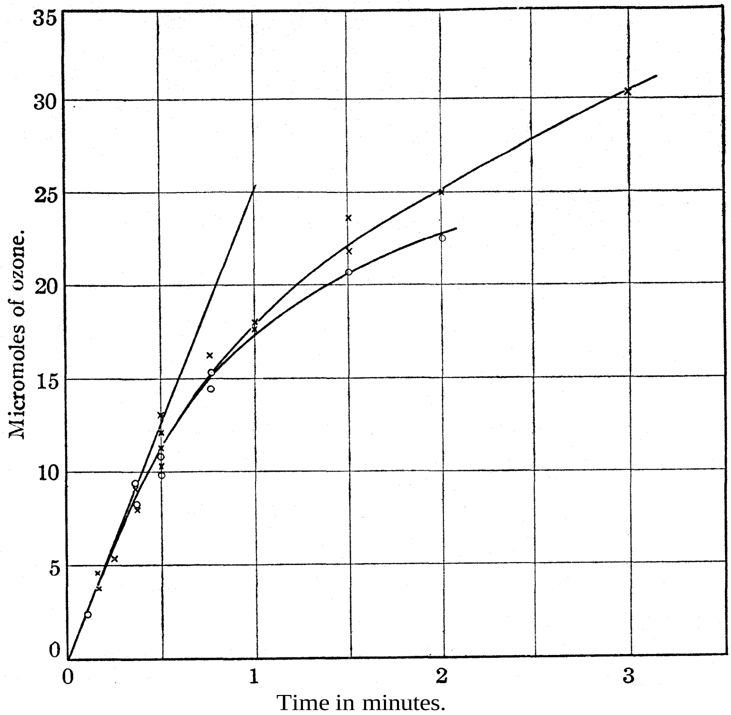
Action of Cathode Rays on Different Gases

Oxygen.—The action of cathode rays on oxygen was studied intensively because ozone, which is the only product, can be determined accurately in small amounts and because an extensive study of ozone formation in the electrical discharge has been made in this Laboratory. The reaction is not as simple as could be desired, however, because the decomposition of ozone very soon affects the yields.

In carrying out these experiments, the reaction cells were filled by sweeping through a rapid stream of oxygen from a tank for an hour or more and then placing the reaction cell in front of the window of the cathode-ray tube. Unless otherwise noted, the distance from the reaction cell to the window of the cathode-ray tube was 2 to 3 mm. The oxygen was then exposed to the cathode rays for the desired time, after which the ozone was determined by sweeping the gas through two bottles containing neutral 5% potassium iodide solutions. The iodine was titrated with 0.005 *N* sodium thiosulfate, 1 cc. of which is equivalent to 2.5 micromoles of ozone.

All the factors which might affect the yield were studied. It was found that for short exposures the yield was a function of the voltage of the cathode-rays, the space current, the time of treatment, the distance from the cathode-ray tube to the reaction cell and the source of the oxygen. The surface of the reaction cells, whether of glass or paraffin, had little effect and no appreciable difference in yield could be detected when using mica, aluminum or cellophane windows for the reaction cells. The yields were not appreciably influenced by the speed of the mercury turbine interrupter, the speed of the intermittent switch, the time the ozone remained in the reaction cell (except after several hours) or the moisture content of the gas.



○, Short reaction cells; X, long reaction cells.

Fig. 3.—Ozone yield from oxygen (0.4 ma.; 185 kv.).

The results of a typical series of experiments are shown in Table I and Fig. 3. In this series the influence of time was studied while the space current ahd voltage were kept constant.

With exposure of less than a minute the yields do not depend on the length (volume) of the tube. In all cases, time was given for diffusion so that the concentration would be nearly uniform throughout the chamber. The exposures were intermittent so that the total time of the exposure was ten to thirty times as long as the net exposure. The experiments marked "b" and "c" show that there is very little difference in the ozone yield when a 90-second exposure is spread over a period of one hour with the shorter tube or spread over a period of two hours with the longer tube. The experiments marked "a" show that only about a third of the

[c] Exposure extended over two hours.

ozone decomposes on standing overnight, so that only a negligible amount can decompose thermally during an ordinary experiment.

The curves of Fig. 3 show that the rate of ozone formation soon falls off markedly, because the ozone is decomposed as well as produced by the cathode rays. The shorter tube with the smaller volume gives a higher concentration of ozone and hence a greater rate of decomposition. This condition gives a lower yield of ozone but the difference is not apparent until after fairly long exposures have built up appreciable concentrations of ozone. The important thing from a theoretical standpoint is not the actual ozone yield for any given exposure but the true rate of formation, that is, the yield that would be obtained if none of the ozone was decomposed. These values can be obtained by taking the tangents to the yield–time curves at zero time, since under these conditions there is no ozone to decompose. On account of the rather large percentage error at the low concentrations the curve and its tangent cannot be drawn with precision but the values are probably accurate to within 10%.

The initial rate of ozone formation, given by the tangent at zero time, is 25 micromoles of ozone per minute with a space current of 0.4 mil. amp. and a potential of 185 kv.; 25 micromoles contains 1.51×10^{19} molecules ($25 \times 10^{-6} \times 6.06 \times 10^{23}$) and 0.4 milliampere for one minute gives 1.5×10^{17} electrons ($0.4 \times 10^{-3} \times 60 \div 1.59 \times 10^{-19}$) and the M/C ratio is, therefore, 100. In other words, 100 molecules of ozone are formed for every electron that crosses the cathode-ray tube.

The influence of the space current is shown in Fig. 4, with the time kept constant at one-half minute and the voltage kept constant at 185 kv. The curve shows that in these short exposures the yield is directly proportional to the space current. This series was made under slightly different conditions than in the preceding series, so that the absolute values of the two series cannot be compared directly.

Figure 5 shows how the ozone yields change with time, when higher currents and longer exposures than those given in Fig. 3 are used. Each point shown on the curves is the average of from two to ten determinations. The long exposures had to be extended over several hours to allow time for diffusion. The short reaction cells gave yields (not shown in Fig. 5) considerably lower than the yields in the large cells because the concentration was higher and the decomposition was greater. It may be noted that with long exposures the ozone yield is not proportional to the space current through the tube.

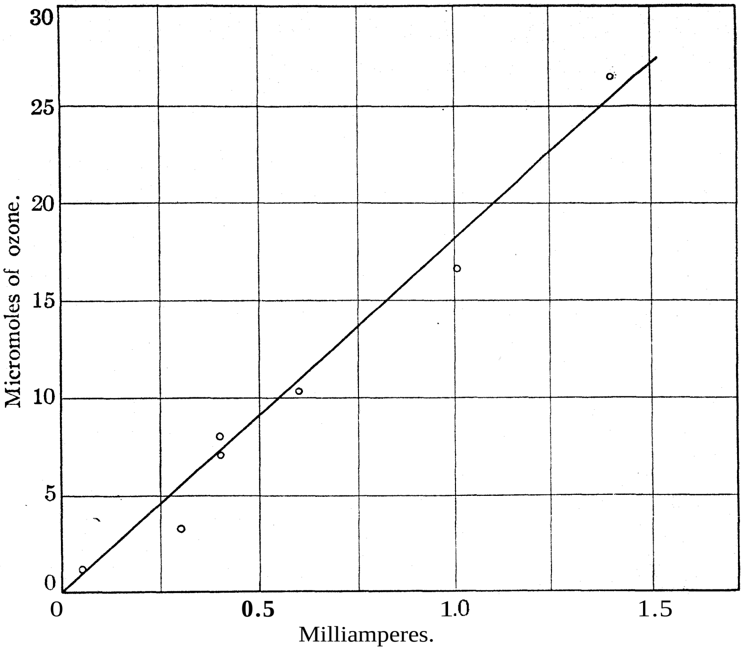

Fig. 4.—Ozone yield from oxygen with various space currents (voltage, 185 kv., time of exposure, 0.5 min.).

The curve for 1 mil. amp. space current seems to be approaching an asymptote at a yield somewhere near 75 micromoles of ozone. Since the reaction cell was 7.5 cm. in diameter and 34 cm. long, this yield corresponds to an ozone concentration of about 0.1%.

The ozone yields obtained with different voltages were studied next. All of these experiments were made with a tank of oxygen which gave low yields, probably due to an oxidizable impurity, but the relative values for the different voltages are comparable. The initial rates of ozone formation as determined by the tangents at zero time are given in Table II, together with the M/C ratios.

TABLE II

EFFECT OF VOLTAGE ON THE INITIAL RATE OF OZONE FORMATION

Voltage, kilovolts	140	102	185	200
Rate of O_3 formation, micromoles per min.	3.2	12	19	27
M/C	12.6	48	76	107

Another factor which affected the ozone yield was the distance between the window of the reaction chamber and the window of the cathode-ray tube. A series of experiments made to test this factor showed that the yield was reduced by about one-half whenever the distance between the reaction cell and the cathode-ray tube was increased by 3.5 cm.

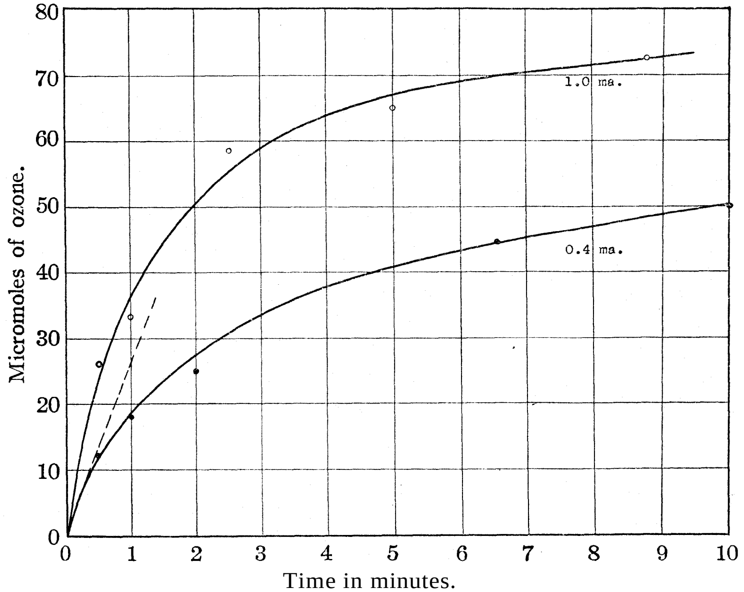

Fig. 5.—Ozone formation in oxygen (large reaction cells, 185 kv.).

Air.—When the cathode rays pass through air, they form not only ozone but also nitrogen oxides which can be determined by absorption in standard alkali before absorbing the ozone in the potassium iodide.

In carrying out these experiments the reaction cell was first filled with carbon dioxide-free, dry air, taken from outdoors to avoid the possible catalytic effect of impurities which might be present in the air of the laboratory. After treating the air with the cathode rays, the air in the cell was sucked out through a bottle of 0.01 N sodium hydroxide and two bottles of potassium iodide. Any nitric oxide formed by the cathode rays was oxidized by the ozone to nitrogen pentoxide and absorbed in the alkaline solution. The excess of sodium hydroxide was titrated with standard acid and each cc. of 0.01 N sodium hydroxide neutralized by the gases from the reaction chamber was equivalent to 5 micromoles of nitrogen pentoxide or 10 micromoles of nitric oxide.

Figure 6 gives the ozone yields for the large and small reaction cells with 186 kv. zero time with 1 mil. amp the yield is 26 micromoles of ozone per minute and the initial rate of ozone formation with 0.4 mil. amp. is 11 micromoles per minute. These data give an M/C ratio of 44, which is about half the M/C ratio in pure oxygen. The initial rates of formation are proportional to the space current but the direct proportionality does not hold for the longer exposures which involve the decomposition of ozone.

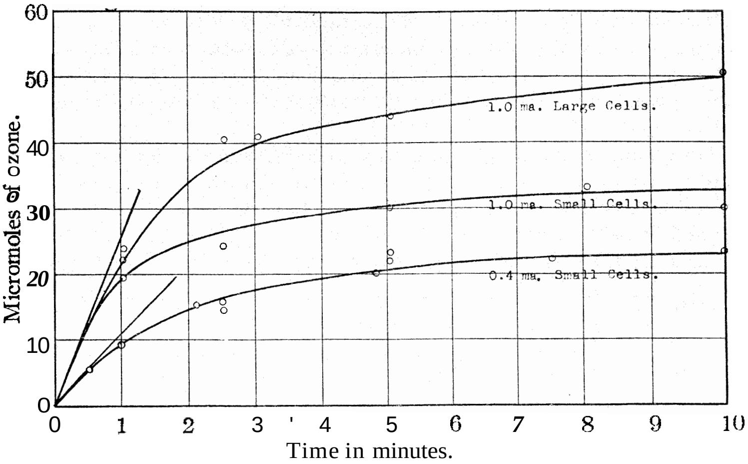

Fig. 6.—Ozone yields with air, (185 kv.).

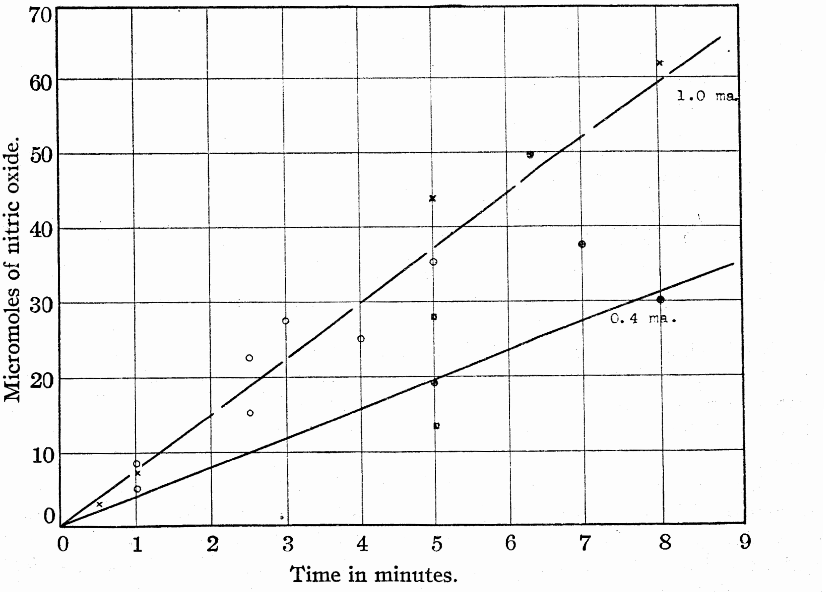

O,⊕—Large cells; ×,□—small cells.

Fig. 7.—Nitric oxide yield with air, (185 kv.).

The nitric oxide yields, expressed in terms of micromoles of nitric oxide, are shown in Fig. 7. While the ozone curves of Fig. 6 soon flatten out on account of the decomposition of ozone, the curves for the nitric oxide show no tendency to reach an equilibrium. There were rather wide variations in the nitric oxide yields, indicating that some unknown factor was affecting the yields, but the rate of formation may be taken as about 8 micromoles per minute with 1.0 mil. amp. and 4 micromoles per minute with 0.4 mil. amp. These data give an M/C ratio of 13.5 and 16.0, or an average value of about 15 molecules per electron

The large and small cells gave the same yields within the limit of accuracy of the experiments, a result which is in accord with the fact that the rate of formation does not decrease at the higher concentrations (Fig. 7). It is probable that the nitrogen pentoxide formed from the nitric oxide is decomposed by the electron bombardment but that it is reoxidized by the excess of ozone. No attempt was made to test for nitrous oxide.

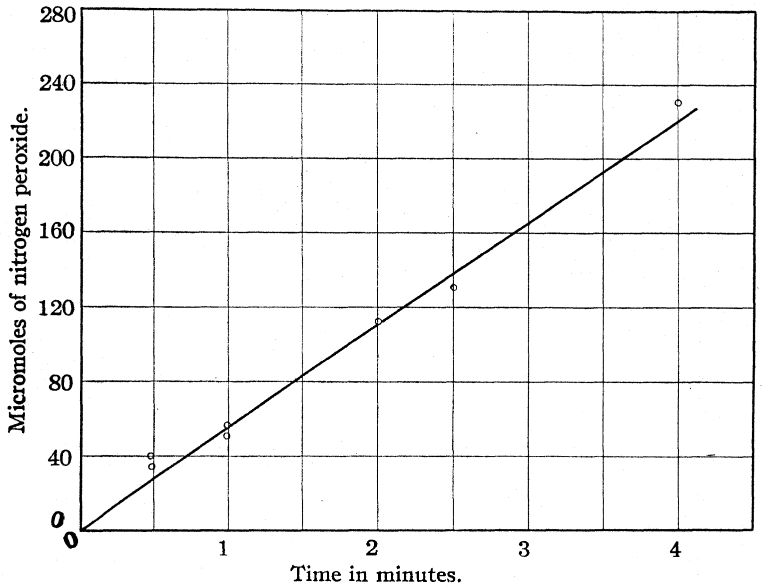

Fig. 8.—Decomposition of nitric oxide (0.4 ma., 185 kv.).

Nitric Oxide.—The nitric oxide was prepared by the action of nitric acid (1.2 sp. gr.) on copper and purified by bubbling through concentrated sulfuric acid. Any nitrogen dioxide was absorbed by the sulfuric acid. To avoid the initial oxidation of the nitric oxide by the air in the reaction cell, the air was first swept out of the cell with nitrogen.

Decomposition of the nitric oxide involved the liberation of oxygen, which then combined with the excess nitric oxide to form nitrogen dioxide. After an exposure to the cathode rays the nitrogen dioxide was determined by sweeping the gas through sodium hydroxide with nitrogen and titrating the excess alkali with 0.1 N sulfuric acid, using methyl red as an indicator.

The reactions are taken to be

$$2NO = N_2 + O_2$$
$$O_2 + 2NO = 2NO_2$$
$$NO_2 + NO + 2NaOH = 2NaNO_2 + H_2O$$

One cc. of 0.1 N alkali is equivalent to 50 micromoles of nitrogen dioxide or 50 micromoles of nitric oxide decomposed.

Great care was necessary to prevent the access of air to the nitric oxide, as it would also give nitrogen dioxide. It was necessary to displace the air in the absorption bottle with nitrogen and to prevent back-diffusion of air with a second wash bottle.

The nitrogen used in these experiments contained a small amount of oxygen and blank experiments were necessary to determine the amount of nitrogen dioxide produced by this oxygen impurity. The same procedure was followed as in a regular experiment except that the nitric oxide was not exposed to the cathode rays. The four blank determinations gave **2.8, 2.9, 2.7** and ***2.6*** cc. of 0.1 N sodium hydroxide. In the last experiment ***(2.6*** cc.) the nitric oxide remained in the cell overnight before being swept out through the alkali, and the close agreement with the other values proved that the cell was air tight and that the cellophane windows were not porous.

The influence of the time of treatment is shown in Fig. **8** and the influence of the magnitude of the space current on the decomposition was studied also. These curves show no equilibrium effect up to four minutes with 0.4 mil. amp. and 185 kv. and indicate either that nitrogen dioxide is not easily decomposed by the cathode rays or more likely that the decomposition products recombine on standing. The rate of nitric oxide decomposition is **57** micromoles per minute with 0.4 mil. amp. space current at 185 kv. and the corresponding M/C ratio is 230.

Carbon Dioxide.—The reaction cells were filled from a tank with carbon dioxide which had been purified by passing through concentrated sulfuric acid and chromic acid and then through phosphorus pentoxide. After treatment with the cathode rays, the gas was swept out with carbon dioxide through a 10% potassium iodide solution to remove any ozone. The exit gases passed through a tube of iodine pentoxide heated to 150° in an oil-bath, and then through 10 cc. of 10% potassium iodide solution to absorb the iodine liberated by carbon monoxide according to the reaction

$$5CO + I_2O_5 = 5CO_2 + I_2$$

The ozone and the carbon monoxide were both determined by titration with $N/200$ sodium thiosulfate.

It was necessary to make a considerable correction for the iodine carried over from the iodine pentoxide when the untreated gas was passed through.

The results were very unsatisfactory and in the first experiments appreciable hut inconsistent amounts of ozone were found. The last two experiments extending over a longer period of time are thought to be more reliable. The rays were passed into the carbon dioxide for a net time of ten minutes at 200 kv. and 1.0 mil. amp. The blank correction amounted to about one-fourth of the total titration; 0.35 and 0.60 mg. of carbon monoxide were obtained. The average, 0.47 mg., corresponds to 10^{19} molecules and the current of 1.0 mil. amp, corresponds to 3.8×10^{18} electrons. The M/C ratio is, therefore, ***3*** molecules per electron crossing the tube when the maximum potential drop across the tube is 200 kv.

Calorimetric Determination of Energy of Cathode Rays

It was desired to study the relation between the energy of the cathode **rays** and the chemical reactions produced, but the wave form produced by the induction coil was so distorted and the loss of energy so great that the energy delivered to the reaction chamber could not be calculated from the voltage and amperage in the cathode-ray tube. A rough measurement was obtained, however, with the help of a special calorimeter placed at a position corresponding to the end of the reaction chamber. It was assumed that all the electrons which would have entered the reaction chamber were stopped by the small calorimeter and converted into heat. It was assumed also that the number of secondary electrons emitted backward was small and sufficiently constant so that no appreciable error was introduced by using copper in the calorimeter and aluminum or cellophane in the reaction cell. Experiments had shown that cellophane and aluminum windows gave the same yield.

A flat, circular chamber was made of thin copper, 7.5 cm. in diameter and 0.7 cm. thick. A horizontal glass capillary was attached to the copper chamber and the apparatus was filled with nitrobenzene and operated simultaneously as a thermometer and a calorimeter. When the cathode rays were stopped by the copper chamber, the heat generated caused the nitrobenzene to expand and move out along the capillary tube. The capillary was calibrated in terms of centigrade degrees by setting the calorimeter into a water-bath at definite temperatures. The distance traveled by the nitrobenzene in the capillary was practically a linear function of the temperature. The heat capacity of the copper was 4.08 and that of the nitrobenzene 6.97, giving a total heat capacity of 11.05 calories per degree.

Heating and cooling curves were plotted and the temperature change was found to be quite uniform after a short initial period. The measurement was complicated by the fact that the framework supporting the window of the cathode-ray tube became hot after a while and radiated heat to the calorimeter, necessitating a somewhat arbitrary correction amounting usually to between 10 and 20% of the total value.

The results are summarized in Table III.

TABLE III

ENERGY OF CATHODE RAYS RECEIVED BY CALORIMETER

Dist. from window to calorim., cm.	Max. voltage, kv.	Current, mil. amp.	Temp. rise in calorim. per min., °C.	Energy rec'd. with intermit. curr., cal./min.	Energy received if current were continuous, cal./min.
0.5	200	1.0	1.50	16.5	66.0
2.0	200	1.0	0.76	8.4	33.6
2.0	200	1.0	.90	10.0	40.0
2.0	200	0.5	.43	4.8	19.2
2.0	200	0.5	.42	4.6	18.4
2.0	185	1.0	.49	5.4	21.6
2.0	185	1.0	.49	5.4	21.6
2.0	185	0.5	.25	2.7	10.8
2.0	162	1.0	.35	3.8	15.2

The energy actually measured per minute while the tube was in operation is given in the next to the last column and these values are multiplied by 4 to give the figures of the last column. The current was on for about $^1/_8$ second and off $^3/_8$ second to keep the window cool, so it was flowing for only one-fourth of the actual time of an exposure.

The results are quite consistent, the temperature rise for 1.0 mil. amp. being twice as great as the rise for 0.5 mil. amp., but the constant error due to the thermal radiation from the window of the tube may be fairly large.

The greatest energy, amounting to 66 calories per minute, was introduced when the calorimeter was half a centimeter from the window. The measurements at 2 cm. are more valuable for the calculations because the absorption by the cellophane window of the reaction chamber was found to be equivalent to 2 cm. of air.

The average value at 2 cm. with 1 mil. amp. and 200 kv. was 36.8 cal. per minute; and at 185 kv. it was 21.5.

The energy registered by the calorimeter is very much smaller than the product of the maximum voltage and the current measured in the cathode-ray tube. At 200 kv. it is 1.3%, and at 185 kv. it is 0.8%. The chief reason for the low percentage lies in the fact that the *maximum* voltage of the induction coil as registered by the spark gap is much greater than the voltage during the rest of the period. Furthermore, the energy reaching the calorimeter or the reaction chamber was less than that in the cathode-ray tube because some of the electrons were stopped by the grid and the window and some were deflected to one side by air molecules before reaching the chamber. The loss of energy was assumed to be the same in both the chemical measurements with the chamber and the energy measurements with the calorimeter.

Conclusions

For the sake of comparison, representative data on the different gases are collected in Table IV.

TABLE IV

SUMMARY OF EFFECTS OF CATHODE RAYS ON VARIOUS GASES

Reaction	Voltage, kv.	Curr., mil. amp.	Micromoles per min.	M/C	Cal. per min.	Cal. per mole
$O_2 \longrightarrow O_3$	185	0.4	25	100	8.6	3.4×10^5
Air $\longrightarrow O_3$	185	.4	11	44	8.6	7.8×10^5
Air $\longrightarrow$ NO	185	.4	4	14	8 6	22×10^5
NO $\longrightarrow O_2$	185	.4	57	230	8 6	1.5×10^5
$CO_2 \longrightarrow$ CO	200	1.0	2	3	37	$180 \times 10''$

In Col. 1 is given the reaction which was measured chemically and in Col. 2 the maximum voltage across the tube as measured with a spark-gap. Col. 3 gives the space current or electron current across the tube. Col. 4 contains the yields in micromoles per minute as obtained by chemical analysis. In cases where known secondary reactions occurred corrections were made. In Col. 5 are found the M/C values or the ratio of the number of molecules of product to the number of electrons passing across the cathode-ray tube. The actual number of electrons entering the reaction chamber is less than C and undetermined in this research, but it is directly proportional to C because the conditions were alike in all the experiments. In the next to the last column the energy of the cathode rays entering the reaction chamber is recorded in calories per minute. The values were obtained by stopping the electrons with a calorimeter. In the last column is given the energy of the cathode rays in calories necessary to give a gram molecule of the product.

An examination of Table IV shows that of these reactions the decomposition of nitric oxide proceeds the most readily and the decomposition of carbon dioxide proceeds the least readily. After the decomposition of nitric oxide, the formation of ozone from oxygen proceeds most easily, followed by the formation of ozone from air, and nitric oxide from air. All these reactions are endothermic reactions but there seems to be no simple connection between the response to cathode rays and the heat of formation, or the free energy of the different gases.

The chemical action of the cathode rays appears rather inefficient in the systems studied. In some cases the efficiencies are low because the cathode rays are used up in producing effects which are not detected by the chemical test employed. For example, the ozone yield in air is less than the ozone yield in oxygen because in air some of the electrons are used up in making nitric oxide instead of ozone.

No direct determinations were made on the decomposition of ozone but it was found that an equilibrium existed at about 0.1% ozone under the cathode-ray bombardment. Since there were about 1000 times as many oxygen molecules as ozone molecules at equilibrium, the decomposition of ozone must be approximately 1000 times as fast as the formation, under the conditions of the experiment. The decomposition of ozone is an exothermic reaction and proceeds much more readily than the endothermic reactions which have been studied. Extensive experiments were carried out also with another exothermic reaction (the union of nitrogen and hydrogen to form ammonia) but the yields were so small and so inconsistent that the data have not been reported.

The total number of ions produced in the reaction chamber could not be determined, although attempts were made to obtain a saturation current with a 2000-volt dry battery. It is possible, however, to estimate from the energy measurements the maximum number of ions which could have been obtained. From the ionization potential of 15 volts it can be calculated that the formation of a pair of ions of molecular oxygen requires 2.4×10^{-11} ergs. The input of 8.6 calories (or 3.6×10^{8} ergs) of energy in the form of cathode rays can produce no more than $3.6 \times 10^{8} \div 2.4 \times 10^{-11}$ or 1.5 X

10^{19} pairs of ions. The 25 micromoles of ozone produced by the same cathode rays contain 1.5×10^{19} molecules. These calculations show that within the limits of accuracy of the thermal measurements the number of molecules is equal to the number of pairs of ions. This estimate checks with the M/N ratio for ozone obtained by Lind[11] using a-ray bombardment, but it is not in agreement with the results of Krueger and Utesch[6] in which the M/N ratio was found to be about 40. If the ionization potential of **23** volts for atomic oxygen is taken, there are 1.5 molecules for every ion pair, and if the resonance potential of 8 volts is taken, there is about one molecule of ozone for every two excited oxygen molecules.

It is to be noted that the M/C ratios discussed before are purely empirical values used for purposes of comparison of different gases under similar conditions. C represents the average number of electrons crossing the tube and it is considerably larger than the number of electrons entering the reaction chamber.

The results of this investigation indicate that the chemical behavior of high voltage electrons is essentially the same as that of a-particles. This similarity in behavior is to be expected because the greater part of the chemical action of a-particles is effected through electrons of high velocity driven out from molecules in the path of the a-particle, and these electrons are the same as the electrons shot out from the cathode-ray tube. The M/N ratio for ozone obtained in oxygen with cathode rays was calculated to be the same within the limits of experimental error as that obtained with a-particles. Moreover, the decomposition of carbon dioxide was found to be very slight and this fact checks well with the facts of radioactivity. Alpha-particles do not produce any change in this gas[12] on account of reversion of the CO_2^+ ions to CO_2. The high yield in the decomposition of nitric oxide is to be expected also, because the ionization potential is only 9 volts instead of the 15 volts for oxygen.

It might he expected that an appreciable part of the energy of the moving electron would be used up in displacing the electrons in molecules rather than in expelling them. From the close relation between ion pairs and molecules and the checks with experiments using a-particles, it appears that nearly all of the energy of the cathode ray goes to complete ionization rather than to the displacements which correspond to resonance potentials. As long as the electron has energy equal to or greater than the ionization potential, most of the effects will be ionizations.

The chemical effects produced by cathode rays of definite voltage depend on the ionization potential of the gas and on the stoichiometrical reactions which follow the ionization, and they are very similar to the chemical effects of a-particles.

The authors are glad to acknowledge assistance received from the Coffin Foundation in the form of a scholarship to one of us.

Summary

1. The chemical effects produced in gases by electrons from a Coolidge cathode-ray tube have been studied. The gases were enclosed in separate vessels not in contact with the window of the tube. The influence of time, voltage and space current has been studied.

2. Ozone was obtained from oxygen and the ozone was in turn decomposed. The rate of ozone formation was obtained by extrapolation to "zero time."

3. The chemical effects were expressed as the ratio of molecules produced per electron crossing the cathode-ray tube. These M/C ratios are as follows: nitric oxide decomposition 230, ozone from oxygen 100, ozone from air 44, nitric oxide from air 14, carbon dioxide decomposition 3.

4. The energy of the cathode rays was obtained with a small calorimeter and it varied from 3 to 16 calories per minute.

5. A calculation of the maximum number of ions was made using the energy input and the ionization potential of oxygen. This estimate gives a ratio of molecules to gas ions approximately the same as has been found with a-particles.

6. The close similarity in chemical behavior of cathode rays and α-particles has been emphasized. The yield depends on the ionization potential of the gas and the stoichiometrical reactions which follow ionization.

THE HEAT CAPACITY AND ENTROPY OF BARIUM BROMATE FROM 16 TO 300° ABSOLUTE. THE ENTROPY OF BROMATE ION

BY BERNARD S. GREENSFELDER AND WENDELL M. LATIMER

RECEIVED SEPTEMBER 10, 1928 PUBLISHED DECEMBER 10, 1928

This work is a part of the program for the evaluation of entropy of aqueous ions as a means of facilitating the thermodynamic treatment of solutions. The general theory has been treated in previous papers by Latimer and coworkers.[1]

The present paper initiates work in the field of the halogenate ions, ClO_3^-, BrO_3^- and IO_3^-, and it is planned to use the entropy values obtained with experimental reaction heats in order to obtain the free energies of these ions. The experimental method follows the general plan of study

of cesium alum by Latimer and Greensfelder,''wherein complete references to specific heat technique and laboratory technique are given.

Material.—Barium bromate monohydrate, $Ba(BrO_3)_2 \cdot H_2O$, was selected because of its low solubility, well-defined monoclinic crystal structure and purity. "C. P." material free from heavy metals, iron and bromide was obtained from the Mallinckrodt Company. A water determination gave 4.42% of water; theoretical, 4.38%. The specific heat measurements were made on a sample weighing 145.80 g.

Measurements.—The molal heat capacity values fall smoothly on a curve with two points of double inflection at 150°K. and at 190°K., too slight to be noticed on the accompanying diagram.

The gold resistance thermometer proved adequate to fix the temperature differences down to 13.92°K., the initial temperature of the first run. The calibrations continuously made against thermocouple No. 109 agreed exactly with two previous sets of comparisons, except in the range 30 to 105°K., wherein the resistance showed a regular deviation, reaching a maximum of 0.012 ohm/ohm at 37°K. This is, incidentally, the point of maximum deviation from rectilinearity of resistance as a function of temperature.

It was also noted that the thermocouple e.m.f. at the temperatures above 200°K. was altered by a change in the temperature of the surrounding block and radiation shield, necessitating the selection of a mean value corresponding to equal temperature of block and radiation shield with respect to the calorimeter. As a check, eight special calibrations were made with an average temperature difference between block and calorimeter of 0.05 degree. The resulting points accurately confirmed the previous mean values.

Heat Capacity and Entropy of Barium Bromate

The experimental data are given in Table I, accompanied by a summary of the entropy calculations and illustrated by Figs. 1 and 2.

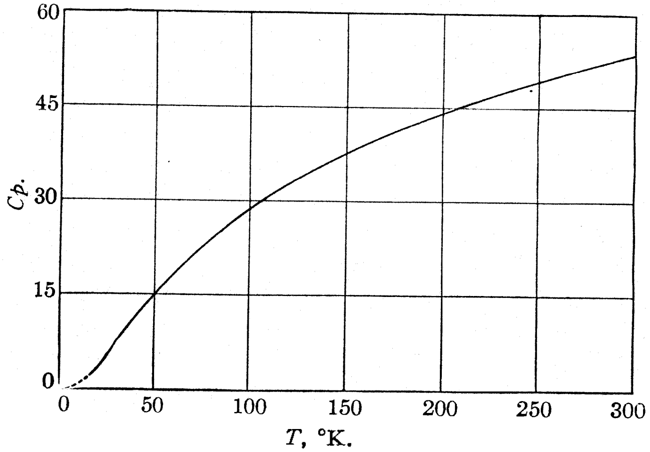

Fig. 1.—Molal heat capacity of barium bromate.

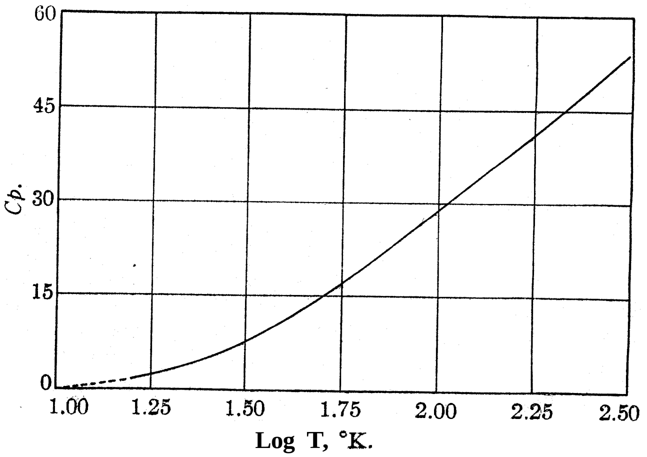

Fig. 2.—Molal entropy of barium bromste.

Heat of Solution.—The ΔH of solution of barium bromate may be calculated from the solubility-temperature coefficient as based on the solubility data of Trautz and Anschütz[2] and Harkins,[3] shown in Fig. 3. The single point of Harkins at 25° closely checks that of Trautz and Anschütz. The equation, originally applied by van't Hoff, may be given in the convenient form $\Delta H = -(R\, d(\ln K)/d(1/T)$.

The validity of the expression is dependent entirely upon the approximation of the given system to the laws of the ideal or perfect solution. In the absence of such complicating factors as hydrolysis and specific ion association, the ionic activity coefficients should accurately correct for the Debye-Hückel deviation. If such activities are then included in the equilibrium constant, K, ΔH will then presumably correspond to the true experimental value.

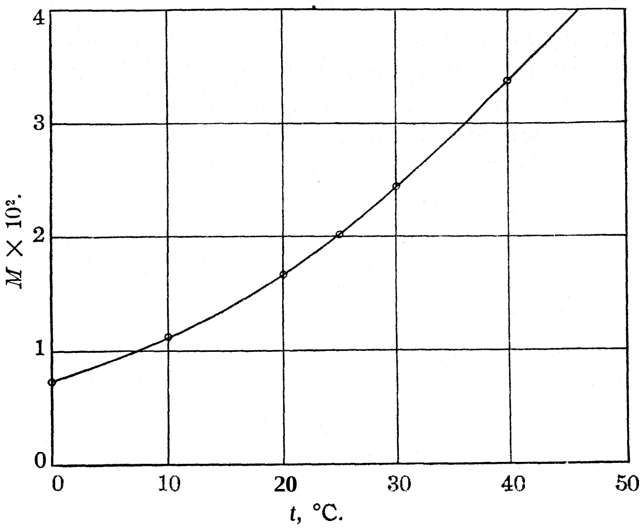

Fig. 3.—Solubility of barium bromate.

In the present case $Ba(BrO_3)_2 \cdot H_2O$ is considered free from hydrolysis or any ion association sufficient to exert perceptible influence on the heat of solution. The activity coefficients have been obtained with the aid of Professor M. Randall after a survey of similar ion types, and also from the data given by Lewis and Randall.[4]

It then follows that $\Delta H = -[4.5746\ d \log (\gamma\, m)^3]/d(1/T)$ and $\Delta H = +15{,}064$ calories.

From the solubility at 25°, we find $\Delta F = -RT \ln K = -1363.7 \log 4 \times (0.550 \times 0.02023)^3 = +7171$ calories.

Then $\Delta S_{\text{sol.}} = (\Delta H - \Delta F)/T = (15064 - 7171)/298.1 = 26.48$ E. U.

Entropy of Bromate Ion.—Now $Ba(BrO_3)_2 \cdot H_2O = Ba^{++} + 2BrO_3^- + H_2O$. Using the value for Ba^{++} given by Latimer and Buffington,[1a] and that for water obtained by Latimer and Greensfelder[1d] from the data of Simon and others, we find $S^\circ_{BrO_3^-} = {}^1/_2(80.72 + 26.48 - 15.92 - 4) = +43.6$ E. U., and the entropy of BrO_3^- at 298.1°K. = +43.6 E. U., with respect to $S^\circ_{H^+} = 0$.

The greatest uncertainty is the value for the heat of solution and it is planned to check this value by a direct experimental determination.

The authors wish to thank Mr. J. Elston Ahlberg of this Laboratory for assistance in the experimental work and calculations.

Summary

The specific heat of $Ba(BrO_3)_2 \cdot H_2O$ has been measured from 16 to 300°K. These values, together with the heat and free energy of solution of barium bromate, have been used to calculate the entropy of bromate ion in hypothetical one molal aqueous solution.

THE COMPRESSIBILITY OF THALLIUM, INDIUM AND LEAD[1]

BY THEODORE W. RICHARDS AND JOSEPH D. WHITE

RECEIVED SEPTEMBER 18, 1928 PUBLISHED DECEMBER 10, 1928

Introduction

Existing data on the compressibility of thallium are in apparent conflict. The first pertinent experimental work[2] on this metal (about twenty years ago) gives the value 2.85 × 10^{-6} for the cubic compressibility at 20° over the pressure range 100–500 megabars. Fifteen years afterwards, P. W. Bridgman published a determination[3] seeming to indicate that the cubic compressibility under the same conditions may be considerably larger—about 3.5 × 10^{-6}. This latter determination was based upon the linear compressibility, actually measured, which was multiplied by three on the assumption that thallium is isotropic. Bridgman pointed out that the large difference between his value and the earlier

---

[1] Note by *the* Editor.—This research was completed in 1927 under the direction of Professor Theodore W. Richards but the present account of it was prepared after the death of Professor Richards by Dr. Lawrence P. Hall.

[2] Richards and Stull, *Carnegie* Institution *of* Washington, Pub. No. 76, 1907, p. 65. The value there given, 2.6, after correction for the new compressibility of mercury, for slight errors in the pressure gage and to the megabar standard, becomes 2.85 X 10^{-6}. The value given on page 62 is wrong through typographical error—a misprint which has unfortunately been copied elsewhere (for example, THIS JOURNAL, **37,** 1646 (1915)).

[3] Bridgman, Proc. Am. *Acad.* Arts *Sci.,* 58, 198 (1922).

one "strongly suggested that the crystal system cannot be cubic."[4] If this were the case, of course, his determination of the linear compressibility means little unless the direction in relation to the crystal axis is known; and since the specimen was an extruded one, definiteness in this respect is unlikely.

The discrepancy prompted further experimental investigation, especially desirable since compressibility has acquired important significance in relation to internal pressure. The earlier work referred to above was of a pioneering nature and was made to discover rather the order of magnitude of various compressibilities than the precise values, although indeed the results have nearly all of them, except this one, been confirmed within a narrow limit of error by subsequent investigators. Accordingly, the present investigation was carried out with greater care.

The earlier result was in fact found to be very close to the true value. Bridgman's inference as to the cause of the discrepancy of his value and ours is supported; it has been confirmed, moreover, very recently by Terpstra, and others,[5] who have shown that the crystal structure of metallic thallium is face-centered tetragonal, similar to that of indium and gallium. Becker and Ebert state that the axial ratios are almost unity, but according to Terpstra the ratio is 1.58. This would account for the wide discrepancy in values for the compression coefficient.

The compressibility of indium also was studied, because of the fact that only a very small amount of the metal had been available for the use of previous experimenters. This outcome also, verified the earlier work at Harvard within a reasonable limit of error.

The compressibility of lead was redetermined as a test of the methods used.

Preparation of Materials

Mercury was purified in the usual fashion by passing it in fine drops through dilute nitric acid and by final distillation, according to Hulett. Toluene was purified by shaking a commercially pure sample with three successive portions of concentrated sulfuric acid, each time washing with water, dilute sodium hydroxide and again with water. After standing over anhydrous calcium chloride, it was shaken with separate quantities of clean mercury until no further tarnishing of the mercury took place; subsequently the toluene was distilled. The middle fraction (mean boiling point, 110° at 760 mm.) was preserved over sticks of sodium hydroxide in a glass-stoppered bottle and used in the determinations.

The lead was a very pure specimen, most of which had previously been used for the purpose.[6]

---

[4] In an anisotropic crystal there is a marked difference in linear compressibility ong its different axes. See, for example, Bridgman's values for zinc, ref. 2, p. 217.

Thallium

The purification of the thallium offered much difficulty. Several hundred grams of crude thallium containing several per cent. of impurities (mostly lead and zinc) served as a starting point. This was dissolved in hot dilute nitric acid and the crystals of nitrate were treated with concentrated sulfuric acid in slight excess. After all of the nitric acid had been expelled at a high temperature and fumes of evaporating sulfuric acid were evolved, the sulfate paste was dissolved in excess of pure water and the residual lead sulfate was separated. Small amounts of thallic oxide formed were reduced with sulfurous acid. The sulfate was once crystallized and from its solution thallium was deposited electrolytically, having present an excess of sulfuric acid sufficient to prevent the deposition of zinc at the cathode and thallic oxide at the anode. It was necessary to make this solution very dilute to avoid the inclusion of sulfate and the current density **was** kept low in order that the metal should be precipitated as compact, well-defined crystals. As usual, great current density produced only a spongy product. From time to time the crystals were removed by means of a small glass fork from the cathode to a casserole, in which they were leached free of salt and acid by many successive additions of pure, boiled but cool water, and preserved in a glass-stoppered bottle filled to the neck with freshly boiled water. These precautions are necessary; otherwise the substance on subsequent fusion will contain sulfate and oxide, rendering fusion difficult and the product impure.

When ready for fusion the thallium was shaken free of all superficial water by centrifuging, dried as rapidly as possible in a vacuum desiccator and fused in a steady flow of pure hydrogen at a temperature of 400°, whereby traces of mercury and other volatile impurities were driven off. The surface of the fused and cooled mass was scraped free of most of the slag (presumably thallium oxide) and the porcelain boat which served to contain the metal was transferred to a specially designed slag funnel. On remelting by uniform heating, the thallium was quickly poured into a clean glazed boat, the slag remaining behind. Finally, the purified metal was cast into a cylinder and turned in a lathe to fit the piezometer.

Indium

The method of preparation of the allied metal, indium, was not dissimilar, although not quite identical. The source was a large quantity of material obtained in several lots as a by-product from a recent research on the atomic weight of gallium.[7] Part had been prepared in preliminary fashion during vacation by Dr. Craig, who very kindly gave it to us for the present purpose. The original source of all was the Oklahoma residues described elsewhere.

The particular specimens used had been largely freed from lead, copper, gallium and arsenic, as well as much of the zinc. Further steps were necessary, however, to obtain adequate purity. The first lot of this material was dissolved by an excess of sulfuric acid and the warm, dilute solution treated with hydrogen sulfide. The precipitate was removed; after partially neutralizing with ammonia, the filtrate was again saturated with hydrogen sulfide, and the small amount of precipitated indium sulfide mixed with impurities was again filtered off. Zinc and iron still remained to be separated, at least in part. For this purpose fractional electrolysis was tried. Neither a strongly acid nor a completely neutralized solution gave satisfactory results, but electrolytic deposition could be effected when the solution was about half normal in acid.

---

[7] Richards and Craig, THIS JOURNAL, 45, 1155 **(1923).**

With suitable current density (easily regulated) the indium was deposited in compact form on stout platinum wires (about 1 cm. long) sealed into soft glass tubing. At first only the tip of the cathode was covered with electrolyte. During six or seven hours, somewhat less than 1 g. per hour could conveniently be deposited on each electrode. The small pieces of indium were washed with water and preserved under freshly prepared distilled water. All the fractions contained zinc, since the current density was too great to separate this metal from indium.

These nuggets, although they had been somewhat protected against oxidation, were so much oxidized that they refused to melt together in a current of hydrogen. To effect coalescence, the drops of melted indium were rubbed together under paraffin at the temperature of about 170° (melting point of indium, 156°).[8] Stirring the material under this protecting environment caused the slag to be suspended in the paraffin, whereas the melted metal easily united into a bright, coherent globule. Some of the material is, of course, lost with the slag, but at least 70% may be recovered.

The clean metal thus prepared, after being all melted together and freed from paraffin with benzene, was re-melted and cast into a cylinder of a proper diameter to fit the piezometer. The tube for casting, of proper bore, containing the indium, was allowed to cool very slowly by being gradually lowered through a ring burner, the solidification of the metal taking place from below upward. Thus the formation of cavities within the cast metal was prevented. The cylinder thus obtained weighed approximately 35 g. and was used for preliminary determinations of compressibility.

Since neither the quantity nor the purity of this specimen was adequate for the best possible results, a larger specimen of purer material was prepared for the final determinations. The 35 g. specimen itself formed part of the raw material for the new sample. It was fractionally crystallized as metal three times, 22 g. of purer material being thus recovered. The several fractions poured off as liquid, which contained much of the zinc, were then dissolved in dilute sulfuric acid, filtered from a trace of lead sulfate, treated with hydrogen sulfide, again filtered and freed from the gas, precipitated as indium hydroxide, leached with 5 separate portions of dilute pure caustic potash to remove as much as possible of the residual gallium and zinc and then washed a number of times by decantation with water. This solution was then combined with other similar ones to be described.

The most impure of the residues were brought to a state of moderate purity before the process of further purification described above in detail was applied. In this preliminary treatment the sulfite method was used to eliminate iron. Several other specimens of indium residue were also worked up by substantially the same method, and added to the material. A number of solutions, all of about the same degree of purity and containing a total of about 105 g. of indium, were combined and electrolyzed; nearly 90 g. of metal was separated and fused together in the way already described.

The solidifying point at this stage averaged 145.1°, as found by the method commonly used for organic compounds, while a sample of the pure indium used by Richards and Sameshima[9] gave a value 156°+ by the same method. Spectrographs were now made by an accurate Féry spectrometer, in order to determine the nature and quantity of the impurities. As was expected, considerable zinc still remained, but only faint traces of gallium were to be seen and nearly all of the lead also had been eliminated.

For final purification the method described by Richards and Craig for freeing gallium from zinc was used. Indium, like gallium, has a very high boiling point, whereas zinc, even from an alloy, has considerable vapor pressure at a bright red heat. Hence,

---

[8] This device was suggested by Dr. Craig, based upon his experience with the material.

[9] Richards and Sameshima, THIS JOURNAL, 42, 49 (1920).

by heating sizable portions of the sample in a large evacuated silica test-tube, the zinc was easily distilled into the upper part of the tube, taking with it only a very small amount of indium. Determinations of the zinc in the sublimates from weighed portions (by titration with ferrocyanide standardized against pure zinc) gave an average of 2.7% of zinc in the original metal. The melting points of different almost non-volatile residues varied from 154 to 156°. A cooling curve of the combined preparations (85 g.) gave a nearly constant temperature (155") for four minutes, during which time almost all of the melted mass solidified (or, on warming, almost all of the solidified mass melted). The specific gravity of the metal thus prepared and very carefully cooled was found to be 7.296. Richards and Wilson[10] found the density to be 7.277, but their samples had not been cooled so carefully and may have contained minute air bubbles. Spectrographs of the non-volatile metallic mass showed it to be free from zinc. The amount of gallium remaining was only a trace and other likely metals were sought for but not found. Thus, although the claim cannot be made that this 85-gram specimen was absolutely pure, it was evidently more than pure enough to serve the purpose in hand. Zinc had been the only substance really difficult to eliminate and that was wholly eliminated by the process of heating to high temperature *in vacuo*.

Standardization of Absolute Gage

Since the exactness of standardization of pressure is important, the weights used in the absolute pressure gage were all carefully compared with a weight standardized by the Bureau of Standards at Washington. A second set of weights was also calibrated for use with a second (auxiliary) absolute gage, which was used only for comparison and calibration of the first gage, as will presently be discussed.

The pistons of both gages were accurately measured with Brown and Sharpe micrometer calipers and with a Newall measuring machine at the Taft-Pierce Co. of Woonsocket, R. I. The diameters of the cylinders to hold the gages were determined by measurement of closely fitting plugs. The first piston (used throughout the experiments) had a diameter of 0.6360 cm. and its cylinder had a diameter of 0.6368 cm. Hence, the value 0.6364 cm. was indicated as the effective diameter.[11] The second piston was 1.4003 cm. in diameter and its cylinder 1.4008 cm., with an effective diameter of 1.4006 cm. Since this second gage had almost five times the area of the first, the percentage accuracy of measurement was greater.

For comparison these two pistons were mounted in the usual way and "in parallel." The weights required to maintain an equilibrium between the two pistons were determined over a range of pressures and the effective area of the first piston was found in terms of the larger one.[12] This method of comparison proved to be an exceedingly sensitive one. By it the effective diameter of the working piston appeared to be 0.6366 cm. From a mean of these two estimates the effective area may be taken as

---

[10] Richards and Wilson, *Carnegie Institution of Washington,* Pub. No. 118, 1909, p. 13.

[11] The effective diameter is taken as the mean of the diameters of cylinder and piston, cf. Richards and Shipley, THIS JOURNAL, 38, 992 (1916).

[12] See Bridgman, *Proc. Am. Acad. Arts Sci., 44,* 214 (1909).

0.31824 sq. cm. One kilogram, then, on the absolute gage, would correspond to 3.0813 megabars (if based in 980.4 as the factor of gravity at Cambridge).

Method

The method employed was essentially identical with that invented twenty-five years ago and used by former workers in the Wolcott Gibbs Memorial Laboratory.[13]

The piezometer was of glass. All precautions (frequently reiterated in the past) were taken to avoid errors from hysteresis, etc. Under these circumstances the glass piezometer has appeared to yield as good results as the more complicated steel one.[14] The piezometer was filled with great care. Bubbles of air were excluded as completely as possible. At first a small amount of a lubricant of rubber and paraffin was used on the stopper of the piezometer. However, because this was so easily dissolved in the toluene, in later experiments either a sirup of phosphoric acid or a warm mixture of dextrose and glycerine[15] was substituted. The thermostat was kept at 24.540 ± 0.002'.

The piezometers were standardized with mercury. Since the metals under investigation were protected from mercury by toluene, the compressibility of toluene also had to be investigated. With piezometer No. 1 filled with mercury alone a change of 0.2685 g. of mercury was made in the side arm in going from 100 to 500 megabars. The constant at 24.84° for the toluene (density = 0.8616) was found to be 0.4219 g. Hg/g. of toluene from 100 to 500 megabars, because 26.5 g. of toluene needed 11.42 g. of mercury in the side tube over the pressure range. These values are the averages of many trials.

Hence, $w' = 0.269$ and $m = 0.4219$ for piezometer No. 1, using the equation $\beta = \frac{(W - w' - mK)}{5425\ W} D + \beta'$, where β is the compressibility sought, w the weight of mercury added in the particular case, w' the weight of mercury added when mercury alone is present, m the additional weight of mercury needed (in the side arm) when one gram of another liquid replaces an equal volume of mercury (within the piezometer), K the weight of the other liquid, D the density of the specimen, W its weight and β' is the compressibility of mercury; 5425 is 400 times the density of mercury at 25° between 100 and 500 megabars.

The value of β at 24.84' for this specimen of toluene is 70.9 X 10^{-6}. Richards and Shipley[16] found 69 X 10^{-6} at 20° for toluene.

Compressibility of Lead

To standardize methods and to relate the results for indium and thallium with older work, the compressibility of lead was redetermined, using a cylinder which had been cast, hammered to remove possible imperfections in casting, and turned on a lathe to fit the piezometer. Its density was 11.346. Toluene was used as the confining fluid to transmit pressure to the specimen and to prevent lead from coming in contact with mercury. Sirupy phosphoric acid was used for lubrication of the stopper. The first experiment to measure the compressibility of lead was interrupted and therefore rejected. The successful experiments are recorded in Table I.

TABLE I

COMPRESSIBILITY OF LEAD AT 25°

Expt.	Wt. of toluene, g.	Wt. of lead, g.	Mercury, 100–500 meg., g.	$\beta \times 10^6$ (meg.)
1	2.663	314.140	1.153,[a] 1.153	2.41, 2.41
2	2.519	314.135	1.096, 1.084	2.43, 2.35
			Av.	2.40

[a] The two values given for each experiment are the weights of mercury required in the side arm. The first represents the weight in going from 100 *up* to 500 megabars, the second from 500 *down* to 100.

The value for β, 2.40 X 10^{-6} (in megabar units), at 25° may be compared with 2.35 X 10^{-6} at 20° found by Richards and Bartlett,[17] who used lead under water and mercury in a steel piezometer. When the value of these experimenters is corrected to 25°, 2.41 × 10^{-6} is obtained. The earlier value of Richards and Stull[2] corrected to present-day standards is also 2.4 X 10^{-6}. Bridgman[3] found 2.40 X 10^{-6} (in megabar units) at 30°.

The agreement of the values found by these new experiments on lead with the values presented in the literature indicated that the experimental method had been correctly executed and gave added weight to the significance of the new values obtained for thallium and indium.

Compressibility of Thallium

In the determination of the compressibility of thallium the value of w' for the piezometer used (No. 2) was found to be 0.2816 as the average of three experiments. The density of the casting used in the determinations was 11.85. In the first experiment a relatively large amount of toluene was used. This was lessened in the second by the addition of a small button of thallium to the piezometer. Sirupy phosphoric acid was used as a lubricant on the stopper.

Experiments 1 and 2 (Table II) were performed in June, 1025. Four months later the compressibility of this casting of thallium was redeter-

---

[17] Ref. 6, p. 479.

mined (Expts. 3, 4 and 5) and essentially the same result for compressibility was obtained as before.

TABLE II

COMPRESSIBILITY OF THALLIUM AT 25°

			1.541	2.79
			Av.	2.80
			Av. of all	2.85

It was discovered during the second series of experiments that there was a minute "pipe" hole in one end of the casting. Although it did not appear that a significant error could be caused by this flaw, the metal was recast. Much experimentation was required to perfect a method of obtaining a casting free from flaws. The final procedure was to pour the melted thallium into a pyrex tube of proper bore, with a lining of magnesium oxide to prevent sticking of metal to glass. The tube had been previously heated. With its molten charge it was lowered vertically through an electric furnace. Cooling was effected from the lower tip very slowly as the tube descended. In this carefully controlled manner there was obtained a casting free from flaws. The specimen was cleaned, hammered, and fitted to the piezometer. The data for the determinations made from this specimen are found under Experiments 6 and 7. Although from these experiments β appears slightly lower than in the previous ones, the average of all the experiments (2.85×10^{-6}) cannot be far from the truth. If the mean is weighted by giving double credit to the last two experiments, since they were performed with a better cast specimen, the average 2.83×10^{-6} is obtained.

Compressibility of Indium

Indium–Zinc Alloy.—A preliminary series of determinations was carried out with a 35-g. sample of indium, containing about 3% of zinc (density 7.292). An iron cylinder was used in the lower part of the barrel of the piezometer to decrease the amount of toluene required. Although individual standardizations with the iron cylinder and also individual determinations of compressibility seemed satisfactory, there was exceedingly poor agreement of successive experiments for an unknown cause. From these preliminary experiments β for indium appeared to be about 2.4 X 10^{-6}.

Since part of the difficulty seemed to be in the lubricant used, Ramsay grease was used on the stopper, which necessitated the use of water as the confining liquid, although it reacts with indium very slowly, generating hydrogen. Contact of the indium with iron slightly accelerates the action. In a loaded piezometer left overnight an appreciable bubble of gas was found. However, a small amount of gas dissolves completely in the confining liquid and appears to cause no appreciable error.

A slight modification of procedure was made in starting at a pressure of 500 megabars, reducing the pressure to 100, and returning to the higher pressure. By this technique the same values of compressibility were usually obtained for "up" and "down" experiments. Standardization of the piezometer showed that 0.2045 g. of mercury was the added weight of mercury required in the side arm over the range 100 to 500 megabars due to the substitution of one gram of water for its volume of mercury within the piezometer (m in the equation), 0.4462 g. of mercury corresponding to 2.182 g. of water.

Mehl and Mair[18] found with a 25-g. sample of water the value 0.2044 at 25°. Three standardization experiments were made with approximately the same quantity of water used when the bar of indium was present. Over the pressure range of 100 to 500 megabars 0.1600 g. of mercury was required when 0.8576 g. of water was present; 0.1895 g. of mercury for 1.005 g. of water; and 0.1665 g. of mercury for 0.8838 g. of water. Hence, from the average of these results, the value of w' is 0.1605 on the basis of 0.8576 g. of water.

TABLE III

COMPRESSIBILITY OF 97% INDIUM ALLOY

Expt	Water, g.	Indium, g.	Mercury, 100–500 meg.	$\beta \times 10^6$
1	1.1896	35.357	0.1895[a]	2.52
2	1.1584	34.215	.1845	2.53
3	1.1110	34.211	.1734	2.48
			Av.	2.51

[a] Identical values were obtained for both the "up" and "down" experiments.

Pure Indium.—The 35-g. sample was purified and combined with more indium to form a larger and purer specimen, which would not re-

---

[18] Mehl and Mair, THIS JOURNAL, 50, 55 (1928).

quire an auxiliary steel bar. The density of this larger casting was 7.296. Its density was redetermined several times during the course of the experiments, since on several occasions a slight amalgamation took place in the process of unloading the piezometer after a determination of compressibility. The spot amalgamated was immediately scraped free from mercury. Since no change in density resulted, it is unlikely that the small amount of surface amalgamation which occurred had any influence on the compressibility.

A piezometer of proper size for the cylinder of indium was standardized with mercury alone and the factor 0.1098 was found for the pressure range of 100 to 500 megabars. With 2.1820 g. of water there was required in the side arm over this pressure range 0.5560 g. of mercury; with 2.0541 g. of water, 0.5300 g. of mercury. This gives a value for m of 0.2045 and for w' a value of 0.5209 on the basis of 2.0541 g. water.

After Expt. 3 (Table IV), the indium was melted and recast, because after scraping of the amalgamated spots the cylinder fitted poorly and required a larger quantity of water. The new casting had a density of 7.297.

Table IV

Compressibility of Indium

				2.52
5	1.7102	84.727	.3700	2.58
			.3720	2.61
			Av	2.56
			Average of all	2.55

The previous value for the compressibility of indium[8] ($\beta = 2.7 \times 10^{-6}$ at 25°) was determined with a sample of only 6.7 g. Essentially in accord with it is the value more recently determined and here presented, which was made with an 80-g. specimen.

From the value 2.55×10^{-6}, β for indium, and the value 1.7×10^{-6} for zinc, it may be calculated that an alloy of 97% indium and **3%** zinc (approximately the amount indicated by analysis and density of the alloy) would have a compressibility of 2.52×10^{-6}, if the rule of mixtures holds. This calculated value is slightly higher than the value actually found for such an alloy (2.51×10^{-6}), as would be expected from the generalization that solid solutions have compressibilities somewhat lower than calculated by the rule of mixtures.[18]

Discussion

In Table V certain properties and constants of the members of the natural group which has recently been studied, together with those of

neighboring groups in the periodic table of elements, are summarized. Most of these data are taken from "International Critical Tables," Vols. I and III. The values for cubic compressibilities and coefficients of expansion are, however, with the exception of germanium and mercury, those compiled by one of us some years ago.[19] The compressibilities of germanium and mercury have been calculated from Bridgman's data.[3,20]

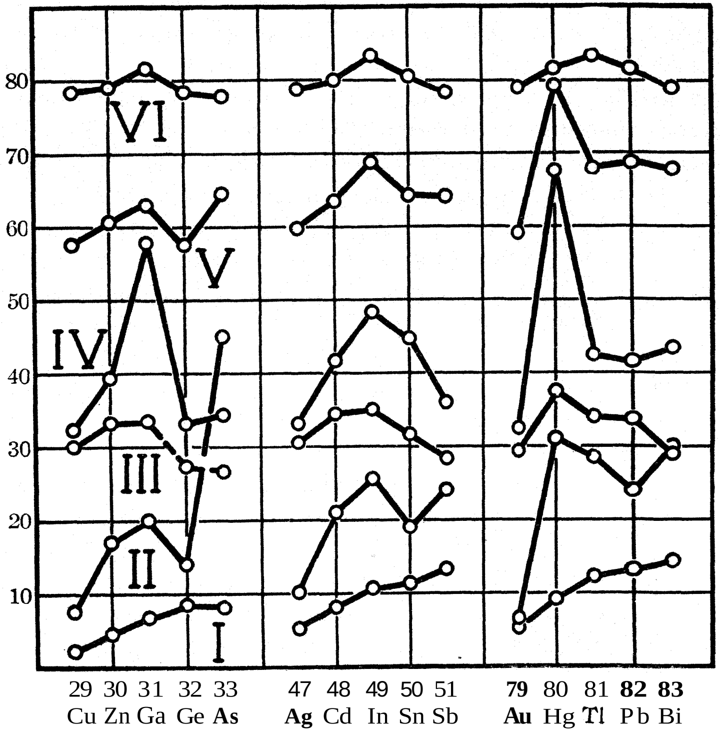

Fig. 1.—Curve I, atomic volume; II, compressibility ($\beta \times 10^7$); III, cubic coefficient of expansion ($\alpha \times 10^5 + 25$); IV, reciprocal of absolute melting point ($^1/_{T_m} \times 10^3 + 40$); V, reciprocal of internal pressure ($^1/_\pi \times 10^3 + 55$); VI, reciprocal of hardness ($\times 10 + 75$).

The hardness values are after Rydberg.[21] The numbers in brackets have been calculated from insufficiently supported data. The values for n', $P\theta$ (thermal pressure) and π (internal pressure) are obtained from calculations making use of Richards' equations of state for solids and liquids.[22] A value of 2 has been assumed for m throughout. The symbols m and n' are the exponents representing, respectively, the rate of increase of the

internal cohesive pressure and of the internal distending pressure with decreasing volume. Values for π for all the elements listed, except germanium, arsenic, antimony and bismuth, were calculated from coefficients of compressibility and expansion data. These four were, for good reasons, calculated from latent heats of vaporization data. The coefficient of expansion for germanium is not known; while the calculation of internal pressures for the anisotropic crystals of the other three elements would lead to only approximate if not very erroneous values. The expansion and compression coefficients for arsenic, antimony and bismuth vary according to the direction chosen in the crystal, which indicates that their internal pressures are distributed very unevenly.[23] This fact applies to members of other groups appearing in Table V but not so rigorously. Consequently it seemed justifiable for qualitative considerations to proceed with the calculations as outlined above. In Fig. 1 are plotted various properties of the members of the groups indicated in Table V in relation to their atomic numbers. In the diagram the lowest curve represents atomic volumes (Curve I) and the one just above it compressibilities (Curve II). In addition, are curves for cubic coefficients of expansion (Curve III), reciprocals of the melting points in degrees absolute (Curve IV), reciprocals of internal pressures in kilomegabars (Curve V), and the reciprocals of hardness (Curve VI).

An examination of the curves in the diagram shows with but few exceptions an approximate proportionality between atomic volumes of the elements of any one family and their other properties. Thus, if the succeeding elements in the group have larger atomic volumes than the first one, then their other properties also have larger values.

On the other hand, an examination of the two lowest curves shows that although the atomic volumes of the elements in the gallium–indium–thallium group are intermediate between the atomic volumes for neighboring elements in the periodic table, the compressibilities are greater than those for either the preceding or succeeding neighbor except for mercury which, being a liquid, has an anomalous behavior. The same relations hold when atomic volumes are compared with coefficients of expansion, reciprocals of melting points and (excepting a reversed relationship between thallium and lead) reciprocals of internal pressure. In other words the members of the gallium family seem to occupy sub-maximum points on the upward slope of the completed periodic curves given in an earlier publication from this Laboratory.[24] This is remarkable in view of the generally accepted conclusion that there is an approximate proportionality between atomic volumes and related properties. The peculiar behavior of the gallium family may be explained in the following

---

[23] Richards, THIS JOURNAL, 47,739 (1925).

[34] Ref. **19** *a*, p. 1649.

manner. Whereas the atomic volumes of its members are intermediate between their neighbors, their compressibilities show a decided maximum because other factors overbalance the effect of atomic volume. That is, their coefficients of expansion are larger, their melting points lower, and their degree of hardness much less.[25] These properties depend upon the important fact that the net internal pressure (that is, the resultant of the cohesive pressure, inherent distending pressure and thermal pressure) of these three metals is decidedly less than the net internal pressures of either the zinc or germanium family.

Acknowledgment is made for essential financial assistance from the Carnegie Institution of Washington and an anonymous benefactor of this Laboratory.

Summary

The compressibility from 100 to 500 megabars at 25° has been measured for lead ($\beta = 2.40 \times 10^{-6}$), thallium ($\beta = 2.53 \times 10^{-6}$), indium ($\beta = 2.55 \times 10^{-6}$) and an indium–zinc alloy containing 97% indium ($\beta = 2.51 \times 10^{-6}$).

The preparation of the pure metals is described. The special precautions and modifications in procedure for determining the compressibility of these specimens are presented in detail.

The thermal pressure ($P\theta$), the internal pressure (Π), and the coefficient (n') of rate of change of the internal distending pressure have been calculated according to Richards' equation of state. The periodic variation of properties is discussed with particular bearing on the gallium, indium, thallium group, which occupies a sub-maximum position.

THE COMPRESSIBILITY OF SODIUM, BARIUM AND BERYLLIUM[1]

BY T. W. RICHARDS, L. P. HALL AND B. J. MAIR

RECEIVED SEPTEMBER 18, 1928 PUBLISHED DECEMBER 10, 1928

Determinations of the coefficient of compressibility have been made during the past twenty-five years for many of the elements by the "constant volume method" developed at the Harvard Laboratories. Values for the less common elements have been determined as such elements have become available. In this paper are presented values for barium, strontium and beryllium, and also for sodium. The latter was redetermined to demonstrate the reliability of the method with the modifications necessary in handling strontium and barium.

Bridgman, measuring the linear compressibility,[2] calculated the cubic compressibility of strontium to be 8.187×10^{-6} at 30° (in kg./cm.^{2}). Shortly after the initiation of the research here presented, Bridgman published values for barium and beryllium[3] of 10.19×10^{-6} and 0.855×10^{-6}, respectively, at 30° and in kg./cm.^{2} units. Nevertheless, corroboration by an independent method was deemed to be of sufficient importance to justify publication of the results.

Preparation of Materials

Barium.—The barium was obtained through the kindness of Dr. Francis C. Prary of the Aluminum Company of America. It was prepared in a special alloy furnace which was provided with a mild steel crucible so constructed that it could be evacuated and filled with some inert gas. Before the barium was melted, the crucible was evacuated to 2 mm. residual pressure and maintained thus until the temperature rose to about 400°.

The barium was then melted in an atmosphere of argon in the steel crucible, the pressure reduced to prevent blow-holes and the barium cast in a mold in the lid of the crucible.

After its receipt the barium was cut under kerosene oil with the aid of a small coping saw and knife into a size and shape suitable for the piezometer. The pieces of barium when not in use were stored in a vacuum desiccator under exceptionally pure kerosene.

During the manipulations involved in three determinations of compressibility over a period of four days, an eighteen-gram sample gained only 1.4 mg., showing that the methods of storage and manipulation ade-

---

[1] As this research was completed shortly after the death of Professor Richards, this report was prepared by the junior authors.

[2] Bridgman, *Proc. Am. Acad. Arts Sci.*, 58, 151 (1923).

[3] Bridgman, *ibid.*, 62, 207 (1927).

quately prevented serious oxidation. The trace of oxide thus formed was present as a superficial layer, which would be without influence on the value for the compressibility.

An examination in a quartz prism spectrometer showed the barium to be of exceptional purity: no iron and only very slight traces of strontium. Analyses indicated a barium content of 99.95%.

Kerosene Oil.—The essential requirements of the kerosene used in the piezometer as a confining liquid for barium are absolute freedom from water, sulfur and unsaturated hydrocarbons. Treatment with sodium wire over a period of one week and subsequent distillation did not yield an anhydrous water-white product. For these reasons the kerosene oil was further treated by shaking with a potassium–sodium alloy (four parts potassium to one part sodium) followed by a careful fractionation. Only the fraction distilling between 185 and 225° was used. Since the potassium–sodium alloy was a liquid at ordinary temperatures, it continually presented a fresh surface to the kerosene. This surface, in conjunction with its great chemical activity, assured the removal of any substances liable to react with barium. The oil was stored over potassium–sodium alloy until ready for use.

Mercury.—The mercury was prepared in the usual manner by treatment in a nitric acid tower and finally by distillation, according to Hulett.

Method and Apparatus

The apparatus and methods used in this research have been described in adequate detail elsewhere.[4] Only modifications of apparatus or procedure will be described here. All measurements were made at 25.00°, instead of the customary 20°. The piezometer, of the type previously used for solids, was made of Pyrex instead of soft glass. This was advantageous in making it less liable to fracture, while its temperature and pressure hysteresis did not appear to be any greater than that of soft glass. One detail of its construction, the taper of the stopper, although mentioned before, seems worthy of repetition since in recent years it appears to have been overlooked. The taper found to be most satisfactory was one in eight. With this taper no difficulty was experienced in removing the stopper, while with less taper, one in twelve or one in sixteen, this difficulty occasionally resulted in breakage of the piezometer. This increased taper also resulted in greater reproducibility of volume.

The barium was held in a thin-walled test-tube which fitted snugly in the piezometer and prevented mercury from coming in contact with it.

The piezometer containing the glass tube, mercury and about 2.5 g. of kerosene (the amount used in actual measurement of the compressibility of barium) was standardized in the usual manner.

The stopper lubricant used was a heavy Ramsay grease. 0.3 ± 0.1 mg. was placed on one spot on the stopper, which was then inserted rapidly in position and turned with considerable pressure until further movement

---

[4] Richards, *J. Franklin Inst*., 198, 25 (1924); Richards and Saerens, THIS JOURNAL, 46, 935 (1924).

was impossible. With this procedure practically none of the lubricant dissolved in the kerosene. A glucose–glycerine lubricant was tried but, although insoluble in kerosene, was much less satisfactory, possibly owing to the presence of small, solid particles which hindered a satisfactory seating of the stopper.

The data for the standardizations of the piezometer are tabulated in Table I in the customary manner.

Table I

Standardization of Piezometer with Oil

Expt	Oil. g.	Mercury, g. 100–500 meg.	Mercury on basis of 2.3132 g. of oil, 100–500 meg.
1	2.3132	1.0905	1.0905
2	2.3132	1.0890	1.0890
3	2.5652	1.2014	1.0882
4	2.7027	1.2645	1.0895
5	2.4408	1.1454	1.0881
		Av.	1.0891 g.

The weights of kerosene used in the different standardization experiments (Col. 2) were not identical. To reduce these to a common basis (Col. 4), it was necessary to determine a correction factor for the oil used. The following table presents the experimentally determined values for the weight of mercury in the side arm when one gram of oil replaces one gram of mercury in the piezometer.

Table II

Experimentally Determined Values

Expt.	Oil, g.	Mercury, g. 100–500 meg.	Oil in excess of 2.3132 g.	Mercury in excess of 10891	Ratio, Hg/oil
1	7.7294	3.5154	5.4162	2.4263	0.4480
2	7.8488	3.5848	5.5356	2.4957	.4508
3	7.2624	3.3106	4.9492	2.2215	.4488
4	7.6397	3.4860	5.3265	2.3969	.4500
				Av	.4494

This factor was also used in calculating the compressibility of sodium, barium and strontium.

Compressibility measurements were first made on a sample of "C. P." sodium to determine whether the special methods necessary for the work with barium would give results, in the case of sodium, in accordance with those generally accepted. As will be seen, the results thus obtained confirm the older value[6] of 15.6×10^{-6}.

The density of sodium (0.972) used was that determined by F. N. Brink.[6]

4	2.5694	1.3811	10.44	18.5392
		Av.	10.48	

When Bridgman's value for barium is corrected to 25° to the pressure units here used, and to the same range of pressure, β equals 10.34×10^{-6}, a reasonably good agreement for the two diverse methods.

Determination of Weight and Density of Barium

The determination of the weight of the sample of barium presented one of the most difficult problems of the research. A special apparatus was designed for complete removal of kerosene in an inert atmosphere. Argon of 99.95% purity was further purified by passage over activated charcoal chilled with solid carbon dioxide in ether. A diagrammatic sketch of the

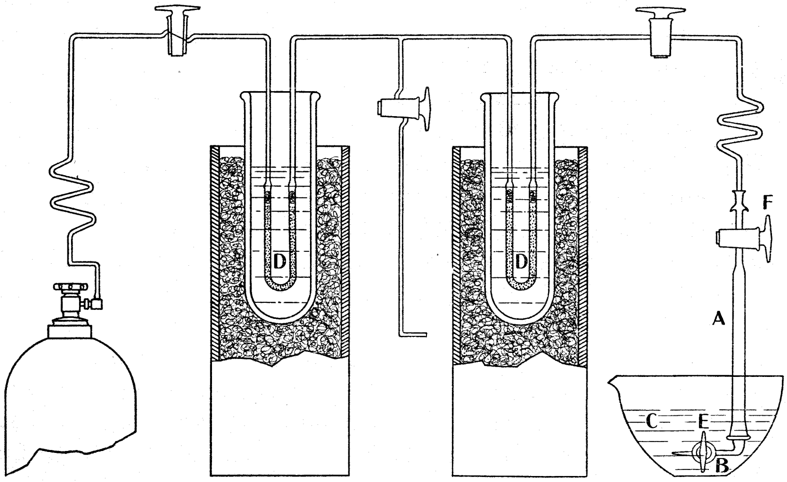

Fig. 1.

apparatus is depicted in Fig. 1. The charcoal in tubes (D,D) was first completely outgassed by heating to 500° in a high vacuum for forty-eight hours. When pure argon was desired, Dewar vessels with carbon dioxide and ether were placed over these tubes. Next, the sample of barium in the tube with kerosene was immersed in a bath of anhydrous, sulfur-free petroleum ether (C), into which the weighing tube (A) dipped. After the apparatus was swept out with pure argon, the cylindrical pieces of barium were introduced into A and the end piece (B) inserted in position. The bath of petroleum ether was removed and the barium dried in a current of argon. The stoppers E and F were closed, the tube was removed and weighed. The sample was again transferred to kerosene and the tube refilled with argon. The difference in weight gave the weight of barium in argon. A buoyancy factor was applied to obtain the weight of barium *in vacuo* and in air. The weight of barium in air was used to compute the weight of oil in the piezometer by difference.

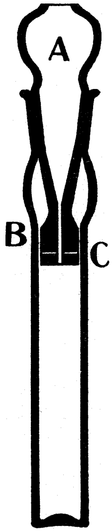

Fig. 2.

The density was determined in a new kind of pycnometer for solids, a modification of a type suggested by Dr. J. C. Woodhouse. The pycnometer used is illustrated in Fig. 2. The ground-glass stopper (A) was of the same type as that used in the piezometer, which had been found to yield a reproducible volume. A capillary tube (B) etched with a fine mark (C) extended into the piezometer. The level of the liquid was adjusted to the mark by means of a capillary pipet inserted through the hollow stopper. Excellent reproducibility of weight was obtained, a maximum variation of only 0.3 mg. being found in successive fillings and settings. The density of the kerosene was determined as 0.79424 by this method, whereas 0.79430 was obtained with a small Ostwald-Sprengel pycnometer. Even greater reproducibility might be possible by the use of a small ground-glass cap fitting on the stopper to prevent evaporation.

Two determinations of the density of barium at 25.00' gave the identical value, 3.661. This value appears to be the most reliable yet obtained.[7]

Strontium, also provided by the Aluminum Company of America, was prepared in a way similar to that used for barium. Since there were some inclusions of strontium hydroxide in the sample, it was more difficult to cut it up. It was undoubtedly on account of these inclusions that the density found (2.737) was higher than is usually reported.[8] The coefficient of compressibility at 25° was found to be 7.22×10^{-6} as the average of

---

[7] Considerable discrepancy exists in the literature for the density of barium. Guntz, *Compt. rend.*, 141, 1240 (1905), found 3.78. Biltz and Huttig, *Z. anorg. Chem.*, 114, 247 (1920), found values ranging from 3.44 to 3.70, using samples of 0 5 to 1.5 g. Kern, *Chem. News*, 31,243 (1875), found 3.75 with an impure sample.

[8] C. E. Glascock, THIS JOURNAL, 32, 1222 (1910).

three experiments. This is distinctly lower than Bridgman's value of 8.32 × 10^{-6} (corrected for temperature and pressure units).

This lowering of the value is in agreement with the high density caused by the presence of compounds. Hence, this value is presented only as a preliminary one.

These determinations complete the compressibility and density data for the family group of Ca, Sr and Ba.

Comparison of their atomic volumes and compressibilities is of interest.

	Mg	Ca	Sr	Ba
Atomic weight	24.32	40.07	87.62	137.37
Density	1.73	1.53	2.55[a]	3.66
Atomic volume	13.3	25.3	34.36	37.52
Compressibility ($\beta \times 10^6$)	2.9	5.7	8.32[b]	10.48

[a] Glascock, ref. 8.

[b] Bridgman, *Proc Am. Acad. Arts Sci.*, *58*, 201 (1923).

Beryllium

A cylinder (1.1 × 9 cm.) of beryllium, over 99% pure, was made by the Beryllium Corporation of America. It was coherent and finely crystalline. The density was found to be 1.85. Since in this case water was used as the confining liquid, it was necessary to standardize the piezometer with water. The results of these experiments will be found in Table V. The factor for the replacement of water for mercury in the piezometer has been determined[9] as 0.2044 and this factor was used to correct the weights of mercury in Table V to a common basis.

[9] Mehl and Mair, THIS JOURNAL, 49, 1892 (1927).

The data for the compressibility of beryllium are presented in Table VI.

Acknowledgment is made for generous financial assistance from the Carnegie Institution of Washington and an anonymous benefactor of this Laboratory.

Summary

1. Coefficients of compressibility were measured by the "constant volume" method at 25° as follows: sodium, $\beta = 15.6 \times 10^{-6}$; barium, $\beta = 10.48 \times 10^{-6}$; strontium (preliminary) 7.22×10^{-6}; beryllium, $\beta = 0.93 \times 10^{-6}$.

2. The densities of the specimens used were for barium, 3.66; for strontium, 2.74; for beryllium, 1.85.

3, Special methods were developed for determining the weight and density of barium and strontium.

BRYN MAWR, PENNSYLVANIA

NOTE

Use of the Hildebrand Hydrogen Electrode in Biological Solutions.—We have found that in certain biological solutions the ordinary Hildebrand[1] hydrogen electrode may attain equilibrium so slowly as to be entirely worthless. The Hildebrand type is obviously inferior to the enclosed electrode involving complete saturation of the solution with hydrogen, but the latter device greatly changes the P_H (as is well known) of mixtures containing reducible substances, or of mixtures partly buffered by hemoglobin or by volatile substances such as carbon dioxide and hydrogen sulfide.

We have put an ordinary rubber bulb from an "atomizer" into our hydrogen supply line so that the hydrogen flows through the bulb. By squeezing the bulb repeatedly the Hildebrand electrode is repeatedly saturated with hydrogen. Obviously, because of possible air leaks, the system should be operated so that at all times the pressure in the hydrogen supply line is slightly greater than atmospheric. It is very important that the solution level be periodically forced entirely below the bottom of the platinum, this being regulated by the rate of squeezing the bulb. In this way nearly constant readings are obtainable within five minutes with a small amount of hydrogen, while the usual arrangement sometimes did not give the right sign of e.m.f. even after an hour with a vigorous stream of hydrogen. This difference is strikingly observed by passing the hydrogen at first without touching the bulb, the e.m.f. being erratic and sometimes off by 0.5 volt. The correct reading is then quickly attained by pressing

THE CARBAZYLIC ACIDS: THE AMMONIA ANALOGS OF THE CARBOXYLIC ACIDS[1]

BY E. F. CORNELL

RECEIVED JUNE 25, 1928 PUBLISHED DECEMBER 10, 1928

The Ammonia System.—Liquid ammonia shows a striking similarity to water in many of its properties, particularly as an electrolytic solvent. This close correspondence purely as solvents has been extended so as to include similarities between derivatives of ammonia and the analogous water compounds. A system of acids, bases and salts related to ammonia as the aquo acids, bases and salts are related to water has been developed by Franklin.[2]

The Carbazylic Acids.—In this paper is given an account of the investigation of a class of ammono acids which are to be regarded as the ammonia or nitrogen analogs of the carboxylic acids. Just as aquo-acetic acid, for example, may be looked upon as being derived from a hypothetical ortho-acetic acid by the loss of a molecule of water, so a analogous ammono-acetic acid may be regarded as being derived from a hypothetical ortho-ammono-acetic acid by the loss of a molecule of ammonia, as represented by the parallel equations

$$2CH_3C(OH)_3 \longrightarrow 2CH_3COOH \longrightarrow (CH_3CO)_2O$$
$$CH_3C(NH_2)_3 \longrightarrow CH_3C(NH)NH_2 \longrightarrow CH_3CN$$

The acid amidines and the nitriles have come to be known as carbazylic acids and acid anammonides inasmuch as they represent the nitrogen analogs, respectively, of the carboxylic acids and acid anhydrides. In the following discussion, it will be shown that the carbazylic acids and their derivatives are identical in several of their reactions with the carboxylic acids or their derivatives.[3]

[1] The material in this paper is from a thesis submitted to the Department of Chemistry and the Committee on Graduate Study of Stanford University in partial fulfilment of the requirement for the degree of Doctor of Philosophy, 1926.

[2] Franklin, Am. *Chem.* J., 47, 285 (1912); Eighth Int. Cong. App. Chem., 6, (1912); THIS JOURNAL, 46, 2137 (1924).

[3] Franklin in his earlier papers [THIS JOURNAL, 27, 800 (1905); Am. *Chem.* J., 47, 291 (1912)] mistakenly refers to acetamide and diacetamide as ammono-acetic acids,

Salts of the Carbazylic Acids.—Pinner[4] describes the formation of the silver salt of benzamidine by the action of silver nitrate on a water solution of benzamidine hydrochloride. The sodium and potassium salts cannot be prepared in such a manner since they are very readily hydrolyzed. Benedict[6] first prepared a salt of benzamidine in liquid ammonia solution by the action of potassium amide on benzamidine. The close analogy between this reaction and that involved in the formation of potassium benzoate by the action of potassium hydroxide on benzoic acid is clear from inspection of the equations

$$C_6H_5C(NH)NH_2 + KNH_2 = C_6H_5C(NH)NHK + NH_3$$
$$C_6H_5COOH + KOH = C_6H_5COOK + H_2O$$

Action **of Ammono** Bases on Acid **Anammonides.**—The preparation of a number of salts of the carbazylic acids by the action of metallic amides on the nitriles will be described in the experimental part of this paper. Just as acid anhydrides react with bases to form salts, so should one expect the analogous reaction to take place when the acid anammonides are treated with ammono bases in liquid ammonia solution.

$$(RCO)_2O + 2KOH = 2RCOOK$$
$$RCN + KNH_2 = RC(NH)NHK$$

The carbazylic acids are formally tribasic acids and as such might be expected to form di- or possibly tri-metallic derivatives. It was found possible, however, to form only the monometallic derivative.

Action of Hydrocyanic Acid on Potassium **Amide.**—Hydrocyanic acid may be looked upon as the anammonide of formic acid and as such might be expected to react with metallic amides in liquid ammonia solution to form salts of ammonoformic acid. Hydrocyanic acid may also be considered as an ammonocarbonous acid,[6] and might be expected to react with an ammono base to form an ammonocarbonite and ammonia. As a matter of fact, this is what happens, for when a solution of hydrocyanic acid in liquid ammonia solution is treated with potassium amide, potassium cyanide is formed and not potassium formamidine.

Action of Cyanogen on Potassium **Amide.**—Cyanogen may be looked upon as the anammonide of oxalic acid. However, when a solution of cy-

to urea as an ammonocarbonic acid and to calcium cyanamide as a salt of ammonocyanic acid. Of course, we now speak of the first two compounds as aquo-ammono-acetic acids and of the latter two as an aquo-ammono-carbonic acid and a calcium ammono-carbonate, respectively. The term carboxazylic acid is now used to denote the mixed aquo-ammono-carboxylic acids of which acetamide is an example, since they represent compounds derived simultaneously from water and ammonia.

[4] Pinner, *Ber.*, 11, 6 (1878).

[5] Benedict, Master's "Thesis," Stanford University, 1924.

[6] Franklin, J. *Phys. Chem.*, 27, 168 (1923), has discussed in detail a number of reactions which have been interpreted in support of the view that hydrocyanic acid is a carbonous acid of the ammonia sytem.

anogen in liquid ammonia is treated with potassium amide, the potassium salt of ammono-oxalic acid is not formed. The products are potassium cyanide and potassium cyanamide, the potassium salts of ammonocarbonous and ammonocarbonic acids, respectively. Cyanogen thus behaves toward potassium amide as a mixed carbonous and carbonic anammonide, C=N—C≡N, rather than as an oxalic acid anammonide.

Action of Aquo Bases on Acid Anammonides.—We have seen that the nitriles react with metallic amides in liquid ammonia solution to give salts of carbazylic acids. It is reasonable to expect that they would also react with aquo bases in liquid ammonia solution to give salts of the carboxazylic acids. Potassium hydroxide does react, slowly at room temperature and fairly rapidly if heated to 100°, with benzonitrile and propionitrile in liquid ammonia solution to give potassium benzamide and potassium propionamide, respectively.

$$C_6H_5CN + KOH = C_6H_5C(NH)OK$$
$$C_2H_5CN + KOH = C_2H_5C(NH)OK$$

Ammonation of the Acid Anammonides in the Presence of Acid.—Benzonitrile and propionitrile, when heated in liquid ammonia solution containing ammonium chloride,[7] are ammonated to benzamidine and propionamidine, respectively, according to the equations

$$C_6H_5CN + NH_3 = C_6H_5C(NH)NH_2$$
$$C_2H_5CN + NH_3 = C_2H_5C(NH)NH_2$$

Attempts to ammonate hydrocyanic acid and cyanogen by heating them with ammonia and ammonium chloride failed, probably because of the polymerization which these substances undergo on heating.

Pyrogenetic Decomposition of Salts of the Carbazylic Acids.—It will be recalled that when an alkali salt of a carboxylic acid is heated with sodium hydroxide, there is produced a hydrocarbon containing one less carbon atom than the parent carboxylic acid and an alkali carbonate.

The analogous reaction has been found to take place with the salts of the carbazylic acids when heated with sodium or potassium amide, the reaction proceeding in the case of sodium ammonobenzoate, for example, as follows

$$C_6H_5C(NH)NHNa + NaNH_2 = C_6H_6 + Na_2NCN + NH_3$$

There are formed a hydrocarbon and sodium cyanamide, the salt of one of the ammonocarbonic acids. This again bears out the striking relationship between the carbazylic and carboxylic acids.

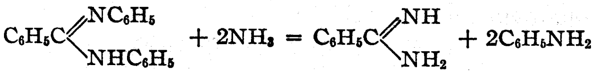
Esters of the Carbazylic Acids.—A large number of compounds are known which are related to the carbazylic acids just as ordinary esters are related to the carboxylic acids. These compounds are of the types $RC(NR)NH_2$, $RC(NR)NHR$, $RC(NH)NR_2$ and $RC(NR)NR_2$ and are

---

[7] Franklin and Kraus [*Am. Chem. J.*, 23, 305 (1900)] have shown that this substance exhibits acidic properties in liquid ammonia solution.

to be regarded as esters of the carbazylic acids. These esters can be prepared by reactions similar to those used in the preparation of aquo esters. For example, ethylbenzamidine, the ethyl ester of ammonobenzoic acid, has been prepared[8] by the action of ethyl iodide on benzamidine, the ammonobenzoic acid. This is analogous to the preparation of an aquo ester by the action of an alkyl halide on a carboxylic acid.

Ammonolysis of Esters of Carbazylic Acids.—Just as esters of the carboxylic acids can be hydrolyzed, so can the analogous process of ammonolysis be carried out with esters of the carbazylic acids. Niemann has ammonolyzed several of these esters. He has shown that diphenylbenzamidine, for instance, undergoes ammonolysis when heated in liquid ammonia solution in the presence of an acid, the products being the carbazylic acid, benzamidine and the ammono alcohol, aniline.



$$C_6H_5C\begin{cases}NC_6H_5\\NHC_6H_5\end{cases} + 2NH_3 = C_6H_5C\begin{cases}NH\\NH_2\end{cases} + 2C_6H_5NH_2$$

This reaction is exactly analogous to the hydrolysis of aquo esters.

Action of Ammonia on the Grignard Addition Product to a Nitrile.—The nitriles form addition products with the Grignard reagent, according to the equation

$$RCN + R'MgBr = RC(NMgBr)R'$$

Moureu and Mignonac[10] have shown that hydrolysis of the addition products at low temperatures gives rise to the ketimines, $R_2C{=}NH$. These compounds, generally speaking, are ammonia analogs of the ketones. However, they are either acids or alcohols at the same time, by virtue of the presence of a hydrogen atom in the imide group.

The writer has shown that ammonolysis of the addition products gives the same compounds.

$$(C_6H_5)_2C{=}NMgBr + NH_3 = (C_6H_5)_2C{=}NH + Mg(NH_2)Br$$

The reaction is analogous to the formation of ketones by the hydrolysis of the addition product of the Grignard reagent to the acid anhydrides.

Experimental

The preparation of nineteen salts of the carbazylic acids was carried out in Faraday tubes, following the manipulation developed in this Laboratory.[11] The reactions generally consisted in the action of a liquid ammonia solution of a metallic amide on a liquid ammonia solution of a nitrile, according to the equation

$$RCN + MNH_2 = RC(NH)NHM$$

---

[8] Pinner and Klein, *Ber.*, 11, 7 (1878).

[9] Niemann, Master's "Thesis," Stanford University, 1926.

[10] Moureu and Mignonac, *Compt. rend.*, 156, 1790 (1900).

[11] Franklin, THIS JOURNAL, 27, 831 (1905); 35, 1460 (1913); *J. Phys. Chem.*, *15*, 609 (1911); 16,694 (1912); Fitzgerald, *ibid.*, 29, 1694 (1907).

The salts described in the table, with four exceptions, were prepared according to this general equation. In the notes following the table is given a description of the methods used in the preparation of these four salts, as well as observations of interest on several of the other salts. The metallic amide was prepared in every case by the reaction of the metal with ammonia, a spiral of iron wire being used as a catalyst. The salt in each case was washed several times by distilling fresh solvent onto it and decanting the wash liquor. Final drying was accomplished at room temperature in a vacuum. All the soluble salts were obtained beautifully crystallized and, in general, of sharply definite composition.

TABLE I

SALTS OF CARBAZYLIC ACIDS

Name	Formula	Solubility[a]	Metal, % Calcd.	Metal, % Found	Nitrogen, % Calcd.	Nitrogen, % Found
Potassium ammonoacetate[b]	$CH_3C(NH)NHK$	ex. sol.	40.7	42.2	29.1	25.8
				42.0		24.8
Sodium ammonoacetate	$CH_3C(NH)NHNa$	ex. sol.	28.8	28.7	35.0	33.7
Potas. ammonopropionate	$C_2H_5C(NH)NHK$	m. sol.	35.5	35.4	25.4	24.9
Sodium ammonopropionate	$C_2H_5C(NH)NHNa$	m. sol.	24.5	24.3	29.7	27.9
Cal. ammonopropionate[c]	$[C_2H_5C(NH)NH]_2Ca$	insol.	21.9	25.9	..	..
Potas. ammono-n-butyrate	$C_3H_7C(NH)NHK$	m. sol.	31.5	31.7	22.6	21.9
Sodium ammono-n-butyrate	$C_3H_7C(NH)NHNa$	m. sol.	21.3	21.2	25.9	25.3

Sodium ammonobenzoate	$C_6H_5C(NH)NHNa$	m. sol.	16.2	16.7	19.8	20.0
Silver ammonobenzoate[e]	$C_6H_5C(NH)NHAg$	insol.	47.6	47.0	12.3	15.5
Calcium ammonobenzoate[c]	$[C_6H_5C(NH)NH]_2Ca$	insol.	14.4	17.4	..	..
Cupric ammonobenzoate[f]	$[C_6H_5C(NH)NH]_2Cu$	insol.	21.1	23.5	18.6	15.2
Cuprous ammonobenzoate[g]	$C_6H_5C(NH)NHCu$	insol.	34.9	34.5	15.3	13.4
Potas. ammono-*p*-toluate	$CH_3C_6H_4C(NH)NHK$	m. sol.	22.7	22.0	16.3	16.2
Sod. dibenzenylimidoimide[h]	$(C_6H_5C{=}NH)_2NNa$	m. sol.	9.4	9.2	17.1	17.0

[a] Rough estimates of solubilities at room temperature are indicated: ex. sol. = extremely soluble; v. sol. = very soluble; m. sol. = moderately soluble; insol. = insoluble or very slightly soluble,

[b] This salt is extremely soluble and could be washed but once. The high analytical values are due to the presence of potassium amide in the sample.

[c] The high values for calcium on this salt and on calcium ammonobenzoate are explained on the basis of the presence of some unchanged calcium amide in the samples. Since both the calcium amide and the salt are insoluble, the reaction is slow and incomplete, even though the nitrile solutions are allowed to stand in contact with the calcium amide for some time.

[d] Benedict, Master's "Thesis," Stanford University, **1924,** first prepared this salt by the action of potassium amide on benzamidine and also upon benzonitrile. Pound: K, **23.9;** N, **18.1.** An attempt was made to prepare the dipotassium salt

by using an excess of two equivalents of potassium amide. The salt was found on analysis to be the monopotassium derivative. Found: K, 24.5; N, 17.6.

[e] Silver amide does not dissolve in either benzamidine or benzonitrile solution. This salt was prepared by the action of silver nitrate on potassium ammonobenzoate, according to the equation $C_6H_5C(NH)NHK + AgNO_3 = C_6H_5C(NH)NHAg + KNO_3$.

[f] The cupric salt was prepared by the action of a solution of $Cu(NO_3)_2 \cdot 4NH_3$ on potassium ammonobenzoate, $2C_6H_5C(NH)NHK + Cu(NO_3)_2 = [C_6H_5C(NH)NH]_2Cu + 2KNO_3$. The analysis of this salt indicates that it is contaminated with some of the cuprous salt.

[g] A quantity of the cupric salt contained in the wash leg of the tube was found to change gradually from a green to a white color. The analysis of this white salt showed it to be cuprous ammonobenzoate. The change from cupric to cuprous condition has also been noted in the case of cupric amide, Fitzgerald, THIS JOURNAL, 29, 657 (1907); Franklin, *ibid.*, 34, 1501 (1912).

[h] Benzonitrile is formed by the loss of a molecule of ammonia from benzamidine. It is possible for two molecules of benzamidine to lose a molecule of ammonia between them. The resulting compound would still be an ammonobenzoic acid. Pinner, *Ber.*, 11, 8 (1878), describes such a compound, dibenzenylimido-imide, $[C_6H_5C(NH)]_2NH$. Sodium amide reacts with this acid to give a salt. An attempt was made to prepare the potassium salt. Because of its high solubility, however, a sample sufficiently pure for analysis was not obtained.

Action of Potassium Amide on Hydrocyanic Acid.—A quantity of hydrocyanic acid, 0.52 g., was obtained in the following manner. A solution of equimolecular quantities of ammonium chloride and sodium cyanide contained in one leg of a reaction tube was evaporated to dryness. The resulting residue was heated to 40° while keeping the empty leg in a bath of liquid ammonia. Ammonium cyanide sublimed over, leaving the sodium chloride as a residue. The leg containing the residue was opened, the residue removed and 0.72 g. of potassium introduced Addition of potassium amide solution to the hydrocyanic acid solution caused the immediate formation of a crop of white crystals of potassium cyanide. Calculated for KCN: K, 60.0. Found: K, 60.8.

Action of Potassium Amide on Cyanogen.—A quantity of cyanogen was liquefied in one leg of a reaction tube. The addition of the potassium amide from 0.80 g. of potassium contained in the other leg produced a heavy white amorphous precipitate of potassium cyanide and potassium cyanamide. The presence of cyanide and cyanamide was demonstrated by the usual qualitative tests. The equation is $C_2N_2 + 3KNH_2 = K_2NCN + KCN + 2NH_3$.

Action of Potassium Hydroxide on Benzonitrile and Propionitrile.—In a straight tube, sealed at one end, were placed 1.31 g. of benzonitrile and 0.71 g. of potassium hydroxide which had been freshly fused and heated to redness to remove traces of water. Ammonia was distilled into the tube until it was about one-third full and the open end sealed off. The tube was heated for sixteen hours at 175°, following the procedure as described by Blair.[12] The solution, after cooling, deposited white flaky crystals of potassium benzamide. Calcd. for C_6H_5CONHK: K, 24.5. Found: K, 21.6.

In a similar manner, 1.39 g. of propionitrile and 1.40 g. of potssaium hydroxide were heated for twenty-four hours at 200°. The solution, upon cooling, contained a quantity of light, flaky crystals of potassium propionamide. Calcd. for C_2H_5CONHK: K, 35.2. Found: K, 35.8.

In both cases, the major portion of the hydroxide and nitrile remained unchanged after heating.

---

[12] Blair, THIS JOURNAL, 48, 91 (1926).

Ammonation of Benzonitrile and Propionitrile.—A solution of 2.45 g. of benzonitrile and 1.32 g. of ammonium chloride was heated for sixteen hours at 200° in the same manner as stated above. The residue, after evaporation of the ammonia and drying in vacuum, was extracted with absolute alcohol. The alcohol solution contained a small quantity of benzamidine, which was identified by forming its insoluble picric acid salt, melting at 225°.

A solution of 1.89 g. of propionitrile and 1.85 g. of ammonium chloride was heated for twenty-four hours at 200°. The residue after evaporation of the ammonia was dried in a vacuum and extracted with absolute alcohol. The alcohol solution was found to contain a small quantity of propionamidine, which was identified through the formation of a double salt with platinic chloride.

Pyrogenetic Decomposition of Salts of Carbazylic Acids.—The potassium salts of ammonobenzoic acid, ammono-*iso*caproic acid, ammono-*n*-valeric acid, ammono-n-butyric acid, ammonopropionic acid and ammono-acetic acid were heated with potassium amide. In the case of the first three, a quantity of a volatile liquid was obtained upon which the molecular weights were determined by the Victor Meyer method. Values of 80.3, 73.3 and 63.4, respectively, were obtained, which correspond fairly closely to benzene, pentane and butane. The hydrocarbons produced by the decomposition of the last three salts, propane, ethane and methane, respectively, had such low boiling points that they could not be condensed readily. It is significant that a combustible gas was produced in each case.

However, in every case the presence of cyanamide in relatively large quantity was demonstrated by the formation of the characteristic yellow precipitate of silver cyanamide on addition of silver nitrate to an ammoniacal solution of the residue. The same reaction takes place when benzonitrile and sodium amide are heated together, benzene and sodium cyanamide being produced according to the equation $C_6H_5CN + 2NaNH_2 = C_6H_6 + Na_2NCN + NH_3$. Experimentally this was realized by sealing up equimolecular quantities of benzonitrile and sodium amide in straight tubes and heating for two hours at 250°.

Preparation of Benzamidine from Potassium Ammonobenzoate.—Benzamidine has been prepared from its potassium salt by treatment in alcohol solution with hydrogen chloride, $C_6H_5C(NH)NHK + 2HCl = C_6H_5C(NH)NH_2\cdot HCl + KCl$.

Potassium ammonobenzoate was prepared from 1.00 g. of benzonitrile and 0.30 g. of potassium in the usual way. The ammonia was allowed to evaporate, the salt was dried in a vacuum at room temperature and the dry salt then treated with absolute alcohol saturated with dry hydrogen chloride. The precipitate of potassium chloride was filtered off. Evaporation of the alcohol yielded 1.35 g. of a white solid This was shown to be benzamidine hydrochloride by its melting point. The yield obtained is 89% of the theoretical.

It was possible also to obtain benzamidine from potassium ammonobenzoate by carefully hydrolyzing this salt. However, the yield was always poor since the hydrolysis proceeds further than with the formation of benzamidine; potassium benzamide and ultimately potassium benzoate are formed.

Action of Ammonia on the Grignard Reagent Addition Product to Benzonitrile.—A quantity of the addition product of phenylmagnesium bromide to benzonitrile was placed in a reaction tube and, after sealing, ammonia was distilled in. The solid was extracted repeatedly with ammonia and the ammonia was then allowed to evaporate completely. There remained in the leg containing the washings a light brown oil. This oil was dissolved in ether and the solution saturated with dry hydrogen chloride. The white crystalline precipitate which formed was filtered off, washed once with ether and recrystallized from chloroform and ether. The analysis showed the compound to

be diphenyl ketimine hydrochloride. Calcd. for $C_{13}H_{12}NCl$: N, 6.4; Cl, 16.3. Found: N, 6.6; Cl, 18.2.

In conclusion, the writer wishes to express his appreciation to Dr. Franklin, under whose kind guidance the work presented here has been carried out.

Summary

1. It is shown in this paper that the amidines are to be regarded as the ammonia analogs of the carboxylic acids. The term carbazylic acid has been used to denote these acids.
2. The alkyl and aryl cyanides have been shown to be the anammonides of the carbazylic acids.
3. The preparation of a number of salts of the different carbazylic acids has been described.
4. The ammonation of the acid anammonides in the presence of an acid has been demonstrated.
5. The decomposition of the salts of the carbazylic acids, when heated with a metallic amide, proceeds with the formation of a hydrocarbon and an alkali salt of cyanamide.
6. The difference in behavior of hydrocyanic acid and cyanogen from that of other nitriles toward potassium amide in liquid ammonia solution has been noted and an explanation offered.

THE MOLECULAR WEIGHTS OF SERUM ALBUMIN AND OF SERUM GLOBULIN

BY THE SVEDBERG AND BERTIL SJÖGREN

RECEIVED JUNE 28, 1928 PUBLISHED DECEMBER 10, 1928

The two chief protein constituents of blood serum are serum albumin and serum globulin. Crystallized serum albumin was obtained as early as 1894,[1] while serum globulin crystals have not as yet been observed. The fact that serum albumin is easily crystallized has been taken as an indication of its homogeneity. Recently, however, the validity of this conclusion has been questioned by Sörensen,[2] who found that by fractional crystallization a series of protein samples with different solubilities could be obtained from serum albumin. The osmotic pressures of the various fractions were, however, the same. The question as to whether serum globulin is a simple protein or a mixture has been the object of much experi-

---

[1] A. Gürber, *Würzburger Physiol.-med. Ges.*, 1894, 113; 1895, 26.

[2] S. P. L. Sörensen, "Proteins," The Fleischmann Company, New York, 1925, p. 40.

mental work and discussion. By the fractional precipitation of serum globulin it is possible to obtain protein samples differing in solubility and in chemical composition, the so-called euglobulins and pseudoglobulins; this fact has been taken as a proof of the complex nature of serum globulin.[3] Sörensen found somewhat higher osmotic pressures for the pseudoglobulin fractions than for the euglobulin fractions[4] and so did Adair.[5]

The molecular weights of serum albumin and of the serum globulin fractions have been calculated by Sörensen and by Adair from their osmotic pressure measurements. Sorensen gives 45,000 and Adair 62,000 for serum albumin. Sörensen's globulin fractions gave values from 140,000 (euglobulins) to 80,000 (pseudoglobuliis), while Adair found for euglobulin 174,000 and for pseudoglobulin fractions 150,000–130,000.

Cohn has made an attempt to estimate the molecular weights of these proteins from analytical data.[6] For serum albumin he arrives at the value 45,000, and for serum globulin he finds 27,000 as the minimal molecular weight, which value he multiplies by three in order to obtain a molecular weight of 81,000 in agreement with Sörensen's osmotic pressure determinations.

In view of the uncertainty involved in many of the analytical data used by Cohn in his calculations and the numerous and uncontrollable sources of error in osmotic measurements, it was thought advisable to undertake an investigation of the molecular weights of these important proteins by means of the centrifugal methods already used in this Laboratory for the determination of the molecular weights of hemoglobin,[7] egg albumin,* phycocyan,[9] phycoerythrin[g] and hemocyanin.[10]

Experimental

The protein material used in this investigation was prepared from horse blood. All determinations were carried out in buffer solutions at the isoelectric point, namely, at *P*H 4.8 for serum albumin and at 5.5 for serum globulin, where the stability of the proteins is greatest and all effects due to the presence of protein ions are at a minimum. A study of the *P*H limits within which these proteins are stable will be carried out later.

Preparation of Material.—Serum albumin was prepared in the following manner.[11] Horse serum free from hemoglobin and containing toluene as a preservative was mixed with an equal volume of a saturated ammonium sulfate solution. After standing for one day at 5°, the globulin precipitate was centrifuged off. To the solution was added slowly 0.1 *N* sulfuric acid half saturated with ammonium sulfate until a permanent cloudiness appeared. Toluene was added and the mixture was left to crystallize at room temperature. After a period of three days, the crystals were filtered off and washed with a weak solution of ammonium sulfate. The serum albumin thus obtained was recrystallized three times and for eight days dialyzed in collodion bags against flowing distilled water saturated with toluene at 0°. In order to remove the last traces of globulin it was finally electrodialyzed in a Pauli apparatus[12] for thirty-six hours at a current density of 0.6 mil. amp. per sq. cm. The concentration of the stock solution made up from this material (called in the following serum albumin I) was 0.76%.

Measurements with the ultracentrifuge showed that the protein of the above solution had been partly split into some non-centrifugible substance. We therefore prepared a second batch of serum albumin, working as quickly as possible. Only one process of crystallization was performed. The dialysis was continued for four days only and the electrodialysis for three days. A stock solution containing 2.80% of organic substance in acetate buffer at P_H 4.8 (0.02 *N* with regard to acetate ion) was made up (serum albumin II). The centrifuging experiments showed that this solution was much less decomposed.

During the work done on proteins in this Laboratory we have often had the opportunity to observe that an elaborate process of purification furnishes a material less homogeneous with regard to molecular weight than does a cruder but quicker method. The preparation of serum albumin is a typical example of this phenomenon. We have the impression that the living organisms always contain proteins of well defined molecular weights, but that many of these proteins are so unstable that they are often decomposed during the process of separation and purification.

Serum globulin was prepared in the following way.[13] The precipitate obtained after half saturating the serum with ammonium sulfate was washed with half saturated ammonium sulfate solution and dissolved in 10% sodium chloride solution, using toluene as a preservative. The protein was again precipitated by half saturating with ammonium sulfate, washed and dissolved as before. This process was repeated a third time, the washing being continued until the biuret reaction was negative. The precipitate was dissolved again in 10% sodium chloride solution and dialyzed against a phosphate buffer of P_H 5.5, 0.19 M in KH_2PO_4 and 0.009 M in Na_2HPO_4. The strength of this solution (serum globulin I) was 2.60%.

A second batch was made in the following way. The material was precipitated three times with ammonium sulfate, washed and dissolved in phosphate buffer and dialyzed against the same phosphate buffer until the outer liquid did not show the presence of sulfate and chloride. The stock solution had a strength of 3.25% (serum globulin II).

part of the serum globulin material was fractionated according to Sörensen[14] by means of ammonium sulfate. The centrifugal study of the different fractions

[14] Ref. 2, p. 44.

showed that a rapid decomposition of the protein took place during the process of fractionation, more and more non-centrifugible material being formed.

Specific Volume.—The partial specific volume was determined pycnometrically at 19.5'. The amount of protein in solution was found by means of the following methods: (a) heating the solution until coagulation occurred, filtering and washing in a Gooch crucible and drying to constant weight at 105°; (b) drying at 105° to constant weight and subtracting the amount of salt in the sample as known from the composition of the buffer. The two methods gave consistent results.

No change of specific volume with concentration was observed for the range 0.75–3.0%. As mean value we obtained for serum albumin **0.748** and for serum globulin **0.745.** These figures are equal within the limits of experimental error. It is worth noticing that according to previous determinations in this Laboratory[7,8,9] the values for egg albumin, hemoglobin, phycocyan and phycoerythrin are almost identical with the value found for serum albumin and serum globulin. These six proteins are, therefore, probably built up according to a plan common to all of them. On the other hand hemocyanin from *Helix*[10] and from *Limulus*[15] have a specific volume of **0.735** near their isoelectric points.

Light Absorption.—Serum albumin as well as serum globulin absorb only in the short-waved ultraviolet part of the spectrum. The measurements were carried out by means of a Judd-Lewis spectrophotometer in 20 mm. cells for solutions of concentration **0.20, 0.10** and **0.05%.** The toluene dissolved in the solutions and serving as a preservative was removed by bubbling moist nitrogen through them before measuring the light absorption. The specific extinction coefficient $\epsilon/c = 1/d \log I_0/I$, where c is the concentration in %, I_0 the intensity of the light beam after passing a layer of solvent d cm. thick and I the intensity after passing the same thickness of solution, is plotted against wave length in Fig. **1.** The absorption curve of serum albumin (A) has a maximum at **278** μμ and **a** minimum at 250 μμ; the corresponding values for serum globulin, curve (B), are **285** μμ and **255** μμ. The positions of the maxima and minima are identical within the limits of error. The values of the extinction coefficients are, however, much higher for serum globulin than for serum albumin. This is probably due to the high tryptophane content of serum globulin compared with that of serum albumin.

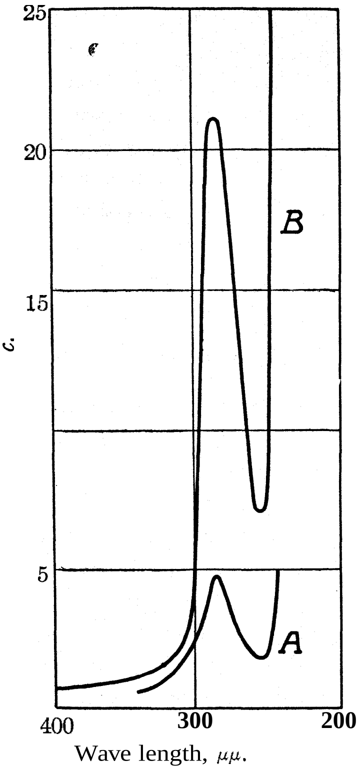

Fig. 1.

The centrifuging experiments have shown that in dilute solutions serum albumin is partly transformed into a non-centrifugible substance. In order to check the influence of this decomposition upon the light absorption some measurements were also made in a **2.80%** solution using a 1-mm. absorption cell. Only a slight decrease in light absorption was observed, indicating that the specific extinction coefficient is almost the same for serum albumin and the decomposition products in question.

Unpublished determinations by Dr. F. F. Hepoth.

Determination of the Molecular Weight

A. Sedimentation Velocity Method.[16]—Because of the more detailed information with regard to uniformity of molecular species and variation of diffusion and molecular weight with concentration which the sedimentation velocity method furnishes, this procedure was first applied.

The molecular weight is given by the relation

$$M = \frac{RTs}{D(1 - V\rho)}$$

where R is the gas constant, T the absolute temperature, s the specific sedimentation velocity or $1/\omega^2 x \cdot dx/dt$, D the diffusion constant, V the partial specific volume of the protein, ρ the density of the solvent, x the distance from the axis of rotation, ω the angular velocity and t the time.

The specific sedimentation velocity and the diffusion constant were calculated from the photographic records as described in previous papers. The values were all reduced to 20° by means of the relations $s_1/s_2 = \eta_2/\eta_1$ and $D_1/D_2 = T_1/T_2 \cdot \eta_2/\eta_1$, where η is the viscosity of the solution.

A few changes in the apparatus were made in order to improve the experimental conditions. Thus a new oil cooler was inserted in the oil circulation system so that the temperature of the oil entering the turbines could be lowered from 25 to 15°. This caused a drop of temperature in the cell from about 30 to about 25°. When working with such unstable proteins as serum albumin and serum globulin, it is of great importance to keep the temperature of the cell as low as possible. Cells of three different thicknesses were used, namely, 2, 6 and 12 mm., in order to obtain suitable light extinction for solutions of various concentrations. The middle or sector plate of the cells previously made of glass was replaced by an ebonite plate. The quartz plates were cemented to the ebonite plate and the steel collar surrounding the plates by means of a cement composed of 2 parts of shellac and 1 part of pine tar heated together at 125° for five hours. These new cells endured the enormous strain in the centrifuge much better than the old ones.

The height of column of solution in the cells was 12 to 14 mm. The speed was chosen as high as possible, namely, around 42,000 r.p.m. corresponding to a centrifugal force about 100,000 times the force of gravity. The protein solutions used in the centrifuging experiments were made up from the stock solution by dilution with buffer immediately before each run and the dissolved toluene was removed by bubbling moist nitrogen through it.

As source of light a vertical quartz mercury lamp with a ground quartz plate as a diffuser was used. Chlorine and bromine quartz filters isolated a suitable range of wave length below 290 μμ, and a quartz water filter re-

155	299.0	.120	14.19 X 10^{-7}

Mixture of different molecules; 43% non-centrifugible substance.

[a] "Mean z" is the mean of the distances from $c = 25$ to $c = 50$ and from $c = 50$ to $c = 75$, the concentration in the unchanged part of the solution being taken as 100 (compare THIS JOURNAL, 49, 2922 (1927)).

The data of a run with the material "serum albumin I" are given in Table I. The distinct drift in the values of the diffusion constant with time indicates the presence of molecules or particles of various sizes. Pure buffer was not formed in the top part of the cell during centrifuging as usual. The light absorption indicated that about 43% of the organic matter was not centrifugible under the present experimental conditions. The material "serum albumin I," therefore, does not represent a pure protein but rather a mixture of molecules of different weight, some of them being so small that they were not influenced by the enormous centrifugal field applied.

In Tables II and III are given the results of two typical runs with the material "serum albumin II." In this case there is no drift in the diffusion constant with time. Pure buffer was formed in the top part of the cell when solutions of concentrations 1.25 to 0.75% were centrifuged. In more dilute solutions (0.50 and 0.25%), however, pure buffer was not formed. The concentration of the non-centrifugible substance increased with the dilution. The fact that there is no drift in the diffusion constant shows that the material "serum albumin II" contains protein molecules of the same weight and shape. The serum albumin is therefore to be regarded as homogeneous with regard to molecular weight. The determinations also show that in dilute solution the serum albumin molecule breaks up into small units. The molecular weight of the centrifugible

part was found to be the same in concentrated solutions where no decomposition had taken place as in the very dilute (0.25%) solutions where

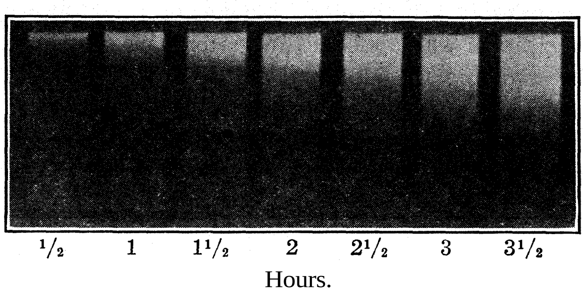

Fig. 2.

about 29% of the protein was decomposed. This shows that the decomposition leads immediately to very small molecules without giving rise to any appreciable amount of intermediate products. The behavior of the material "serum albumin I" indicates that the elaborate purification used in that case has caused a rather complicated decomposition and aggregation process to take place, the result being a less pure material than when a cruder and quicker purification method was used (Material II).

The photographs from which the data of Table II have been derived are reproduced in Fig. 2. The corre-

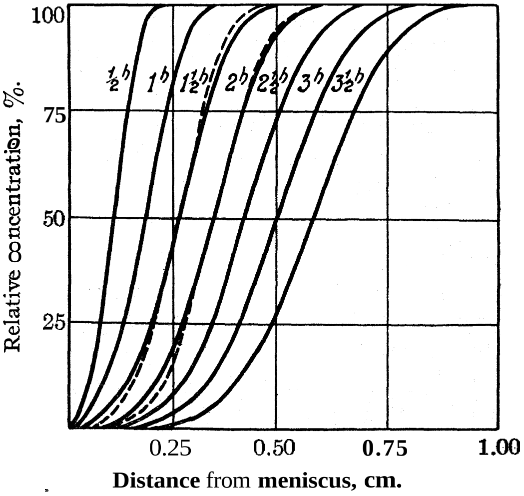

Fig. 3.

sponding concentration curves, corrected for the sector shape of the cell and the variation of centrifugal force with distance from the center of rotation,[16] are given in Fig. 3. The dotted curves for one and one-half and tow hours represent the theoretical diffusion curves of a substance of only one molecular species if subjected to the same experimental conditions. The deviation from the experimentally determined variation of concentration is within the limits of experimental error.

In order to ascertain whether the formation of the non-centrifugible substance in the dilute serum albumin solutions is a reversible or an irreversible process, the following experiment was performed. A 0.25% solution was precipitated by saturating with ammonium sulfate. A measurement of the light absorption of the liquid from which the precipitate had been filtered off showed that all the albumin and its decomposition products had really been completely salted out. The biuret reaction was also negative. The precipitate was dissolved in water, the solution was dialyzed and electrodialyzed and the albumin studied in the ultracentrifuge at a concentration of 1.1% in an acetate buffer of PH 4.8, as usual. The protein this time sedimented with normal molecular weight, leaving pure buffer in the top part of the cell, showing that the breaking up of the serum albumin in dilute solution is a reversible process.

	Mean	4.21×10^{-13} Mean	6.10×10^{-7} Mean	66,740

The results of all the sedimentation velocity runs with serum albumin are summarized in Table IV. The mean value of the molecular weight is 66,740 ± 2000.

In Tables V and VI are given the results of two typical runs with serum globulin (Material I and II, respectively). The photographs and the concentration curves corresponding to the data of Table V are reproduced in Figs. 4 and 5. No drift in the diffusion constant occurs and pure buffer is formed in the top part of the cell at all concentrations studied (1.00 to 0.12%). It is therefore obvious that serum globulin is a homogeneous substance with regard to molecular weight. The results of all sedimentation velocity runs with serum globulin are given in Table VII. The mean value of the molecular weight is 104,400 ± 3000.

As already mentioned under "Preparation of Material" an attempt was

made to study the "euglobulins" and "pseudoglobulins" obtained by fractionating serum globulin with ammonium sulfate. It was found, however, that the process of fractionation causes decomposition of the globulin, more and more non-centrifugible substance appearing during the course of the operations. From our experiences, therefore, it seems possible that the so-called pseudoglobulins are just artificial products representing mixtures of undecomposed serum globulin and decomposition products generated by the fractionating process. This important question will be dealt with fully in a subsequent communication.

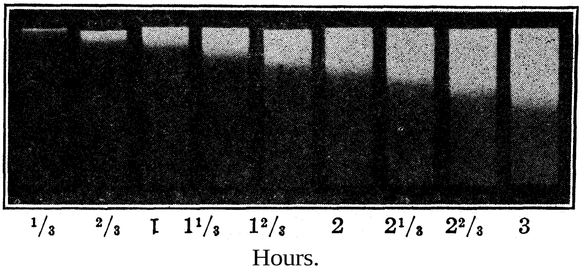

Fig. 4.

B. Sedimentation **Equilibrium Method.**[7a,8,17]—The molecular weight is given by the relation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\, \omega^2(x_2^2 - x_1^2)}$$

c_1 and c_2 are the concentrations at the distances x_1 and x_2 from the center of rotation and the other symbols have the same significance as previously.

Because of the decomposition of serum albumin observed in the sedimentation velocity experiments, this protein was only studied in relatively high concentration using a 2 mm. cell. On the other hand, serum globulin, which was found to be stable also in dilute solution, was investigated at lower concentrations by means of a cell 8 mm. in thickness.

The source of light, the light filters and the lens were similar to those used in the sedimentation velocity runs. The same plates and the same developer were used. Pictures were taken with three different times of exposure in order to obtain suitable photographic densities for the various concentrations. Changes in the intensity of the lamp were corrected for by having another cell of the centrifuge filled with a solution of potassium chromate of suitable strength and photographing this cell at the same time as the cell filled with the protein solution.

4.38	4.33	.104	.093	2	97,900
				Mean	103.400

Details of a run with serum albumin (Material II) are given in Table VIII. A typical serum globulin run is shown in Table IX (Material II). The results of all the sedimentation equilibrium runs are summarized in Table X.

TABLE X

SUMMARY OF SEDIMENTATION EQUILIBRIUM MEASUREMENTS

Subs.	Concn. at start, %	Mean speed, r.p.m.	Mol. wt.
Serum albumin II	0.92	8540	67,900
Serum albumin II	1.00	8200	68,400
Serum globulin I	0.10	7000	102,900
Serum globulin I	.15	6900	103,100
Serum globulin II	.15	6920	103,400
	Mean for serum albumin		68,150
	Mean for serum globulin		103,100

The values of the molecular weight calculated from measurements at different distances from the center of rotation were identical within the limits of error as demonstrated by Tables VIII and IX. The study of serum albumin and serum globulin by means of the sedimentation equilibrium method, therefore, confirms the result arrived at by means of the sedimentation velocity method, namely, that these proteins are to be regarded as homogeneous with regard to molecular weight. The mean value of the molecular weight found by the equilibrium method is 68,150 ± 2000 for serum albumin and 103,100 ± 3000 for serum globulin. These figures are identical within the limits of error with those furnished by the velocity method.

Discussion of Results

The measurements described in this paper have shown that serum albumin and serum globulin isolated from horse blood by means of a rapid process of purification must be regarded as two proteins homogeneous with regard to molecular weight. The value for serum albumin is 67,500 ± 2000 and that for serum globulin 103,800 ± 3000. This is rather surprising when compared with the results of earlier investigations of these proteins. As already mentioned, Sorensen found that serum albumin could be divided into a series of fractions possessing widely different solubilities.[2] His figure for the molecular weight calculated from osmotic measurements was 45,000, which is about 33% lower than our value. The fact brought to light by our experiments that serum albumin is a very unstable protein easily decomposed during the process of purification and always partly decomposed in dilute solutions seems to indicate that the discrepancy might be explained by assuming that Sorensen's carefully purified albumin had undergone partial decomposition. An abnormally high osmotic pressure would probably have been the result of such a change. Adair's serum albumin, which showed an osmotic pressure corresponding to a molecular weight of 62,000, seems to have been less decomposed. The different solubilities found by Sorensen in his different serum albumin fractions could be interpreted by assuming that serum albumin, although homogeneous with regard to molecular weight, is a mixture of two or more proteins of different chemical properties. The simplest explanation, however, seems to be that the differences in solubility are caused by the presence in the fractions of varying amounts of decomposition or aggregation products.

The fact that serum globulin was found to be homogeneous with regard to molecular weight is perhaps still more surprising than the behavior of serum albumin. Most of the previous work on this protein seemed to indicate that serum globulin was to be regarded as a rather complicated mixture of euglobulins and pseudoglobulins. Our fractionation experiments controlled by measurements in the ultracentrifuge, although only of a preliminary nature, have shown, however, that this protein also is liable to break up during the usual process of fractionation. It seems, therefore, probable that the so-called euglobulins and pseudoglobulins do not exist in the blood but are to be regarded as artificial products.

In a previous communication attention was drawn to the fact that the molecular weights of hemoglobin, phycocyan and phycoerythrin as determined by the centrifugal methods were all very nearly simple multiples of the molecular weight of egg albumin.[9] It is of considerable interest to note that the molecular weight of serum albumin is now found to be almost exactly two times the molecular weight of egg albumin, while the molecular weight of serum globulin is three times the weight of egg albumin. Thus we now have six proteins of widely different origin obeying this rule of simple multiples. Perhaps of equal importance is the information that there exist proteins possessing widely different chemical and physical properties but having approximately the same molecular weight. We now know two such pairs, hemoglobin and serum albumin on the one hand and phycocyan and serum globulin on the other. The detailed discussion of these regularities will be reserved for a subsequent communication.

Summary

1. The centrifugal sedimentation velocity and sedimentation equilibrium methods have been applied to the study of the molecular weights of serum albumin and serum globulin in buffer solutions at their isoelectric points, using various protein concentrations.

2. The serum albumin was found to have a molecular weight of 67,500 ± 2000 and the serum globulin 103,800 ± 3000, both being independent of concentration.

3. It was found that within the limits of experimental error both these proteins are homogeneous with regard to molecular weight and that they therefore may represent pure chemical individuals.

4. It was found that both these proteins, but especially the serum albumin, are rather unstable substances easily decomposed during the process of purification. Serum albumin is always partly, although reversibly, decomposed in dilute solution. These facts seem to afford an explanation for the discrepancies between the results of various investigators working on the proteins of the serum.

5. It was pointed out that the molecular weights of serum albumin and serum globulin are, like the molecular weights of hemoglobin, phycocyan and phycoerythrin, very nearly simple multiples of that of egg albumin.

6. It was pointed out that these new molecular weight determinations show that there exist proteins of different chemical composition and widely different properties but possessing very nearly the same molecular weight. Hemoglobin and serum albumin with molecular weights near 68,000 and phycocyan and serum globulin with molecular weights near 105,000 are two such pairs.

THE ACTION OF PYRIDINE AS A CATALYST IN PERKIN'S SYNTHESIS OF CINNAMIC ACID

BY GEORGE BACHARACH AND FRANCIS BROGAN

RECEIVED JULY 16, 1928 PUBLISHED DECEMBER 10, 1928

Our search for a catalyst to enhance the velocity of the reaction in Perkin's synthesis of cinnamic acid led us to study the action of pyridine on the usual mixture of benzaldehyde, sodium acetate and acetic anhydride.

Twenty grams of freshly distilled benzaldehyde was mixed with 30 g. of redistilled acetic anhydride and 10 g. of anhydrous sodium acetate. To this, S drops of pyridine was added. The mixture was heated in a first experiment for four hours on an air-bath, a reflux condenser being used. After this, water was added (1200 cc.) and an excess of benzaldehyde distilled off by steam; 5 cc. of benzaldehyde was recovered. Concentrated hydrochloric acid was now added until the mass became acid to Congo Red. We were able then to observe a rapid precipitation of the cinnamic acid, which was filtered off by suction and dried. The yield was 18.8 g. or 67.1% of the theoretical. The acid needs no further purification, its melting point being 132'.

In a second experiment, conducted in the same way as before and using the same proportions, we continued the period of digestion for six hours and obtained 23.2 g. of cinnamic acid or 83% of the theoretical. The melting point was again 132°.

In a third experiment, the digestion was continued for a period of eight hours, everything else being equal. The result was a yield of 23.8 g. or 85% of the theoretical; melting point, 132.5'.

In each of these two latter experiments we naturally recovered a correspondingly lower amount of unchanged benzaldehyde. We have also performed experiments with a period of digestion of ten hours, but the yields were the same as in the eight-hour experiment. We can, therefore, consider the yield of the eight-hour experiment as the highest obtainable in this reaction. Furthermore, we have also conducted experiments with amounts of pyridine as large as 2 cc. but the results were the same as above.

It should be noted that the cinnamic acid thus obtained is pure and needs no further recrystallization with charcoal with its inevitable loss of material.

The following table shows a comparison of yields obtained with pyridine as a catalyst and those obtained without pyridine.[1]

The yields reported in the literature are usually given as between 15 and 20 g. with the proportions used in the above experiments, that is,

---

[1] These latter experiments were performed with the collaboration of Mr. P. Conroy.

TABLE I

COMPARISON OF YIELDS

Hours of digestion	Without pyridine Actual yield, g.	% of the theoretical	With pyridine Actual yield, g.	% of the theoretical
4	10.3	36.7	18.8	67.1
6	15.00	53.6	23.2	83
8	17.00	60.7	23.8	85

between 53.6 and 70% of the theoretical; furthermore, after a digestion period of eight hours, the yield is similar to the one obtained in four hours when pyridine is used. When the digestion is continued for eight hours in the experiment with pyridine, the yield becomes 85% of the theoretical and considering also that no charcoaling is necessary, we may say that we have here a decided improvement.

Summary

A substantially increased yield (up to 85%) of cinnamic acid in the Perkin synthesis has been produced by using pyridine as a catalyst at the rate of 8 drops for 20 g. of benzaldehyde, the time of reaction being eight hours. Additional pyridine and longer heating do not increase the yield. The product is obtained in very pure condition.

SOME SIDE REACTIONS IN THE PREPARATION OF ALKYLMAGNESIUM HALIDES

BY HENRY GILMAN AND ROBERT E. FOTHERGILL

RECEIVED JULY 20, 1928 PUBLISHED DECEMBER 10, 1928

Introduction

In connection with studies concerned with the analysis of gases evolved in Grignard reactions it is necessary to know the nature and extent of gas evolution *during the preparation* of several typical organomagnesium halides. The present paper discusses some results obtained in the preparation of methyl-, ethyl- and n-butylmagnesium halides.

It has long been known that in addition to the formation of RMgX compound in the reaction between RX compound and magnesium in ether, the following side reaction occurs

$$2RX + Mg \longrightarrow R{\cdot}R + MgX_2 \qquad (1)$$

Until recently this side reaction was supposed to increase markedly with the weight of the R-group and its greater branching (particularly with tertiary groups), so that with a hexyl or octyl group the extent of Reaction 1 equaled or exceeded the yield of RMgX compound.[1] Even in the

---

[1] Grignard, *Ann. chim. phys.*, [7] 24,433 (1901).

preparation of benzylmagnesium chloride the yield of dibenzyl has equaled 30%;[1] and in the reaction between allyl bromide and magnesium it has long been thought impossible to prepare allylmagnesium bromide because of the quantitative formation of di-allyl.[2] As a consequence, practically all reactions involving "allylmagnesium bromide" have been carried out in accordance with Barbier's original procedure: namely, allyl bromide and the other reactant have been added to magnesium in ether so that the allylmagnesium bromide is brought into reaction simultaneously with its formation.

However, studies in this Laboratory have shown that under suitable conditions excellent yields of Grignard reagents are generally obtainable,[3] and that Reaction 1 takes place to but a minor extent in most cases. In particular it has been possible to prepare *tert.*-butylmagnesium chloride in satisfactory yields (70%),[4] and to prepare allylmagnesium bromide directly and in excellent yields (over 90%).[2] There is little doubt but that the improved methods of Gilman and Zoellner[4] and Gilman and McGlumphy[2] will make it possible to obtain satisfactory yields with other RX compounds where the halogen is very highly active and, therefore, favorable to Reaction 1 at the expense of RMgX compound. Two such RX compounds are benzohydryl chloride, $(C_6H_5)_2CHCl$, and cinnamyl chloride.[5] The most recent[6] reaction between benzohydryl chloride and magnesium gave an extraordinarily large quantity of coupling product (Reaction 1), namely, 95.5% of tetraphenylethane.

The formation of R·R compound as illustrated in Reaction 1 has been variously interpreted. In addition to the usual Wiirtz–Fittig reaction, some have proposed Reaction 2

$$RMgX + RX \longrightarrow R{\cdot}R + MgX_2 \qquad (2)$$

Some splendid studies by Fuson[7] show that under certain conditions the coupling reaction is best interpreted as follows

$$2RX + 2R'MgX \longrightarrow R{\cdot}R + R'{\cdot}R' + 2MgX_2 \qquad (3)$$

In Fuson's articles there is a review of related work by Späth,[8] Gomberg

and Cone,[9] Schmidlin and Massini,[10] Schmidlin,[11] Gomberg and Kamm,[12] Binaghi and Oddo[13] and Binaghi.[14]

We are inclined to agree with Gomberg and Bachmann[15] that the R·R compound results, at least in part, as a consequence of the initial formation of free radicals.

$$2RX + Mg \longrightarrow 2R- + MgX_2 \qquad (4)$$
$$2R- \longrightarrow R{\cdot}R \qquad (5)$$
$$2R- \longrightarrow R(+H) + R(-H) \qquad (6)$$

The free radicals so formed may then combine with the magnesium halide (MgX) of Gomberg and Bachmann[15] to give the RMgX compound; or with itself to give the R·R compound according to Reaction 5; or it may disproportionate, and if it is an alkyl group the products of such disproportionation would be a saturated and an olefinic hydrocarbon. Admittedly there is no convincing experimental proof as yet for the preliminary formation of such free radicals.[16] We are nevertheless led to such an opinion, first, because of the formation of small quantities of di-*p*-tolyl in the preparation of benzylmagnesium chloride, and, second, because of the disproportionation evidenced by the evolution of saturated and olefinic hydrocarbons, see Reaction 6 in the preparation of alkylmagnesium halides. The formation of free radicals from the Grignard reagent in reactions of it after it has been prepared has been suggested by several.[8,17]

The side reactions leading to the formation of R·R, R(+H) and R(−H) are undoubtedly the chief reactions when the oxygen, carbon dioxide and moisture of the atmosphere are excluded. Some other side reactions that can take place to a minor extent when the Grignard reagent is prepared in an inert atmosphere like nitrogen or hydrogen are due to contaminations of the ether (dissolved oxygen and water, and peroxides[18]) and the

[18] Unless the ether is of an extreme degree of purity it contains small amounts of ether peroxide. See Gilman and Wood, THIS JOURNAL, 48,806 (1926), and Gilman and Adams, *ibid.*, **47**, 2816 (1925).

splitting[19] of the ether by the RMgX compound or by MgX_2 and MgX formed as by-products in the preparation of the Grignard reagent. We assume here that the RX compound and magnesium are pure.

The reactions already considered are not the only ones that take place, because minute quantities of hydrogen were detected in some preparations.

Related studies have been made by Jolibois,[20] Job, Reich and Dubien,[21] Chelinzev,[22] Chavanne and DeGraef,[23] Leroide,[24] Bouveault,[25] Madelung and Volker,[26] Grignard,[1] and Gilman and Zoellner.[4]

Experimental Part

The alkylmagnesium halides were prepared in the customary manner, essentially after the general procedure followed by Gilman and McCracken[3] in determining the yields of some typical Grignard reagents. The apparatus used in the experiments with 0.2 and 0.5 mole of reagents consisted of a 150-cc. wide-necked flask having a tight-fitting rubber stopper provided with a small dropping funnel, a 6-inch condenser and a mechanical stirrer with a mercury seal. The condenser outlet was connected, through a drying tube filled with calcium chloride, to a 2-liter eudiometer containing water. A small crystal of iodine was used as a catalyst in each experiment. The preparations were carried out in carefully dried apparatus and after the alkyl halide had been added the solution was refluxed for at least one hour to expel dissolved gases.

The gas evolved was analyzed by standard procedures. Diethyl ether vapor was removed by absorption in water; unsaturated gases were removed by bromine water followed by washing with 30% potassium hydroxide; carbon dioxide by 30% potassium hydroxide; oxygen by alkaline pyrogallate; hydrogen by palladium black at 100°; and the saturated hydrocarbons were analyzed by combustion with oxygen in an explosion pipet. Check analyses were obtained with aliquots from a given experiment. Some inherent errors in such gas analyses were minimized by uniformity of procedure and by corrections for dissolved gases. The quantities of gas obtained in the several runs were too small to permit of careful fractionation by the use of liquid air. In a few cases the volume of hydrogen measured was close to the experimental error. However, from Table I it is evident that the volume of hydrogen in other cases is unquestionably beyond any experimental error. The total gas collected was the volume obtained after the removal of ether and includes the air displaced by the gas. In order to have a basis for comparison with earlier studies, all yields are expressed as percentages of alkyl halide used.

Two Mole Experiments. **(a)** Methyl Iodide.—This large run was carried out in a

---

[19] Such splitting of diethyl ether takes place, if at all, to a negligible extent under ordinary conditions. However, methylmagnesium iodide will split di-n-butyl ether to an appreciable extent if, during its preparation, the solution is allowed to become too warm.

n-C_4H_9Br[e]	.2	α-Butylene	.308	.0	Butane	1.16	.....	...

[a] The methyl iodide was added rapidly in this experiment in order to increase the volume of evolved gas. However, the addition was so rapid that part of the methyl iodide was vaporized and collected in the eudiometer; 42% of unused magnesium was recovered. The total volume of gas collected was 535.1 cc., of which 7.24% was ethylene, 0.34% hydrogen, 36 5% methane and 18 93% ethane. The yields given in the table are based on the total quantity of methyl iodide used.

[b] In this experiment 130 cc. of di-n-butyl ether was used as the solvent and after the addition of halide over a thirty-minute period, the mixture was refluxed for one hour. The total gas collected was 561 cc., of which 19.03% was unsaturated, 38.7% was methane and 4.64% was ethane. The high yield of unsaturated gas is probably due to a splitting reaction of the butyl ether by methylmagnesium iodide. This finds confirmation in other studies on the Zerewitinoff analysis, where it has been shown that gases are evolved when the methylmagnesium iodide solution in butyl ether is heated to 140–150°. Ethylmagnesium bromide is stable at 175° in boiling cymene.

[c] In this experiment, 130 cc. of di-n-butyl ether was again used as the solvent. However, the reaction flask was cooled below 70° during the addition of methyl iodide and when all of the iodide had been added the reaction mixture was stirred at 70° for two hours. The total gas evolved was 269.1 cc. and the percentage of hydrogen determined in this case was too near the experimental error to warrant its serious consideration as one of the evolved gases.

[d] One hundred and thirty cc. of di-n-butyl ether was used as the solvent in this experiment and after adding the ethyl bromide the mixture was stirred and heated at 70° for 2.25 hours.

[e] In the analysis of the saturated hydrocarbons in the two *n*-butylmagnesium bromide experiments, the contraction after explosion of a sample was always slightly greater than that calculated for the quantity of butane present as based on the volume of carbon dioxide formed. This corresponds with values obtained by Fuson[7] in the analysis of ethane by the same method. If free radicals are formed (see Discussion of Results) then according to Taylor [*Proc.* Am. Phil. *Soc.*, 65, 90 (1926)] and Bates and Taylor [THIS JOURNAL, 49, 2439 (1927)] such free radicals may under some conditions add to the ethylenic compounds (see Ref. 16) to give hydrocarbons of higher molecular weight. It is apparent that such mixtures of higher hydrocarbons would affect the gas analysis. If disproportionation is the true explanation for the formation of R(+H) and R(— H) compounds, then the excess of R(+H) compound is to be expected in view of traces of moisture and ether peroxide[18] in the already carefully prepared ether.

by the formation of ethylene di-*p*-tolylsulfone prepared from sodium *p*-toluenesulfinate. A mixed melting-point determination with an authentic specimen showed no depresssion. Only a part of the gas evolved was collected and it had the following composition: **31.0%** methane, **12.1%** ethane, **0.417%** ethylene and **0.326%** hydrogen.

(b) *n*-Butyl Bromide.—The gases evolved in a 2-mole run were first passed into a dilute solution of bromine in carbon tetrachloride and almost all dissolved in this solution. From this solution there was obtained **1640** cc. of gas of which 65.13% was butane and **4.0** g. of α-butylene bromide, which agreed in b. p., density and refractive index with the compound reported in the literature.

Gases Evolved on the Hydrolysis of Methylmagnesium Iodide

The analysis of **409.6** cc. of gas evolved from the dil. sulfuric acid hydrolysis of an ether solution of methylmagnesium iodide showed 77.8% methane, **0.515%** ethylene and a negligible quantity (0.095%) of hydrogen. The analysis of **393.9** cc. of gas evolved from the hydrolysis of methylmagnesium iodide prepared in di-n-butyl ether showed **69.3%** methane, 2.6% ethylene and 0.285% hydrogen. The higher percentages of ethylene and hydrogen in the experiment where di-n-butyl ether was used as a solvent are probably due, in part, to the collection of the gases over water which had previously been saturated with ethylene and hydrogen. In the diethyl ether experiment, the gas was collected over fresh water.

The gas explosion values of the saturated hydrocarbons obtained in these two experiments did not entirely agree for methane. The combustions gave a greater contraction than that required for the methane present as based on the volume of carbon dioxide formed.

Discussion of Results

Entirely apart from the future consideration of the evolved gases on the possibility of the initial formation of free radicals and their disproportionation,[16] the results have a direct bearing on some problems concerned with the Grignard reagent. First, the extent of gas evolution accounts, in part, for the 90% and greater yields of most RMgX compounds.[2,3,27] Second, one of the five methods investigated by Gilman, Wilkinson, Fishel and Meyers[28] for the quantitative estimation of Grignard reagents was a gas analysis based on the following reaction

$$\text{RMgX} + \text{HOH} \longrightarrow \text{RH} + \text{Mg(OH)X} \qquad (7)$$

Ob iously, in any determinations carried out without refluxing the solution to expel dissolved gases before hydrolysis, the results of the gas analysis would be too high. Also, the gases evolved on hydrolysis (see Experimental Part) show that Reaction 1 is not the only one that takes place.

Third, the Zerewitinoff[29] method for the estimation of active hydrogen

---

[27] Gilman and Meyers, THIS JOURNAL, **45,159 (1923).**

[28] Gilman, Wilkinson, Fishel and Meyers, *ibid.*, **45,150 (1923);** Gilman and Meyers, Rec. trav. chim., **45, 314 (1926);** Job and Reich, *Bull. soc. chim.*, **33, 1414 (1923);** Job, Reich and Dubien, *ibid.*, **37,976 (1925).**

[29] In one of the most recent studies on this method, Kohler, Stone and Fuson [THIS JOURNAL, **49,** 3181 (1927)] have described an ingenious, workable and accurate method for determining simultaneously the amount of gas evolved and the amount of reagent consumed in reactions of methylmagnesium iodide.

is affected not only by the gases evolved during the preparation of the Grignard reagent but also by the gases evolved when a compound having an active hydrogen is treated with an RMgX compound. The danger of dissolved gases formed during the preparation of the Grignard reagent in solutions like amyl and butyl ether is slight if the customary procedure of heating to remove excess methyl iodide is followed, but active hydrogen determinations with diethyl ether as a solvent may introduce larger errors because of the low boiling point of this ether.[30] The gas measured in a Zerewitinoff analysis where methylmagnesium iodide, for example, is used may not be pure methane, for if the disproportionation of free radicals should be the true explanation for the formation of olefins on hydrolysis of RMgX compounds, then it is reasonable to assume that free radicals are formed transitorily in all decompositions with active hydrogen compounds.

Fourth, the mixture of gases obtained on the hydrolysis of Grignard reagents shows that this reaction cannot be used directly for the preparation of pure hydrocarbons and related derivatives. This, however, is not peculiar to this method for it is quite probable that no method of preparation of hydrocarbons will give pure compounds without some subsequent rectification. With the Grignard reaction, the extent of such impurities is not large.

Fifth, many reactions involving reduction by the Grignard reagent are accompanied by the evolution of olefins. Allowances should be made, therefore, for any olefins formed during the preparation of RMgX compounds or as a result of subsequent treatment with active hydrogen compounds.

The evolution of ethylene and hydrogen in the preparation of methylmagnesium iodide indicates that the methyl radical undergoes secondary reactions in a manner contrary to the predictions of some. Of course, it is possible that these gases may owe their formation to other reactions like that involving the direct removal of hydrogen iodide.

$$2CH_3I + 2Mg \longrightarrow CH_2{=}CH_2 + 2MgHI \qquad (8)$$

If this were the case, and if no disproportionation took place, one would expect equal volumes of ethylene and hydrogen. The nearest approach to this in the results so far obtained is in the 2-mole run with methylmagnesium iodide where the percentage of ethylene was 0.417, and that of hydrogen, 0.326. The hydrogen evolved on hydrolysis may be due to a reaction between magnesious bromide and water.

Both the nature of the gases and the extent of their formation appear to vary with the solvent.

---

[30] References to this method are contained in an article by **Gilman** and **Fothergiil,** THIS JOURNAL, 49,2815 (1927).

Summary

A study has been made of the gases formed during the preparation and in the hydrolysis of some alkylmagnesium halides. From the nature of these gases it appears that the free radicals that are probably formed prior to the formation of organomagnesium halides undergo disproportionation and coupling to varying degrees.

THE SYNTHESIS OF MESOXALATES BY INTERACTION OF NITROGEN TETROXIDE WITH ESTERS OF MALONIC ACID[1]

BY ELIZABETH GILMAN[2] AND TREAT B. JOHNSON

RECEIVED JULY 24, 1928 PUBLISHED DECEMBER 10, 1928

Only a few examples of organic compounds are known in which two hydroxyl groups appear to exist in stable union with a single carbon atom. What influence such linkages have on physiological activity is not well understood. Although the physiological action of chloral hydrate is not definitely linked with the property of hydrate formation, and while the effect of this drug is regarded as due to the organic radical containing chlorine, yet the prevalence of activity among hydrated constructions of the type which we are investigating (alloxan, for example) leads the writers to suppose that mesoxalates may be of pharmacological interest. As far as we have been able to ascertain, mesoxalates have never been investigated physiologically. They are admirably suited to intravenous injection. The diethyl ester is soluble in its own weight of water and it has been our experience that even the esters of higher molecular weight are surprisingly soluble in water. Diethyl mesoxalate is also a valuable reagent for synthetic work and any method that can be devised for preparing it more easily and cheaply will undoubtedly find important applications.

Bouveault and Wahl,[3] in 1903, provided the basis for the present method of preparing mesoxalates when they succeeded in obtaining diethyl mesoxalate from diethyl isonitrosomalonate by the action of oxides of nitrogen generated from sodium nitrate and nitrosyl-sulfuric acid. The principal oxide generated in this manner is nitrogen tetroxide (N_2O_4). They made their isonitrosomalonate from diethyl malonate in alcoholic sodium ethylate solution by interaction with methyl nitrite. Treatment with an ex-

[3] Bouveault and Wahl, Compt. rend., 137,196 (1903).

cess of nitrogen tetroxide at 0° then led to the formation of the mesoxalates, as expressed by the following equation

$$2ON\cdot CH(COOC_2H_5)_2 + N_2O_4 \longrightarrow OC(COOC_2H_5)_2 + O_2NCH(COOC_2H_5)_2$$

These same investigators later prepared ethyl diketobutyrate from ethyl acetoacetate by action of nitrous oxide (N_2O_3) in acetic anhydride solution and mention the fact that either N_2O_3 or N_2O_4 will give the desired ketone.[4] Schmidt[5] applied this latter procedure for the preparation of diethyl mesoxalate, and later Curtiss[6] utilized the Schmidt reaction, using no solvent, and reported a yield of 95% of the theoretical. Several investigators who have followed the directions of Curtiss for the preparation of diethyl mesoxalate have not been able to obtain the yield reported by him.[7] The latest work on this preparation is that of Dox,[8] who followed the Curtiss procedure with the exception that his nitrous oxide was dried over calcium chloride before being brought into reaction with diethyl malonate. He quotes yields of diethyl mesoxalate corresponding to 74–75% of the theoretical.

We are now able to report new data contributing to our knowledge of the methods applicable for the synthesis of mesoxalates. In the study of the reactivity of nitrogen tetroxide toward organic combinations, now in progress in this Laboratory,[9] we have investigated the action of this oxide on diethyl malonate and find that the reaction can be so well controlled as to be productive of a nearly quantitative yield of the mesoxalate. A detailed account of the technique of our modified method of preparation is given in the Experimental Part of this paper. Empirically this reaction may be represented as below, but it was our experience that an excess of the oxide is necessary in order to obtain a maximum yield of the mesoxalate.

$$N_2O_4 + CH_2(COOC_2H_5)_2 \longrightarrow OC(COOC_2H_5)_2 + H_2O + 2NO$$

In order to ascertain whether the reaction between nitrogen tetroxide and diethyl malonate is a general one and applicable to other esters of malonic acid we selected the following three representatives for further research: di-β-chloro-ethyl malonate, di-β-bromo-ethyl malonate and di-β-diethylamino-ethyl malonate. Of these only the chlorine compound has hitherto been described in the literature, and indeed our knowledge of any malonic ester derivatives of this type is very limited.

[9] In the development of a new synthetical method for the preparation of alkaloids of the ephedrine type, we have made a new application of the reactivity of N_2O_4 in preparing one of our intermediate products utilized in the process. This work will be described in a future publication (T. B. J.).

Theoretically these ester combinations would yield three new esters of mesoxalic acid of immediate pharmacological interest if found reactive toward nitrogen tetroxide in the same manner as diethyl malonate. This is particularly true of the amino ester $(C_2H_5)_2NCH_2CH_2OOCCH_2COOCH_2CH_2N(C_2H_5)_2$ and the corresponding mesoxalate, both of which contain part of the molecular structure functioning in the well-known local anesthetic, novocaine. In consequence of this structural relationship aliphatic combinations of this type should possess intrinsic interest pharmacologically.

When subjected to the action of nitrogen tetroxide these three malonic esters presented individual problems. Di-β-chloro-ethyl malonate behaved almost exactly like diethyl malonate and gave consistently a 90% yield of the corresponding mesoxalate. Di-β-bromo-ethyl malonate was more sluggish in its reactivity toward nitrogen tetroxide. This ester was likewise more unstable and could not be heated to its boiling point at atmospheric pressure without decomposition. Conditions were found, however, under which good yields of di-β-bromo-ethyl mesoxalate could be obtained. Di-p-diethylamino-ethyl malonate presented many difficulties when treated with nitrogen tetroxide, behaving individually when allowed to interact with the oxide, and thus far we have not succeeded in isolating the corresponding pure mesoxalate. The free ester and the hydrochloride react with the oxide giving unstable oils which cannot be purified by distillation. The free base decolorizes three equivalents of nitrogen tetroxide while the hydrochloride reacts with only one, so that the amino groups apparently do not interact when protected by hydrochloric acid. It seems probable that the insoluble and unstable oil obtained in the case of the hydrochloride represents an intermediate formed by interaction of nitrogen tetroxide with the methylene carbon atom.

Pharmacological Report

Pharmacological experiments of a preliminary nature have thus far been carried out on three of these compounds by Professor Henry G. Barbour of the University of Louisville, Louisville, Kentucky, and the effects thus far reported to us are recorded below.

Diethyl Mesoxalate.—This ester has no hypnotic action but shows marked stimulative effects on respiration and blood pressure which last about thirty and ten minutes, respectively, and can be repeated. It can be injected intravenously into dogs and the fatal dose for mice is 0.3 g. per kilo.

Di-β-chloro-ethyl Mesoxalate.—The same tendency to produce sympathetic stimulation of the circulation is shown by this chlorine derivative accompanied by other effects suggestive of choline or eserine, that is, salivation and tremors. It is far more toxic than the diethyl mesoxalate, and increases the percentage of blood sugar.

Di-β-diethylamino-ethyl Malonate.—This ester is especially interesting. It is much less toxic than the two preceding esters and has a very definite, long-continued effect on the total metabolism which is stimulating. Both heat and blood sugar outputs are very noticeably increased for quite an extended period of time. It has little effect on blood pressure and respiration and does not show marked anesthetic properties.

The series of compounds under investigation is unusually interesting from a physiological standpoint, and offers many possibilities for future research. The effects thus far recorded were entirely unexpected, but are exceedingly interesting and somewhat extraordinary.

Experimental Part

Preparation of Diethyl Mesoxalate by the Action of Nitrogen Tetroxide on Diethyl Malonate.—Nitrogen tetroxide was supplied for our research in a large bomb, and an all-glass apparatus was constructed for drying the gas over phosphorus pentoxide, condensing it at 0°, and weighing the condensate. No attempt was made to purify the gas from traces of nitrogen trioxide since either oxide produces the desired reaction. Units of about 25 g. of purified diethyl malonate were used for most of the experiments, cooled to 0°, and the calculated quantitities of nitrogen tetroxide added in the liquid state. All reagents were protected from moisture during the time of reaction. The yield was calculated in percentage of the theoretical weight of the crystalline hydrate of diethyl mesoxalate obtained, in accordance with the equation $N_2O_4 + CH_2(COOC_2H_5)_2 = 2NO + H_2O + CO(COOC_2H_5)_2$.

The reaction between nitrogen tetroxide and diethyl malonate was found to proceed slowly at low temperatures. Temperatures above the boiling point of nitrogen tetroxide did not prove beneficial, since much of the oxide was lost by evaporation, and a smaller amount of nitrogen tetroxide, if allowed to interact a longer time at low temperatures, accomplished quite as complete a reaction. Slightly more than the theoretical quantity of nitrogen tetroxide required by the above equation was found desirable, but no more than a quantity equal in weight to that of the malonic ester was used.

In applying reactions with nitrogen tetroxide, ether, acetic anhydride, and carbon tetrachloride were incorporated as solvents but the best results were obtained when the last solvent was used. It was found, however, that this was unnecessary and all solvents were finally abandoned except for the purpose of rinsing, when carbon tetrachloride was employed.

In one experiment phosphorus pentoxide was introduced into the reaction mixture in the hope that the presence of this dehydrating agent would facilitate the desired reaction. A most surprising result was obtained in the quantitative recovery of unaltered malonic ester. This result led us to search for an alkaline catalyst which could be introduced without producing side reactions, and metallic sodium was found to serve this purpose. A small piece of sodium introduced into a mixture of anhydrous malonic ester and liquid nitrogen tetroxide at 0° appeared to undergo no reaction, and when withdrawn at the end of three hours had suffered practically no loss in weight. At the end of the reaction period, the precaution was taken of pouring the reaction mixture upon phosphorus pentoxide in order to insure removal of any trace of alkali. The use of sodium was found to increase the yield of mesoxalate quite appreciably and our adopted procedure for preparing the mesoxalate was as follows.

Twenty-five grams of diethyl malonate was mixed with an equal weight of liquid nitrogen tetroxide at $-5°$ and a freshly cut piece of sodium weighing one gram was introduced. The mixture was maintained at $-5°$ for three hours with frequent shaking and protecting, as usual, from moisture by a calcium chloride tube. The sodium, apparently, did not enter into reaction and when removed at the end of three hours still weighed one gram. The reaction mixture was allowed to stand for two days at room temperature and was then poured into a flask containing phosphorus pentoxide and heated gently to the boiling point of the carbon tetrachloride which had been added as rinsings. It was then decanted into a Claisen flask, the pentoxide residue well rinsed with carbon tetrachloride and the rinsings added to the main lot. Heat was applied at ordinary pressure, when the decomposition of the oil took place in steps. The main distillate boiled almost entirely between 103 and 105° at 19 mm. representing 85% of the theoretical amount of anhydrous mesoxalate expected. The calculated amount of water converted it quantitatively into its crystalline hydrate. The residue in the distilling flask contained crystals of the hydrated mesoxalate and no indication of any other reaction product was observed. The hydrate when recrystallized from chloroform melted at 57". The total yield, including the mesoxalate isolated from both residue and water distillate, was 90% of the theoretical.

The nature of the gas evolved in the above reaction was also studied. During the first two hours of reaction at 30° all of the gas evolved was collected over a 10% solution of alkali, all the air in the system having been previously displaced by carbon dioxide. No brown color developed as usual over the solution and 600 cc. of a colorless gas was collected which was very soluble in ferrous sulfate solution and produced brown fumes when exposed to air. Thus, during the first stages of the reaction, the principal gas evolved was nitric oxide.

Preparation of Some Substituted Ethyl Malonates

Di-β-chloro-ethyl Malonate, $CH_2(COOCH_2CH_2Cl)_2$.—This ester has been prepared according to another method by George Bennett,[10] and its boiling point is given as 164° at 15 mm. We prepared it by esterifying malonic acid with ethylene chlorohydrin, using hydrogen chloride as a catalyst. Two hundred grams of ethylene chlorohydrin was added to 50 g. of diethyl malonate and 50 g. of sodium sulfate (anhydrous). Dry hydrogen chloride was passed into the suspension to saturation and the

---

[10] G. M. Bennett, *J. Chem. Soc.,* **127**, 1277 (1925).

mixture heated at 60° for three hours. It was then cooled, filtered, and excess of hydrochloric acid and ethylene chlorohydrin removed by heating under diminished pressure. The heavy oil remaining behind was washed with sodium bicarbonate solution until neutral and finally with pure water. After drying over anhydrous sodium sulfate it was distilled at 24 mm. and 90 g. of a colorless oil boiling at 178–182° was obtained. This represented a yield of **82%** of the theoretical. On redistillation the oil had a boiling point of 143–144° at 4 mm. The ester is a heavy oil, insoluble in water and soluble in the ordinary organic solvents.

Anal. Calcd. for $C_7H_{10}O_4Cl_2$: Cl, 30.96. Found: Cl, 30.90.

Di-p-bromo-ethyl Malonate, $CH_2(COOCH_2CH_2Br)_2$.—This ester was prepared in a manner exactly analogous to the procedure used for the di-β-chloro ester, using ethylene bromohydrin and malonic acid. The yield of crude di-β-bromo-ethyl malonate was 84% of the theoretical, but it was found to contain considerable quantities of ethylene bromohydrin, which is insoluble in water and cannot be removed by washing with water as in the case of the chloro ester. The pure ester was obtained by fractional distillation as a heavy, colorless oil boiling at 153° at 1 mm. It decomposes if low pressures are not employed in its distillation and tends to turn dark on standing for long periods. It is soluble in all organic solvents, especially carbon tetrachloride and chloroform, and is very insoluble in water.

Anal. Calcd. for $C_7H_{10}O_4Br_2$: Br, 50.28. Found: Br, 49.7.

Di-p-diethylamino-ethyl Malonate, $CH_2(COOCH_2CH_2N(C_2H_5)_2)_2$.—We first attempted to prepare this ester by the action of diethylamine on di-β-chloro-ethyl malonate. Experiments were conducted at atmospheric pressure under a reflux, in bomb tubes at 110°, and also at room temperature under pressure, but in all cases the reaction was incomplete and none of the desired ester was obtained.

The procedure applied successfully for the preparation of this ester was the reaction of malonyl chloride on diethylamino-ethyl alcohol, and we operated as follows.

Forty-eight grams of β-diethylamino-ethyl alcohol was dissolved in 500 cc. of dry chloroform and hydrogen chloride gas passed into the solution until it was just acid to methyl red. After cooling, 28 g. of malonyl chloride dissolved in an equal volume of chloroform was added slowly through a dropping funnel. The reaction mixture was refluxed for three hours. Dry potassium carbonate was then added to the boiling mixture until it showed a neutral reaction, when it was filtered. The excess of chloroform was distilled off and on cooling the solution became solid with crystalline material. Purification was accomplished by trituration with acetone, when 55 g. of the reaction product was obtained, melting between 120 and 140° with decomposition. Two recrystallizations from absolute alcohol and acetone yielded 25 g. of a pink powder melting at 152–154° with decomposition. This was identified as the hydrochloride of the desired ester.

The free base, $CH_2(COOCH_2CH_2N(C_2H_5)_2)_2$, was prepared from its hydrochloride by digesting the salt in anhydrous chloroform with dry sodium bicarbonate and sodium sulfate. Ten grams of di-0-diethylamino-ethyl malonate dihydrochloride (m. p. 153–154°) was dissolved in chloroform, an excess of sodium bicarbonate and sodium sulfate added and the mixture refluxed for ten to fifteen minutes. After standing for two days, it was filtered and the chloroform distilled off, giving an orange oil with a pungent odor. This was dissolved in anhydrous ether, filtered to free it from traces of hydrochloride and the oil distilled under diminished pressure. The product distilled at 163° (4.5 mm.). and yielded quantitatively the original hydrochloride when treated with hydrogen chloride gas. The ester is soluble in all common organic solvents and also appears to be completely soluble in water, producing a strongly basic solution.

The dihydrochloride of di-β-diethylamino-ethyl malonate is a colorless powder soluble in alcohol and chloroform, insoluble in ether, and very difficultly soluble in acetone. It deposits in opaque clusters from absolute alcohol and will dissolve in its own weight of this solvent at the boiling point. It is extremely soluble in water, producing a neutral solution, and the amino ester cannot be recovered from water by adding alkali and extracting the free base without considerable hydrolysis. It takes up water whenever exposed to moist air for any considerable length of time. When pure it melts at 154° with decomposition.

Anal. Calcd. for $C_{15}H_{32}O_4N_2Cl_2$: Cl, 18.9; N, 7.47. Found: Cl, 18.93; N, 7.72.

Action of Nitrogen Tetroxide on the above Malonates

Preparation of **Di-β-chloro-ethyl** Mesoxalate, $CO(COOCH_2CH_2Cl)_2$.—Thirty grams of di-β-chloro-ethyl malonate was mixed with 44 g. of liquid nitrogen tetroxide at −5° and a small piece of sodium added. After removing the sodium at the end of three hours, the mixture was allowed to stand for two to three days at room temperature and was then poured upon phosphorus pentoxide, heated at atmospheric pressure and finally distilled. Twenty-nine grams of a yellow oil boiling at 155–160° (6 mm.) was obtained, representing a yield of 90%. After redistillation this gave a fraction boiling at 148° at 3 mm. The ester is a greenish-yellow oil with a pungent odor similar to that of anhydrous diethyl mesoxalate. It is soluble in the common organic solvents and combines with a molecular equivalent of water with evolution of heat and almost complete decolorization. The hydrate formed is an oil and could not be induced to crystallize even when cooled to 25'. Further addition of water is accompanied by a yellow color which disappears again as the dilution is increased. The ester is apparently soluble in water in all proportions.

Anal. Calcd. for $C_7H_8O_5Cl_2$: Cl, 29.18. Found: Cl, 29.07.

Preparation of **Di-β-bromo-ethyl** Mesoxalate, $CO(COOCH_2CH_2Br)_2$.—Eight grams of di-β-bromo-ethyl malonate was mixed with 10 g. of liquid nitrogen tetroxide and a piece of metallic sodium added at −5°. The sodium was allowed to remain in the solution for twelve hours at 0° and then removed. After standing for two days at room temperature, the reaction mixture was dissolved in chloroform, phosphorus pentoxide added, and excess nitrogen tetroxide boiled off. The yellow solution was then heated to remove chloroform, whereupon decomposition set in with evolution of oxides of nitrogen. As soon as the oil assumed a yellow color, heating was discontinued and the product distilled at 1 mm. pressure. We obtained 6 g. of a yellow oil boiling at 158–159". This ester interacted with water with evolution of heat and almost complete decolorization but did not crystallize on cooling to 0°. It is soluble in an excess of water. On redistillation after removing water with phosphorus pentoxide, the anhydrous oil had a boiling point of 155° at 0.8 mm.

Anal. Calcd. for $C_7H_8O_5Br_2$: Br, 48.17. Found: Br, 48.16.

Action of Nitrogen Tetroxide on **Di-β-diethylamino-ethyl Malonate.**—The reaction between nitrogen tetroxide and the above ester proved to be explosively violent. Liquid nitrogen tetroxide could not be introduced and gaseous nitrogen tetroxide could be passed in only slowly at low temperatures. Three equivalents of nitrogen tetroxide were completely decolorized before any green color was imparted to the solution and an orange oil insoluble in carbon tetrachloride collected on the surface of the solution. The dihydrochloride of the malonic ester in question produced a much less vigorous reaction with nitrogen tetroxide and only one equivalent was decolorized, but an insoluble orange oil collected as before on the surface. None of the desired mesoxalate was isolated from either reaction. The reaction product decomposed violently upon gentle heating. A great many factors combine to make this preparation difficult; the amino malonic ester employed is peculiarly sensitive to hydrolysis, the alkyl amino groups are apparently attacked in anhydrous solution by nitrogen tetroxide, the avidity of the methylene carbon atom for nitrogen tetroxide is apparently increased and no satisfactory method of decomposing the intermediate to yield mesoxalate has thus far been discovered.

Summary

1. An improved method for preparing diethyl mesoxalate has been described. It involves the action of nitrogen tetroxide on diethyl malonate.

2. Two new mesoxalates prepared by application of this nitrogen tetroxide reaction are: di-β-chloro-ethyl mesoxalate and di-β-bromo-ethyl mesoxalate.

3. Di-0-diethylamino-ethyl malonate has been prepared for the first time.

4. The pharmacology of these new ester combinations is being investigated.

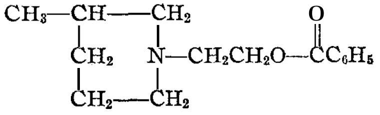
PIPERIDINE DERIVATIVES. VI. 3-METHYLPIPERIDINO-ALKYL BENZOATES[1]

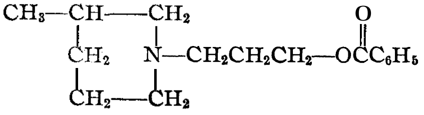
BY J. R. THAYER AND S. M. McELVAIN

RECEIVED AUGUST 3, 1928 PUBLISHED DECEMBER 10, 1928

In a previous communication[2] a number of substituted and unsubstituted piperidino-alkyl benzoates were described together with a brief report on their pharmacological behavior. Of these compounds it was noted that those containing an alkyl group substituted in the piperidine nucleus possessed the greatest local anesthetic efficiency. It seemed, therefore, advisable to ascertain the effect of variations in the alkylene group on the pharmacological properties of the type of compound represented by 3-methylpiperidino-ethyl and propyl benzoates (I and II).



I



II

In the previous work it was found that the number of carbon atoms in the alkylene group that joins the nitrogen to the oxygen was quite important. In I where there are two carbon atoms in this alkylene group,

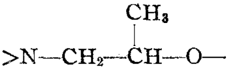
---

[1] This paper is an abstract of a portion of the thesis submitted by J. R. Thayer to the Graduate School of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

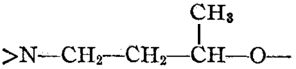
[2] McElvain, THIS JOURNAL, 49,2835 (1927).

the compound was found to have no local anesthetic action on mucous membranes, while in II the presence of the third carbon atom caused the compound to show appreciable anesthetic action on mucous membranes.[3] The work reported in this paper is concerned with the preparation and attempted preparation of a number of 3-methylpiperidino-alkyl benzoates in which the alkylene group between the nitrogen and the oxygen (Types I and II) contains one or more substituent methyl groups.

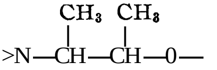
The structures which were considered and whose syntheses were attempted may be represented as follows



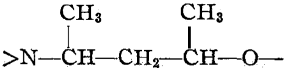
$$>\mathrm{N-CH_2-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-O-}\quad\text{(III)}$$



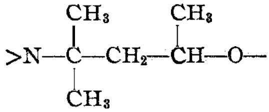
$$>\mathrm{N-CH_2-CH_2-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-O-}\quad\text{(IV)}$$



$$>\mathrm{N-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-O-}\quad\text{(V)}$$

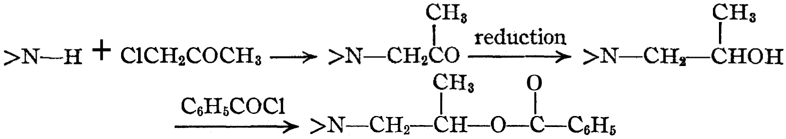


$$>\mathrm{N-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-CH_2-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-O-}\quad\text{(VI)}$$



$$>\mathrm{N-}\underset{\mathrm{CH_3}}{\underset{|}{\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}}}\mathrm{-CH_2-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-O-}\quad\text{(VII)}$$

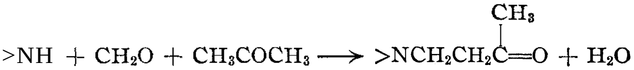
Of the above types only III and IV were successfully synthesized. The former (III) was prepared by a series of reactions which may be indicated thus (>NH in all succeeding formulas = 3-methylpiperidine)



$$>\mathrm{N-H} + \mathrm{ClCH_2COCH_3} \longrightarrow\ >\mathrm{N-CH_2}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{O} \xrightarrow{\text{reduction}}\ >\mathrm{N-CH_2-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{HOH}$$

$$\xrightarrow{\mathrm{C_6H_5COCl}}\ >\mathrm{N-CH_2-}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{H-O-}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{-C_6H_5}$$

The desired structure (IV) was prepared by a method which has been developed by Mannich and his coworkers[4] for the synthesis of 1,3-keto bases. This synthesis involves a reaction between a secondary amine, paraformaldehyde and acetone. Using 3-methylpiperidine as the secondary amine, this reaction may be indicated as follows



$$>\mathrm{NH} + \mathrm{CH_2O} + \mathrm{CH_3COCH_3} \longrightarrow\ >\mathrm{NCH_2CH_2}\overset{\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}\mathrm{=O} + \mathrm{H_2O}$$

The catalytic reduction of this keto amine yielded the corresponding alcohol, which was converted into Structure IV by benzoylation with benzoyl chloride.

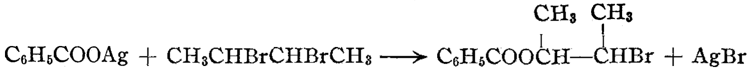
The preparation of V and VI was attempted by condensing α,β-dimethyl-β-bromo-ethyl benzoate and α,γ-dimethyl-γ-chloropropyl benzoate with 3-methylpiperidine just as I and II were prepared by the condensation of chloro-ethyl and chloropropyl benzoates with the secondary amine. The α,β-dimethyl-β-bromo-ethyl benzoate was prepared by the action

---

[3] Ref. 2, p. 2839.

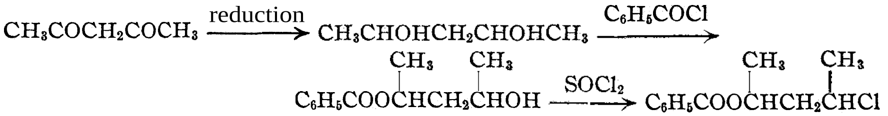
[4] Mannich and others, Arch. *Pharm.*, 255,261 (1917); 265,589 (1927).

of 2,3-dibromobutane on silver benzoate, thus



$$\mathrm{C_6H_5COOAg + CH_3CHBrCHBrCH_3 \longrightarrow C_6H_5COO\overset{\overset{CH_3}{|}}{C}H—\overset{\overset{CH_3}{|}}{C}HBr + AgBr}$$

α,γ-dimethyl-γ-chloropropyl benzoate was prepared from acetylacetone by the following reactions

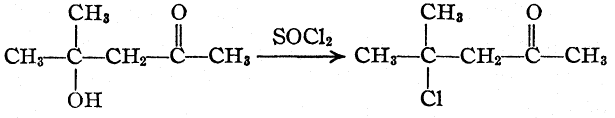


$$\mathrm{CH_3COCH_2COCH_3 \xrightarrow{\text{reduction}} CH_3CHOHCH_2CHOHCH_3 \xrightarrow{C_6H_5COCl}}$$

$$\mathrm{C_6H_5COO\overset{\overset{CH_3}{|}}{C}HCH_2\overset{\overset{CH_3}{|}}{C}HOH \xrightarrow{SOCl_2} C_6H_5COO\overset{\overset{CH_3}{|}}{C}HCH_2\overset{\overset{CH_3}{|}}{C}HCl}$$

In the preparation of I and II it was found that one mole of β-chloroethyl benzoate or γ-chloropropyl benzoate reacted smoothly in twenty to thirty minutes at 100° with 2 moles of 3-methylpiperidine to give one mole of the tertiary amine (3-methylpiperidino-ethyl (or propyl) benzoate) and one mole of 3-methylpiperidine hydrochloride. In the case of α,β-dimethyl-β-bromo-ethyl benzoate and α,γ-dimethyl-γ-chloropropyl benzoate, no such reaction was found to take place. Under the conditions (thirty minutes at 100°) which caused complete reaction when the halogen was attached to a primary carbon atom, practically no reaction was obtained with the compounds having the halogen attached to a secondary carbon atom. The extent of reaction was judged in all cases by the amount of 3-methylpiperidine hydrochloride that was precipitated when the reaction mixture was diluted with ether. It was found in the cases of the secondary halogen compounds that if the reaction mixture was heated for twelve to fifteen hours at 100° or three to four hours at 130° and then cooled and diluted with ether, a fairly complete recovery of one mole of 3-methylpiperidine hydrochloride (or hydrobromide) could be made. But the ether solution contained no tertiary amine, for when it was treated with dry hydrogen chloride only 3-methylpiperidine hydrochloride precipitated. The total recovery of the secondary amine salt practically corresponded to the secondary amine that was originally a part of the reaction mixture. From these results it is apparent that the tendency of secondary halogen esters of this type is to lose a molecule of halogen acid when they are treated with a secondary amine rather than to form a tertiary amine.

The attempted synthesis of the compound containing Structure VII started with diacetone alcohol, which on treatment with thionyl chloride was converted into 2-methyl-2-chloropentanone-4.



$$\mathrm{CH_3—\underset{\underset{OH}{|}}{\overset{\overset{CH_3}{|}}{C}}—CH_2—\overset{\overset{O}{\|}}{C}—CH_3 \xrightarrow{SOCl_2} CH_3—\underset{\underset{Cl}{|}}{\overset{\overset{CH_3}{|}}{C}}—CH_2—\overset{\overset{O}{\|}}{C}—CH_3}$$

Should this chloro ketone react with 3-methylpiperidine to give a tertiary amine, then reduction of the ketone and benzoylation of the resulting alcohol would give the desired structure (VII). After the experience with the secondary halogen esters it was not expected that the 2-methyl-2-chloropentanone-4 would react with the secondary amine to give the tertiary amine, but the reaction was tried in order to ascertain what the behavior of such a tertiary halogen compound would be. It was found that this chloro ketone reacted with the secondary amine at room temperature and after about twelve hours approximately one-half of the secondary amine was precipitated as the hydrochloride when the reaction mixture was diluted with ether. The ether solution when treated with dry hydrogen chloride yielded only 3-methylpiperidine hydrochloride. These results indicate that halogen attached to secondary and tertiary carbon atoms in compounds of the type studied here do not react with secondary amines to give tertiary amines, but rather lose a molecule of halogen acid to form, presumably, an unsaturated compound.

Experimental

1-(3-Methylpiperidino)-propanone-2 Hydrochloride.—Ten g. (1 mole) of freshly distilled chloro-acetone, dissolved in 200 cc. of ether, was treated with 20 g. (2 moles) of **3-methylpiperidine,** dissolved in 200 cc. of ether. A precipitate of 3-methylpiperidine hydrochloride appeared immediately. The mixture was allowed to stand with occasional shaking for about one hour and then the precipitated amine hydrochloride was filtered off. Dry hydrogen chloride was then passed into the filtrate until the precipitation of the keto base was complete. The hydrochloride of the keto base could not be obtained crystalline at this point so the free base was liberated with 40% sodium hydroxide and extracted with ether. After removal of the ether the product was distilled under diminished pressure. Thirteen *g.* of a product boiling at 101–102° (18 mm.) was obtained. This free base was then dissolved in ether and reprecipitated as the hydrochloride. On recrystallization it melted at 162–163°.

Anal. Subs., 0.2031, 0.1889: AgCl, 0.1511, 0.1406. Calcd. for $C_9H_{18}ONCl$: Cl, 18.51. Found: 18.40, 18.42.

1-(3-Methylpiperidino)-propanol-2 Hydrochloride.—A solution of 15.5 g. of 1-(3-methylpiperidino)-propanone hydrochloride in 75 cc. of alcohol was reduced catalytically using 0.3 g. of Adams' platinum-oxide platinum black catalyst. The reduction was complete in three and one-half to four hours. The catalyst was removed from the reduced solution and the alcohol evaporated off under diminished pressure. The residue was treated with 40% sodium hydroxide and extracted with three 100-cc. portions of ether. The ether solution was dried over anhydrous sodium sulfate, after which the solvent was removed and the amine distilled under diminished pressure. The amino alcohol boiled at 98–100° (18 mm.); yield, 9 *g.* It was converted into the hydrochloride by precipitation from ethereal solution with hydrogen chloride and analyzed in this form. The hydrochloride melted at 184–185°.

Anal. Subs., 0.1633, 0.2710; AgCl, 0.1220, 0.2020. Calcd. for $C_9H_{20}ONCl$: Cl, 18.32. Found: 18.47, 18.43.

α-Methyl-β-(3-methylpiperidino)-ethyl Benzoate Hydrochloride (III).—The residue obtained after the evaporation of the solvent from the reduction of 1-(3-methylpiperidino)-propanone hydrochloride was benzoylated by heating with benzoyl chloride at 150–160° for twenty to thirty minutes. The acylation proceeded normally and the amino ester hydrochloride was isolated by diluting the reaction mixture with ether.

After several recrystallizations from an alcohol–ether mixture the product melted at 165–166°; yield, 5 g.

Anal. Subs., 0.2370, 0.1982: AgCl, 0.1165, 0.0980. Calcd. for $C_{16}H_{24}O_2NCl$: Cl, 11.92. Found: 12.16, 12.23.

1-(3-Methylpiperidino)-butanone-3 Hydrochloride.—A mixture of 13.5 g. of 3-methylpiperidine hydrochloride, 3.6 g. of paraformaldehyde, 30 cc. of acetone and 5 cc. of absolute alcohol was heated on a water-bath until the paraformaldehyde went into solution. This required three to four hours. The reaction mixture was then diluted with 100 cc. of dry ether and allowed to stand in an ice box until crystallized. This precipitated keto amine hydrochloride after recrystallization from an alcohol–ether mixture melted at 151–152°; yield, 12 g.

Anal. Subs., 0.1980, 0.2061: AgCl, 0.1378, 0.1431. Calcd. for $C_{10}H_{20}ONCl$: Cl, 17.25. Found: 17.22, 17.18.

α-Methyl-γ-(3-methylpiperidino)-propyl Benzoate **Hydrochloride (IV)**.—A solution of 7 g. of 1-(3-methylpiperidino)-butanone-3 hydrochloride in 50 cc. of alcohol was reduced catalytically with Adams' platinum–oxide platinum black catalyst. The reduction was complete in one to two hours with the absorption of the theoretical amount of hydrogen. The catalyst was filtered off from the reduced solution and the alcohol removed from the filtrate under diminished pressure. The residue was benzoylated with benzoyl chloride as described above for α-methyl-β-(3-methylpiperidino)-ethyl benzoate hydrochloride. The amino ester hydrochloride after recrystallization melted at 178–180°; the yield was 3.5 g.

Anal. Subs., 0.1441, 0.1659: AgCl, 0.0666, 0.0781. Calcd. for $C_{17}H_{26}O_2NCl$: Cl, 11.38. Found: 11.42, 11.64.

α,β-Dimethyl-β-bromo-ethyl Benzoate.—To 216 g. (1 mole) of β-butylene bromide (Eastman) dissolved in 200 cc. of toluene, was added 114 g. (0.5 mole) of silver benzoate. The mixture was stirred and refluxed for six hours. After this period of heating another 114 g. of silver benzoate was added and the mixture refluxed for an additional six hours. The reaction mixture was then filtered to remove the insoluble silver salts and the precipitate washed with 100 cc. of toluene. The filtrate was shaken with 10% sodium hydroxide to remove any benzoic acid that was present and then distilled under diminished pressure. Eighty g. (31%) of a product that boiled at 139–141° (4 mm.) was obtained. In spite of the apparent purity of the compound it failed to show the correct halogen content upon analysis by the Carius method. The analysis showed 20.5–21.0% of bromine, whereas the theoretical amount for the bromo ester is 31.10%. On redistillation of the product through a 15-cm. fractionating column, it boiled at 140–141 (4 mm.), but the analysis of the product so obtained gave practically the same results as indicated above. The only explanation of these low analyses that seems possible is that a small amount of the dibenzoate was present in the bromo ester and that the two could not be completely separated by fractional distillation.

α,γ-Dimethyl-γ-chloropropyl Benzoate.—Acetylacetone was reduced catalytically with Adams' platinum–oxide platinum black catalyst to pentane-diol-2,4, which was isolated in 60% yield. This diol has previously been prepared by the action of methyl magnesium iodide on aldol[5] and by the reduction of pentane-01-4-one-2 with sodium amalgam.[6] Twenty-six g. (0.25 mole) of this glycol was heated at 110–120° and to this was added slowly from a dropping funnel 35 g. (0.25 mole) of benzoyl chloride. The mixture was kept at this temperature for about half an hour after all the benzoyl chloride had been added. The reaction mixture was then cooled, 60 g. of thionyl

[6] Poray-Coschitz, *Chem. Centr.*, [I]1327 (1904).

chloride added, and the resulting solution heated for about half an hour under a reflux on a water-bath. Water was then added to decompose the excess of thionyl chloride and the chlorobenzoate was extracted with ether and dried over calcium chloride. After the removal of the solvent the chloro ester was distilled under diminished pressure. There was obtained 18–20 g. of product, b. p. 134–135° (2 mm.); n_D^{20}, 1.5074; d_{20}^{20}, 1.1008.

Anal. Subs., 0.4813, 0.4749: AgCl, 0.3031, 0.2981. Calcd. for $C_{12}H_{15}O_2Cl$: Cl, 15.65. Found: 15.58, 15.53.

Reaction of **α,β-Dimethyl-β-bromo-ethyl** Benzoate **and α,γ-Dimethyl-γ-chloro-**propyl Benzoate with **3-Methylpiperidine.**—A mixture of 0.1 mole of 3-methylpiperidine and 0.05 mole of the halogen ester was heated on a steam cone for thirty minutes. At the end of this time the mixture was cooled and diluted with ether in order to precipitate any of the 3-methylpiperidine hydrohalide that would have been formed had any reaction taken place. There was no indication of reaction during this period of heating. The time of heating was extended to four hours and dilution with ether showed that some reaction had taken place, but it was not nearly complete. After twelve hours of heating at 100°, however, approximately half of the 3-methylpiperidine originally used was precipitated by ether as the hydrobromide, showing that the reaction had been completed. The ether solution after the removal of the secondary amine hydrobromide was treated with dry hydrogen chloride. A precipitate was obtained which proved to be 3-methylpiperidine hydrochloride. The combined hydrobromide and hydrochloride obtained was practically equivalent to the total amount of 3-methylpiperidine started with. There was no qualitative difference in the behavior of α,β-dimethyl-β-bromo-ethyl benzoate and α,γ-dimethyl-γ-chloropropyl benzoate toward the secondary amine.

2-Chloro-2-methylpentanone-4.—To a solution of 58 g. of diacetone alcohol in 100 cc. of ether was added 60 g. of thionyl chloride and the mixture was refluxed for thirty minutes. Water was then added to decompose the unreacted thionyl chloride and the ether solution of the chloro-ketone dried over anhydrous sodium sulfate. The ether was distilled off and the chloro-ketone distilled under diminished pressure. The product boiled at 50–52° (14 mm.) and the yield was 50 g. (74%). When first distilled it was a colorless oil, but it began to darken almost immediately on standing. After standing for three to four hours, there was sufficient hydrogen chloride evolved to cause noticeable fumes when the bottle containing the product was unstoppered. The chloro-ketone was washed with dilute sodium carbonate solution, dried with calcium chloride, redistilled and immediately weighed out for analyses. A chlorine content of 23.05% was found, whereas the theoretical is 26.39%. On account of its instability no other physical constants of the chloro-ketone were determined.

Reaction of **2-Chloro-2-methylpentanone-4** with **3-Methylpiperidine.**—To a solution of 6.8 g. (0.05 mole) of the chloro-ketone in 100 cc. of ether was added 10 g. (0.1 mole) of 3-methylpiperidine and the mixture allowed to stand at room temperature. Precipitation of 3-methylpiperidine hydrochloride began at once and after twelve hours' standing the reaction mixture was filtered. Approximately one-half of the secondary amine was recovered as the hydrochloride. The filtrate was treated with dry hydrogen chloride and the precipitate was 3-methylpiperidine hydrochloride, which together with that obtained by the first filtration of the reaction mixture corresponded to practically all of the 3-methylpiperidine that was originally put into the reaction.

Pharmacological Report

α-Methyl-β-(3-methylpiperidino)-ethyl benzoate hydrochloride (III) and α-methyl-γ-(3-methylpiperidino)-propyl benzoate hydrochloride (IV)

are being studied pharmacologically by Mr. Charles L. Rose of the Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana. A brief report of a portion of this work is given in the table below. For comparison the corresponding values for β-(3-methylpiperidino)-ethyl benzoate hydrochloride (I), γ-(3-methylpiperidino)-propyl benzoate hydrochloride (II), cocaine and procaine are included. The anesthetic efficiencies were determined in the usual way by the application of a 2% solution of the anesthetic to the rabbits cornea and noting the duration of anesthesia. The toxicities were determined by subcutaneous injection into white mice and also by intravenous injection into white rats.

TABLE I

PHARMACOLOGICAL DATA

	Av. duration of compound anes., min.	Subcutaneous toxicity to white mice (mg./kg.)			Intravenous toxicity to white rats (mg./kg.)		
		M. T. D.	M. L. D.	No. of mice used	M. T. D.	M. L. D.	No. of rats used
I	0	3000	3500	29	25	30	11
II	11	450	500	7	20	25	9
III	2.5	2000	2500	30	20	25	14
IV	28	250	300	40	12.5	15	10
Cocaine	29.0	200	250	18	15	17.5	12
Procaine	0	900	1000	17	45	50	10

Discussion of the Pharmacological Data

A comparison of compounds I and I1 with III and IV shows that the introduction of a methyl group in the alkylene group that separates the oxygen and nitrogen in these substances causes a considerable change in their pharmacological behavior. The compounds (III and IV) containing the methyl substituted alkylene group have distinctly higher anesthetic effect and higher toxicities than the corresponding compounds (I and II) in which the alkylene group is unsubstituted. Compound IV has practically the same pharmacological properties as cocaine. It may be of interest to note that in compounds II and III where there are the same number of carbon atoms in the alkylene groups, the straight chain compound (II) appears to be the most efficientanesthetic.

Summary

1. α-Methyl-β-(3-methylpiperidino)-ethyl benzoate and a-methyl-γ-(3-methylpiperidino)-propyl benzoate have been prepared as the hydrochlorides. They have been found to have higher anesthetic efficiencies and higher toxicities than the corresponding compounds in which the alkylene group between the oxygen and nitrogen is unsubstituted.

2. It has been found that certain halogen compounds in which the halogen is attached to a secondary or tertiary carbon atom do not react

with a secondary amine to give a tertiary amine, but undergo an internal loss of halogen acid to form, presumably, an unsaturated compound.

A PRELIMINARY EXAMINATION OF ROTENONE AND SOME OF ITS DEGRADATION PRODUCTS

BY GORDON MITCHELL WRIGHT

RECEIVED AUGUST 11, 1928 PUBLISHED DECEMBER 10, 1928

For many years considerable interest has been taken in a number of tropical plants, extracts of which have been used as fish and arrow poisons. More recently there has been a commercial development of these plants as sources of insecticides, and in this connection the root of *Derris elliptica Benth.* or *Tuba* has been widely used. On the agricultural side considerable attention has been given to the properties of *Derris* and it seemed of interest to obtain some light on the chemical structure and properties of the toxic principle.

A toxic principle from the root was first isolated as an amorphous substance by Greshoff,[1] who assigned it the name "Derrid." This worker showed that derrid did not contain nitrogen and was not a glucoside. Wray[2] also appears to have isolated the same substance, though he assigned to it the name "Tubain."

Derrid was also obtained by van Sillevoldt[3] as an amorphous powder, m. p. 73°, with an empirical formula $C_{33}H_{30}O_{10}$. It was suggested that it contained three mexthoxyl groups and two hydroxyl groups, although benzoylation or acetylation failed. Further, "anhydroderrid," yellow needles, m. p. 210–214°, of formula $C_{33}H_{28}O_9$, was obtained. A crystalline substance, m. p. 158°, from the roots of *Derris elliptica Benth.* was obtained by Lenz,[4] who gave it the name "Derrin." Takeo Ishikawa[5] isolated *a* toxic substance, m. p. 163.5°, from the same source and assigned to it the name "tubotoxin" and the empirical formula $C_{18}H_{18}O_5$. The work of the previous author was extended by Kariyone and Atsumi,[6] who confirmed the above formula. This compound, which in alcoholic solution reduced Fehling's solution, formed a phenylhydrazone, $C_{18}H_{18}O_5{=}N\cdot NHC_6H_5$, m. p. 255°, and a monoxime, $C_{18}H_{18}O_5{=}NOH$, m. p. 245°. It was suggested that a diacetyl derivative, m. p. 125–155°, was obtained but

the analyses did not bear this out. A methoxyl estimation showed the presence of 1.5 methoxyl groups in the molecule. Further work by Kariyone, Kimura and Kondo[7] showed that tubotoxin in hot alcoholic solution added on a molecule of hydrogen chloride (needles, m. p. 194°) and a molecule of hydrogen bromide (needles, m. p. 185°). Tubotoxin, whose formula in conformity with more recent work had been altered to $C_{19}H_{18}O_5$, on reduction in presence of palladium and barium sulfate, yielded dihydrotubotoxin, $C_{19}H_{20}O_5$, m. p. 216°, which was confirmed by the preparation of an oxime. When warmed with alcoholic potash at water-bath temperature, tubotoxin yielded "tubaic acid," $C_9H_{10}O_3$, m. p. 129°, which decolorized bromine and potassium permanganate solutions, and formed a methyl ester, m. p. 54°, and a mono-acetyl derivative, m. p. 133°. This acid may be reduced under the same conditions as tubotoxin to give dihydrotubaic acid, m. p. 166°, which was also obtained by the fission of dihydrotubotoxin with alcoholic potash. The methyl ester of this acid melts at 79° and the acetyl derivative at 169°.

In a later communication Kariyone and Kondo[8] revised the formula of tubaic acid to $C_{12}H_{12}O_4$ and stated that this acid is isomeric with "rotenic acid," m. p. 182°, obtained by the fusion of tubotoxin with potash, and which yielded an acetyl derivative, m. p. 154°.

Contemporaneous with Kariyone and his collaborators, Takei[9] was also examining the same toxic substance from *Derris elliptica Benth.* He found that this principle was identical with rotenone isolated by Kazuo Nagai[10] from *Derris chinensis Benth.* Takei[9] had shown that rotenone had the formula $C_{19}H_{18}O_5$, which was supported by an examination of the phenylhydrazone, m. p. 254°. He found that rotenone contained 1.5 OCH_3 groups; was converted into isorotenone by concentrated sulfuric acid; was degraded into an acid, $C_{10}H_{10}O_3$, m. p. 129°, which reacted with bromine; and on fusion with potash was transformed into rotenic acid, $C_9H_{10}O_3$ (or $C_6H_6O_2$). Further, the acid $C_9H_{10}O_3$ (m. p. 182°) yielded a mononitro derivative (m. p. 168°) and from its reaction with ferric chloride he suggested that it was a dimethyl-o-hydroxybenzoic acid.

On treating rotenone at 150° with acetic anhydride in acetic acid, or with chromic anhydride in acetic acid at 50°, a compound of empirical formula $C_{18}H_{16}O_5$ (m. p. 233°) was obtained. On oxidation of rotenone with chromic anhydride in acetic acid at a higher temperature, a compound of empirical formula $C_{17}H_{14}O_5$ (m. p. 298°) was produced to which he assigned the name "rotenonone." The heating of rotenonone with fused potash yielded rotenic acid.

[10] Kazuo Nagai, J. *Chem. Soc. Tokyo,* **23, 740 (1902).**

In a later communication Takei[11] revised almost completely his original paper. Rotenone was now assigned the formula $C_{23}H_{22}O_6$ and this formula was confirmed by analysis of the phenylhydrazone, the oxime, the addition product with hydrogen chloride and a re-examination of isorotenone and its oxime. At the same time rotenic acid was given the formula $C_{12}H_{12}O_4$ and was further confirmed by acetylation and preparation of a dimethyl derivative and its nitration product.

It was found on gradually raising the temperature of rotenic acid to 210° and then to 300° two products were obtained: a phenol, $C_{11}H_{12}O_2$ (m. p. 42°), and an alkali-insoluble substance (m. p. 136°) of probable formula $C_{22}H_{22}O_4$. The phenol was characterized by the preparation of a *p*-tolylsulfonyl derivative and of a methyl ether.

In 1925, and therefore previous to the publication by Takei,[11] the discrepancies between the results of the various investigators had been noticed, and it was decided to reopen the problem in an attempt to establish a formula and a partial structure for the same principle of *Derris elliptica Benth.* In view of the drastic revision to which Takei[11] has subjected his previous work,[9b] it seems necessary to obtain independent confirmatory evidence. It has now been shown that the composition of rotenone is best expressed by the molecular formula $C_{23}H_{22}O_6$ and that it forms an oxime, $C_{23}H_{22}O_5{=}NOH$, a phenylhydrazone, $C_{23}H_{22}O_5{=}N{\cdot}NHC_6H_5$, and an addition product with hydrogen chloride, $C_{23}H_{22}O_6{\cdot}HCl$. Further proof is afforded by the preparation of the hydrobromide of rotenone and the oxime of the hydrochloride. The formation of isorotenone, its oxime and its phenylhydrazone has been established, again confirming the work of Takei.[11]

On oxidation of rotenone with chromic anhydride in acetic acid under conditions described by Takei,[9b] a substance having the same analysis and melting point was obtained, agreeing with a revised formula $C_{21}H_{18}O_6$.

The action of alcoholic potash yielded an acid $C_{12}H_{12}O_4$ (m. p. 129°)[8] which is presumably identical with $C_{10}H_{10}O_3$ described by Takei.[9b] Rotenic acid, which was obtained by the fusion of rotenone with potash, has been shown to have the formula $C_{12}H_{12}O_4$.[8,11] The formula of this acid has been further confirmed by the preparation of a mononitro derivative and a methyl ester. Rotenic acid on heating at about 210° until evolution of carbon dioxide had ceased yielded a compound $C_{23}H_{22}O_5$ (m. p. 103°).

Experimental

Rotenone (m. p. 163°) was prepared by extracting the powdered root with ether and crystallization of the product, which separated on cooling from carbon tetrachloride and then alcohol.

Anal. Calcd. for $C_{23}H_{22}O_6$: C, 70.05; H, 5.6; OCH_3, 15.7; mol. wt., 394. Found:

---

[11] Takei, *Ber.*, 61, 1003 (1928).

C, 69.6, 69.5, 69.7; H, 5.85, 5.6, 5.9; OCH_3, 15.0, 15.1; mol. wt. in $C_2H_4Br_2$: 403, 376, 381; in $CHBr_3$, 386.

Rotenone-oxime.—A mixture of 5 g. of rotenone, 3.7 g. of hydroxylamine hydrochloride and 4.2 g. of fused sodium acetate dissolved in 80 cc. of absolute ethyl alcohol was refluxed for three to four hours. The hot solution was filtered and the crystals which separated from the filtrate on cooling were filtered, washed with water and on repeated recrystallization from methyl alcohol formed colorless needles, m. p. 252°.

And. Calcd. for $C_{23}H_{22}O_5$=NOH: C, 67.5, H, 5.6; N, 3.4. Found: C, 67.9, 67.4, 67.75; H, 5.3, 5.65, 5.85; N, 3.4, 3.5, 3.45.

Rotenone phenylhydrazone was prepared by refluxing for five hours a mixture of 5 g. of rotenone, 7.5 g. of phenylhydrazine hydrochloride and 4.2 g. of fused sodium acetate dissolved in 50 cc. of absolute alcohol. The solid product which separated was filtered, washed with water and on crystallization from alcohol yielded fine yellow needles, m. p. 245°.

Anal. Calcd. for $C_{23}H_{22}O_5$ = $NNHC_6H_5$: C, 71.9; H, 5.8; N, 5.8. Pound: C, 71.6; H, 5.7; IS, 6.0.

Rotenone hydrochloride was best prepared in the cold by dissolving with shaking 2 g. of rotenone in 100 cc. of glacial acetic acid saturated with hydrogen chloride and leaving for two to three days. The greenish-yellow solution, on addition of water, precipitated a solid which after filtering, drying and recrystallizing from alcohol had a m. p. of 197°. On concentration of the alcoholic mother liquors, in addition to a further quantity of rotenone hydrochloride, there was obtained a very small quantity of a solid forming yellow crystals from alcohol (m. p. 255°) containing chlorine.

Anal. Calcd. for $C_{23}H_{22}O_6 \cdot HCl$: C, 64.1; H, 5.35; Cl, 8.25; OCH_3, 14.4; mol. wt., 430.5. Found: C, 64.2, 63.95, 64.5; H, 5.35, 5.3, 5.5; Cl, 8.1, 7.95; OCH_3, 14.1; mol wt., 442.

The **oxime** of rotenone hydrochloride was obtained by refluxing a mixture of 5 g. of rotenone hydrochloride, 3.7 g. of hydroxylamine hydrochloride and 4.2 g. of fused sodium acetate, dissolved in 100 cc. of absolute alcohol, for six hours. The hot solution after filtering deposited crystals which gave on repeated crystallization from alcohol colorless needles, m. p. 239° (with decomposition).

Anal. Calcd. for $C_{23}H_{22}O_5$=$NOH \cdot HCl$: C, 61.95; H, 5.4; Cl, 7.95; OCH_3, 13.9. Found: C, 62.65, 62.60; H, 5.45, 5.60; Cl, 7.95; OCH_3, 14.0.

Rotenone hydrobromide was prepared in a manner similar to rotenone hydrochloride using glacial acetic acid saturated with hydrogen bromide. In this case the product separated from solution and after twenty-four hours was filtered off; it crystallized from methyl alcohol in long white needles, m. p. 190".

Anal. Calcd. for $C_{23}H_{22}O_6 \cdot HBr$: C, 58.1; H, 4.85; Br, 16.85. Found: C, 57.7, 58.1; H, 4.85.4.95; Br, 16.75.

Isorotenone was obtained by the gradual addition of 30 cc. of concentrated sulfuric acid to 5 g. of rotenone in 40 cc. of glacial acetic acid. After addition was complete the red solution was poured into ice water; the solid which was precipitated was crystallized from alcohol in small needles, m. p. 184°.

Anal. Calcd. for $C_{23}H_{22}O_6$: C, 70.05; H, 5.6. Found: C, 69.5; H, 5.65.

Isorotenone phenylhydrazone, which was prepared in the same manner as rotenone phenylhydrazone, on crystallization from alcohol formed fine yellow needles, m. p. 230°.

Anal. Calcd. for $C_{23}H_{22}O_5=NNHC_6H_5$: C, 71.9; H, 5.8; N, 5.8. Found: C, 71.95. 71.43; H, 5.73, 5.5; N, 5.85, 6.05.

No appreciable action takes place on passing hydrogen chloride into a hot alcoholic solution of isorotenone for fourteen hours nor had concentrated sulfuric acid any action on rotenone hydrochloride.

Rotenonone was obtained by the slow addition of a solution of 10 g. of chromic anhydride in glacial acetic acid to a hot acetic acid solution of 5 g. of rotenone. On crystallization of the product from acetic acid, yellow needles were obtained, m. p. 300°.

Anal. Calcd. for $C_{21}H_{18}O_6$: C, 68.85; H, 4.9. Found: C, 68.7; H, 5.3.

Rotenic acid, obtained by the fusion of rotenone with potash, crystallized from benzene in white needles, m. p 183°.

Anal. Calcd. for $C_{12}H_{12}O_4$: C, 65.45; H, 5.45; equiv., 220. Found: C, 65.4; H, 5.35; equiv., 220,226.

A Zeisel determination for the methoxyl group gave a negative result.

Methyl Ester of Rotenic Acid.—A solution of 1 g. of rotenic acid in ether was treated with an ethereal solution of diazomethane prepared from 3 cc. of nitrosomethylurethan and allowed to stand at ordinary temperature for three days. On evaporating the ether, an oil was obtained which went solid after washing with dilute sodium carbonate and water. On crystallization from methyl alcohol, colorless prisms (m. p. 39–40°) were obtained. This ester may also be prepared by the action of methyl iodide on the silver salt of rotenic acid.

Anal. Calcd. for $C_{12}H_{11}O_4CH_3$: C, 66.65; H, 6.0. Found: C, 66.15, 66.7; H, 5.6, 5.8.

Nitrorotenic acid was obtained by the careful addition of 2 cc. of a 10% solution of nitric acid (sp. gr. 1.42) in glacial acetic acid to 0.5 g. of $C_{12}H_{12}O_4$ dissolved in 15 cc. of glacial acetic acid. The solution was warmed gently for a few minutes and left overnight. On addition of water a yellow solid was precipitated which crystallized from alcohol and water in yellow needles, m. p. 187°.

Anal. Calcd. for $C_{12}H_{11}O_4NO_2$: N, 5.3. Found: N, 5.2, 5.1.

Action of Heat on Rotenic Acid.—Two g. of rotenic acid was heated between 216 and 225° until evolution of carbon dioxide had ceased. The oily residue was washed with dilute caustic soda and the residual white solid crystallized from methyl alcohol; it formed small, white crystals (m. p. 104°). In alcoholic solution it gave a green color with ferric chloride.

Anal. Calcd. for $C_{23}H_{22}O_5$: C, 73.0; H, 5.8; mol. wt., 378. Found: C, 73.0, 73.4; H, 5.9, 6.15; mol. wt., 396, 405.

The alkaline filtrate on acidification gave a substance of phenolic character which could not be obtained in a pure state.

Tubaic acid, which was prepared by the action of alcoholic potash on rotenone. yielded colorless needles on crystallization from water, m. p. 128–129°.

Anal. Calcd. for $C_{12}H_{12}O_4$: C, 65.45; H, 5.45; equiv., 220. Found: C, 65.55 65.5; H, 5.45, 5.65; equiv., 221.

No methoxyl grouping was found to be present.

The author wishes to thank Messrs. Guthrie and Co., Ltd., East India merchants, London, and the Agricultural Department F. M. S. for the gift of a considerable amount of the Derris used in the above work.

Summary

1. Rotenone has been shown to have the formula $C_{23}H_{22}O_6$ and to form a monoxime and a phenylhydrazone. It adds on one molecule of hydrochloric acid or hydrobromic acid.

2. Isorotenone is formed by the action of sulfuric acid on rotenone, and yields a phenylhydrazone.

3. Rotenic acid, which is obtained by the fusion of rotenone with potash, has the formula $C_{12}H_{12}O_4$. It yields a monomethyl ester and a mononitro derivative.

THE ACTION OF ALKYL CHLOROCARBONATES ON STIBANILIC ACID[1]

By Cliff S. Hamilton and R. E. Etzelmiller

Received August 15, 1928 Published December 10, 1928

Studies in the field of organic antimonials have been carried out in connection with investigations of protozoal diseases because in some of these diseases the antimonials appear to be of greater value than the arsenicals.

It was the object of this investigation to prepare some of the carbalkoxy derivatives of p-aminostibinic acid and to study some of their properties. Methyl, ethyl, propyl, *iso*propyl, butyl, *iso*butyl, β-chloro-ethyl and y-chloropropyl chlorocarbonates were condensed with p-stibanilic acid. Only one of the products, *p*-carbethoxyaminophenylstibinic acid was found reported in the literature.[2]

Two general methods, with various modifications, have been used for the preparation of *p*-aminophenylstibinic acid or p-stibanilic acid from *p*-aminoacetanilide; the first, by diazotization of *p*-aminoacetanilide and subsequent addition to alkaline antimony trioxide;[3] the second, by formation of the double salt in acid solution[4] and its addition to a solution of sodium hydroxide.[5] In both cases the acetyl group was removed by hydrolysis with a 5% solution of sodium hydroxide.

In this study both of the above methods were tried in the preparation of p-stibanilic acid with about equal results. With either method several difficulties were encountered. Not only was the material hard to handle mechanically but the yields were low. In the method finally adopted *p*-amino-acetanilide was diazotized and slowly added to an alkaline solution of antimony trioxide containing a little glycerol. The foam which forms was kept down by vigorous stirring and by regulating the

---

[1] Some of the compounds described in this paper are being studied pharmacologically under the direction of Dr. A. S. Loevenhart, Department of Pharmacology, University of Wisconsin.

[2] Brachmachari, *Indian* J. Med. *Research, 10, 508* (1922).

addition of the diazonium solution. At the conclusion of the reaction, the crude *p*-acetylaminophenylstibinic acid was precipitated with dilute acetic acid, hydrolyzed with a solution of sodium hydroxide and the crude stibanilic acid precipitated with dilute acetic acid. The derivatives prepared from this crude acid always analyzed too high in antimony content and it was found necessary to purify the acid before making the chlorocarbonate derivatives.

The several carbamates were prepared by dissolving the purified stibanilic acid in a slight excess of N sodium carbonate solution and adding slowly a slight excess of the chlorocarbonate. Their sodium salts separated out from the sodium carbonate solution and were converted to the free acids by use of hydrochloric acid. These carbamates were almost colorless powders insoluble in benzene, water or dilute acids. Concentrated hydrochloric acid changed them into a tarry oil. They showed but slight solubility in dilute sodium hydroxide solution, their solubility decreasing with an increase in their carbon content.

When 4-carbo-β-chloro-ethoxy- and 4-carbo-γ-chloropropoxyamino-phenylstibinic acids were heated with four equivalents of aqueous alkali, β- and γ-phenylstibino-alkylamino alcohols, respectively, were obtained as illustrated by the formation of the β-compound.

$$H_2O_3SbC_6H_4NH_2 \longrightarrow H_2O_3SbC_6H_4NHCOOCH_2CH_2Cl \longrightarrow H_2O_3SbC_6H_4\underbrace{NCOOCH_2CH_2} \longrightarrow H_2O_3SbC_6H_4NHCH_2CH_2OH$$

No attempt was made to isolate the substituted oxazolidone shown in the above formulation but it was no doubt formed as an intermediate product.

Experimental

p-Aminophenylstibinic Acid (**p-Stibanilic** Acid), $NH_2C_6H_4SbO_3H_2$.—Ninety grams of *p*-amino-acetanilide was added to 600 cc. of boiling water and decolorized with charcoal. One hundred and forty-four cubic centimeters of concentrated hydrochloric acid was then added and the solution cooled to 0–5°, when white crystals of the hydrochloride separated out. This mixture was diazotized with a solution of 42 g. of sodium nitrite in 250 cc. of water. The nitrite solution was introduced through a capillary tube at the bottom of the beaker, with mechanical stirring. The diazotized solution was then slowly added through a capillary tube to a jar containing a cold alkaline solution of antimony trioxide, prepared by dissolving 150 g. of antimony trichloride or 80 g. of antimony trioxide in a small amount of warm concentrated hydrochloric acid and 200 cc. of glycerol and adding this solution to just sufficient 5 N sodium hydroxide to dissolve the oxide that forms, followed by dilution with ice and water to eight liters. By regulating the addition of the diazonium solution and by vigorously stirring the mixture, a heavy foam which tends to form was prevented. During the addition of the diazonium solution the antimony trioxide was kept in solution by adding 10% sodium hydroxide solution from time to time as needed. When the reaction was complete the mixture was almost neutralized with hydrochloric acid and saturated with carbon dioxide to precipitate the unchanged antimony trioxide and tarry products. Before filtering the mixture was heated to 75° to coagulate the precipitated products; otherwise the finely divided particles clogged the filter paper and a considerable time was required to filter. After filtering the *p*-acetylaminophenylstibinic acid was precipitated from the warm solution with dilute acetic acid and filtered. The acetyl group was removed by hydrolysis during one hour, in 1 liter of 5% sodium hydroxide solution at 90°. The crude acid was precipitated with acetic acid. The yields varied from 35 to 50%.

Purification of **Stibanilic** Acid.—Purification was accomplished by adding the moist crude acid, in small portions, to ice-cold, concentrated hydrochloric acid and stirring into a paste. After standing for a short time, the tetrachloride thus formed was filtered, washed with cold, concentrated hydrochloric acid and dissolved in just the required amount of 10% sodium hydroxide. This solution was warmed to 90°, decolorized with charcoal and the stibanilic acid precipitated with dilute acetic acid. To obtain a pure product consistently the process as outlined above was repeated. Yields of the purified acid were low and varied from 8 to 15% based on the crude acid.

Preparation of **Alkyl** and **Chloro-alkyl Chlorocarbonates.**—Following the method of Rose[6] these were prepared from the corresponding alcohols and phosgene at 0°.

Carbo-alkoxy-aminophenylstibinic Acids.—Purified *p*-stibanilic acid was dissolved in a slight excess of N sodium carbonate solution. To this solution a slight excess of the alkyl or chloro-alkyl chlorocarbonate was added, drop by drop, the reaction mixture frequently being shaken. The sodium salt of the carbo-alkoxy-aminophenylstibinic acid soon began to separate but the reaction mixture was allowed to stand overnight. The sodium salt was filtered off and suspended for a time in N hydrochloric acid to convert it into the free acid. The carbo-alkoxyaminophenylstibinic acid was washed with 2 N hydrochloric acid, to insure complete removal of any unchanged *p*-stibanilic acid, and then with water. When dried over sulfuric acid in a vacuum an almost colorless powder was obtained.

TABLE I

YIELDS AND ANALYTICAL DATA

4-Carbo-( )-aminophenylstibinic acid	Yield, %	Analysis			
		Subs., g.	0.0559*N* I_2, cc.	Sb, % Calcd.	Sb, % Found
Methoxy, $CH_3OCONHC_6H_4SbO_3H_2$	73	0.1582	17.40	37.83	37.45
Ethoxy, $C_2H_5OCONHC_6H_4SbO_3H_2$	85	.1790	19.10	36.25	36.33
Propoxy, $CH_3CH_2CH_2OCONHC_6H_4SbO_3H_2$	87	.1573	15.93	34.80	34.48
Isopropoxy, $(CH_3)_2CHOCONHC_6H_4SbO_3H_2$	89	.1602	16.47	34.80	35.01
Butoxy, $CH_3CH_2CH_2CH_2OCONHC_6H_4SbO_3H_2$	70	.1577	15.46	33.46	33.38
*Iso*butoxy, $(CH_3)_2CHCH_2OCONHC_6H_4SbO_3H_2$	85	.1616	15.97	33.46	33.66
β-Chloro-ethoxy, $ClCH_2CH_2OCONHC_6H_4SbO_3H_2$	Good	.1576	16.02	32.88	34.61
γ-Chloropropoxy, $ClCH_2(CH_2)_2OCONHC_6H_4SbO_3H_2$	Good	.1579	14.68	31.68	31.66

***p*-Stibino-phenylamino** Alcohols.—One molecular equivalent of the 4-carbo-β-chloro-ethoxy- or 4-carbo-γ-chloropropoxy-aminophenylstibinic acid was suspended in 4 molecular equivalents of a 5% aqueous solution of sodium hydroxide and heated on a water-bath at 70–75°, with occasional stirring, for about thirty minutes. The gummy material which first formed soon dissolved, leaving a small residue of dark-colored material. Dilute acetic acid was then added until a precipitate just began to form. The mixture was decolorized with a small amount of charcoal, filtered and the amino alcohol precipitated with dilute acetic acid. The product was washed with a small amount of water and dried in a vacuum over sulfuric acid.

The amino alcohols thus produced were almost colorless powders, readily soluble in dilute alkali and soluble in hydrochloric acid.

Table II

Yields and Analytical Data

p-Aminophenylstibinic acid	%	Analysis Subs., g.	0.0606 N I_2, cc.	Sb, % Calcd.	Found
β-Hydroxy-ethyl-, $HOC_2H_4NHC_6H_4SbO_3H_2$	25	0.1592	17.28	39.55	40.05
γ-Hydroxypropyl-, $HOC_3H_6NHC_6H_4SbO_3H_2$	25	.1608	17.22	37.83	39.51

Determination of Yields.—Since *p*-stibanilic acid decomposes quite rapidly when dried, a weighed sample could not be used in making the derivatives and the yield directly calculated. The amount of acid used was determined by analyzing a 5-cc. aliquot taken with a pipet from the sodium carbonate solution used in the preparation of the derivatives, and from the amount of antimony in this sample the amount of stibanilic acid in the known volume of solution was determined.

Analytical

Different methods were tried for the analysis of these compounds and only fair agreement was obtained. A modification of the iodimetric method of Ewins[7] for arsenic was finally adopted.

A mixture of 0.2 g. of the substance, 10 g. of potassium sulfate and 0.2 to 0.3 g. of starch in a Kjeldahl flask was treated with 20 cc. of concentrated sulfuric acid and heated until colorless. At first a small flame was used, but after half an hour a much hotter one was applied. The clear solution was cooled, diluted with 100 cc. of water and made just alkaline with 10 N sodium hydroxide. In order to dissolve any precipitated oxide, tartaric acid was then added until the solution was faintly acid. To the cooled solution, solid sodium bicarbonate was added in excess, the solution diluted to 350 cc. and titrated with *N*/20 iodine solution using starch as the indicator. The iodine solution was standardized each time with a weighed sample of antimony trioxide using the above procedure. The pure antimony trioxide used for this standardization was prepared by precipitating it from a boiling solution of tartar emetic (1 part to 10 parts of water) with ammonium hydroxide. After boiling for a time the trioxide was filtered and carefully washed.[8]

Summary

1. Methyl, ethyl, propyl, isopropy., butyl, *iso*butyl, β-chloro-ethyl and y-chloropropylchlorocarbonates have been condensed with stibanilic acid and the products isolated and identified (Table I).

2. The dried products were almost colorless powders, insoluble in water, dilute acids, benzene or ether. The methyl, ethyl and β-chloro-ethyl derivatives were slightly soluble in very dilute sodium hydroxide or carbonate solutions; the others were relatively insoluble. All were soluble in alcohol.

3. Two stibinophenylamino alcohols have been prepared (Table II).

THE CONSTITUTION OF FLAX CELLULOSE

BY GEORGE W. RIGBY[1]

RECEIVED AUGUST 16, 1928 PUBLISHED DECEMBER 10, 1928

A convenient hypothesis employed for many years by those investigating natural carbohydrates has been to assume cellulose to be a definite compound common to all plants. Cotton, however, containing relatively large percentages of easily purified cellulose, has been accepted quite generally as the source of material to be used as a "standard cellulose." The properties of the cellulose obtained from cotton have been determined with considerable accuracy and these properties have been assumed, in turn, for "cellulose" derived from other sources.

Although there is considerable evidence to justify the assumption that cellulose is a definite compound universally present in plant tissues, as yet no proof has been offered and many contradictory statements are found as to the properties of cellulose when isolated from various sources. In an attempt to aid in clarifying some of the confusion in regard to the universal occurrence of one cellulose and in order to afford a sound basis for the future investigations of the cell walls of the flax fiber,[1a] it was thought worth while to undertake the present research.

Throughout the present investigation each step has been duplicated with both flax and cotton cellulose, thus affording an accurate check on the results and a dependable basis of comparison for the cellulose derived from both sources.

Before proceeding to a discussion of the results of the present investigation, it is well to recall the outstanding researches which have a direct bearing on the present question. No work, however, has been done on the *Constitution of Flax Cellulose.*

As early as 1819 Braconnot[2] prepared glucose from fully bleached linen by the action of sulfuric acid. Blondeau de Caroles[3] isolated a compound to which he ascribed the formula $C_{18}H_{36}O_{18}(SO_3)_2BaO{\cdot}2H_2O$ which, incidentally, corresponds to a compound of a trisaccharide and H_2SO_4. H. Fehling[4] claimed isolation of a compound $C_{90}H_{180}O_{90}(SO_3)_2BaO$, which would correspond to 15 glucose residues. It has been a common observation[5] that mineral acids effect a weakening of linen cloth, with the forma-

tion of "hydrocellulose" in the same way that these acids affect cotton. H. de Mosenthal[6] has shown the "recovered" cellulose obtained by denitration of cellulose nitrate obtained from wood, ramie, flax and cotton to have approximately the index of refraction n_D, 1.5310. The specific heat[7] of linen is given as 0.321 and of cotton as 0.319, while the rotation of a copper–ammonium solution of the cellulose obtained from both sources is identical at $(\alpha)^{20}_{D} = 1000°$.[8] Furthermore, Schwalbe ("Die Chemie der Cellulose") has found highly purified flax cellulose and highly purified cotton cellulose to have practically no reducing properties.

Experimental

In order to secure the purest possible flax cellulose it was found entirely satisfactory to employ the general procedure recommended by the American Chemical Society for use with cotton.[9]

Flax fibers (obtained through courtesy of the Stevens Linen Works of Boston and of the Miles Linen Company of Salem, Oregon) were procured which previously had been retted, scutched and hackled. These fibers were thoroughly combed to remove all adhering woody tissue. At this stage the fibers showed a moisture content of 8%, which, however, is roughly proportional to the relative humidity. Analysis showed an ash content of 0.78% and an amount of wax extractable with hot petroleum ether of 1.65%, after which ethyl ether extracted 0.67% of wax. The same samples extracted with alcohol were found to contain 1.45% of a substance having the odor of burned sugar. (All of the alcohol extract was soluble in dilute alkali.) By the Cross and Bevan method 80.1% of cellulose was found.

About 200 g. of the thoroughly combed flax was placed in *a* large container filled with 1% Ivory soap solution on a steam table. The soap solution was changed daily and the fibers were thoroughly washed before being placed in a new solution. The preliminary soap treatment was deemed complete when, after being in contact with the fibers for a day, the solution remained colorless and the fibers themselves were leached to a very light yellow color. The washed and air-dried material showed: moisture, 7 to 8%; ash, 0.13%; petroleum ether extract, 1.28%; ethyl ether extract, 0.32%; alcohol extract, 0.84%; cellulose (Cross and Bevan), 90 to 95%.

In order to remove all extraneous material before the final purification, the soap-leached fibers were treated directly with 10% sodium hydroxide

[8] A. Levallois, *Compt.* rend., 99, 1122 (1884); *ibid.*, 100, 456 (1885); K. Hess and E. Messmer, Ber., 55, 2432 (1922).

[9] Report of Committee of the American Chemical Society, J. Ind. Eng. *Chem.*, 15, 748 (1923).

and gaseous chlorine, as in the Cross and Bevan method for estimating cellulose. Bleaching was best effected by using 100-g. samples and continuing the bleach for fifteen-minute intervals, followed by washing and treatment with sodium bisulfite, the process being repeated until a perfectly white, homogeneous material was obtained. The air dry fibers were then subjected to extraction in a Soxhlet apparatus with ethyl ether for eighteen hours, followed by a similar treatment with ethyl alcohol.

Final purification was effected in an apparatus exactly similar to that recommended for making "standard cellulose," the alkali treatment being continued for as much as a week without interruption.[9] In the case of flax the chlorine bleach was found necessary since experiments performed without bleaching, as recommended by Corey and Grey,[10] did not give a homogeneous product. In passing it is significant to note, however, that fibers purified without bleaching yielded cellobiose octa-acetate in spite of their obvious impurity. This result is striking since L. E. Wise[11] has claimed the formation of cellobiose octa-acetate from wood pulp to be an indication of the identity of wood cellulose and cotton. Furthermore, J. C. Irvine[12] points out that with esparto-cellulose "in no case was cellobiose octa-acetate obtained from material which had not been fully exhausted with alkali."

Purified flax cellulose was perfectly white, soft and very lustrous. All of the original long bast fibers were disintegrated into short lengths due to removal of the intercellular matter. The pure flax cellulose was entirely a hexose cellulose, since distillation with 12% hydrochloric acid and subsequent calculation of the phloroglucide by Kröber's tables gave only 1.13% of pentosans, while purified cotton gave 0.95% calculated as pentosans. The pure cotton showed a moisture content of 4.0% when dried at 100° to a constant weight and also when dried over phosphorus pentoxide, while flax cellulose under similar conditious showed **3.5%** moisture. Halides, sulfur, phosphorus and nitrogen were definitely absent, The ash content in both cases was negligible.

Having obtained a highly purified flax cellulose and a generous supply of purified cotton (furnished by the Eastman Kodak Company, copper reduction value 0.001, ash content 0.0001%, a-cellulose 99%), the next problem was to compare the structure of **flax** cellulose with that of cotton cellulose. This was accomplished first by the method of methylation.

The method adopted was essentially the same as was used by Denham.[13] In no case was copper-ammonium used to remove lower methylated derivatives. The first four methylations were made using 30% aqueous

---

[11] L. E. Wise and others, J. *Ind. Eng. Chem.*, **15,** 711–713, 815–818 (1923)

[12] Irvine and Hirst, J. *Chem. Soc.*, *125,* 15 (1924).

[13] W. S. Denham, J. *Chem. Soc.*, **119,** 77 (1921); *W.* S. Denham and H. Woodhouse, *ibid.*, 111,244 (1917).

sodium hydroxide and in the later treatments 30% methyl alcoholic potassium hydroxide was used. After three methylations the methoxy content, as determined in a modified Pregl semi-micro methoxy determination outfit, showed 23.6% of methoxy groups. After the fifth treatment, analysis showed 41.1% of methoxy groups. In all treatments the methyl sulfate was dissolved in ether before adding.

After 18 treatments the methoxy content had risen to 44.7% and continued methylation up to 26 treatments failed to exceed this maximum. The theoretical for trimethylcellulose is 45.6%—this figure, however, having never been reached by any investigator because of experimental difficulties.

Simultaneous hydrolysis and condensation of the methylated cellulose with methyl alcohol in a sealed tube, using 1% hydrochloric acid in methyl alcohol according to the directions of Irvine,[14] gave a clear liquid from which was obtained a golden-yellow sirup of n_D, 1.4632. Since this index of refraction was comparatively low, the sirup was thought to be a mixture of trimethyl- and dimethylglucose. Fractional distillation under 0.003 mm. pressure yielded a perfectly clear and colorless sirup which was collected in three fractions. The first fraction failed to show any tetramethylmethylglucose. This derivative would have been evident by a depression of the index of refraction and an elevation of the methoxy content. The constants obtained for the first and second fractions are compared, for convenience, with the accepted constants for 2,3,6-trimethylmethylglucose in the following tabulation:

Found (first and second fraction) n_D, 1.4592; $(\alpha)^{23}_D$, 67.1° for c = 0.669; MeO, 51.6%.
Accepted constants n_D, 1.4583; $(\alpha)^{20}_D$, 66.1° for c = 1.34; MeO, 52.6%.

The third fraction was found to be a mixture of 2,3,6-trimethylmethylglucose and of the dimethyl derivative. No 2,3,5-trimethylmethylglucose was found.

The conclusion is therefore drawn that completely methylated cotton and flax cellulose yield only 2,3,6-trimethylglucose on hydrolysis

$$\underbrace{\mathrm{ROCHCHOMeCHOMeCHORCH}}_{\mathrm{O}}\mathrm{CH_2OMe}$$

The formation of only 2,3,6-trimethylglucose from both cotton and flax cellulose indicated a similarity between the two, but reveals nothing of the size of the molecule. Furthermore, starch has been found to yield only 2,3,6-trimethylglucose, hence the next step was to prepare cellobiose octa-acetate from both cotton and flax and compare the yields.

As early as 1901, Skraup and König[15] noted that filter paper, from which they prepared cellobiose octa-acetate, consisted of a mixture of cotton and linen fibers. This result indicates that the presence of linen fibers did

---

[14] J. C. Irvine and E. L. Hirst, J. *Chem. Soc.*, 123, 518 (1923).

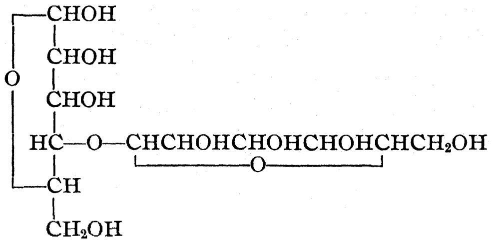
[15] Z. H. Skraup and J. König, *Monatsh.*, 22, 1011–1036 (1901).

not hinder the formation of cellobiose octa-acetate, but does not necessarily show that cellobiose octa-acetate was actually prepared from flax. In the present investigation the work of Skraup and Konig was, therefore, repeated, using highly purified flax cellulose.

Cellobiose octa-acetate was prepared from flax cellulose both according to the directions of Skraup and König[16] and after the method of Haworth and Hirst.[17]

Five grams of flax cellulose yielded, after four recrystallizations from hot 95% alcohol, two grams of cellobiose octa-acetate. This yield is exactly comparable with that obtained from pure cotton under parallel conditions.

Eighteen successive crystallizations from 95% alcohol yielded a material, m. p. 233.9' (corr.), showing no depression when mixed with an authentic sample prepared from cotton. In chloroform solution the rotation was found to be $(\alpha)^{23}_{D} + 40.9°$ for $c = 5.452$ and $(\alpha)^{23}_{D} + 41.4"$ for $c = 7.834$ in chloroform. C. S. Hudson[18] reports $(\alpha)^{20}_{D} + 41.95°$ for $c = 9.87$ and $(\alpha)^{20}_{D}$, + 40.87' for $c = 5.85$ in chloroform. As further identification the acetate was saponified in the cold with alcoholic sodium hydroxide and the phenylosazone of the liberated cellobiose prepared, m. p. 207–208°. Schliemann[19] gives 208–211° (corr.) as the melting point. Thus the cellobiose residues may be considered as integral parts of the flax cellulose molecule, as surely as of the cotton cellulose molecule.



Finally it was found that the flax cellulose molecule must contain at least three glucose residues. The method adopted was graded acetolysis after the directions of Irvine.[20] There was obtained by this method at the end of 168 hours a mixture of acetates of a trisaccharide and of an anhydro-trisaccharide, just as in the case of cotton after 100 hours. Six recrystallizations produced by dissolving the acetate in alcohol and precipitating with water yielded a material showing $(\alpha)^{23}_{D} +19.6°$ for $c = 10.608$ and $(\alpha)^{23}_{D} +19.2°$ for $c = 1.721$ in chloroform. Irvine reports $(\alpha)^{20}_{D} +19.4°$ for $c = 2.58$ in chloroform solution. The acetate

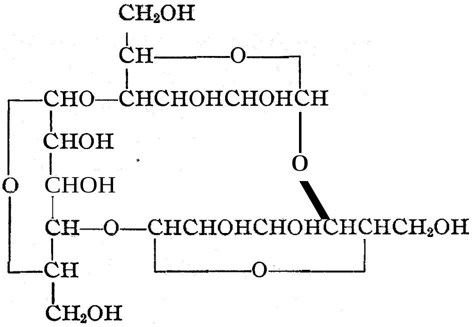
[20] J. C. Irvine and G. J. Robertson, *J. Chem. Soc.*, 128, 1496 (1926).

is very soluble in cold 95% alcohol. Cellulose triacetate gives $(\alpha)^{20}_{D}$ $-22.3'$ with $c = 0.8092$ in chloroform solution and is insoluble in hot 95% alcohol. Cellobiose octa-acetate a-form is soluble in hot alcohol, but insoluble in the cold and gives a specific rotation of $(\alpha)^{20}_{D}$ $+41°$. The β-form is more soluble in cold alcohol, but has $(\alpha)^{22}_{D}$ $-14.48'$ for $c = 10.88$ and m. p. 202°.

The above described acetates were also obtained by fractional crystallization of the alcohol mother liquor from preparations of cellobiose octa-acetate, after the method of Bertrand and Benoist.[21] Parallel experiments using pure cotton completed the evidence that graded acetolysis yielded the same product from both cotton and flax cellulose.

Hence the unit structure for both cotton and flax cellulose, to the best of our present knowledge, may be represented by an anhydro-trisaccharide formula as proposed by Irvine.



Summary

From the above reported results the following general conclusions are proposed:

1. Flax bast fibers consist of cells composed of pure cellulose and an intercellular material containing a furfural-yielding constituent.

2. The glucose residues in flax cellulose are joined together in positions one and four by glucoside linkages, as are those in cotton.

3. Cellobiose is obtained from flax cellulose in yields equivalent to those from cotton. This assures that at least two glucose residues are combined in the cellulose and suggests that probably at least three are combined in a unit from which the cellulose molecule is constructed—as proposed by J. C. Irvine.

4. Acetates of a trisaccharide and of an anhydro-trisaccharide may be obtained from flax cellulose. This supports the proposed anhydro-trisaccharide unit formula.

5. The above submitted results point to the chemical identity of cotton

CATALYTIC REDUCTION OF NITRILES AND OXIMES

BY WALTER H. HARTUNG

RECEIVED AUGUST 30, 1928 PUBLISHED DECEMBER 10, 1928

In a study undertaken in this Laboratory it became desirable to reduce oximes and nitriles catalytically to pure primary amines. A review of the available literature showed that a large amount of research has been done on this type of reduction but that invariably a mixture of primary and secondary bases was obtained, with the latter often predominating.

Benzonitrile and benzaldoxime when reduced by gaseous hydrogen with palladium or nickel catalysts gave mixtures of benzylamine, dibenzylamine and ammonia.[1] From α- and β-naphthonitriles, phenylacetonitrile and β-phenylpropionitrile, Rupe and his coworkers obtained mixtures of the corresponding primary and secondary amines with ammonia. From acetaldoxime and propionaldoxime triethyl- and tripropylamines, respectively, and ammonia were obtained, while from benzophenone-oxime Paal and Gerum isolated a 57% yield of primary amine. Mignonac[2] obtained ketimines from the oximes of cyclohexanone, acetophenone and propiophenone. Braun, Blessing and Zobel,[3] by reducing nitriles in various non-aqueous solvents, found that they obtained both primary and secondary amines, the amount of each depending on the concentration and on the nature of the solvent. Vavon and Berton[4] report that cyclic ketoximes reduced with platinum from hydroxylamines.

Rosenmund and Pfankuch[5] were the first to forestall the formation of secondary amine by using the acetate of the oxime and an acetic acid solution of the nitrile. Thus benzaldoxime acetate gave a 91% yield and benzonitrile an 80% yield of benzylamine, benzylcyanide gave a 73% yield of phenylethyl amine, while *p*-hydroxybenzylcyanide again formed secondary amine.

Hence it appears that except for the methods of Rosenmund and Pfankuch and Carothers and Jones,[6] there is no known general procedure for

[6] Carothers and Jones, THIS JOURNAL, 47, 3051 (1925), using platinum catalyst in acetic anhydride solvent, reduced several nitriles to the corresponding primary amines,

the catalytic hydrogenation or reduction of nitriles and oximes to the corresponding pure primary amines.

An investigation in this Laboratory shows that it is possible to reduce benzonitrile and benzaldoxime to primary amine without contamination from the secondary base, by carrying out the reduction with palladinized charcoal in a solution of absolute alcohol containing hydrogen chloride, the base being isolated as the salt. Benzonitrile with one equivalent, or more, of hydrogen chloride was reduced very smoothly to benzylamine hydrochloride. Benzaldoxime yielded similar results when three equivalents of hydrogen chloride were used, whereas with one equivalent a mixture of the salts of the primary and secondary bases was obtained. When no acid was present both the nitrile and oxime formed benzylamine, dibenzylamine and ammonia, as previous investigators have found.

Mandelonitrile was also reduced under similar conditions. The product, however, was not phenylethanolamine, as one might expect, but phenylethylamine, for the alcoholic hydroxyl was also reduced; this happened even when the reaction was stopped on the absorption of sufficient hydrogen to reduce theoretically only the nitrile group; but the yield of primary amine salt was very low, 52% of the theoretical, and a non-basic by-product was formed which was not identified. Much better yields of phenylethylamine hydrochloride were obtained by starting with the benzoic and acetic acid esters of mandelonitrile. Esterification of the hydroxyl group did not protect it, for both the benzoate and acetate resulted in good yields of phenylethylamine hydrochloride. A similar reduction of the hydroxyl group, also catalytically, is recorded by Rosenmund and Schindler,[7] who obtained phenylethylacetic acid and substituted phenylethylacetic acids from mandelic and substituted mandelic acids where the hydroxyl group had been esterified.

An attempt to reduce benzonitrile in a solution of dibutyl ether without hydrogen chloride was a failure for only about a tenth of the hydrogen calculated for the complete reduction was absorbed. That the catalyst had not become poisoned was demonstrated by the fact that it subsequently reduced benzonitrile in absolute alcoholic solution. An attempt to reduce mandelonitrile acetate in benzene solution also resulted in failure.

Procedure and Apparatus

The reduction was carried out by shaking the substance to be reduced in an atmosphere of hydrogen delivered from a graduated cylinder under a pressure of approximately 30 inches of water.

The oxime or nitrile was dissolved in the proper amount of absolute alcohol and placed along with the catalyst in the reaction flask. The

isolating them as their acetyl derivatives, from which the free amine could be obtained by subsequent hydrolysis.

[7] Rosenmund and Schindler, *Arch. Pharm.*, **266**, 281 (1928).

reaction flask was connected to the hydrogen delivery train by means of a ground-glass joint held together with rubber bands caught over small projecting glass hooks. The only rubber connection throughout the whole apparatus was that joining the hydrogen tank to the delivery tube. The air was removed by evacuating the apparatus, filling with hydrogen and repeating the process at least four times, which left an atmosphere of practically pure hydrogen. No hydrogen was taken up until agitation was begun.

Reagents and Materials

The catalyst was palladinized charcoal, prepared according to the directions of Ott and Schroter.[8] Three grams of pure animal charcoal from Merck and Co. was shaken with an aqueous solution of 0.45–0.50 g. of palladium chloride in an atmosphere of hydrogen until saturated. The charcoal was then filtered off, washed, dried and kept in *vacuo* over sulfuric acid until used. Each catalyst could be used for three or four experiments.

The hydrogen was a pure, commercial, electrolytic product. Before reaching the reduction flask it was passed through an alkaline solution of pyrogallol, a solution of sodium hydrosulfite and then through a long tube containing calcium chloride and soda lime. The hydrogen so purified was entirely satisfactory and good results were obtained with it.

The benzonitrile was used as obtained from Eastman Kodak Company.

The benzaldoxime was prepared from benzaldehyde and hydroxylamine and boiled at 101–103° at 6–7 mm.[9]

The mandelonitrile was prepared according to the directions of Ultée.[10] To a mixture of 26.5 g. (0.25 mole) of freshly distilled benzaldehyde and 8.2 g. (0.3 mole) of hydrogen cyanide[11] was added a few drops of concentrated potassium hydroxide solution as catalyst. The temperature rose spontaneously to 50°; after it began to cool, the mixture was placed in a freezing bath and within about an hour, with occasional shaking, crystals began to appear on scratching the walls of the container, and very soon almost the whole mixture was solid. The crystals were removed by suction on a previously cooled Buchner funnel and by again freezing the filtrate more crystals were obtained. The crystalline product was pressed, in the ice-box, between two porous plates to remove non-crystallizable matter; this left a beautiful white product that melted at 20°, which agrees with the figure given by Ultée. "International Critical Tables," Vol. I, gives the melting point for mandelonitrile as −15°. No medium was found for recrystallizing the mandelonitrile, not even when the solutions were chilled in a mixture of ether and carbon dioxide snow.

Mandelonitrile benzoate was prepared as described by Francis and Davis.[12]

Mandelonitrile acetate was prepared according to the directions of Michael and Jeanprêtre.[13]

Experimental Results

Reduction of Benzaldoxime.—Three grams of benzaldoxime (0.025 mole) was dissolved in 40 cc. of absolute alcohol containing 3 equivalents of hydrogen chloride, and

[13] Michael and Jeanprêtre, *Ber.*, 25, 1681 (1892).

in ninety minutes reduction was complete. The catalyst was removed by filtration, the first aqueous washing evaporated to dryness, the residue taken up in hot absolute alcohol and added to the filtrate. The alcoholic filtrate was partially evaporated and diluted with excess ether. The crystals thus obtained melted at 258°; the yield of hydrochloride was practically quantitative. When but one equivalent of hydrogen chloride was used the product melted at 220–230°; it formed two benzenesulfonyl derivatives, the alkaline insoluble one melting at 67°,[14] and the alkaline soluble derivative melting at 86–87°.[15] The primary amine predominated, however. When no hydrogen chloride at all was used, a mixture of primary and secondary bases resulted.

Benzonitrile reduced under the same conditions as described for benzaldoxime resulted in pure benzylamine hydrochloride. Here, however, one equivalent of hydrogen chloride, or more, prevented the formation of secondary amine, whereas without hydrogen chloride a mixture of benzylamine, dibenzylamine and ammonia was obtained.

Reduction of Mandelonitrile.—A solution of 5.8 g. of mandelonitrile (0.0436 mole) in 90 cc. of absolute alcohol containing 0.049 mole of hydrogen chloride absorbed 2080 cc. of hydrogen in ninety minutes; the amount calculated for reduction to phenylethanolamine was 1970 cc.; for complete reduction to phenylethylamine, 2950 cc. The catalyst was removed by filtration and the filtrate was reduced to a volume of about 15 cc. and diluted with excess ether, which caused a crystalline solid to settle out; the solid, after recrystallization from absolute alcohol, melted at 215°.[16] The free base distilled at 200°[17] and when exposed to the air quickly formed a solid which effervesced with dilute acid and after washing with ether melted at 103°.[18] The product formed an alkali-soluble benzenesulfonyl derivative which melted at 68–69°.[19] It formed a benzoyl derivative which melted at 120°.[20] Comparison of the product here obtained and its derivatives with known phenylethanolarnine hydrochloride and its corresponding derivatives, showed them to be distinctly different compounds. Thus mandelonitrile was reduced to phenylethylamine. The salt is, however, obtained in small yield (52%) for rectification of the alcohol-ether mother liquors showed that a non-basic by-product was formed which was not identified.

Reduction of Mandelonitrile Benzoate.—A solution of 5.9 g. (0.025 mole) of mandelonitrile benzoate in 60 cc. of absolute alcohol containing 0.057 mole of hydrogen chloride absorbed, in sixty minutes, 1640 cc. of hydrogen; calculated for reduction to the benzoate of phenylethanolamine, 1125 cc.; for reduction to phenylethanolamine, 1680 cc. The product, isolated in the usual manner, gave the characteristic tests for phenylethylamine hydrochloride and was obtained in 84.5% yield. Attempts to use only one equivalent of hydrogen chloride, added during the course of reduction, also resulted in phenylethylamine but in poorer yields and with contaminating by-products.

[17] Boiling point of phenylethylamine, 197–198" at 725 mm. (Mulliken, ref. 16).

[18] Phenylethylamine carbonate melts at 101–104° [Fileti and Piccini, *Ber.*, **12**, 1700 (1879)].

[19] Johnson and Guest, *Am. Chem.* J., **42**, 248 (1909), give the melting point of N-phenylethylbenzenesulfonamide as 68–69°.

[20] Melting point of N-phenylethylbenzamide, 113–114° [Bischler and Napieralski, *Ber.*, **26**, 1905 (1893)].

The reduction of mandelonitrile acetate was carried out after the manner of the benzoate. From 4.4 g. (0.025 mole) of the nitrile acetate there was obtained in seventy-five minutes 3.9 g. of phenylethylamine hydrochloride, a yield of 74.5%.

Conclusions

1. Benzonitrile was reduced catalytically in absolute alcoholic solution to pure benzylamine by means of palladinized charcoal when one equivalent, or more, of hydrogen chloride was present; without hydrogen chloride a mixture of benzylamine, dibenzylamine and ammonia was formed.
2. Benzaldoxime was similarly reduced to pure benzylamine when three equivalents, or more, of hydrogen chloride were present. With one equivalent, or more, of the acid a mixture of the primary and secondary bases resulted.
3. Mandelonitrile was reduced in absolute alcoholic solution containing hydrogen chloride to phenylethylamine, but the yields of primary amine were poorer because a non-basic by-product was formed.
4. The benzoate and acetate of mandelonitrile were also reduced; though the esters of phenylethanolamine were not formed, good yields of phenylethylamine were obtained.

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XVIII. PARA-NITROBENZYLIDENE GLYCOLS AND GLYCEROLS

BY HAROLD HIBBERT AND MURRAY G. STURROCK[1]

RECEIVED SEPTEMBER 28, 1928 PUBLISHED DECEMBER 10, 1928

In order to facilitate the isolation of the various isomeric forms obtained in condensing an aldehyde with glycerol,[2] it seemed advisable to try to find some aldehyde capable of yielding crystalline cyclic acetals.

Experiments carried out with *p*-nitrobenzaldehyde show that this material condenses readily with both ethylene and 1,3-trimethylene glycol, yielding crystalline five- and six-membered cyclic acetals, respectively. Preliminary experiments using glycerol in place of the glycols gave a mixture of a crystalline and liquid *p*-nitrobenzylidene glycerol, a detailed investigation of which is recorded in the following communication (Part XIX).

---

[2] Hibbert and coworkers, THIS JOURNAL, 50, 2235, 2242, 3120 (1928).

Experimental Part

Preparation of *p*-**Nitrobenzylidene Ethylene** Glycol.—Twenty g. of *p*-nitrobenzaldehyde was mixed with 31 g. of ethylene glycol (2.5 times the theoretical) and 0.2 cc. of 40% sulfuric acid and the mixture heated, with agitation, on the steam-bath for six hours. On cooling, the product set to a solid mass of crystals. The latter were washed well with water, then a number of times with a saturated solution of sodium bisulfite and again with water. Recrystallization from alcohol gave 15 g. (60%) of pure *p*-nitrobenzylideneethylene glycol; m. p. 90.5°.

Anal. Subs., 0.1689; CO_2, 0.3430; H_2O, 0.0700. Calcd. for $C_9H_9O_4N$: C, 55.38; H, 4.60. Found: C, 55.08; H, 4.57.

The product is soluble in cold acetone, chloroform and pyridine, in *hot* carbon tetrachloride, alcohol and carbon bisulfide, but is insoluble in ligroin.

Preparation of *p*-**Nitrobenzylidene** Trimethylene Glycol.—Using a procedure similar to the above, 25 g. of 1,3-trimethylene glycol yielded 10 g. (71%) of pure *p*-nitrobenzylidene trimethylene glycol, m. p. 111.5°, having approximately the same solubilities as its lower homolog.

Anal. Subs., 0.2306; CO_2, 0.4873; H_2O, 0.1100. Calcd. for $C_{10}H_{11}O_4N$: C, 57.4; H, 5.31. Found: C, 57 6; H, 5.31.

Preparation and Separation of the Isomeric *p*-**Nitrobenzylidene Glycerols.**—Twenty g. of p-nitrobenzaldehyde, 24 g. of glycerol and 0.2 cc. of 40% sulfuric acid were heated, with stirring, for about six to ten hours. The temperature used in different experiments varied from 100 to 160". After cooling, water was added and the mixture extracted twice with ether. The latter solution was washed with a concentrated solution of sodium bisulfite and a small amount of water. The ether was evaporated under reduced pressure and the residue taken up with warm benzene. On cooling (and further evaporation, if necessary) crystals separated which were filtered off. Evaporation of the mother liquor yielded a second crop and the process was repeated until no further crystallization took place on long standing in the cold.

The combined yield of crystals was treated with animal charcoal and recrystallized from hot benzene, giving pure *p*-nitrobenzylidene glycerol, m. p. 85°, initially, increasing on standing to 99°.

Anal. Subs., 0.1224; CO_2, 0.2411; H_2O, 0.0535. Calcd. for $C_{10}H_{11}O_5N$: C, 53.5; H, 4.93. Found: C, 53.7; H, 4.84.

The oil from the mother liquor was dissolved in benzene, the solution heated with animal charcoal, filtered and the oily layer which separated on cooling further purified by precipitating several times from small volumes of benzene at −15°. The oil thus obtained proved to be the isomer of the above crystalline compound.

Anal. Subs., 0.2004; CO_2, 0.3028; H_2O, 0.0888. Calcd. for $C_{10}H_{11}O_5N$: C, 53.3; H, 4.93. Found: C, 53.5; H, 4.84.

Preparation of the Benzoates of the Isomeric *p*-**Nitrobenzylidene** Glycerols.—The benzoates of the two isomeric glycerol acetals were prepared in each case by dissolving 3 g. of the acetal in dry pyridine, adding an equal volume of benzoyl chloride and then warming slightly. After allowing ten minutes for completion of the reaction, the product was poured into 250 cc. of water, when the benzoates separated as a white or yellow paste.

The benzoate of the crystalline isomer was recrystallized from benzene; m, p. 198°.

Anal. Subs., 0.1388; CO_2, 0.2924; H_2O, 0.0524. Calcd. for $C_{17}H_{15}O_6N$: C, 62.07; H, 4.59. Found: C, 61.92; H, 4.52.

The benzoate of the liquid isomer was recrystallized from alcohol; m. p. 178°.

Anal. Subs., 0.1284; CO_2, 0.2909; H_2O, 0.0513. Calcd. for $C_{17}H_{15}O_6N$: C, 62.07; H, 4.59. Found: C, 61.78; H, 4.43.

Summary

1. p-Nitrobenzaldehyde condenses readily with ethylene glycol and 1,3-trimethylene glycol to give the corresponding cyclic acetals.
2. Preliminary experiments indicate that p-nitrobenzaldehyde readily condenses with glycerol to give an isomeric mixture of cyclic acetals.

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XIX. STRUCTURAL, GEOMETRICAL AND OPTICAL ISOMERISM OF THE PARA-NITROBENZYLIDENE GLYCEROLS AND THEIR DERIVATIVES

BY HAROLD HIBBERT AND NEAL M. CARTER[1]

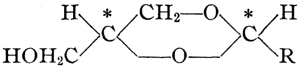
RECEIVED SEPTEMBER 28, 1928 PUBLISHED DECEMBER 10, 1928

Introduction

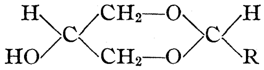
In previous communications[2] it has been pointed out that when an aldehyde (RCHO) condenses with glycerol, there results a "partition" of the aldehyde between the 1,2- and the 1,1′-hydroxyl groups, so that in the subsequent condensation structural isomers are formed, namely, five- and six-membered cyclic acetals.

An examination of these general types A and B

(A)



(B)



shows that the five-membered ring (A) should exist in two geometrically isomeric, optically resolvable racemic forms, due to the presence of the two asymmetric carbon atoms (*). On the other hand, the six-membered acetal, (B), representing as it does a case of pseudo-asymmetry, should exist only in two geometrically isomeric, non-resolvable modifications.

Only a few references to geometrical isomerism in heterogeneous ring systems are to be found in the literature. Among the better-known examples is its application to explain the difference between paraldehyde

---

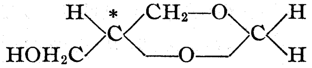
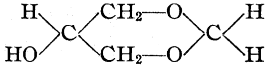
and metaldehyde.[3] Peacock,[4] in drawing attention to the existence of two optically active centers in cyclic acetals of type (A), mentions the possibility of geometrical isomerism, but his product was .of such a character that the isomerism might well have been due to a double bond in the aldehydic residue. A recent paper by Boeseken and Felix[6] is also of interest in this connection. The five-membered cyclic acetals of glycerol (with the exception of that from formaldehyde) should therefore show the interesting property of possessing simultaneously all three types of isomerism: structural, geometrical and optical. The six-membered acetals cannot give rise to optical isomerism due to absence of an asymmetrical carbon atom.[6]

The substitution of HCHO for RCKO in the formation of acetals, for example, the condensation of formaldehyde with glycerol, results in the synthesis of the two structurally isomeric acetals (C) and (D) (methylidene glycerols) in which geometrical isomerism is no longer possible.

(C)



(D)



and the authors have shown[2c] that only two structural isomers are actually formed, one of which, however, the five-membered acetal, should be capable of further resolution into two optically active enantiomorphs, due to the asymmetric carbon atom (*).

Following this, attempts were made to find a suitable product capable of yielding crystalline glycerol acetals of both types (A) and (B) and, while this has proved unsuccessful, it has nevertheless been possible (as is shown

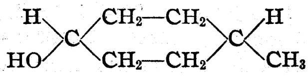
[5] Böeseken and Felix, *Ber.*, **61B**, 787–790 (1928).

[6] If the ring of formula (B), symmetrical about a line joining its terminal carbon atoms, be reduced to its simplest form, namely a double bond, a compound of the following type would be created:  $\begin{matrix}H\\HO\end{matrix}\!>C=C<\!\begin{matrix}H\\R\end{matrix}$. This, although unstable in itself, closely corresponds to the structure of cinnamyl alcohol:  $\begin{matrix}H\\HOH_2C\end{matrix}\!>C=C<\!\begin{matrix}H\\C_6H_5\end{matrix}$, which is admittedly an inactive compound. Compare Perkin, Pope and Wallach, J. *Chem. Soc.*, *95*, 1790–1791 (1909), and the structure of hexahydroterephthalic acid.

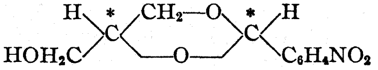
Confirmation of this view is found in the work of Gough, Hunter and Kenyon, *J. Chem. Soc.*, 2055 (1926), on the optical activity of secondary alcohols. In working with 2-, 3- and 4-methylcyclohexanols these authors found that the 2- and 3-isomers were resolvable while the 4-isomer, in accordance with the classical theory of symmetry, resisted all efforts at resolution. It will be observed that the structure of this compound



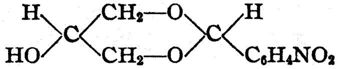
cis and *trans* forms, is quite analogous to the structure of a six-membered cyclic acetal of type (B).

in the experimental part) to isolate, in the case of the *p*-nitrobenzylidene glycerols, not only the two structurally different five- and six-membered ring isomers, but also to obtain, in the case of certain of their derivatives, the total number of isomers theoretically possible, namely, the two geometrically isomeric, racemic forms[7] of the five-membered ring type, (E), and the two geometrical isomers corresponding to the six-membered acetal, (F).

(E)



(F)



Preliminary experiments in this Laboratory[8] showed that the condensation of p-nitrobenzaldehyde with glycerol yielded two easily separable *p*-nitrobenzylidene glycerols, one crystalline and the other a slightly viscous oil. The former, even after repeated crystallizations, still exhibited a rise in melting point from 88°, when freshly crystallized, to 95–98° after standing for some days in a stoppered bottle. This change corresponds closely with that recorded by Irvine and coworkers[9] when investigating the benzylidene glycerols, and was attributed by them to partial decomposition.

The solid 1,1′-*p*-nitrobenzylidene glycerol (I) thus appeared to consist of a mixture of two geometrical isomers. Attempts to obtain the higher melting form in a pure state by recrystallization were unsuccessful due to the above-mentioned fact that the more stable derivative under these conditions again yields crystals with the lower melting point.[10] This change was at first attributed to a partial conversion of one ring structure into the other, but this did not explain why the melting-point of the crystals should *rise* if they tended to revert to the viscous, oily isomer. Work was therefore undertaken with the object of obtaining crystalline derivatives by replacement of the hydrogen in the remaining hydroxyl group of the free acetals, so as no longer to permit of such a *structural* change, thereby facilitating the isolation of the theoretically possible geometrical isomers. This has now been successfully accomplished and the synthesis and relationship of these derivatives is indicated below.

Isomeric Derivatives from 1,1′-*p*-Nitrobenzylidene Glycerol (I).—Methylation of the crystalline mixture of isomeric 1,1′-*p*-nitrobenzylidene glycerols (I) yielded two isomeric 1,1′-*p*-nitrobenzylidene glycerol 2-methyl ethers (III and IV), the constitution of each being definitely

---

[7] The resolution of certain of these racemic forms will afford additional evidence of the ring structures, and is shortly to be undertaken.

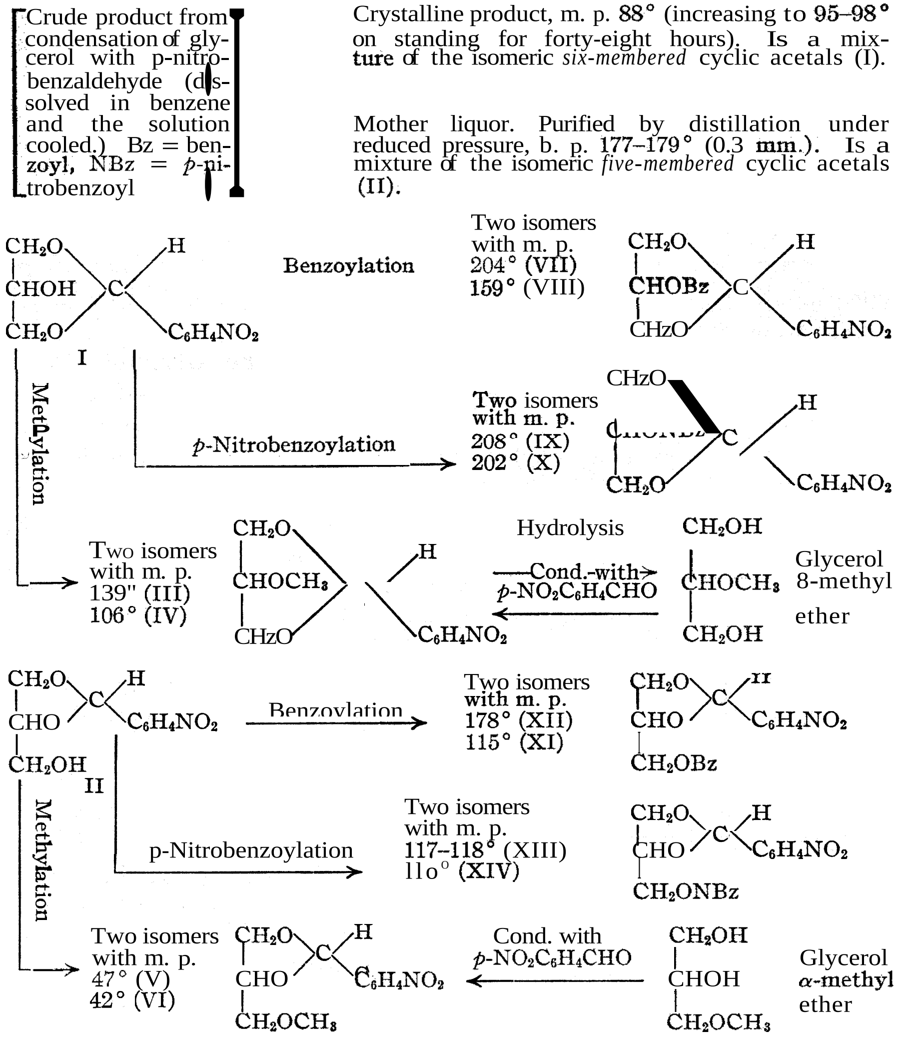
[9] Irvine, Macdonald and Soutar, J. Chem. *Soc.*, 107, 344 (1915).

[10] A similar case of conversion of geometrical isomers on solution occurs with iodoacrylic acid. The isomer melting at 65° is converted into that melting at 139–140° on recrystallization from ligroin [Stolz, *Ber.*, 19, 542 (1886)].



Crude product from condensation of glycerol with p-nitrobenzaldehyde (dissolved in benzene and the solution cooled.) Bz = benzoyl, NBz = *p*-nitrobenzoyl

Crystalline product, m. p. 88° (increasing to 95–98° on standing for forty-eight hours). Is a mixture of the isomeric *six-membered* cyclic acetals (I).

Mother liquor. Purified by distillation under reduced pressure, b. p. 177–179° (0.3 mm.). Is a mixture of the isomeric *five-membered* cyclic acetals (II).

proved by their separate hydrolysis, and identification in each case of the resulting product by means of its physical properties (boiling point and refractive index), as glycerol β-methyl ether.

This result was further confirmed by condensing *p*-nitrobenzaldehyde with glycerol β-methyl ether (obtained by hydrolysis of 1,1′-benzylidene glycerol 2-methyl ether), and again identifying the resulting product as a mixture of III and IV. This latter experiment also served to definitely identify acetal I and its derivatives as belonging to the six-membered ring type.

In separating III from IV by fractional crystallization there was observed the same peculiar tendency for crystals of one form to commence growing on facets of the other that was experienced in separating other pairs of stereoisomeric derivatives of this acetal. In some cases when working initially with small quantities, the presence of two isomers of different melting points was only established by isolating the two forms by hand, using for the purpose a needle point under a lens. Ordinary careful recrystallization yielded a product of indefinite melting point unless the process was at least partially mechanical.

Following the isolation of the two isomeric methyl ethers, that of the corresponding benzoates VII and VIII and of the p-nitrobenzoates IX and X was accomplished.

Isomeric Derivatives from **1,2-*p*-Nitrobenzylidene** Glycerol (II).—The 1,2-*p*-nitrobenzylidene glycerol (II) was purified by distillation under very low pressure (0.5 mm.). The distillate obtained was an apparently homogeneous, slightly viscous, amber-colored oil which resisted all attempts at crystallization. On methylation it was converted into a yellowish oil which crystallized only after inoculation with crystals of the two forms of the anticipated 1,2-*p*-nitrobenzylidene glycerol 1′-methyl ethers (V and VI), which were obtained by direct synthesis from glycerol α-methyl ether and *p*-nitrobenzaldehyde. Although two isomeric methyl ethers should be formed in the methylation of the 1,2-*p*-nitrobenzylidene glycerol II, it was only possible to isolate one of these (V) in appreciable amount, due probably to the further depression of their already low melting points (42 and 47°, respectively), by impurities in the mother liquor. It is also possible that in the distillation process, or during methylation, conditions exist which favor the formation of the one ether (V) at the expense of the other (VI). Nevertheless, it was found possible to obtain definite evidence of the presence of the second isomer (VI), and the simultaneous production of traces of 1,1′-*p*-nitrobenzylidene 2-methyl ether (III) showed that the method of purification of the 1,2-*p*-nitrobenzylidene glycerol (II) by distillation was not sufficient to free it from the last traces of its structural isomer, the 1,1′-*p*-nitrobenzylidene glycerol (I).

Both isomeric forms (XIII and XIV) of the p-nitrobenzoate of the five-membered acetal (II) were prepared from the latter, and one form (XI) of the benzoate. The second isomeric benzoate (XII) had been previously isolated[7] in this Laboratory in connection with work done on another phase of this general problem.

Failure to isolate the two stereoisomeric forms of each of the two free acetals (I and II) is possibly to be attributed to the influence of the higher polarity associated with the hydrogen of the free hydroxyl group in facilitating the conversion of the labile into the stable form.[11] The pro-

---

[11] By conversion of the liquid acetal (II) into a mixture of its corresponding isomeric

duction, however, of both cis and *trans* isomers from apparently homogenous products upon treatment with certain reagents has been recorded.[3,12]

The close similarity of the melting points of certain of the stereoisomers obtained in this investigation is in accord with other known cases.

	Cis isomer, m. p.	*Trans* isomer, m. p.
1,2-Cyclobutane	137–138°	131°
Limonene nitrosochloride	103–104"	105–106°
Menthylamine	207–208°	209–210°

No efforts have as yet been made to determine the exact configuration of the geometrical isomers. The repeated occurrence of one well-developed crystalline, yellow or greenish form, and one more or less amorphous, white form in the case of certain of the stereoisomeric pairs suggests that the former may be the *trans* form.[13]

Experimental Part

Preparation and Separation of the 1,1′- and 1,2-*p*-Nitrobenzylidene Glycerols I and 11.—After several standard methods of acetal preparation had been attempted, a new procedure for this condensation was developed which is apparently applicable to any case where the aldehyde and polyalcohol have sufficiently high boiling (or melting) points.

One hundred and sixty-six g. of *p*-nitrobenzaldehyde (m. p. 106°, recrystallized from hot water) was heated for twenty niinutes at 120° with 110 g. (3% excess over the theoretical amount) of glycerol and six drops of 40% sulfuric acid as catalyst. During this period suction was gradually applied to the reaction flask until toward the end a pressure of 15 mm. was reached. This removed the water formed in the reaction as fast as it was generated; loss of weight calculated as water, 20.1 g. (105% of theoretical). The resulting homogeneous, light reddish oil was dissolved in sufficient benzene to keep in solution at 30° the crystals that tend to separate. The solution was washed at this temperature with dilute aqueous sodium bicarbonate to remove the excess glycerol and the sulfuric acid, then with water, and finally dried over sodium sulfate. On cooling the benzene solution to 0° overnight, large yellowish needle-like prisms of 1,1′-p-nitrobenzylidene glycerol (I) formed, both in the benzene solution and in the reddish oil which settled out during the cooling. These were filtered off and on recrystallization from benzene melted initially at 88°. On standing for a week the melting point had risen to 95° and the clear crystals had lost their transparency. After some time a maximum melting point of 98° was apparently reached, although recrystallization from benzene, at any stage, yielded crystals with the original m. p. of 88°.

The product is readily soluble in alcohol, ether, acetone, ethylene bromide and warm benzene but insoluble in ligroin and water. It is odorless and exhibits no tendency toward hydrolysis even after exposure to the air for prolonged periods of time.

benzoates XI and XII, and subjecting each of these separately to an alkaline hydrolysis involving only the benzoyl group, it is hoped to isolate the two forms of the acetal in a crystalline state.

[13] Paal and Schulze, *Ber.*, 35, 168 (1902).

53.35; H, 4.93. Found: C, 53.70; H, 4.84. Mol. *wt.* Subs., 0.3001; ethylene bromide, 39.50; *ΔT*, 0.404°. Mol. wt. found: 222. Theoretical: 225.

The mixture of reddish oil and benzene obtained as a filtrate in the separation of the above crystals became homogeneous on warming, and evaporation to one-fourth of its original bulk, followed by cooling yielded a second small crop of the crystalline isomer (I). This was removed by filtration and the oil thus obtained, when distilled under a pressure of approximately 0.5 to 1.0 mm., yielded at first a trace of unchanged *p*-nitrobenzaldehyde, later, a clear, amber colored, slightly viscous oil boiling between 195–215°. Redistillation of the latter under slightly lower pressure (approximately 0.3 mm.) yielded 95 g. of a similar oil boiling between 177 and 179°. Later experiments showed that this product still contained a small amount of the crystalline isomer (I). This distillate, which is the purest sample of 1,2-*p*-nitrobenzylidene glycerol (II) yet obtained, resisted all efforts at crystallization. When cooled to −70° a hard glass resulted, and a methyl alcohol solution, cooled to the same temperature, yielded an amorphous sludge which melted during the filtration at −20°. Other solvents proved equally ineffective as crystallizing media.

The liquid isomer is practically odorless and has the same solubilities as the crystalline isomer (I). Analysis, which would not be affected by contamination with (I), gave the following results.

Anal. Subs., 0.1833: CO_2, 0.3556; H_2O, 0.0810. Calcd. for $C_{10}H_{11}O_5N$: C, 53.35; H, 4.93. Found: C, 52.90; H, 4.94.

Total yield of mixed I and II (crude): 248 g. (99%); yield of I (crude): 121 g. (48%); yield of II (crude): 127 g. (51%).

It will be noted that this does not give the same ratio of I to II that was found in the interconversion experiment described later.

Synthesis of the Isomeric 1,1′-*p*-Nitrobenzylidene Glycerol 2-Methyl Ethers (III and IV)

(A) Methylation of the Isomeric 1,1′-*p*-Nitrobenzylidene Glycerols (I).—One hundred grams of 1,1′-*p*-nitrobenzylidene glycerol (I) was methylated with 160 g. of dry silver oxide and 100 g. of methyl iodide at 30° over a period of three hours, sufficient dry ether being added at intervals to keep the mass well mixed by the mechanical stirrer. The bulky reaction mixture was extracted five times with boiling benzene and once with boiling ethyl alcohol. Removal of both solvents under reduced pressure left 70 g. (68%) of the crude crystalline ethers. These were dissolved in warm ethyl alcohol (60°) and the flask was then allowed to cool until spontaneous crystallization set in at around room temperature, when the remaining solvent was poured off. If the cooling is too sudden, or the liquid is agitated, an apparently homogeneous, crystalline mass of needles with indefinite melting point (90°) results, which under a lens appears as small granules (m. p. 106°) growing from the facets of well-developed needles, melting at 139°. To obtain a satisfactory separation of the two isomers which appeared to be present, the following procedure was adopted.

The total yield of mixed ethers was dissolved in one liter of absolute alcohol at 70° and all traces of crystals removed by washing down the neck of the Erlenmeyer flask with hot alcohol. The flask was then surrounded by a large volume of water at 65–70° and the whole allowed to cool slowly until approximately one-fourth of the weight of the solid had crystallized out, which necessitated lowering the temperature to nearly 0°. The crystals were filtered off and the mother liquor was then evaporated down under reduced pressure to two-thirds its original bulk, and the same procedure of cooling followed. By repetition of this process until cooling of the final mother liquor to −10°

yielded only a negligible amount of crystals, four or five successive crystalline crops were obtained. The first two had a melting point of 137–139°, the middle crop an indefinite melting point around 90°, and the final crops a melting point of 102–105°.

By suitable recrystallization and combination of these fractions from the same solvent, the two pure 1,1'-*p*-nitrobenzylidene glycerol 2-methyl ethers were isolated to the extent of 30 g. of III, 35 g. of IV and 5 g. of the unseparated isomers.

III was obtained as grayish needles (m. p. 139°), odorless, readily soluble in warm alcohol and ligroin, soluble in cold benzene, ether and acetone and insoluble in water.

Anal. Subs., 0.1937: CO_2, 0.3923; H_2O, 0.0938. Calcd. for $C_{11}H_{13}O_5N$: C, 55.21; H, 5.48. Found: C, 65.21; H, 5.42. *Mol. wt.* Subs., 0.2144; ethylene bromide, 43.40; AT, 0.240°. Mol. wt. found: 243. Theoretical: 239.

IV preponderated as silky white needles (m. p. 106°), odorless, and slightly more soluble in organic solvents than its isomer, III.

Anal. Subs., 0.2030: CO_2, 0.4169; H_2O, 0.1007. Calcd. for $C_{11}H_{13}O_5N$: C, 55.21; H, 5.48. Found: C, 55.38; H, 5.52. *Mol. wt.* Subs., 0.2089; ethylene bromide, 42.62; AT, 0.234". Mol. wt. found: 251. Theoretical: 239.

That III and IV are two geometrical isomers is further substantiated by the following experiment.

(B) Condensation of Glycerol &Methyl Ether with *p*-**Nitrobenzaldehyde.** Synthesis of **1,1'-*p*-Nitrobenzylidene** Glycerol 2–Methyl Ethers.—One g. of glycerol *β*-methyl ether (prepared by hydrolysis of 1,1'-*benzylidene* glycerol 2-methyl ether)'" was condensed with 1.5 g. (slight excess) of recrystallized p-nitrobenzaldehyde, using a small drop of 40% sulfuric acid as catalyst. The reaction flask was placed under reduced pressure and heated to 120° for fifteen minutes. Spontaneous crystallization of the resulting material readily took place on cooling and from the crystalline product two isomers melting at 139 and 106" were obtained by careful crystallization from methyl alcohol, following the procedure outlined above. These proved to be identical with the previously prepared isomers (III and IV). Glycerol 8-methyl ether obtained by hydrolysis of 1,1'-*methylidene* glycerol 2-methyl ether[So] also yielded these same isomers (III and IV).

Hydrolysis of the Isomeric **β-Methyl** Ethers of 1,1'-*p*-Nitrobenzylidene Glycerol **(III and IV).—The** hydrolysis of the higher melting isomer III was effected by refluxing it for five hours with 60% ethyl alcohol in the presence of 2 cc. of concentrated hydrochloric acid, and subsequent removal of the acid with lead carbonate. The lower melting isomer IV was hydrolyzed by refluxing it for eight hours with 10% methyl alcohol and 2 cc. of concentrated hydrochloric acid, and removal of the acid by careful neutralization with potassium hydroxide solution. In both cases the neutral solution was then evaporated to less than one-fourth of its bulk. This removal of the alcohol, followed by cooling to a few degrees below 0°, brought about the separation of the greater part of the *p*-nitrobenzaldehyde formed in the reaction. This was filtered off, the filtrate evaporated under diminished pressure and the glycerol 6-methyl ether distilled from the remaining solids under a pressure of 13 mm. with as low a bath temperature as possible. In both cases glycerol 8-methyl ether, b. p. 122–3° (13 mm.), refractive index (n^{20}_D = 1.4480), was the sole liquid reaction product. The yield from isomer III was 8.3 g.; from isomer IV, 8.8 g., that is, approximately 90% in both cases.

Synthesis of the Isomeric 1,2-*p*-Nitrobenzylidene Glycerol 1'-Methyl Ethers (V and VI)

A preliminary methylation of a small quantity of 1,2-*p*-nitrobenzylidene glycerol (II) yielded only a non-crystallizable oil. It was therefore thought advisable to effect the synthesis of the expected methyl ethers by a more direct process in which, due to the use of fewer reagents, a purer product capable of crystallization might be obtained. The following procedure proved satisfactory.

(C) Condensation of Glycerol or-Methyl Ether with **_p_-Nitrobenzaldehyde.**—Twenty g. of glycerol α-methyl ether, prepared by hydrolysis of 1,2-*iso*propylidene glycerol 1′-methyl ether was condensed with the calculated amount (30 g.) of recryss tallized *p*-nitrobenzaldehyde under the influence of 2 drops of 40% sulfuric acid, by heating for twenty minutes at 110° under 20 mm. pressure. The resulting clear, amber-colored liquid was dissolved in ether, washed with dilute potassium carbonate solution and dried over solid potassium carbonate. On evaporation of the ether, a clear, light-colored oil remained which did not crystallize even on long standing at 0°. Fortunately, however, a single crystal had been obtained in a preliminary trial experiment where the product had been accidentally subjected to a temperature of −20° for some days. Inoculation with this crystal at 0° caused the immediate solidification of the above oil. Methyl alcohol was chosen as most suitable for recrystallization since on just dissolving the product in this solvent at 18°, crystallization rapidly begins below 0°. The process of deposition was carefully watched during the cooling from 0 to −20° and as soon as the characteristic formation of a lattice work of large yellow, prismatic crystals ceased (−10°), the mother liquor was then allowed to warm a few degrees and the crystals separated. Upon further cooling to −20° a deposit of white, feather-like crystals appeared on the sides and bottom of the container.

The yellow prisms proved to be 1,2-*p*-nitrobenzylidene gycerol 1′-methyl ether (V), m. p. 47°, soluble at 20° in all ordinary organic solvents except ligroin, but insoluble in water.

Anal. Subs., 0.1903: CO_2, 0.3856; H_2O, 0.0896. Calcd. for $C_{11}H_{13}O_5N$: C, 55.21; H, 5.48. Found: C, 55.21; H, 5.26. *Mol. wt.* Subs., 0.2016; ethylene bromide, 42.42; AT, 0.217'. Mol. wt., found: 258. Theoretical: 239.

The white, feathery crystals retained their characteristics, even after recrystallization from the same solvent, thus sharply distinguishing them from the above yellow prisms. Analysis proved the compound to be 1,2-*p*-nitrobenzylidene glycerol 1′-methyl ether (VI), m. p. 42°, isomeric with the above ether (V). It is slightly more soluble in most solvents than its isomer.

Anal. Subs., 0.1926: CO_2, 0.3933; H_2O, 0.0927. Calcd. for $C_{11}H_{13}O_5N$: C, 55.21; H, 5.48. Found: C, 55.65; H, 5.38. *Mol. wt.* Subs., 0.2759; ethylene bromide, 44.51; AT, 0.284". Mol. wt., found: 257. Theoretical: 239.

These results, keeping in mind the difficulty experienced by Gilchrist and Purvis[14] in analyzing glycerol methyl ethers, and the confirmative results obtained in the following synthesis by direct methylation, leave no doubt that V and VI are the two geometrical isomers sought.

(D) Methylation of the Isomeric **1,2-_p_-Nitrobenzylidene** Glycerols (II).—Twenty g. of the redistilled 1,2-*p* nitrobenzylidene glycerol (II) was methylated by the addition of 35 g. of dry silver oxide and 55 g. of methyl iodide over a period of three hours at 30°. The reaction mixture was extracted with boiling methyl alcohol and the extract dried over solid potassium carbonate. The alcoholic solution was evaporated to a volume of 30 cc. and then cooled to −20°, when a lower oily layer separated out. This could not be induced to crystallize until inoculated with a trace of the mixture of the two isomers obtained in synthesis (C), just described. The resulting sludge which formed at −20° was separated by filtration at this low temperature as a crystalline product which melted at room temperature (yield, 15 g., 75% of the theoretical). Careful

---

[14] Gilchrist and Purvis, J. Chem. *Soc.*, 127,2744 (1925).

fractional crystallization from methyl alcohol at −20° yielded three distinct products. The first fraction, melting at 138°, proved to be identical with one of the 1,1′-*p*-nitrobenzylidene glycerol 2-methyl ethers (III) obtained by methylation of the six-membered acetal (I), although the very small amount obtained (0.5 g.) indicated that its presence was due to the impossibility of completely separating the two structurally isomeric #-nitrobenzylidene glycerols (I and II) by distillation. The middle fraction consisted of 7 g. of yellow crystals melting at 47°, and was recognized by means of its melting point, crystalline form and solubilities as one of the two isomeric 1,2-*p*-nitrobenzylidene glycerol 1'-methyl ethers (V) synthesized in the previous experiment *(C)*. The remaining fraction yielded 2 g. of white, fluffy crystals melting at 41–42', identical in every respect with the second of the above two ethers (VI). The isolation of this product was rendered very difficult by its ill-defined crystalline form and the extraordinary tendency of remaining impurities in the last fraction to depress the melting point of the mixture to approximately room temperature.

Conversion of the Isomeric **1,1′-*p*-Nitrobenzylidene** Glycerols (I) into the Two **1,1′-*p*-Nitrobenzylidene** 2-Benzoyl Glycerols (VII and **VIII**).—Five g. of 1,1′-*p*-nitrobenzylidene glycerol (I) which had stood until its melting point had risen from 88 to 96" was benzoylated in the usual manner by mixing with 5 g. of anhydrous pyridine, then adding 3.1 g. of benzoyl chloride and allowing to stand for twenty-four hours at room temperature. The mixture was then treated for five minutes with 100 cc. of a 1% solution of sulfuric acid at 20° to remove excess pyridine. After washing with warm water, the apparently amorphous granular mass was dried at 70° and dissolved in ethyl acetate at 60°. On cooling slowly, the deposition of two crystalline forms was observed. To isolate these, the containing vessel was heated until the crystals had redissolved and was then immersed in a large volume of water at 60°, and the whole allowed to cool slowly to room temperature. A straw-colored mass of lustrous plates formed on the sides of the vessel, which increased in bulk until the temperature was lowered to 0°. Further lowering caused the separation of a white, fluffy precipitate in the body of the liquid, which redissolved on allowing it to warm to 0°. Separation and analysis of the first crystalline product showed it to be 1,1′-*p*-nitrobenzylidene 2-benzoyl glycerol (VII), m. p. 204°, soluble in ether, acetone, warm ethyl acetate, benzene and boiling ligroin, but insoluble in water; yield, 2 g.

Anal. Subs., 0.1388: CO_2, 0.2924; H_2O, 0.0524. Calcd. for $C_{17}H_{15}O_6N$: C, 62.07; H, 4.56. Found: C, 61.92; H, 4.52.

By evaporation of the mother liquor from the above crystals to half its bulk and again cooling to 0°, a dense, white mass coagulated in the body of the liquid. Filtration yielded an almost amorphous, fluffy, lustrous white mass (m. p. 159°), which also proved to be 1,1′-*p*-nitrobenzylidene 2-benzoyl glycerol (VIII), isomeric with VII. It is slightly more soluble in organic reagents than its isomer; yield, 1.5 g.

Anal. Subs., 0.1385: CO_2, 0.3127; H_2O, 0.0564. Calcd. for $C_{17}H_{15}O_6N$: C, 62.07; H, 4.56. Found: C, 61.60; H, 4.55.

From a sample of the freshly recrystallized 1,1′-*p*-nitrobenzylidene glycerol (I) only the benzoate melting at 204° (VII) was obtained.

Conversion of **1,1′-*p*-Nitrobenzylidene** Glycerol (I) into the Two Isomeric **1,1′-*p*-Nitrobenzylidene 2-*p*-Nitrobenzoyl** Glycerols (**IX** and **X**).—Twenty-five g. of *p*-nitrobenzylidene glycerol (I), which had stood until the melting point had risen from 88 to 96°, was dissolved in hot chloroform and 5 g. of pyridine added. This was run slowly into a mixture containing 21 g. of *p*-nitrobenzoyl chloride, 10 g. of pyridine and sufficient chloroform to keep the product liquid at 70". An exothermic reaction took place, the product after standing overnight at room temperature changing into a solid mass. This was dissolved in more chloroform, washed with dilute sodium bicarbonate solution, dried over calcium chloride and the chloroform and pyridine removed as far as possible by heating under reduced pressure; yield, 32 g. The resulting amorphous product was shaken thoroughly with 0.1 N sulfuric acid to remove the remaining traces of pyridine, then washed with water and dried at 70°. Recrystallization from hot toluene yielded two distinct crystalline forms of the *p*-nitrobenzoate, which persisted in growing jointly from separate nuclei. It was not found possible, using this or other solvents, to obtain well-formed crystals. The separation of the two isomeric *p*-nitrobenzoates (IX) and (X) was effected by separating the crystals from appropriate nuclei by hand, using a hand lens. The higher melting isomer (IX) was obtained in the form of straw-colored, well-developed, brittle spicules (m. p. 208°). It dissolves to an appreciable extent in hot benzene, alcohol, carbon tetrachloride and chloroform, although solution only takes place slowly. It is readily soluble in ethyl acetate, ether, acetone and hot toluene, but is insoluble in water.

Anal. Subs., 0.2035: CO_2, 0.4072; H_2O, 0.0686. Calcd. for $C_{17}H_{14}O_8N_2$: C, 54.53; H, 3.77. Found: C, 54.68; H, 3.77.

The second isomer (X) was isolated by hand, in the same manner, in the form of rosets of microscopic, white needles, m. p. 202°, possessing similar solubility relations to those of the corresponding isomer (IX).

Anal. Subs., 0.1219: CO_2, 0.2446; H_2O, 0.0412. Calcd. for $C_{17}H_{14}O_8N_2$: C, 54.53; H, 3.77. Found: C, 54.72; H, 3.74.

Conversion of 1,2-*p*-Nitrobenzylidene Glycerol (II) into 1,2-*p*-Nitrobenzylidene 1'-Benzoyl Glycerol (XI).—Five. g of the redistilled 1,2-*p*-nitrobenzylidene glycerol (II) was benzoylated in exactly the same manner as its isomer I. The benzoylated product, after recrystallization from ethyl acetate, yielded only one benzoate in the form of greenish-yellow, granular crystals, m. p. 115°. Its behavior toward solvents was similar to that of the benzoate (VII) obtained from the six-membered acetal (I).

Anal. Subs., 0.1320: CO_2, 0.3001; H_2O, 0.0529. Calcd. for $C_{17}H_{15}O_6N$: C, 62.07; H, 4.56. Found: C, 62.02; H, 4.48.

It was not possible to isolate tie second, theoretically possible isomer, although investigation by another worker,[8] using the crude, undistilled acetal (11), yielded a product with m. p. 178°. This was soluble in warm benzene, and appears to be the second isomer (XII).

Anal. Subs., 0.1284: CO_2, 0.2909; H_2O, 0.0513. Calcd. for $C_{17}H_{15}O_6N$: C, 62.07; H, 4.56. Found: C, 61.78; H, 4.43.

Conversion of 1,2-*p*-Nitrobenzylidene Glycerol (II) into the Two 1,2-*p*-Nitrobenzylidene 1'-p-Nitrobenzoyl Glycerols (XIII and XIV).—Twenty-five g. of undistilled 1,2-*p*-nitrobenzylidene glycerol (II) was *p*-nitrobenzoylated, using the same procedure as that adopted for the p-nitrobenzoylation of acetal I. The reaction mixture took much longer to crystallize prior to removal of the pyridine, and finally yielded 21 g. of a yellow, amorphous powder. The solubility of this mixed product in toluene is much greater than that of the structurally isomeric mixture of IX and X, hence benzene was used for recrystallizations. The same peculiar, simultaneous growth of two crystal forms from different nuclei was noted, as encountered when separating IX from X.

By manual separation under a lens, straw-yellow, brittle needles (smaller than those of the corresponding structural isomer IX) of m. p. 117–118° were obtained. These were soluble in toluene, ether, acetone, chloroform, hot alcohol or benzene, but insoluble in water. Analysis proved the product to be 1,2-*p*-nitrobenzylidene 1'-*p*-nitrobenzoyl glycerol (XIII).

Anal. Subs., 0.2033: CO_2, 0.4059; H_2O, 0.0676. Calcd. for $C_{17}H_{14}O_8N_2$: C, 54.53; H, 3.77. Found: C, 54.40; H, 3.72.

The isomeric 1,2-*p*-nitrobenzylidene 1'-*p*-nitrobenzoyl glycerol **(XIV)** was also isolated by manual separation as small, white nodules of microcrystalline structure with m. p. 110°, closely resembling the isomer **(XIII)** in solubilities and crystalline form. Only a very small amount was obtained, due to the laborious manipulation necessary to separate it from the corresponding isomer (XIII), since although considerable amounts of each were present, they were frequently too overgrown to permit of satisfactory separation.

The following summary of the properties of the *p*-nitrobenzoates of the two *p*-nitrobenzylidene glycerols shows the definite relationships existing between the pairs of corresponding isomers.

p-Nitrobenzoates of	Crystalline form	M. p.	Soluble in toluene
1,1'-*p*-Nitrobenzylidene glycerol **(I)**	Brittle, yellowish spicules **(IX)**	208°	Only when hot
	White, microcrystalline nodules **(X)**	202°	„
1,2-*p*-Nitrobenzylidene glycerol **(II)**	Brittle, yellowish spicules **(XIII)**	117–118°	In the cold
	White, microcrystalline nodules **(XIV)**	110"	„

Mutual Interconversion of the Five- and Six-Membered Acetals.—Addition of 0.01% by weight of dry hydrogen chloride to either 1,1'-*p*-nitrobenzylidene glycerol **(I)** or 1,2-*p*-nitrobenzylidene glycerol **(11)**, followed by heating to 130° for a period of one and one-half hours, brought about the establishment of an equilibrium between I and II. Several experiments were carried out, varying the quantities of materials, but using the same amount of catalyst. The same proportions of I and II, in approximately the ratio of 1 to 5, were always obtained.

The separation of the equilibrium mixture into its components was carried out as previously described (p. 3381) by the use of warm benzene. Moreover, as an additional test of the permanence of this phenomenon, the two isomeric acetals (I and II), isolated from one equilibrium experiment, were each allowed once more to attain equilibrium separately. A similar ratio to that above was again obtained.

Summary

1. *p*-Nitrobenzaldehyde condenses with glycerol to give two different structural types of cyclic acetals: a five- and a six-membered *p*-nitrobenzylidene glycerol, respectively.
2. From the five-membered 1,2-*p*-nitrobenzylidene glycerol two isomeric 1,2-*p*-nitrobenzylidene glycerol 1'-methyl ethers, presumably corresponding to the two theoretically possible, geometrically isomeric, racemic forms, have been prepared.
3. From the structurally isomeric six-membered 1,1'-*p*-nitrobenzylidene glycerol two isomeric 1,1'-*p*-nitrobenzylidene glycerol 2-methyl ethers, corresponding to the two theoretically possible, non-resolvable, geometrically isomeric forms, have been isolated.
4. The corresponding benzoates and *p*-nitrobenzoates of the free five- and six-membered cyclic acetals have been prepared and identified.
5. The ready interconversion under the influence of a trace of dry hydrochloric acid of each of the two structurally isomeric acetals, namely,

1,2-*p*-nitrobenzylidene glycerol and 1,1′-*p*-nitrobenzylidene glycerol, into an equilibrium mixture has been shown.

NOTE

A Temperature Regulator for Carius Furnaces.—The constant attention necessary to regulate the temperature of an ordinary gas-fired Carius furnace may be avoided by equipping it with a thermostat used to control the temperature of ovens on gas cooking stoves. Such a thermostat[1] is very easily installed, inexpensive and is accurate to about 5". The approximate range of the device is 100–325°.

The only precaution to be observed is not to turn the burner on full if, for example, a temperature of 100° is required, for the heat from the walls of the furnace will raise the temperature above 100° even after the thermostat has reduced the flame. The burner should be turned on approximately as it would be if no regulator were being used.

Thermostats of this type should be satisfactory for controlling the temperature of other gas-fired furnaces used in chemical work.

ADDITIONS AND CORRECTIONS

1922, VOLUME 44

The System Fe_2O_3–SO_3–H_2O, by E. Posnjak and H. E. Merwin.

P. 1984. In line 19 from the bottom read 1.681 instead of 1.618.

1927, VOLUME 49

Substituted O-Alkyl Hydroxylamines Chemically Related to Medicinally Valuable Amines, by Lauder W. Jones and Randolph T. Major.

The authors write as follows: "On p. 1531, line 9, the statement, 'Although O-methylhydroxylammonium chloride has been known for some time, the properties of the free base have not been described.' This statement is incorrect since the free base has been prepared by Traube and others, as described in *Ber.*, 53, 1485 (1920). This reference was accidentally overlooked. On p. 1486 of the article by Traube, the preparation of methoxy-urea was also described. However, no analysis of the compound was given and the melting point ascribed to it, 82–83°, was lower than that found for it by us and given on p. 1537, line 17, of our article. On p. 1533, line 27, the statement is found, 'Pure formyl *p*-nitrophenylhydrazone forms red crystals;' this should be, 'Pure formaldehyde-p-nitrophenylhydrazone forms yellow crystals.' The heading 'α-Alkyl-β-methoxythiourea' near the top of p. 1539 should bc 'α-Allyl-β-methoxythiourea.' In the next line the work 'alkyl' should be 'allyl.' "

P. 3063. In lines 4–5 from the bottom of the page "1-propyl-2-ethylcyclo-ethylcyclopentanol-1" should read "1-propyl-2-ethylcyclopentanol-1."

P. 3064. In the first line of the third paragraph of the Experimental Part "a-Ethyl-a-carbethoxy-cyclopenienone" should read "a-Ethyl-a-carbethoxy-cyclopentanone."

NEW BOOKS

Theoretical and Experimental Physical Chemistry. By J. C. CROCKER AND FRANK MATTHEWS. The Macmillan Company, New York, 1928. viii + 581 pp. 146 figs. 16 × 25.5 cm. Price, $6.00.

This large book is presented as a combination laboratory manual and textbook as well as a syllabus of physical chemistry for qualifying examinations.

As a laboratory manual it is inferior to the separate practical physical chemistries already published. The details of laboratory technique are inadequately considered and the errors of measurement (their sources, magnitudes and modes of decrease and of correction) are not presented. An insufficient number of experiments is offered, with the omission of such exercises as thermometry, barometry, pyrometry, colorimetry, nephelometry, standardizations of weight volume and balance, specific gravity of solids and volumenometry, the effusiometer and the gas balance, velocity of reaction, transition points, glass working and the calculation and plotting of results. Furthermore, the following particular forms of apparatus are omitted: Westphal balance, isoteniscope, Abbé refractometer, immersion refractometer, dropweight surface tension apparatus, Bingham viscometer and plastometer

As a textbook, it is, in many ways, an excellent presentation. The paper is good, the type is large and the drawings are clear. Practically all the parts of Physical Chemistry are taken up and they are adequately dcveloped. It is an unusually complete syllabus. However, the instructor will feel the lack of a list of problems and queries at the end of the chapters. The parts of the book have this sequence: gases, spectrometry, constitution and physical properties, chemical energetics, heterogeneous equilibrium, solutions and disperse systems, electrochemistry, chemical kinetics and reactivity and the theory of the atom.

A few minor criticisms should be noted. Illinium is not mentioned although rhenium and brevium are placed among the elements. Cassiopeium is given as an alternate name for the accepted element lutecium. "The Phase Rule" by Findlay is not in the list of reference books on that subject. The applications of active carbon and silica gel are not mentioned. In three-component systems, the right-angled isosceles triangle is used instead of the customary equilateral triangle.

However, the unusual attractiveness and completeness of the book recommend it for every library and for use as a textbook. A particularly meritorious quality is the proportionate development of all the topics in the entire field of physical chemistry so that no part is over-emphasized or neglected but each is given about the same extent of consideration.

RESTON STEVENSON

Physikalish-chemische Übungen. **(Manual of** Physical Chemistry.) By Dr. W. KUHN, Lecturer in Physical Chemistry at the University of Ziirich. **Verlag** A.-G. Gebr. Leeman and Co., Ziirich, Switzerland, 1928. 102 pp. 25 **figs.** 15.5 × 22.5 cm.

Most of the experiments covered in this small manual are chosen from the old and reliable group. The absence of any work on the densities of gases, and the inclusion of an experiment on the quinhydrone electrode, and of one on the simultaneous effect of two catalysts (iron and copper on the hydriodic acid–persulfate reaction), are perhaps the most novel features. Each experiment or topic is introduced by a concise statement and discussion of the principles involved, these theoretical portions occupying more than half of the book. They are generally well written, though there are a few weak points, such as the prominence given to the long-discredited capillary electrometer method for determining "absolute" potentials, and a serious error on page 11, where the relation between freezing-point lowering and activity coefficient of an electrolyte is stated in a way which is inadmissible even as an approximation.

The experiments themselves are very briefly described and no references are given, so some supplementary information to the student would usually be necessary or desirable. A feature which will recommend the manual to many is the fact that the apparatus required is all comparatively simple and inexpensive,

R. G. VAN NAME

The Properties of Silica. An Introduction to the Properties of Substances in the Solid, Non-Conducting State. BY ROBERT B. SOSMAN, Ph.D., Member of the Staff of the Geophysical Laboratory, Carnegie Institution of Washington. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1927. 856 pp. Illustrated. 15.5 X 23.5 cm. Price, $12.50.

This volume is a comprehensive treatise on the properties of substances in the crystalline and glassy states with special reference to silica. The subject is treated in the following parts: 1, Fundamentals; 2, Phases and their Transformation; 3, Symmetry and Structure; 4, Thermal Energy; 5, Mechanical Energy; 6, Silica in the Electric and Magnetic Fields; 7, Silica in the Periodic Electromagnetic Field; 8, Applications. An introductory chapter on the properties of substances in general is followed by chapters on the constitution and polymorphic forms of silica and their specific properties. The several chapters dealing with properties contain a brief statement of the meaning of the property under consideration; a summarized statement of present knowledge of the property as applied to silica; in some cases, a discussion of the degree of constancy of the "constants" for the forms of silica; a critical review of the experimental work which has led to general statements; and the formulation of hypotheses useful in summarizing the facts already known or in pointing the way to productive research. The author's recognition of the importance of hypotheses in the development of science renders the work of particular value in classifying and interpreting the voluminous literature on silica and in directing future experimentation. His statement of one essential quality of a genuine hypothesis, page 244, is quoted in full as an illustration of the author's point of view. "It [an hypothesis] must not explain the phenomena with too much facility. It is no real virtue in a theory of polymorphism, for instance, that it is capable of explaining not only all the existing data but also any imaginable facts of polymorphism which remain undiscovered. A theory which is capable of explaining all imaginable data in its field is, conversely, incapable of predicting any one experimental fact to the exclusion of any other; or, in the pragmatic philosophy, it is not a theory at all but a form of words. It has happened more than once in the history of science that two formulas which sounded very different, but whose corollaries were experimentally indistinguishable, have led to needlessly long and bitter polemics. Hence it will be well to devote our closest scrutiny to the deductions that follow from a given hypothesis, rather than to the plausibility and general attractiveness of the formulation itself."

In the presentation of the subject matter the author has made free use of section and paragraph headings and of carefully prepared tables and illustrations. The completeness and authoritative character of the book render it indispensable to those interested not only in the specific properties of silica but in the general characteristics of substances in the solid, non-conducting state.

HARRY B. WEISER

The Modern Calorimeter. By WALTER P. WHITE, Ph.D., Physicist in the Geophysical Laboratory of the Carnegie Institution of Washington. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 194 pp. 16 figs. 15 5 X 23.5 cm. Price, $4.00.

"The whole plan of the present book illustrates one method in scientific work, namely, the guidance of experimentation by analysis of the various physical processes and sources of error concerned. . . . . Its main idea is not instruction, though it should have some value as such, but the development of the subject through criticism and discussion. . ." In these words, the author strikes the keynote of the book.

Probably no technique in physical chemistry has ever been subjected to more careful scrutiny nor more scholarly analysis than has calorimetry in this book by Dr. White. The author has rendered a real service in collecting together in one convenient place all his work of the past twenty years in this field.

The book will not be read easily by the casual reader. The new worker in calorimetry would prefer to find specific directions for making a calorimeter, gladly accepting arbitrary, authoritative statements in which the author could rightfully indulge. But such is not the purpose of the book. The author gives all the factors which must be considered and references to modern literature but he does not give exact dimensions, nor the way to wind and insulate a heating coil, nor how to set the leads into the cover. In fact very few experimental data are included and in no case is an actual thermochemical experiment with its calculation given.

The investigator in this field may be confused by the large number of suggestions. He may prefer to plough ahead and amass data, evaluating his accuracy by experimental tests with his own apparatus under his own working conditions. He may rely on checking his results with accepted values and thermodynamic relations. But this is exactly the author's point—he warns the experimenter against starting his work until he has all the variables clearly before him. This careful, deductive analysis of errors emphasized by Dr. White should more often precede careful experimental work in all fields of research.

Not every worker in calorimetry will agree with the author in the relative evaluation of various factors but all workers will unite in expressing appreciation for the scholarly treatment and helpful collection of material.

In the first chapter the author gives an excellent discussion of errors, which is equally applicable to any experimental work. He distinguishes clearly between accidental and systematic errors and between accuracy and delicacy of measurement.

The various sources of error in calorimetry are discussed fully—radiation, convection, evaporation, adsorption, conduction, heat of stirring, time lag and thermal lag. Then follows a description of various methods including the constant temperature jacket, the adiabatic method, the vacuum-walled calorimeter, the twin calorimeter and the aneroid calorimeter. Special apparatus is fully discussed, including covers, stirrers, convection shields, leads and electrical connection, but detailed descriptions are not given. The last chapter summarizes in a very satisfactory manner the precautions necessary for different degrees of precision from 1 part in 300 to 1 part in 10,000.

Accessory manipulations are not given. The discussions are limited to "the measurement of heat by means of temperature change in suitable bodies." Accordingly no mention is made of heat of combustion, heat of mixing or heat of vaporization or specific heats or the flow method of calorimetry.

The book is well organized and free from errors.

No one should undertake a research in calorimetry without first studying this book.

FARRINGTON DANIELS

Bibliography of Crystal Structure. BY JARED KIRTLAND MORSE. Bulletin of the Crystal Structure Laboratory, Department of Physics, Ryerson Physical Laboratory, University of Chicago. The University of Chicago Press, Chicago, Illinois, 1928. xix + 164 pp. 8 figs. **15 × 23** cm. Price, $3.00.

This new monograph contains the following sections: an introduction, six papers originally published in the *Proceedings of the National Academy of Sciences* and a bibliography of crystal structure. The introduction describes the facilities, program and aspirations of the Crystal Structure Laboratory at the University of Chicago, ending with a somewhat thinly veiled solicitation of funds for the establishment of research fellowships and assistantships for the Laboratory. The papers represent the contributions from the Laboratory and with the exception of one devoted to the space group of potassium, rubidium and cesium sulfates, are very largely the theoretical deductions of the author of the monograph, particularly the structure and dimensions of the benzene ring and of ethane and methane. The bibliography is arranged alphabetically by authors under each year from 1912 to 1927. It is based admittedly on the bibliography published by Dr. Wyckoff in 1924 and brought up to date. This bibliography will undoubtedly prove useful to some workers in the field of crystal structure, although arrangement by subject matter such as is found, for example, in the "International Critical Tables," presents data in a more readily available form. No bibliography can be expected to be perfect in completeness, and in the present instance there are numerous omissions, particularly of papers the titles of which may not clearly indicate x-ray studies. Although the abbreviations for periodicals recommended by Chemical *Abstracts* are used, some of the spellings of chemical terms adopted by the American Chemical Society are overlooked. For example, "caesium" is used instead of the approved "cesium" and "sulphate" instead of the approved "sulfate." The price of three dollars for this paper-bound monograph is undoubtedly toq high, particularly inasmuch as the volume seems to be designed as a missionary for the author's laboratory. It seems, therefore, that in spite of the very evident painstaking work of Dr. Morse in preparation, the circulation and utilization will be limited.

GEORGE I,. CLARK

Photometric Chemical Analysis (Colorimetry and Nephelometry). By JOHN H. YOE, Ph.D., Professor of Chemistry, University of Virginia. Volume I, Colorimetry. John Wiley and Sons, New York, 1928. xxi + 771 pp. *72* figs. **15.5 × 23.5 cm. Price 58.50.**

This welcome addition to the reference books of analytical chemistry possesses many features which will be of interest to those who frequently have occasion to use colorimetric methods. The first seven chapters are devoted to a discussion of the general principles of colorimetry, colorimeters, methods of calculation, calibration errors, colloids and colorimetric stabilizers. Parts II, III and IV deal with the estimation of inorganic, organic and biological substances. Part V comprises a very extensive bibliography (181 pages) of the literature of colorimetry. The bibliography not only lists the publications bearing upon the subject, but is made much more useful by including with each reference a summary of the important points of the investigation. Under the methods of analysis each determination is discussed in detail, so that reference to the original article is rendered practically unnecessary. The discussion of each method usually includes notes which are of value in deciding upon its applicability. While the book is unusually complete and encyclopedic in character, it would have added to its value considerably had the author adopted a more critical attitude. The evaluation of a single method where several different methods are discussed for the determination of a given substance is left to the judgment of the reader. This, however, was apparently not done without deliberation. "The author earnestly hopes that workers in this field will cooperate in improving (and 'weeding out' if necessary) some of the less accurate and imperfectly studied methods given in this treatise. It is mainly with this idea in mind that these procedures have been included." The book is well indexed and type and binding are excellent.

LAWRENCE T. FAIRHALL

Organic Chemistry for Advanced Students. BY JULIUS B. COHEN, Ph.D., D.Sc., F.R.S., Emeritus Professor of Organic Chemistry in the University of Leeds. Fifth edition. Longmans, Green and Co., 55 Fifth Avenue, New York, 1928. Three volumes. Part I, Reactions. vii + 427 pp. 5 figs. Part II, Structure. vii + 487 pp. 63 figs. 2 plates. Part III, Synthesis. vii + 440 pp. 14 × 22 cm. Price, $6.00 per volume.

The fifth edition of this well-known work is composed in essentially the same manner as the earlier editions. The same subjects are now discussed more fully, with the inclusion of recent material to bring the treatment up to date. .Certain new subjects are introduced and constitute additions to the structure which supports the substance—but the structure is recognizably the same. Professor Cohen originally made an excellent choice of the significant facts and theories of organic chemistry. With each new edition he has, in general, treated the same features of the science, expanding the discussion as indicated by new research in the particular fields. He has exercised good judgment in the addition of significant new material. The work may perhaps be criticized for not making mention of certain new developments—chaulmoogric acid, high-pressure synthesis of methanol, etc., and organic compounds of germanium and lead, to specify a few of the omissions. It may be criticized for including in this fifth edition too much discussion of certain topics which were undoubtedly of prime importance at the time of the appearance of the first edition. Tautomerism is not now as mysterious as it used to be; its phenomena may be generalized and the wisdom of distinguishing various types of tautomeric change may perhaps be questioned. The relative merits of the several formulas early proposed for benzene have not been a live issue since Thiele proposed his doctrine of partial valence. Too much discussion of such matters gives the student a false idea of the present status of organic chemistry. Paradoxical as it seems, the science by dealing with an increasing diversity of facts is attaining a simplicity of point of view and an increasing power of correlation. A textbook which will make this situation clear to the student is now needed.

The faults of Cohen's work increase its value for certain purposes. The first chapter of the first volume is the best survey in English of the early history of organic chemistry. No student can read the entire three volumes without gaining an excellent idea of the history of the most important theories and lines of research. He will see how mankind has acquired the present science—and that seeing is probably the best way by which he may acquire the science for himself. He may or he may not chance to notice that the organic chemistry so acquired comprises, like the chemistry of the time of Robert Boyle, not only gold, and silver, and ivory, but apes and peacocks, too. Advanced students of organic chemistry have need of a textbook in which all of the important facts are suggested, all of the important lines of research are indicated, in which—apes and peacocks thrown overboard—all of the important correlations are set forth in a simple manner.

Volume I, entitled "Reactions," deals with the valency of carbon, the mechanism and dynamics of organic reactions and with abnormal reactions. Its most noteworthy new material is on the electron theory of valence, in particular on its application to aromatic compounds. Volume II, entitled "Structure," deals almost entirely with the relations between chemical constitution and physical properties, density, color, optical activity, etc., with the various types of isomerism, and with the structure of benzene. It contains new material on Sugden's principle of the "parachor," on the Walden inversion and the pinacoline rearrangement, and on the stereochemistry of the hydro-aromatic compounds and of organic compounds of inorganic elements. Volume III, entitled "Synthesis," deals with special types of complex molecules, the carbohydrates, enzyme action, the purines, proteins, terpenes and camphors, and the alkaloids—and appears to the reviewer to treat the special subjects in a well-balanced and adequate manner. The arrangement, however, is one which might well confuse a student. Substitution in aromatic compounds is discussed in one volume, the structure of benzene in another. If our knowledge of structure is gained from an observation of reactions, and if it is the mechanism of reactions which indicates the possibilities of synthesis, then the student will wonder how reactions, structure and synthesis can be treated separately, and will probably feel—as the reviewer does—that some other manner of subdividing the subject would result in greater fluency of understanding. The work suffers from having been revised, not that the revision hasn't been well done upon the old structure, but that some other structure—some other topical outline of the subject—would be better.

The books are well printed and are equipped with adequate subject and author indexes.

TENNEY L. DAVIS

Aids to Biochemistry. BY E. ASHLEY COOPER, D.Sc., F.I.C., A.R.C.S.. and S. D. NICHOLAS, B.A., A.I.C., Lecturers in Chemistry, University of Birmingham. William Wood and Company, 51 Fifth Avenue, New York, 1927. vii + 188 pp. 12 figs. 11 X 16.5 cm. Price, $1.50.

This book was written to present the general principles of biochemistry to medical and science students who have already studied the subject by means of larger textbooks or lecture courses. It is intended primarily for "purposes of revision." The subject is arranged both for reading and as a manual for experimental work.

The success of such a work for revision, or review, of specific courses of study depends upon the extent to which the material presented parallels that given in the study courses. This book will probably not appeal to those in this country who are prone to follow course work. On the other hand, it should prove valuable to one who desires short, concise statements of the fundamental facts and tests of biochemistry. The material is well and accurately presented; there are included chapters on naturally occurring amines and amides, biochemical mechanism of physiological action (disinfectants), alkaloids and tests for alkaloidal compounds and identification of organic compounds which are not usually met in biochemical books current in this country.

PAUL E. HOWE

A Textbook of Biochemistry for Students of Medicine and Science. BY A. T. CAMERON, M.A., D.Sc. (Edin.), F.I.C., F.R.S.C., Professor of Biochemistry, University of Manitoba. The Macmillan Company, New York, 1928. x + 462 pp. 12 figs. 2 plates. 14 X 21 cm.

The material is divided into seven sections as follows; Introduction and some Physical–Chemical Conceptions, Chapters 1–3; The Foodstuffs, their Derivatives and Related Compounds, Chapters 4–11; The Chemistry of Digestion, the Circulation and the Excreta, Chapters 12–18; Intermediate Metabolism, Chapters 19–28; The Chemistry of Reproduction, the Chemical Controlling Agencies of the Organism, Chapters 29–30; Quantitative Metabolism, Chapters 31–32; and a supplementary section with chapters entitled, An Introduction to the Chemistry of Immunology, The Utilization of Biochemical Processes in Industry and A Biochemical Introduction to Pharmacology. This is a first-class textbook with few errors and few misleading statements. After having read on p. *36* that from the crystal form of osazones "it is possible to identify the sugars that give rise to them" the student will be disappointed to read later that three of the four important hexoses give the same osazone. It is evident from the discussion on p. 162 that the author is unfamiliar with Cleveland's study of the role of protozoa in digestive processes in termites. In the discussion of the buffering system of the blood on pp. 201–205 the role of carbonic acid is given due attention but the importance of proteins is minimized. Strangely enough in a table on p. 177 showing the composition of normal human blood carbonic acid is classed simply as a waste product. The amounts of sodium and potassium in blood are correctly given in this table but an incorrect ratio of the two in blood is given on p. 347. Aside from a few such errors as these there is ample proof of a thorough knowledge of biochemical literature. The subject matter is presented logically and in good style. This textbook should be particularly useful to the student of biochemistry seeking reliable information of a general character unaccompanied with unwarranted speculation.

D. B. DILL

Biologische Kolloidchemie. (Biological Colloid Chemistry.) By DR. RAPHAEL ED. LIESEGANG. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1928. xii + 127 pp. 15.5 × 22.5 cm. Price, unbound, RM 8; bound, RM 9.50.

The author of this monograph covers a large field of literature inspiring those who search for problems still open for research, and with a very personal shade. The following chapters are treated: the colloidal medium of organisms, changes of dispersity, electric charge adsorption, swelling, surface tension, viscosity.

L. MICHAELIS

Physiology and Biochemistry of Bacteria. Volume I. Growth Phases, Composition and Biophysical Chemistry of Bacteria and their Environment and Energetics. By R. E. BUCHANAN, Ph.D., Professor of Bacteriology, Iowa State College and ELLIS I. FULMER, Ph.D., Professor of Biophysical Chemistry, Iowa State College. The Williams and Wilkins Company, Baltimore, Maryland, 1928. xi + 516 pp. 78 figs. 15.5 × 23.5 cm. Price, $7.50.

After a brief introductory statement, the subject matter of this book is divided into four chapters dealing, respectively, with growth phases, chemical composition, physico-chemical characteristics and energy relationships. Presumably, a consideration of bacterial enzymes, nutritive requirements, products of growth and so on are to be covered in a second volume. It is apparent on cursory inspection that at least one of the authors is a mathematician and physico-chemist who seems, in obeying his impulse in favor of mathematical treatment, to have to a great degree lost sight of the stated subject of the book. The reviewer does not wish in any way to minimize the importance of a mathematical treatment, however involved, of any biological phenomenon which thereby may be clarified. The reasons for his criticism of Buchanan and Fulmer's book will perhaps become clearer after an analysis of the contents.

The chapter on growth phases concerns itself with a subject upon which the authors have in the past done considerable experimental work and there may be justification in treating this at length, and mathematically. On the other hand, the chapter by the same authors in Jordan and Falk's recent book, together with the original papers which are available in most libraries, would appear adequately to cover the ground.

The chapter on chemical composition, some 75 pages in length, brings together a mass of material on this still relatively obscure subject. Many of the references are very old, and little critical analysis of the facts appears to have been attempted, nor is there any relationship evident between space allotment and importance of the various topics. For example, a consideration of bacterial pigments covers 20 pages, while "bios" is dismissed in two paragraphs. Thirteen pages are devoted to a discussion of carbohydrates and gums, of which an extremely inadequate account of the recent work of Heidelberger, Avery and others occupies only half a page. It must be obvious to most students who have followed this subject that both the chemical and biological work done on the polysaccharides of, for example, the pneumococci far outweighs both in accuracy and in significance any reports on the same subject preceding the year 1923.

The chapter on physico-chemical relationships covers some 230 pages, of which perhaps 25 pages deal with bacteriology in any apparent way. Surface tension, for example, is considered at some length, but with only occasional references to possible applications to bacteriology. Reference is made to the meiostagmin reaction on page 156 and again on page 172, but not by name, nor with any reference to Ascoli and Izar's work in 1910, since which the method appears to have been no further investigated. It would seem, moreover, that some review of the recent work by Larson and others on soaps in bacterial cultures should have been undertaken. The chapter contains, in all, about 150 numbered equations, and some 65 tables of physical constants, etc. If the gas laws and one or two other matters had been included, it might well serve as a textbook of physical chemistry.

The last chapter commences with a consideration of laws of motion, units of force and work, and a table of the values of the gravity constant at various positions on the earth's surface. This is followed by a long mathematical discussion of energy in its various forms, chemical thermodynamics and entropy. The book ends with an excellent compilation of existing information on the energy sources available to, and types of oxidation used by, bacteria. It might, perhaps, have been well to include some account of the work of Hopkins and his collaborators in connection with the mention of "philothion" on page 434, but in a bacteriological book this omission is not serious.

To the reviewer it seems that the field of physiology and biochemistry of bacteria is full of fascinating and important problems, many of which can here be investigated under optimal experimental conditions, and may have intensely significant bearings in broader fields. For this reason, he feels that a short book, so written as to stimulate interest rather than to discourage it, which would collect into compact form all the available information in a really critical way, would be of great value. The present volume falls far short of attaining this end. There are plenty of authoritative textbooks of physical chemistry and physics to which the earnest student of biology can readily go for the information he needs in a specific problem. The difficulty in Buchanan and Fulmer's book is to pick out from the mass of mathematics the biological facts which he may require.
