The heats of neutralization of these acids with changing concentration are recorded in Table VII. The results were calculated from the heats of dilution of factors and products with the aid of the well-known thermochemical equations.

TABLE VII

HEAT OF NEUTRALIZATION AT VARIOUS CONCENTRATIONS IN JOULES

(TEMPERATURE, 20°)

Moles of H_2O in factors	50 + 50	100 + 100	200 + 200	400 + 400	800 + 800
In products	101	201	401	801	1601
$H_3C_6H_5O_7$ + NaOH	53881	53298	52965	52825	52806
$H_2NaC_6H_5O_7$ + NaOH	52934	53130	53332	53489	53582
$HNa_2C_6H_5O_7$ + NaOH	53406	54663	55716	56441	56680

The values for the heat of neutralization of these acids are much smaller than those obtained by Richards and Rowe for strong inorganic acids. Furthermore, they do not approach the value 57.07 kj. to which these stronger acids tend at infinite dilution. These substances are, however, only slightly ionized even in the most dilute solutions investigated, so that it is probable that heat effects due to their ionization continue into solutions infinitely dilute.

The authors take pleasure in acknowledging their indebtedness to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory for essential financial assistance in carrying out this research.

Summary

1. The heats of dilution of citric acid, the acid citrates and sodium citrate have been measured at 16 and 20° over the concentration range of 50 moles to 1600 moles of water per mole of substance.

2. The heat capacities over the same range have been calculated with the aid of the Person–Kirchhoff equation.

3. No relationship has been found to exist between the degree of ionization and heat of dilution. Hence some factor or factors other than ionization play a predominant part in the heat of dilution of these solutions.

4. The regularity in the decrease of heat capacity of these solutions has been explained as due to the number of ions formed.

5. The heat of neutralization of citric acid and the acid citrate has been measured. The values found are much less than for strong acids. The temperature coefficient of the heat of neutralization of these acids is decidedly smaller than for inorganic acids and, indeed, in one case, is of opposite sign. These results are discussed.

THE VAPOR PRESSURE AND VAPOR DENSITY OF INTENSIVELY DRIED AMMONIUM CHLORIDE[1]

BY WORTH H. RODEBUSH AND JOHN C. MICHALEK

RECEIVED OCTOBER 8, 1928 PUBLISHED MARCH 6, 1929

The anomalous behavior of intensively dried ammonium chloride was first reported in the literature by Baker,[2] who found that the vapor density as determined by a Victor Meyer method indicated no dissociation into ammonia and hydrogen chloride. Baker's work was repeated by Gutmann,[3] who obtained results indicating complete dissociation. Baker[4] again repeated his measurements and remained convinced that the vapor density of intensively dried ammonium corresponds to no dissociation. Two determinations of vapor density were made upon dried ammonium chloride by Johnson[5] with contradictory results. Smith, Eastlack and Scatchard[6] report that Smith and Lombard found no dissociation for dry ammonium chloride vapor but these results have not been published. Most investigators have found the vapor of moist ammonium chloride to be completely dissociated, but here again there is lack of complete agreement and Smith and Lombard[7] in an extensive investigation found only partial dissociation for undried ammonium halides.

---

[1] This manuscript was prepared for publication some months ago but publication has been delayed because of the appearance of a preliminary report by A. Smits [*Rec. trav. chim.*, **46**, 445 (1927)] of a similar series of experiments, with results differing from those here reported. A note was published by the authors [*Proc. Nat. Acad.*, **14**, 131 (1928)] commenting on the discrepancies between the two series of experiments. Since a detailed report of Smits' experiments has not appeared, it seemed advisable to submit the manuscript for publication as originally prepared. Meanwhile a paper has appeared by Braune and Knoke [*Z. physik. Chem.*, **135**, 49 (1928)] reporting measurements on undried ammonium chloride which are in substantial agreement with those described in this paper.

Several determinations[8] have been made upon the vapor pressure of undried ammonium chloride, of which the work of Smith and Calvert is probably the best. Johnson, however, made measurements on both dried and undried specimens of ammonium chloride. His measurements were made with a spiral glass manometer under conditions which did not ensure high accuracy, but they indicated that the vapor pressures of the dried and undried forms were identical. This last result has appeared to many as very surprising indeed and the theoretical implications have been discussed at some length by Abegg[9] and Wegscheider.[10]

If the vapor pressures of the dried and undried forms are the same and the vapor of the one is dissociated while the vapor of the other is not, we have a situation very difficult to explain, for there must exist an equilibrium between the dissociated and undissociated molecules in the vapor state and in turn between each of these and the solid. The removal of the last traces of moisture must be supposed to shift this equilibrium. The most probable way in which this could be imagined to come about would be for the removal of the last traces of moisture to increase the free energy of the solid and in addition prevent the establishment of the dissociation equilibrium. This is not necessarily a thermodynamic impossibility, since the removal of traces of moisttire might conceivably involve large energy changes, but it is certainly contrary to experience. Results so surprising as these cannot be accepted without ample experimental confirmation and it appeared to the authors that it would be worth while to redetermine the vapor pressures and vapor density of ammonium chloride in various stages of dryness.

Experimental

Method of Drying.—The term "intensively dried" used in this paper is, of course, relative. In his work on liquids, Baker[11] used materials which had been dried for several years. In the case of ammonium chloride, however, all authors who observed abnormal behavior have obtained this result after drying for a period of a few days to a few weeks. The following general procedure was used in the preparation of what we designate as "intensively dried" material.

The apparatus of pyrex glass was baked out for eight to ten hours at 400–500°. During this outgassing process it was connected to the drying pump system and the highest possible vacuum maintained. Attached to the apparatus by a tube which projected outside the furnace was a bulb containing the sample of ammonium chloride

which was to be introduced. When the apparatus was cool this sample was introduced by repeated sublimations until it was spread in a thin layer over the inside of the apparatus. A high vacuum was maintained during this process so that the salt as introduced was free from all but minute traces of moisture. The temperature of the apparatus was then raised to the highest point (60–70°) which could be maintained without driving the salt out of the apparatus and the pumping out process was continued for five to ten days. The pump and drying-tube system merit a detailed description. The apparatus containing the salt to be dried was connected to a mercury vapor diffusion pump of special design and high capacity. Beyond this pump was a drying tube containing phosphorus pentoxide which had been introduced by distillation in a current of oxygen. Beyond this drying tube was an ordinary diffusion pump, another phosphorus pentoxide tube and then a high-vacuum type of oil pump. Liquid-air traps were used whenever their use appeared advantageous. It must be recognized, however, that a liquid-air trap in a line has the same effect on the passage of water vapor as a very narrow constriction.

The "superpump" was designed by one of the authors to take care of a defect in the ordinary diffusion pump that has been pointed out by Molthan.[12]

In the ordinary type of diffusion pump the mercury is condensed against a cold surface and runs back into the reservoir whence it is reevaporated and goes around the circuit again. Any substance, e. g., water, which the pump is removing from the vessel to be evacuated will be to a slight extent dissolved in and adsorbed on the surface of the condensing drops of mercury. This establishes in the ascending column of mercury vapor a small but definite partial pressure of water vapor and the limit of exhaustion is reached when the partial pressure in the vessel to be evacuated has reached this value. The phosphorus pentoxide tube immediately beyond the pump would tend to overcome this difficulty but it was felt that the design of the pump could be materially improved and the model shown in Fig. 1 was devised. It is not possible to avoid the condensation against a cold surface but the drops of mercury flow down against a refluxing stream of hot mercury vapor, so that any volatile constituent should be distilled out before the mercury reaches the reservoir. For the construction of the difficult seal we are indebted to Dr. Phipps of this Laboratory. The pump functioned perfectly and showed a high capacity on test with a McLeod gage. No stopcocks or rubber connections were used between the apparatus containing the material to be dried and the diffusion pumps. The tube connecting the apparatus to the pump system was preheated thoroughly at the point where the final seal off was to be made. It is believed that drying under the above-described conditions of high vacuum and elevated temperature is far more rapid than with the ordinary technique that has been used by previous investigators.

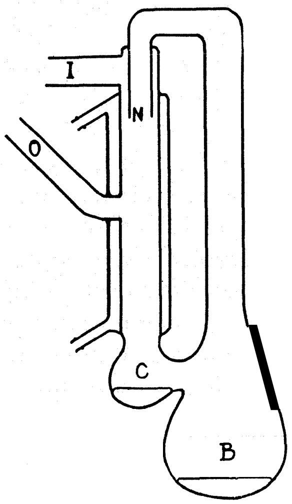

Fig. 1.

Materials.—The ammonium chloride used was either Mallinckrodt's or Kahlbaum's reagent quality. It did not give tests for other halogens and left no residue on sublimation. It was always introduced into the apparatus by repeating sublimation. Upon prolonged heating the ammonium chloride took on a yellowish tinge but there was no evidence of appreciable decomposition. The phosphorus pentoxide was Mallinckrodt's reagent quality. It was purified by distillation in a current of oxygen.

---

[12] Molthan, Z. *Physik*, 39, 1 (1926).

The distillation of phosphorus pentoxide in pyrex glass was always a troublesome operation.

The Vapor Pressure of Moist and Dry Ammonium Chloride.—By far the most satisfactory apparatus for measuring vapor pressures of substances like ammonium chloride is the glass diaphragm manometer. We are indebted to Professor Farrington Daniels for his experience in the construction of this gage and the apparatus shown in Fig. 2 embodies his latest ideas in its construction. The side tube A contains the ammonium chloride and is kept cool while the rest of the apparatus is being baked out. When the ammonium chloride is introduced into the main part of the apparatus the side tube A is sealed off. Connection is made with the drying pumps through the Tube G. When vapor pressure determinations are to be made the Tube G is sealed off under a high vacuum and the apparatus is introduced into a fused nitrate bath to the level shown at I. The details of the gage have been described by Professor Daniels. It is only necessary to note one point. The zero point of the gage changes with the temperature and (possibly) with the lapse of time, so that it must be rechecked after each determination. The tube G projects above the bath and may be cooled by a blast of air. When this is done the ammonium chloride sublimes out of the bulb and condenses in the tip of G, giving practically zero pressure in the apparatus. When a determination is to be made a heating coil is slipped over the end of the tube and the salt is driven back into the main part of the apparatus. The nitrate bath was provided with a thermo-regulator and while measurements were being taken the temperature was held constant to 0.02°. Temperatures were registered by means of thermocouples calibrated against fixed points recommended by the U. S. Bureau of Standards and temperature control of the bath was maintained by an automatic regulator which was actuated through a contact galvanometer by a thermocouple. The pressures on the outside of the diaphragm were measured by a mercury U-tube manometer. The vacuum above the mercury on the high side of this manometer was maintained by a mercury vapor pump. The heights of the mercury columns were measured with a cathetometer and repeated readings taken during a period of some hours usually checked to a few hundredths of a millimeter. The height of the mercury column was corrected to 0°. For the determinations on the moist salt the apparatus was sealed off from the pumps as soon as a good vacuum was obtained. The dry material was prepared by holding the apparatus at 60° for four days with the pumps operating continuously. A liquid-air trap was put into operation sometime before sealing off to remove mercury vapor.

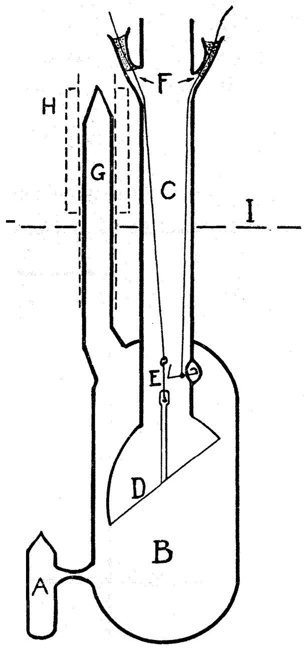

Fig. 2.

The data obtained are shown in Table I and the graph in Fig. 3. The figures given are in each case the means of several observations. The data obtained from the dried sample are indicated by asterisks. The results are in as good agreement as could be expected with the results of Johnson and Smith and Calvert, in view of the uncertainty in their measurements especially as regards temperature. The figures in Col. 4 are calculated from the equation $\log p = -(4402.1/T) + 10.1070$.

Table I

Vapor Pressure of Ammonium Chloride

	Temp., °K.	Obs. press., mm.	Log p (obs.)	Log p (calcd.)
1	557.0	159.63	2.2031	2.2030
2	546.1	111.19	2.0461	2.0460
3	523.2	49.47	1.6940	1.6940
4	507.1	26.46	1.4226	1.4260
5*	533.7	73.17	1.8643	1.8590
6*	532.6	69.76	1.8436	1.8400
7*	532.3	62.87	1.7984	1.8400
8*	529.9	63.63	1.8037	1.8010
9	532.5	69.31	1.8408	1.8410
10	471.3	5.93	1.7733	1.7660
11	501.3	21.68	1.3361	1.3250

The deviation is of the order of 1% except in the case of No. 7 and here there is reason to believe that the gage was not functioning properly. In

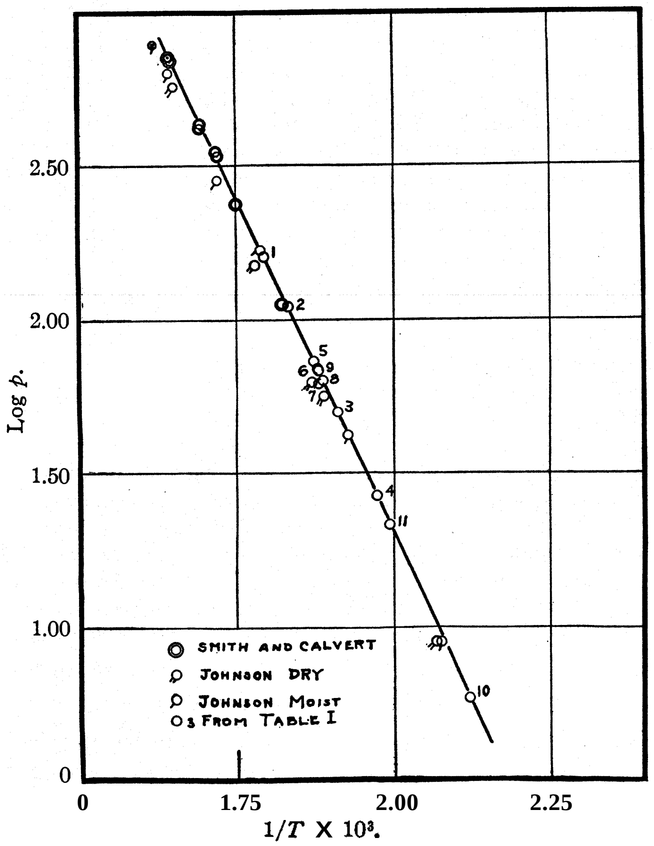

Fig. 3.

view of Johnson's results and ours there is no ground for believing that drying affects the vapor pressure of the salt. One effect of drying was unmistakable, however. This was the slowing up of the rate of evaporation and condensation. When the bulb contained moist salt and the Tube G was cooled the pressure fell very rapidly so that ten minutes would suffice for the pressure to fall to a value of a few mm., which corresponds to the transition temperature 184.3°, where the pressure would remain constant for some time. With the dried salt several hours would be required for all of the ammonium chloride to sublime out of the bulb and condense in the tube. So far as rate of evaporation and condensation were concerned the salt scarcely seemed to be volatile at all. This behavior would tend to confirm the reports that are to be found in the literature to the effect that gaseous ammonia and hydrogen chloride will not react when intensively dried. Another point requires comment. The heat of sublimation *per mole of vapor* as calculated from the vapor pressure equation above the transition point is 20,139. The heat of dissociation of solid ammonium chloride as measured calorimetrically is 41,900 Cal. per mole at 18°.[13] Allowing for a heat of transition of 970 Cal.,[14] but neglecting the difference in heat capacities of the solid and vapor, this gives a heat of sublimation above the transition point of 20,465 Cal. per *mole of vapor* for the completely dissociated salt. This figure is in such close agreement with the heat of sublimation obtained above from the vapor pressure equation that it is evidence in favor of complete dissociation for the vapor under all conditions. If the dissociation is not complete, then this agreement can only occur provided the heat of sublimation to the undissociated molecule be almost exactly half the heat of dissociation of the solid.

Vapor Density of **Ammonium** Chloride.—As was mentioned in the introduction to this paper, the experimental results on the vapor density of dried ammonium chloride which are given in the literature are not convincing. The methods which have been used are for the most part modifications of the Victor Meyer or Dumas methods. Neither of these methods is adapted for use in a determination where moisture is to be excluded or upon a substance which volatilizes slowly. The method of Knudsen[15] for the determination of vapor pressure by the rate of diffusion through an orifice is equally applicable to vapor density when the vapor pressure is known. This method has been used in this Laboratory for the determination of vapor pressures with success,[16] the only particular precaution necessary being that the surface of substance exposed be at least 100 times

the area of the orifice in order that the pressure of vapor in front of the orifice be kept at saturation. Such a method would seem to be ideal from the standpoint of intensive drying, since the solid salt will be subject to a continuous drying action during a run and successive runs should show a progressive drying effect, if such exists, in the apparent molecular weight. The apparatus is shown in Pig. 4.

The orifice was made by grinding away a tip drawn in the end of a pyrex tube. The edges of the orifice were very thin and the opening was nearly round. A large number of measurements of the diameter of the opening in different directions were made under a microscope with a step micrometer eyepiece. The diameter varied by only a small amount in different directions so that the area of the opening could be calculated with satisfactory accuracy. The orifice tube was sealed into the Bulb C, which was about 6 cm. in diameter. The ammonium chloride was introduced either directly or by sublimation from the side Tube B. The Bulb C was immersed in an oil-bath thermostat and a tube furnace was placed around the tube leading from the orifice to prevent premature condensation of the salt. During a run the ammonium chloride was condensed in the U-shaped bend T, which was surrounded by liquid air. The end of the tube was connected to the cascade of diffusion pumps and drying tubes.

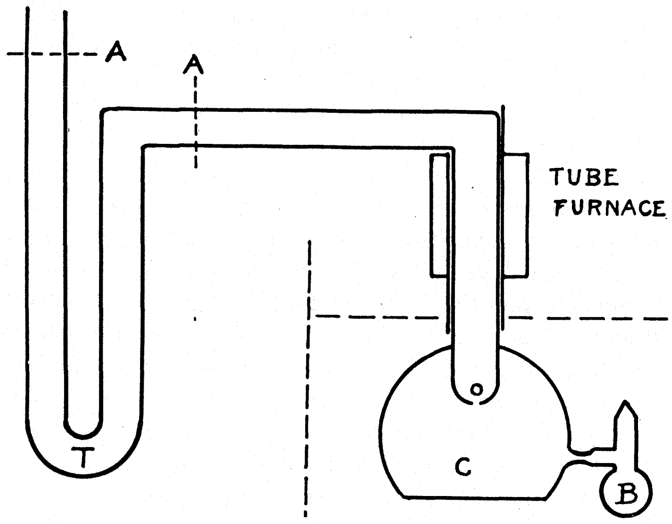

Fig. 4.

The temperature control was of the same accuracy as in the vapor pressure experiments and the same precautions were taken in the preliminary outgassing of the apparatus. In order to obtain a pressure low enough so that the simple kinetic theory could be applied to the process of effusion, it was necessary to work at temperatures below 100°. The pressures at these temperatures were calculated by means of the vapor-pressure equation, taking account of the heat of transition at 184.3 which has been determined by Bridgman[17] to be 970 cal. per mole. In making this calculation the vapor was assumed to be undissociated. The equation for rate of diffusion is

$$w = pat\sqrt{\frac{M}{2\pi RT}}$$

where w is the weight diffusing, p is the pressure in dynes, a is the area of the orifice, t is the time, M is the molecular weight, R is the gas constant in c. g. s. units and T is the absolute temperature. In case the vapor is not dissociated, this equation may be used directly to solve for the molecular weight. If the ammonium chloride is completely dissociated into ammonia and hydrogen chloride, it is easy to show that an apparent molecular weight will be obtained which is slightly different from the average for the two gases.

The preliminary drying was carried out in the manner previously described. When the apparatus was ready to begin a run it was brought to the desired temperature and the trap was immersed in liquid air. The time was noted with an accurate watch. The runs were of several hours duration. At the end of a run the trap was cut out of the apparatus at **A,** A, (Fig. 4) and the ammonium chloride was determined by precipitation of the chloride with silver nitrate. It was feared that the ammonia and hydrogen chloride might condense separately and escape on warming, so in several instances the trap was sealed off before the liquid air was removed, but no difference was noted in the results.

Results.—The results are shown in Table II. Except for No. 13, which is included for sake of completeness since the temperature got out of control during the overnight run, the results are uniformly low. Only one result is even high enough to correspond to complete dissociation. Since the surface of ammonium chloride exposed in the flask was more than 1000 times the area of the orifice, we are forced to conclude that a pronounced drying effect is obtained as soon as a vacuum is established, which slows up the rate of evaporation so that the pressure below the orifice falls below the saturation pressure. Even when moist ammonium chloride was introduced and the run started immediately the results obtained were low. When a preliminary pumping with the drying tubes was carried out, the results obtained were much lower still. If in extrapolating the vapor pressure to this temperature we had assumed complete dissociation, we should have obtained a higher pressure and consequently a still lower result would have been calculated for the apparent molecular weight. No conclusion may be drawn from these experiments as to the vapor density but the effect of drying on the rate of evaporation which was noticed in the vapor pressure

---

[17] Bridgman, *Proc. Am. Acad.,* **52**, 89 **(1916)**.

measurements is here confirmed in a positive manner. It must be noted that this slow rate of evaporation must be reckoned with in any method for the determination of vapor density.

Vapor Density by the Microbalance

The determination of vapor density by means of the buoyancy effect upon a thin-walled bulb has been developed to a high degree of precision by Stock.[18] A microbalance patterned after the design of Stock was constructed of quartz (see Fig. 5). The balance was enclosed in a tube which was maintained at a temperature constant to 1° by a surrounding furnace which was regulated by automatic thermostatic control. The balance case was connected by a tube to a bulb which was surrounded by a second furnace with an independent automatic temperature control. When solid

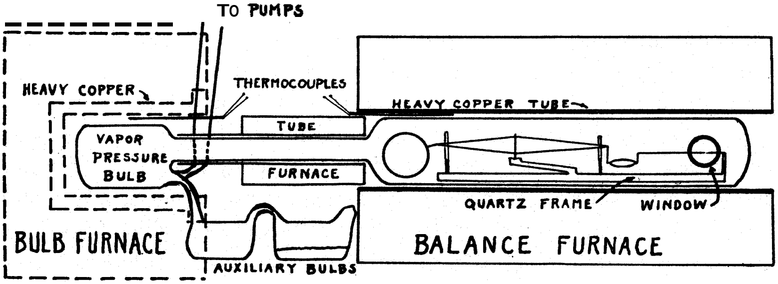

Fig. 5.

---

[18] Stock and Siecke, *Ber.*, 57,562 (1924).

ammonium chloride was placed in the bulb any desired pressure could be maintained in the balance case by varying the temperature of the bulb and hence the vapor pressure. This furnace could be held at a temperature constant to 0.1° for long periods.

Mode of Operation.—The apparatus was outgassed for ten hours at 480–500° under a high vacuum. The apparatus was then cooled and dried air introduced for the purpose of calibrating the balance. From the pressure and temperature the density necessary to bring the balance to the zero point was calculated by the gas laws. The data for the calibration are given in Table III. The two sets of figures given represent the extreme values of a series of determinations. A displacement of the pointer of 0.2 mm. corresponds to a change in density of about 0.001 g. per liter, and while it was possible to bring the pointer within 0.2 mm. of the zero position, accidental factors due to the high temperature and complicated apparatus caused a variation of an amount indicated by the figures in Table III. The temperature coefficient of the balance is negligible.

After the air had been removed, ammonium chloride was introduced into the vapor-pressure bulb and dried for ten days with the pump system operating continuously. The bulb containing the ammonium chloride was maintained at 60° and the rest of the apparatus at 300–400° during the drying operation.

A liquid-air trap was put into operation in the last twenty hours of drying. The apparatus was then sealed off according to the usual technique and the furnace brought to such temperatures that the density of the ammonium chloride vapor in the balance case was just sufficient to bring the balance to the zero point. The temperatures and corresponding vapor pressures for a series of observations are given in Table IV. In the fourth column are the apparent molecular weights as calculated by the gas laws from the pressures and temperatures. It will be seen that apparent molecular weights correspond to complete dissociation.

In order to be sure that complete equilibrium had been established between the vapor and solid, the apparatus was held at constant temperature

for twenty-four hours. When the temperature of the vapor-pressure bulb was changed by 1°, more than an hour was required for the resulting change in the microbalance pointer, showing again the effect of drying on the rate of establishment of equilibrium between vapor and solid.

Conclusions

It is impossible, of course, to assert positively that the ammonium chloride was sufficiently dried to produce the results reported by Baker and co-workers. It appears to the authors, however, that under the high vacuum and elevated temperature used in these experiments a few days' drying should be equal to several weeks by the methods used by previous workers in the field. The remarkable lag in the evaporation and condensation of the ammonium chloride observed in every case where the salt was dried would appear to be a satisfactory criterion of intensive drying. This slow vaporization would account for the high results obtained by Baker in his use of the Victor Meyer and Dumas methods, just as it caused low results in the effusion method as described in this paper. It must be remembered that Gutmann was not able to reproduce the work of Baker and that Johnson's results were contradictory. Smith and Lombard's results on the vapor density of the moist salt indicating incomplete dissociation are believed by the authors to be due to experimental error. In their determinations they distilled the salt into a bulb at constant temperature and the bulb was sealed off when filled with the saturated vapor. It seems likely that an excess of ammonium chloride was introduced into the bulb either by absorption on the glass surface or by mechanical convection. Smith argued that the vapor should be at the saturation pressure in order to show abnormal vapor density, but from the standpoint of thermodynamics there is nothing unique about the saturated vapor. In our experiments the temperature of the balance case was maintained 20–30" above the temperature of the vapor pressure bulb in order to avoid the adsorption of ammonium chloride on the microbalance. Since the largest area of surface was offered by the float bulb, adsorption would cause low results for the density. The temperature difference we believe would prevent any appreciable adsorption. On the other hand, if the dissociation is nearly complete at this temperature an extraordinary temperature coefficient would be required for any considerable reduction in the percentage dissociation at a temperature 25° lower. As has been pointed out earlier the hypothetical value for the heat of dissociation in the vapor phase is 20,000 Cal., which gives only a small temperature coefficient.

Summary

The vapor pressure of ammonium chloride is unaffected by intensive drying. This result confirms the work of previous investigators.

The rate of vaporization and condensation is affected to a remarkable degree by the state of dryness.

Ammonium chloride which has been dried for ten days at 60° in a high vacuum appears to be completely dissociated in the vapor state.

SONIC STUDIES OF THE PHYSICAL PROPERTIES OF LIQUIDS. I. THE SONIC INTERFEROMETER. THE VELOCITY OF SOUND IN SOME ORGANIC LIQUIDS AND THEIR COMPRESSIBILITIES[1]

BY EGBERT B. FREYER[2] WITH J. C. HUBBARD AND DONALD H. ANDREWS

RECEIVED OCTOBER 27, 1928 PUBLISHED MARCH 6, 1929

A number of investigators[3] have studied the velocity of sound in liquids at audible frequencies but the methods are beset with so many difficulties and involve the use of such large quantities of liquids that few results of adequate precision for thermodynamic treatment have been obtained. More recently[4] the field of high frequency sound production using piezoelectric crystals has been entered, and Hubbard and Loomis[5] have developed a method which has yielded very accurate values for the velocity of sound in liquids. The investigation recorded here was conducted according to their method and is a part of the general program of thermodynamic research on organic compounds now being undertaken at this Laboratory. The sonic interferometer has been further developed with especial reference to temperature control, the prevention of evaporation of the liquid being studied and of contamination by water vapor from the air.

Apparatus and Method

The electrical equipment is shown in Figs. 1, 2 and 3. When the circuit Y is tuned by means of the condenser (15), a heterodyne is produced between the two oscillating circuits. When the note is made to coincide in pitch with that produced by the tuning fork, the crystal in the interferometer is known to be vibrating with the same frequency

as circuit X[6] (this being fixed and determined by crystal (7)), plus or minus 1000 cycles, the frequency of the fork. Exact coincidence of the two audible frequencies is indicated by the disappearance of the easily discernible beats heard when the fork is operated.

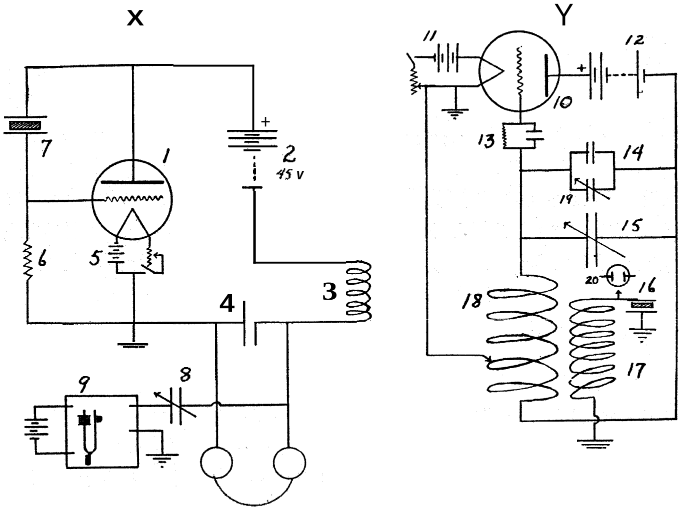

Fig. 1.—X, ***The Pierce Oscillator:*** 1, *UX*, 199 tube; 2, 45 volts; 3, choke, 30 millihenries; 4, 0.002 mf.; 5, two dry cells in series; 6, grid leak, 1 megohm; 7, crystal, see Fig. 2; **8**, 0.0005 mf.; 9, 1000-cycle electrically driven tuning fork (General Radio). Y. ***The Hartley Oscillator:*** 10, UX–171 or UX–210 tube; 11, 7 volts, D. C.; 12, 180 to 300 volts D. C.; 13, grid leak, 1 megohm; 0.002 mf.; 14, 1 to 3 mf. (so arranged that 1, 2 or 3 mf. may be used); 15, 0.001 mf.; 16, sonic interferometer, see Fig. 3; 17, 60 to 90 turns of No. 25 B. and S. insulated copper wire, wound closely, diameter of coil, 4"; 18, 30 turns of No. 16 B. and S. bare copper wire, coil 5" in diameter, 6" long, alternate turns provided with projections to clip onto; 19, two plate vernier condenser; 20, neon lamp, see Fig. 4.

The final tuning is effected by means of the vernier condenser. Assuming the lower surface of the interferometer piston to be in a nodal plane, *i. e.*, assuming a system of "stationary waves" in the liquid, the beats will return if the piston is raised or lowered even a very slight distance (0.002 mm.). By a proper simultaneous manipulation of

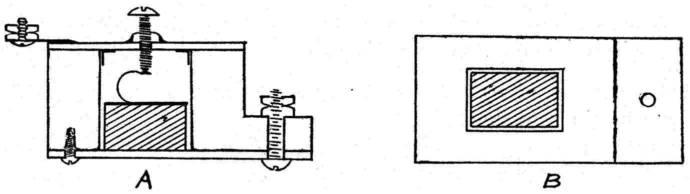

Fig. 2.—Housing for control crystal (7) in Fig. 1.

[6] G. W. Pierce, *Proc. Am. Acad.*, *60*, 269 (1925). For other circuits see *Proc. Inst. Radio Eng.*, **15**, 9 (1927).

the vernier condenser and the micrometer screw on the interferometer the nodes are located and their relative positions read from the micrometer screw scale. A reading of the screw setting is taken when the beat frequency is zero (piston in node); calling this reading x, and lowering the piston through the liquid for a distance of about two centimeters, counting meanwhile the number of nodes, n, a second screw reading, y, is taken for the position of another node. Then $(x - y)/n = \lambda/2$ and $2\omega \times (x - y)/n = v$, where ω is the frequency of oscillator Y, and v is the velocity of sound in the liquid.

The accompanying drawings illustrate the essential details of the apparatus. Brief mention may be made of the experimental arrangement.

The circuits were mounted on a board bearing a hard rubber panel supporting the condensers and rheostats; this was in turn mounted in a copper-lined box for shielding. The control dials were placed on the outside of this box to be within easy reach. As measurements were made in a number of different thermostats, the entire apparatus was made portable. The box was screwed to the top of a table mounted on rubber-tired casters. Several inches from the floor was a large shelf supported by the table legs; this carried all of the batteries. These and the leads to the circuits above them were shielded by enclosing the whole in copper window screening, using the table to support this. The wire leading from the secondary coil to the sonic interferometer was shielded by running it through a brass tube three centimeters in diameter by thirty centimeters long. It was attached to the side of the box through a universal joint. The lead was maintained rigid in the tube by having it pass through a glass tube supported at either end by corks. As there was a considerable potential between this wire and the shielding (about 1000 volts if a UX 210 tube is used), a pronounced condenser action resulted between the two; to keep this at a minimum, the lead was as short as possible and not too close to its shielding. Contact with the interferometer was made by a clip on the same, the contact itself being shielded by a sheath which slid over the brass tube bearing the lead.

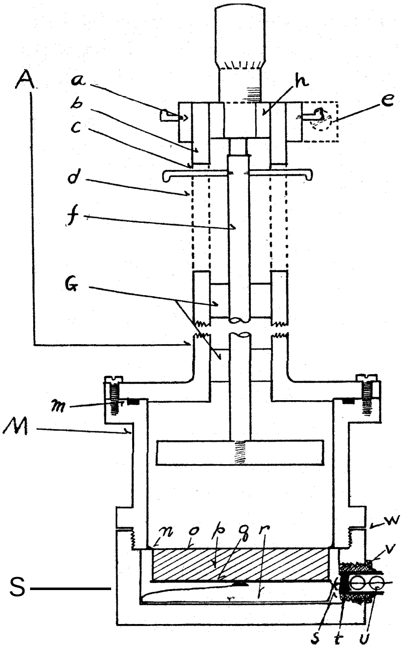

Fig. 3.—*The* **Sonic** *Interferometer:* Materials: *A*, bronze; *M*, iron; *S*, bakelite; f, "Invar" steel; *a*, *e*, clamp; *b*, four vertical slots, not shown; c, hook for rubber bands; *d*, slot; *g*, guide collars; m, rubber gasket, slightly thicker than depth of groove; *n*, Solder; o, phospho-bronze, 0.005" thick; *p*, quartz disk; *q*, bronze or brass; *r*, spring; *s*, good contact; *t*, deKhotinsky; *u*, glass beads; *v*, brass bushing into which is soldered the copper tube bearing the lead wire; *w*, water-tight seal. The piston and inside of the cup were gold plated.

An alternate, though less precise, method of detecting the nodes involves the use of a neon lamp (20). This was mounted in a tube as shown in Fig. 4; whenever the circuit was oscillating, the lamp exhibited a red glow. When the piston was exactly in a node, however, the glow either disappeared entirely (owing to the drop in the value of the current) or so changed in shape and intensity that there was no mistaking the position of the node as read on the micrometer screw. Even when this device was not used for the precise determination of the separation of the nodes, it very conveniently served as an indication of when the circuit was oscillating. The character of the glow was determined by the distance between strip (a) and the lamp. Cemented to the screw was a glass tube to insulate the high tension wire against the hand when adjustments were made. In general, for detecting nodes, the distance (a) was such that the glow was quite faint when the piston was *not* in a node. The lens rendered a better view of the glow. The device was mounted by a universal joint to the top of the box containing the circuits and could thus be made visible from any angle.

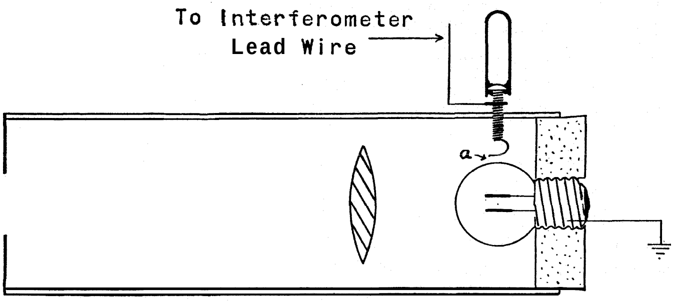

Fig. 4.

Materials.—With a few exceptions the samples studied in this investigation were prepared as follows: "Baker's C.P. Analysed" liquids were distilled through a three-foot punched-in column, only those cuts being taken for measurement that boiled within 0.1" of the latest published boiling points. Appropriate barometric and stem corrections were made. Those liquids that tend to dissolve water vapor were carefully dried and protected during storage. The glycerin (Baker's Analysed) was dried for several hours at water-bath temperature through phosphorus pentoxide. The purity of the bromoform and α-bromonaphthalene was questionable, but these liquids were included in the investigation only because they, like benzene, melt at a convenient temperature and it was desired to ascertain if the break in the velocity of the sound–temperature curve, noticed first in the case of benzene, was a phenomenon of general occurrence. The isomeric heptanes were prepared in the research laboratory of the Ethyl Gasoline Corporation and kindly loaned to us for use in this investigation.

Sources of Error and the Precision.—A possible source of error was the absorption of water vapor from the air during the actual measurement. This apparently was quite appreciable in the case of acetone, as manifested by the difference between two readings made an hour and a half apart. It was avoided by using a fresh sample of the liquid for each measurement. This error was borne in mind throughout the investigation and appropriate precautions were taken to avoid it. A new design of the spring mechanism on the piston entirely eliminates this source of error by closing up the slots (d).

For some reason not yet ascertained the oscillations were considerably weakened at temperatures above 50° and with some liquids they disappeared entirely. The values given for the velocity of sound at this temperature are extrapolated ones. If an air bubble is entrapped under the piston when it is inserted, the sonic "reaction" may be greatly weakened or entirely absent.

As a rule screw readings were taken on three or four adjacent nodes when the piston was near the upper limit of its range and three or four when it was near the lower limit, the number of nodes in the interval being, of course, known. Occasionally, however, the position of each node was determined, as sometimes the $\lambda/2$ value between two nodes near the center of the liquid column would be a freak one, differing for no apparent reason from all of the others. Such a value was ignored in averaging the values of $\lambda/2$. It is felt that this procedure was justified, considering the close agreement between all of the normal values and the great discrepancy between the normal ones and the "freak" datum, as illustrated in a sample determination shown in Table I.

As the data in the last column of (A) represent a precision greater than could be attained using different samples of a liquid, only four significant figures are retained for the most part in the final value of the velocity of sound. Usually independent measurements gave results that checked to one meter per second. The velocity of sound in water, for example, was found on two different occasions to be **1498.6** and **1498.3** m./sec. The average of a large number of determinations by Hubbard and Loomis with a different interferometer and at a different frequency gave **1498.1.** The former figures were obtained without making any special effort to attain the maximum precision of which the method is capable.

Mention should be made of the behavior of the frequency control crystal during these measurements. The crystal and its principal frequency calibration was furnished by the Naval Research Laboratory. In addition to the principal frequency, the crystal exhibited others, as is usually the case: a parallelopipedal oscillator may vibrate along three axes under proper circumstances, each of these periods may have overtones and the crystal may also oscillate with a period which results from the coupling of vibration of two of these modes. When these "overtones" are present they are quite definite and sharp (but easily distinguishable from the fundamental by the character of the audible heterodyne note). At one time, however, the constants of the circuit were such that abrupt changes in frequency occurred, the crystal vibrating now in one, now in the other, fundamental frequency. A careful check showed which liquids had been measured on the new frequency and its value was established in the following manner. Six careful determinations of the wave length in several different samples of pure, air-free distilled water were made. From the accurately known values of the velocity of sound in water-at the temperatures of measurement[5] the frequency was calculated. The velocity of sound values used were taken from a curve drawn through a large number of points (about 50) in a 40° temperature interval. They are believed to be accurate to one part in ten thousand. The values of the frequency thus found are as follows: 414.0, 414.1, 414.3, 414.1, 413.8, 413.8—mean, 414.0(1) kilocycles.

These were checked to about 1% with a wavemeter, and, further, at different intervals of time by other sound wave-length determinations. The definiteness and constancy of the new frequency was thus firmly established.

Results and Calculations.—In the following tables are given the

results of the velocity of sound measurements and the compressibilities and compressibility ratios calculated from them.[7]

The blanks are due to the absence of certain specific heat and coefficient of expansion data. It is hoped to fill these soon by measurements to be undertaken in this Laboratory. The density, specific heat and coefficient of expansion values used were the same as those used by Tyrer,[8] in the cases where comparison is made of the measured adiabatic compressibility data with those calculated from the velocity of sound. They are believed to be very trustworthy. Those not from this source were taken from the Landolt-Bornstein "Tabellen" and the "International Critical Tables." Table III is given to indicate briefly how the calculated compressibilities compare with those experimentally determined. In Figs. 5 and 6 are shown the velocities of sound and adiabatic compressibilities plotted against temperature. Tyrer's values for the compressibility of ether are included, since the compressibility data from the two sources for this liquid show a greater disagreement than do the data for any of the other liquids.

Attention is called to the slight deviation from linearity of the velocity of sound curve for benzene in a short temperature range just above the melt-

---

[7] The following are the equations used

$$V = \sqrt{\frac{1}{\beta_\varphi \rho}} \qquad \beta_T = \beta_\varphi + \frac{\left(\frac{dv}{dT}\right)^2 \rho T}{JC_p} \qquad \frac{C_p}{C_v} = \frac{\beta_T}{\beta_\varphi}$$

where V is the velocity of sound; β_φ is the adiabatic compressibility; β_T is the isothermal compressibility; dv/dT is the differential of the specific volume; J is the mechanical equivalent of heat; ρ is the density; C_p is the specific heat at constant pressure at $T°$ absolute.

[8] Tyrer, J. *Chem. Sec.*, 103, 1684 (1913).

ing point. This behavior suggested the measurements on aniline, bromoform, a-bromonaphthalene and glycerin. Except in the case of glycerin, somewhat similar breaks in the curves occur. The glycerin did not freeze.

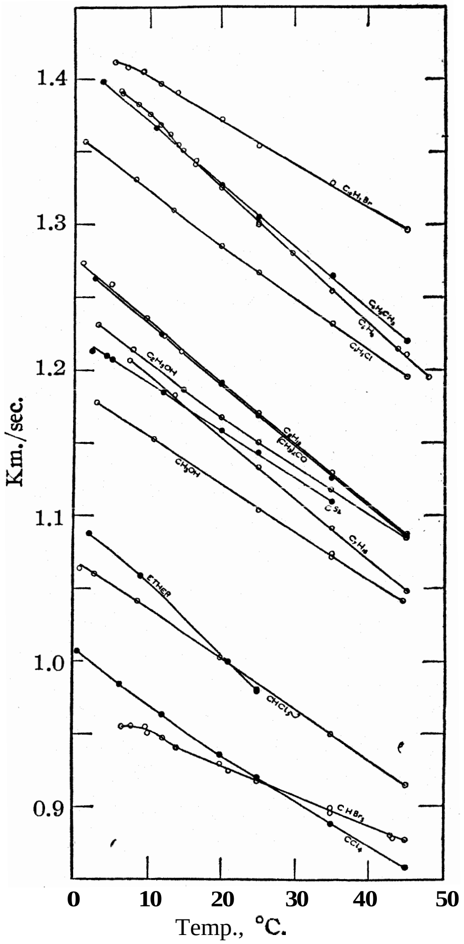

Fig. 5.

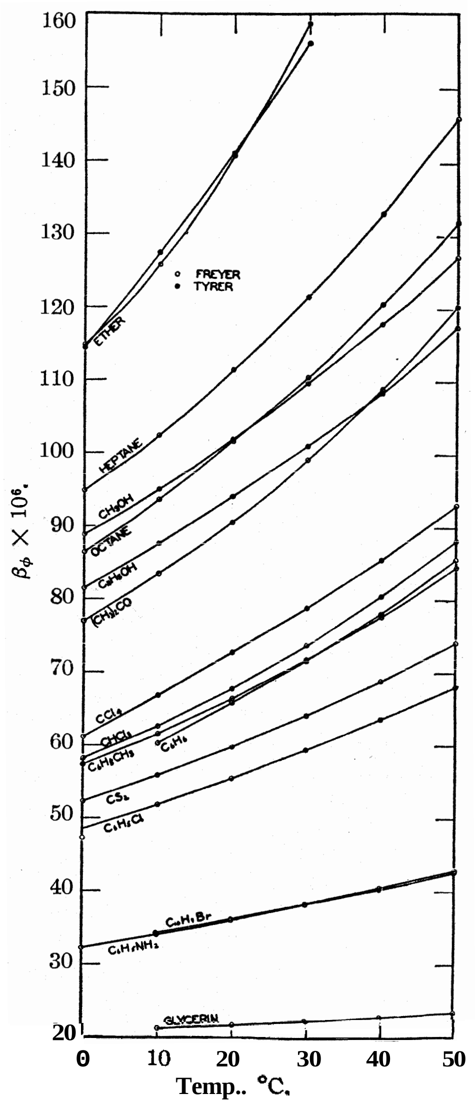

Pig. 6.

It seems reasonable to expect some sort of orientation or grouping of the molecules of liquids to occur preliminary to freezing that would occasion such a change, because the velocity of sound in a liquid is a function of properties directly depending on the molecular arrangement.

Discussing the dipole character of liquids, Gerlach[9] observes, "Dipoles, by their very nature, are favorable to association—after a fashion—a preliminary stage of microcrystalline character; .... it is not definitely known whether such a character is in evidence during the solidification of substances like benzol whose molecules exhibit not even the slightest dipole nature. Attention may be directed in this connection to certain experiments of Isnardi in which he has observed variations in the dielectric constant of benzene at temperatures slightly above its crystallization point. This would indicate, under such conditions, the existence of a dipole moment, but since Graffunder's results fail to confirm such a conclusion, further experimental evidence must be awaited." Unfortunately the compressibility measurements of Tyrer[8] do not cover the temperature range in question in sufficient detail to permit a confirmation of this irregularity in the velocity of sound in benzene by calculation.

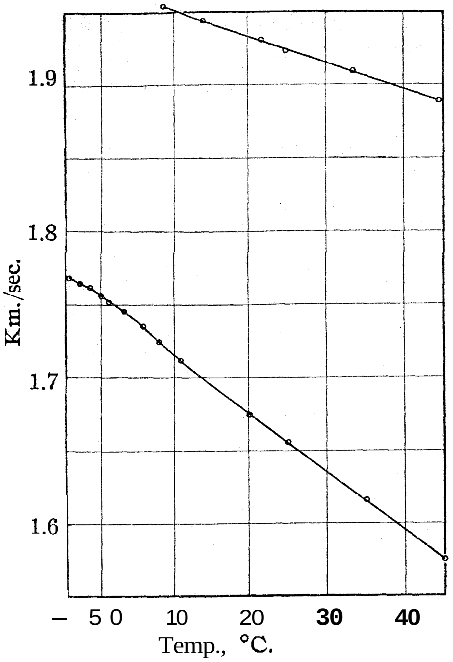

Fig. 7.—Upper curve, glycerin; lower curve, aniline.

The authors are indebted to Mr. Alfred L. Loomis for the use of quartz plates in the interferometer and to the U. S. Naval Research Laboratory for supplying the calibrated quartz frequency control crystal. Grateful acknowledgment is made to Dr. Graham Edgar of the Ethyl Gasoline Corporation for the loan of the isomeric heptanes and for the values of their densities.

Summary

An explanation of the method developed by Hubbard and Loomis for measuring the velocity of sound in small quantities of liquids has been given. The apparatus consists of an electrical oscillator for producing a high frequency field, an oscillator of fixed frequency to control the frequency of the field, and a "sonic interferometer" for producing and determining the wave length of sound waves. The instrument described in this paper is of a new design. The velocity of sound in and the adiabatic

and isothermal compressibility of the following liquids are given: benzene, acetone, ethyl alcohol, methyl alcohol, chlorobenzene, toluene, chloroform, ether, carbon tetrachloride and carbon bisulfide.

The velocity of sound in and the adiabatic compressibility of heptane, octane, aniline, α-bromonaphthalene, glycerin, bromoform and the isomeric heptanes are given.

Some of the compressibility values have been compared with those found by direct measurement by other investigators.

THE PHOTOSYNTHESIS OF HYDROCHLORIC ACID AT LOW PRESSURES

BY GERHARD K. ROLLEFSON

RECEIVED OCTOBER 29, 1928 PUBLISHED MARCH 6, 1929

The mechanism of the photochemical combination of hydrogen and chlorine has been the subject of investigation for many years. The results prior to 1926, summarized by Thon,[1] show that the reaction which occurs with the visible and near ultraviolet light must be considered as proceeding according to a chain mechanism starting with the photo-activated chlorine. The nature of this activation has been the subject of speculation, and the assumptions which have been made fall into two groups; first, those that postulate that the light excites the chlorine molecule to a higher quantum state; second, those that consider that the chlorine molecule is dissociated by the light. From the nature of the absorption spectrum of chlorine the dissociation hypothesis is the more probable of the two,[2] and it is the purpose of this paper to present experimental evidence for this view.

Before describing the experimental procedure let us consider what conditions are necessary to show a difference between the two theories. If we have an excited chlorine molecule it may undergo one of the following changes: (1) return to its normal state by emitting light, (2) lose its energy by collision of the second kind, (3) enter into some reaction. At high pressures an excited molecule undergoes so many collisions in its life period that the number returning to the normal state by fluorescence is negligible, but as the pressure is reduced the number fluorescing increases until, at such low pressures that the time between collisions is long compared to the life period of the excited molecule, fluorescence is practically the only process involved. On the other hand, if the chlorine is dissociated

---

[1] Thon, *Fortschritte Chem., Physik, physik. Chem.*, *18*, No. 11 (1926).

[2] For this interpretation of the chlorine spectrum see Franck, *Trans. Faraday Soc.*, 21, 536 (1925); and Kuhn, *Z. Physik*, 39, 77 (1926).

by light into a normal and an excited atom in the $^2P_1$ state[2] the possibility of fluorescence is eliminated[3] and the life periods of the normal and excited atoms are so long that even at low pressures there remains a great probability that they will enter into reaction. Therefore, if we study the photochemical reaction rate at various pressures, we should find that the velocity constant would decrease rapidly at very low pressures if the active form of the chlorine is an excited molecule, but if the active substance is a normal or an excited chlorine atom the velocity constant should be independent of the pressure.

The pressure at which this difference should appear may be estimated with the aid of the kinetic theory. The number of collisions which a molecule suffers in a mixture of two gases is given[4] by

$$Z_1 = \sqrt{2N_1}\pi\sigma_1{}^2\bar{C}_1 + \sqrt{\frac{m_1 + m_2}{m_2}}\, N_2\pi\sigma_2\bar{C}_1$$

where Z_1 is the total number of collisions per second for a molecule of Type I, N_1 is the number of molecules of Type 1, N_2 the number of Type 2, $\bar{C}_1$ is the mean velocity of the molecule of Type 1, σ_1 the diameter of the molecule of the first kind and σ_2 the average molecular diameter of the two kinds of molecules. The first term represents the number of collisions of the molecule with other molecules of the same kind, the second term gives the number of collisions with those of the other kind. It readily follows that the time between collisions of a chlorine molecule with a molecule of another kind is given by

$$\frac{1}{\sqrt{\frac{m_1 + m_2}{m_2}}\, N_2\pi\sigma^2\bar{C}_1}$$

The only uncertain quantity in this expression is a, the molecular diameter, and it is sufficiently accurate for this calculation to assume a value of 3×10^{-8} cm. At a pressure of 0.1 mm. of the other gas the time between collisions is 7.6×10^{-7} sec. According to the work of Wien[5] and Kerschbaum,[6] the life periods of atoms in excited states, which are not metastable, range from 0.1 to 1.5×10^{-7} sec. It seems reasonable to assume that the life period of an excited chlorine molecule is of the same order of magnitude and, therefore, if we are dealing with a reaction between an excited chlorine molecule and some other molecule, we should expect the rate

---

[3] The transition from the $^2P_1$ to the $^2P_2$ state of the chlorine atom with emission of light is forbidden by the selection principle for azimuthal quantum numbers. The other possibility. namely, the recombination of the normal and excited atoms with the emission of light can be neglected since the extremely low concentrations of the two kinds of atoms make the probability of such a transition extremely slight.

[5] Wien, Ann. *Physik,* 83, 1 (1927).

[6] Kerschbaum, *ibid.,* 83, 287 (1927).

constant to decrease rapidly as the pressure of the other molecules was reduced below 1 mm.

In the particular reaction under consideration the active form of the chlorine must react either with water or hydrogen. For reasons which will be given later the reaction with water seems to be the more probable, but since it is not definitely established the effect of varying both the hydrogen and water vapor pressures must be considered. Coehn and Jung[7] found that the rate of the reaction is independent of the pressure of water vapor down to 10^{-5} mm. It follows immediately that if the first step in the chain mechanism is a reaction between the active chlorine and a water molecule, the active form of the chlorine cannot be an excited molecule, as the life period of such a molecule would be very much shorter than the time between collisions with water molecules. It remains to be shown that the same is true if the active chlorine reacts with *a* hydrogen molecule.

In order to make the effect of diminishing pressure on the rate easy to detect, it is desirable to have the rate equation as simple as possible. From the work on the reaction between H_2 and Cl_2 at high pressures, we know that if the chlorine is much in excess the reaction follows the law

$$\frac{d(HCl)}{dt} = -2\,\frac{d(H_2)}{dt} = KI_0(H_2)(Cl_2)$$

By keeping the Cl_2 pressure constant or putting in so much chlorine that the change in pressure may be neglected, this equation may be integrated to give

$$\log (H_2) = -Kt + a$$

where K includes the chlorine pressure, the light intensity and any numerical constants, and a is the constant of integration. Now if we are dealing with active molecules, K will not be constant as the pressure is lowered, whereas if the chlorine is dissociated it will be constant over the entire pressure range down to 0.001 mm. pressure of H_2 and probably lower, although the accuracy of the measurements decreases rapidly at lower pressures.

Experimental

The reaction was studied by illuminating the mixture of the moist gases in a pyrex glass bulb of about 300 cc. capacity with white light from a 100-watt tungsten filament lamp placed about 2 cm. from the reaction chamber. At intervals the chlorine and hydrochloric acid were frozen out with liquid air and the pressure of the residual hydrogen was measured by means of a modified Pirani gage which had only glass exposed to the reaction mixture.[8]

The hydrogen, prepared electrolytically from a potassium hydroxide solution, was passed over hot copper to remove oxygen, then over phosphorus pentoxide, and through a liquid-air trap into the apparatus.

The chlorine was prepared by two different methods. First, it was prepared by

---

[7] Coehn and Jung, Z. *physik. Chem.*, **110**, 705 (1924).

[8] Rollefson, THIS JOURNAL, **51**, 804 (1929).

treating maganesc dioxide with hydrochloric acid and washing the liberated chlorine with water and concentrated sulfuric acid, and then condensing for introduction into the apparatus. The second method was to heat anhydrous cupric chloride. In both cases the chlorine was distilled at least once in a high vacuum and was introduced into the reaction bulb at its own vapor pressure at the melting point of ether or methyl alcohol, depending on the conditions desired, In some experiments the chlorine pressure of Cl_2 was kept constant during the experiment by leaving the reaction chamber connected to the supply of chlorine in the freezing bath. In the other experiments the pressure of hydrogen used was so small compared to the chlorine pressure that the chlorine supply could be sealed off without making the percentage change in the chlorine pressure very large. The vapor pressure of the chlorine at the melting point of ether as interpolated from data in the Landolt-Börnstein "Tabellen" is 1.4 mm. The value at the melting point of methyl alcohol is obtained from Harteck's data[9] as 13.7 mm.

TABLE I

DATA FOR A TYPICAL RUN

Reaction vessel filled with chlorine at vapor pressure at melting point of ether (−116°). Pressure of chlorine, 1.4 mm. Chlorine supply sealed off before experiment. Temperature, 24.8°.

t, min.	Gage reading	Press. of H_2, mm.	Log p	t, min.	Gage reading	Press. of H_2, mm.	Log p
0	1040	0.078	−1.108	256	793	0.0195	−1.710
31	998	.066	−1.180	401	739	.0080	−2.097
106	910	.045	−1.347	461	728	.0055	−2.260
166	855	.032	−1.495	609	712	.0018	−2.745
196	830	.0275	−1.561	692	707	.0007	−3.155
				1400	704	.0000	.....

These results are plotted in Fig. 1. From the straight line obtained for the log p-t plot, we may conclude that there is no change in the rate constant as the pressure of H_2 is diminished. The slight curvature in the region of low pressures can be attributed to a small error in the zero reading of the gage. The value for $d(\log p)/dt$ in this case is —0.144, using the pressure in mm. and time in hours. In ten other experiments, six being with the chlorine reservoir in a freezing bath of melting ether left connected to the reaction vessel, the slope did not vary from this by more than a factor of two.

In order to find the effect of varying the chlorine pressure, runs were made at the two pressures previously mentioned. As the sensitivity of H_2 and Cl_2 is not the same for all mixtures, the reaction vessel was left connected to the source of chlorine and the rate constant determined with the chlorine at the melting point of ether, then at the melting point of methyl alcohol and then again at the melting point of ether using one filling of H_2. The ratio of the rates was found to be about 10 ± 1 in four experiments, which is the same as the ratio of the pressures, so we may conclude that the rate equation at low pressures with excess chlorine remains

$$-\frac{d(H_2)}{dt} = KI_0(Cl_2)\,(H_2)$$

---

[9] Harteck, *Z. physik. Chem.*, **134,** 21 **(1928).**

Theoretical

The results have shown that whether we consider that the active form of chlorine reacts with H_2O, H_2 or Cl_2, this active form must have a life period considerably longer than has been found for any optically excited states. It follows that the chlorine molecule must be dissociated by the light presumably, according to Franck's theory, into a normal atom and one in the $^2P_1$ state. The next stage in the problem is to decide whether one or both of these start the reaction chain and what the first step in this chain is. Since we have no HCl formed by visible light if the gases are carefully dried, we may conclude that water enters into the reaction chain before any HCl is formed. It can have no effect on the initial absorption process since it has been shown by Kornfeld and Steiner[10] that moist and dry chlorine have identical absorption spectra. Assumption of an addition product with water which has too small an absorption to be noted is invalid since the concentration of such a complex, and therefore the reaction rate, should be dependent on the water vapor pressure up to a much higher pressure than the experimentally found 10^{-5} mm. It follows that one or both of the atoms formed by the action of the light must react with water to start the chain process. The most probable type of reaction is the formation of an addition compound, $Cl\cdot H_2O$, since any other reaction such as $Cl + H_2O = HCl + OH$ might be expected to be followed by reactions which would result in oxygen being formed, and there is no evidence for such a step. Furthermore, the nature of the effect of the water-vapor pressure on the reaction rate indicates that it is the chlorine atom

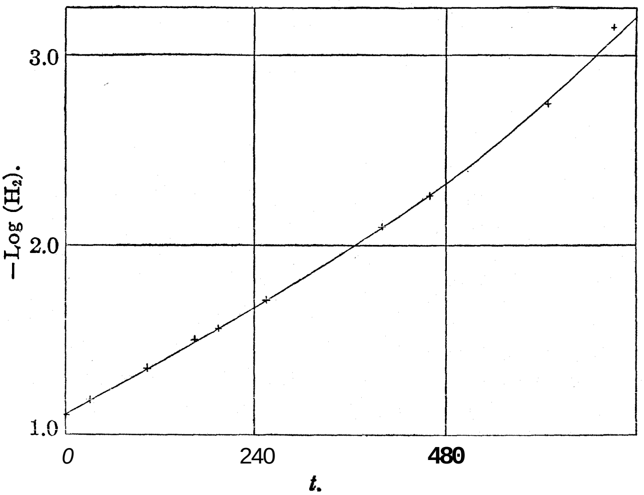

Fig. 1.

---

[10] Kornfeld and Steiner, Z. *Physik*, 45,325 (1927).

in the $^2P_1$ state which reacts. If it were a normal atom which reacted, the rate should depend on the relative number of water molecules and chlorine atoms, which means that under a given set of conditions the rate should be approximately linearly proportional to the water-vapor pressure. On the other hand, if it is the activated atom which reacts, the number remaining in the active state long enough to react with a water molecule falls off exponentially as the water-vapor pressure is decreased. This is in accord with the experiments of Coehn and Jung.[7] Using their data the life period of the metastable state of chlorine may be estimated to be about two hundredths of a second, which is a reasonable value.

Starting in this way we may build up the following series of reactions

$$Cl_2 + h\nu = Cl + Cl(^2P_1) \qquad (1)$$
$$Cl(^2P_1) + H_2O = Cl{\cdot}H_2O \qquad (2)$$
$$Cl{\cdot}H_2O + H_2 = HCl + H_2O + H \qquad (3)$$
$$H + Cl_2 = HCl + Cl(^2P_1) \qquad (4)$$

The chain may be terminated by such reactions as

$$Cl{\cdot}H_2O + Cl = Cl_2 + H_2O \qquad (5)$$
$$Cl(^2P_1) + Cl = Cl_2 + h\nu \qquad (6)$$
$$H + H = H_2 \qquad (7)$$
$$Cl + Cl = Cl_2 \qquad (8)$$
$$H + Cl = HCl \qquad (9)$$

With low hydrogen pressures (5), (6) and (8) will be the limiting reactions, whereas with low chlorine pressures Reaction (7) may play an important role.

The observed reaction rate is determined by the number of reaction chains started and the length of these chains. The number of chains which are started will depend on the number of $Cl(^2P_1)$ atoms formed by the absorption of light which react according to (2) before they lose their activation by collision. In ordinary moist gases (2) is very fast, so that (1) becomes the determining reaction for the number of chains started. For small absorption of light the rate for (1) becomes

$$\left(\frac{d[Cl(^2P_1)]}{dt}\right)_1 = k_1I_0(Cl_2)$$

where k_1 is a constant including such factors as the absorption coefficient and thickness of the absorbing layer. I_0 is the intensity of the incident light.

The other factor in determining the observed reaction rate, the length of the chains, is determined by the preponderance of (3) and (4) over the reactions (5) to (9). In the experiments described in this paper we have found that the reaction rate is proportional to the hydrogen pressure if the chlorine pressure and light intensity are constant. This may be interpreted by saying that the length of the reaction chains is determined by the extent that (3) predominates over (5), as (4) under these conditions is one of the fast reactions of the system. At high hydrogen pressures **(3)** becomes fast and (4) is the rate-determining reaction. From these conditions we obtain the limiting rate laws (1) for excess chlorine

$$\frac{d(HCl)}{dt} = kI_0(Cl_2)(H_2)$$

and (2) for excess hydrogen

$$\frac{d(HCl)}{dt} = kI_0(Cl_2)^2$$

Several writers have attempted to give derivations of these equations based on the mechanisms they have proposed. In these derivations it has been common practice to calculate steady state concentrations of such intermediate substances as chlorine atoms, hydrogen atoms and various active molecules. In view of the fact that we have very little information concerning the factors influencing the existence of such substances in a gas mixture, such calculations require the introduction of so many assumptions that they must be considered extremely approximate. We shall take the stand that it is unnecessary to consider these steady state concentrations, but instead we shall say that each step in the mechanism is to be considered as having a group of side reactions associated with it. If a particular step is one of the rate-determining steps, then these side reactions proceed with a rate comparable with the main reaction. Thus when we have excess chlorine we have said that the rate is determined by the predominance of **(3)** over (5), but there may be other unknown side reactions as well. The net result, however, is such that if we consider the conditions favoring the side reactions involving $Cl{\cdot}H_2O$ as constant, then the relative number of $Cl{\cdot}H_2O$ molecules reacting with H_2 and entering into side reactions is determined by the pressure of H_2.

In the intermediate region the rate equation as given by Thon (omitting the factor due to oxygen) is

$$\frac{d(HCl)}{dt} = \frac{kI_0(Cl_2)(Hz)}{k'(H_2) + k''(Cl_2)}$$

This equation may also be explained on the basis of the proposed mechanism. The numerator of the right-hand member of the above equation has the form given, since the rate depends on the amount of light absorbed and on Reactions **3** and 4. The denominator is due to the fact that the chain-terminating reactions, 7 to 9, require triple collisions in order to dispose of the energy of reaction, and therefore their rates will depend on the total pressure, thus making the rate of formation of HCl inversely proportional to the total pressure, that is, to (Hz) + (Cl_2). Since the hydrogen and chlorine molecules are not equally efficient in removing the reaction energy in these triple collisions, the coefficients of the two terms in this sum will not be identical; hence we find the coefficients k' and k'' in the rate equation. This effect due to the total pressure in the system would ultimately reduce the rate equation to the simple limiting forms which have been given, but is scarcely sufficient to account for these simple forms holding over as wide a range as they do. However, when we introduce the additional condition that **(3)** shall be the principal rate-determining reaction at low hydrogen pressures and (4) at high hydrogen pressures, we see that the two effects aid each other in reducing the rate equation to the simple forms, so that it is to be expected that the more complex form will be required only in a rather narrow range. This range will be determined by the relative values of the rate constants for **(3)** and (4) and the coefficients k and k". Experimentally it has been found to lie between (Hz) $> {}^1/_4(Cl_2)$ and $(H_2) < 2(Cl_2)$, the upper limit being somewhat uncertain.

Another point for discussion is the assumption in (4) that the chlorine atom formed by that reaction is in the $^2P_1$ state. This assumption is not necessarily true, so that formation of a normal chlorine atom in this reaction must be considered as one of the ways of terminating the chain. However, the energy of activation of the chlorine atom is so small that the atom may acquire this activation by collision as the HCl molecule and Cl atom fly apart. Whether the $Cl(^2P_1)$ is formed directly or by collision, the ultimate result may be considered as corresponding to (4).

In comparing the mechanism proposed in this paper with others which have been proposed, it is to be noted that the principal change made is the introduction of water into the reaction chain. This point has already been discussed. With regard to other features of mechanism, an interesting one is the assumption made by Cremer[11] that the reaction chain involves the formation of Cl_3. She disregards the role of water in setting up her mechanism, but otherwise she is able to account for the observed rate equations. The experimental data available are insufficient to decide whether Cl_3 is formed in the chain or not, but some experiments have been planned which it is hoped will throw some light on this point. If such a mechanism should be adopted, water would enter the chain prior to the formation of Cl_3.

One objection which has been raised against the atomic chain mechanism is that all the experiments which have been tried in which the chlorine has been illuminated and then mixed with hydrogen have failed to show the formation of hydrochloric acid, although the time between illumination of the chlorine and its mixing with hydrogen has been less than the life period of the $Cl(^2P_1)$ as calculated in this paper. These experiments have been tried in narrow tubes and under such conditions that it is quite likely that the $Cl(^2P_1)$ atoms are deactivated by collisions with the walls as they are swept through the tube in a much shorter time than would

---

[11] Cremer, *Z. physik. Chem.*, *128*, 285 (1927). See *also* Gohring, *Z. Elektrochem.*, *27*, 511 (1927).

be the case if they were left in the middle of a large volume of gas. Before such experiments can be considered as being definitely against an atomic chain theory, it must be established that chlorine atoms could survive under the experimental conditions used long enough to get mixed with the hydrogen.

So far no account has been taken of the various substances which act as inhibitors for this reaction. The only one which has been studied quantitatively is oxygen, in which case it has been found that the rate of formation of hydrochloric acid is roughly inversely proportional to the pressure of the oxygen. In the proposed mechanism the oxygen could diminish the rate of formation of HCl by removal of the hydrogen atoms or by deactivating the $Cl(^2P_1)$; in other words, it diminishes the length of the chain. The magnitude of this effect is proportional to the oxygen pressure which makes the length of the chains and therefore the rate of the reaction inversely proportional to the oxygen pressure. This proportionality will hold only as long as the oxygen is one of the principal causes for the termination of the reaction chain. At very low oxygen pressures the other factors influencing the length of the chain predominate and the oxygen effect becomes negligible.

Summary

The photosynthesis of hydrochloric acid has been studied at low pressures with excess chlorine and has been found to follow the rate law

$$\frac{d(HCl)}{dt} = kI_0(H_2)(Cl_2)$$

From these experiments and the work of other observers it is concluded that the action of light on this reaction is to form chlorine atoms in the $^2P_1$ state which serve as the starting point for the reaction chain. **A** mechanism is formulated which accounts for the action of water in this system and is in accord with the observed rate equations.

THE HEAT CAPACITIES OF ETHYL AND HEXYL ALCOHOLS FROM 16°K. TO 298°K. AND THE CORRESPONDING ENTROPIES AND FREE ENERGIES

BY KENNETH K. KELLEY[1]

RECEIVED OCTOBER 31, 1928 PUBLISHED MARCH 6, 1929

In an earlier paper low temperature thermal data were given for methyl alcohol.[2] This paper presents similar results for ethyl and hexyl alcohols. The ethyl alcohol has been studied by Gibson, Parks and Latimer[3] and by Parks,[4] whose measurements go down to liquid-air temperature. The measurements here go to liquid-hydrogen temperatures and omit no large temperature intervals between determinations.

The apparatus and methods used have already been described[2] and need not be mentioned here.

Materials

Ethyl Alcohol.—A good grade of ethyl alcohol was allowed to stand on a steam-bath over lime for one week and distilled. It was then put over lime for five days and redistilled. Finally, three fractionations were made, two with lime present and one with metallic calcium. The final product of about 500-cc. volume had a boiling point range of 0.03" and a density, d_4^{25}, 0.78520. This density corresponds to 99.96% ethyl alcohol if the impurity is assumed to be water. The data in the "International Critical Tables"[5] are the basis for this estimate.

Hexyl Alcohol.—The hexyl alcohol was a Kahlbaum product. It was dried with sodium carbonate and with lime and fractionated twice. The middle portion used, 50 cc. in volume, boiled at 157.0–157.1° (760 mm.). Its density was found to be $d_4^{23.7}$, 0.8165.

The Specific Heats

The specific heat values expressed in 15" calories per mole are given in Tables I and II and plotted against the temperature in Figs. 1 and 2.

TABLE I

SPECIFIC HEATS OF ETHYL ALCOHOL

Ethyl alcohol may be obtained at low temperatures in either the crystalline or the glassy state. At hydrogen temperatures the curves for glass and crystals are nearly parallel but are converging slightly. At 50°K. the increase in slope of the glass curve over that of the crystals is easily perceptible in the figure. Between 90 and 96°K. the heat capacity of the glass undergoes a rapid increase of over 50%. This phenomenon is typical of heat-capacity curves for glasses and has been previously studied for ethyl alcohol by Gibson, Parks and Latimer[3] and by Parks,[4] for glycerin by Simon[6] and by Gibson and Giauque,[7] and for propyl alcohol and propylene glycol by Parks and Huffman.[8] When the ethyl alcohol glass is warmed to 110°K. crystallization invariably begins. This is similar to the behavior of propyl alcohol glass.[8] For this reason no measurements are given between 110° and the melting point temperature of the crystals. Parks and Huffman[8] found that the shape of the curve in the region of the rapid rise depended upon the previous history of the glass, that is, upon the annealing. Therefore care was taken in this work always to prepare the glass in the same manner. This was done by breaking the vacuum with approximately the same pressure of hydrogen (1 cm. of mercury) each time and then cooling as rapidly as possible to the temperature of liquid air. Two sets of measurements which are in complete agreement

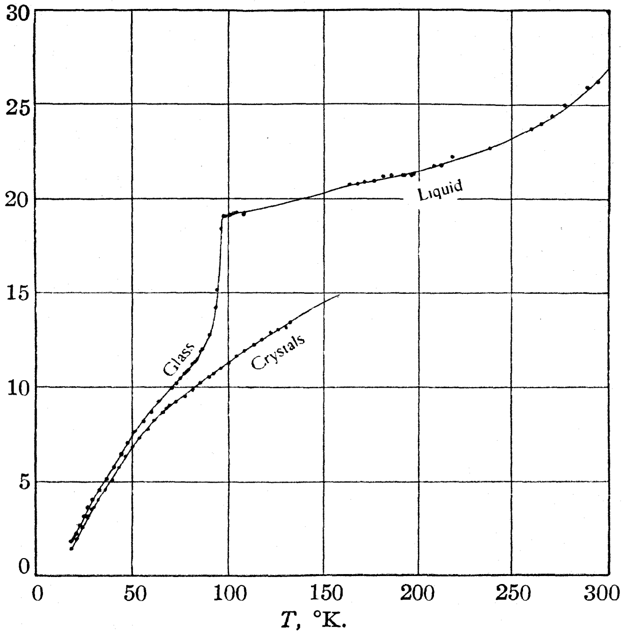

Fig. 1.—Heat capacity of ethyl alcohol in calories per mole.

[6] Simon, Ann. *Physik*, [4] 68, 241 (1922).
[7] Gibson and Giauque, This Journal, 45, 93 (1923).
[8] Parks and Huffman, *J. Phys. Chem.*, 31, 1842 (1927).

were made in this region and are distinguished in Table I by "a" and "b." The point marked "c" was obtained just prior to cooling the glass to liquid-hydrogen temperature.

In the region of the rapid rise the thermal conductivity is poor and the corrections for heat interchange with the surroundings are abnormally large due to the long equilibrium period at the end of each determination. However, equilibrium was rapid below **90"** and above **100"**. To test the accuracy obtained in this range a determination was made starting at **86.02"** and ending at **103.14'**. The heat necessary to raise the temperature of the calorimeter and contents through this interval was **273.7** calories,

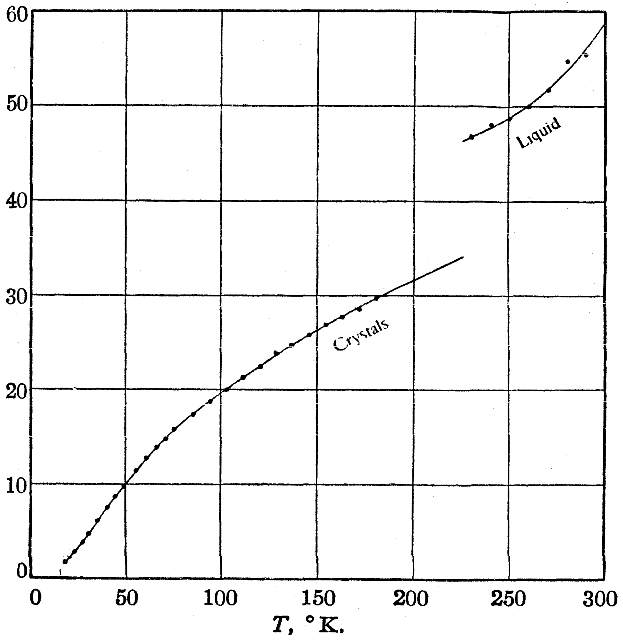

Fig. 2.—Heat capacity of hexyl alcohol in calories per mole.

while the graphical calculation from the C_p *vs.* T plot gave **275.2** calories, a difference of 0.55%. It seems safe to say, therefore, that the accuracy obtained for the glass in this region is about **0.5%** less than that for the crystals.

Two sets of determinations were made on the ethyl alcohol crystals below **35°K.** and are in very good agreement. Above 158.6°K. this alcohol was liquid.

Except for the short interval on the ethyl alcohol glass which has already been discussed, the specific heat measurements have the same accuracy as that given for those on methyl alcohol. That is, "the accuracy of the results depends upon the temperature. Below 20° the error may be of the order of 1% due to the rapid decrease of the dR/dT for the resistance thermometer. Between 20 and 40" the error decreases to about 0.2% and remains such to about 130°. Between 130 and 200" the error increases to about 0.5%. Above 200° certain points may be in error by 1% due primarily to large corrections caused by increased radiation."

The hexyl alcohol was studied in the crystalline and liquid forms only, since it showed no appreciable tendency to form the glass. It melts at 225.S°K. Its specific heat curves are normal in all respects.

The Temperatures and Heats of Fusion

The temperatures and heats of fusion were measured by the methods used by Gibson and Giauque[7] for glycerin. Near the melting point the specific heats of both substances showed considerable increases, which were assumed to be due to premelting caused by small amounts of impurities, and consequently the usual practice of considering the heat involved in excess of the "normal" heat-capacity curves for the crystals as part of the heat of fusion was followed. The mean values in Table III are considered accurate to 0.5%. The result for ethyl alcohol is about 1% higher than the mean of Parks' measurements.

TABLE III

HEATS OF FUSION

Substance	Temp., °K.	Heat of fusion, Cal. per mole 1st result	 2nd result	 3rd result	 Mean
Ethyl alcohol	158.5	1200.8	1200.3	1198.5	1200
Hexyl alcohol	225.8	3679	3672	....	3676

The Entropies

The entropy from 0°K. to the initial temperature of the lowest measurement was obtained by extrapolation using Debye functions with Θ's as

TABLE IV

ENTROPIES

Ethyl Alcohol

0–16°K. (extrap.)	crystals	= 0.45	0–16°K. (extrap.)	glass	= 0.67
16–158.5	crystals	= 16.20	16–158.5	glass + liq.	= 20.94
1200/158.5	fusion	= 7.57	158.5–298.1	liquid	= 14.18
158.5298.1	liquid	= 14.18	$S_{298.1} - S_0$	glass	= **35.8**
			S_0	glass	= 2.6 E. U. per mole

$S_{298.1}$ for one mole of liquid C_2H_5OH = 38.4 ± 0.3 E.U.

Hexyl Alcohol

0–15°K. (extrap.)	crystals	= 0.43
15–225.8	crystals	= 37.82
3676/225.8	fusion	= 16.28
225.8–298.1	liquid	= 14.10

$S_{298.1}$ for one mole of liquid $C_6H_{13}OH$ = 68.6 ± 0.4 E. U.

follows: 109 for ethyl alcohol crystals, 94 for ethyl alcohol glass and 104 for hexyl alcohol crystals. The extrapolated values are small so that this procedure can cause no appreciable errors in the S_{298} values given in Table IV. The entropy between the temperature at the start of the lowest determination and 298.1°K. was obtained in the usual manner.

The value 2.6 E. U. is obtained for the entropy of ethyl alcohol glass at 0°K. Parks[4] obtained 1.79 E. U. but the difference is almost entirely due to the error made in extrapolating from 90 to O°K. by means of the "n" formula of Lewis and Gibson? In the case of the ethyl alcohol crystals this formula causes an error of 3.7 E. U. or 28% in the extrapolated value.

The Free Energies

The free energies of formation of the compounds at 298.1°K. were calculated by means of the fundamental thermodynamic equation, $\Delta F = AH - TAS$.

In obtaining AH for ethyl alcohol the heat of combustion measured by Richards and Davis[10] was used, namely, 7110 Cal. (18°) per g. (in air) at constant volume. This value was corrected to 15° calories, to vacuum weighing and to constant pressure, with 327,340 Cal. per mole as the result. Since this measurement was made at about 291°K. a further correction of −180 Cal. is necessary to correct it to 298.1°K., which gives 327,160 Cal. per mole. For hexyl alcohol the value, 9314 Cal. (15") per g. (in air) at constant volume, obtained by Verkade and Coops[11] was similarly corrected, the result being 951,540 Cal. per mole (measured at 292.6°K.) or 951,200 Cal. per mole at 29S.1°K. These values when combined with the heats of formation of carbon dioxide and water at 298.1°K. which were adopted in previous work[2] give the values of $\Delta H_{298 \cdot 1}$ in Col. 3 of Table V.

The values of $\Delta S_{298 \cdot 1}$ given in the fourth column of Table V are based upon the measured entropies and the values 1.3 units per gram atom for carbon, 29.6 units per mole for hydrogen and 48.9 units per mole for oxygen, the sources of which were also given in the earlier paper. Col. 5 contains the free energies of formation of the compounds at 298.1°K.

Discussion

Parks and his co-workers[12] have shown that in an homologous series of normal saturated aliphatic compounds there is an increase in entropy of about nine units per CH_2 group if the substances are considered in the liquid state at 298.1°K., while the free energies of formation from the elements have the same value. The present work bears out these conclusions qualitatively. If the entropy of methyl alcohol, 30.3 * 0.2 E. U. per mole, previously reported[2] is compared with the values in Tables IV, it may be seen that the entropy difference between methyl and ethyl is 8.1 units and between ethyl and hexyl alcohols 30.2 units, or on the average about 7.7 units per CH_2 group. A similar comparison of the free energies shows differences of 700 Cal. between methyl and ethyl and 1600 Cal. between ethyl and hexyl or a change of about 500 Cal. per CH2 group.

The heat of combustion data of Richards and Davis[10] and of Verkade and Coops[11] show a definite increment of about 156,000 Cal. per CH_2 group in the alcohol series from methyl to decyl. The first of these differences is somewhat large and upon this basis Verkade and Coops think that Richards and Davis' value for methyl alcohol is low by 0.1%. If this claim should prove true, the free energy difference between methyl and ethyl alcohols would be reduced to 500 Cal. It is obvious, of course, that if regular differences appear in the consecutive values of any two of these properties (free energies, entropies and heats of combustion) they must appear in the third.

If the free energy difference per CH_2 group found here persists throughout the series, then the higher alcohols are thermodynamically less stable toward the elements than are the lower.

For all practical purposes the author certainly would not hesitate to employ these differences in the calculation of the entropies and free energies of the normal alcohols, propyl, butyl and pentyl.

It is interesting to compare the entropy of ethyl alcohol glass at O°K. reported with the available data for other glasses. Table VI contains these values.

TABLE VI

ENTROPIES OF GLASSES AT O°K.

Quartz glass	Ethyl alcohol	Propyl alcohol	Glycerol
0.9	2.6	3.1 (?)	4.6

The data for quartz glass and glycerol were calculated by Simon and Lange.[13] The value for propyl alcohol is that of Parks and Huffman[12d] corrected as well as possible for the error made in extrapolating below 86 °K.

---

[12] (a) Parks, ref. 4; (b) Parks and Kelley, THIS JOURNAL, 47, 2089 (1925); (c) Parks and Anderson, *ibid.*, 48, 1506 (1926); (d) Parks and Huffman, *ibid.*, 48, **2788** (1926).

[13] Simon and Lange, *Z. Physik,* 38,227 (1926).

It thus appears as would be expected that the entropy of the glass at 0°K. increases with the complexity of the molecule.[14]

Summary

1. The specific heats from 16 to 298°K. of ethyl alcohol crystals, glass and liquid and of hexyl alcohol crystals and liquid have been measured.
2. The heats of fusion and the temperature of fusion have been determined.
3. The entropies and free energies of ethyl and hexyl alcohols at 298° K. and the entropy of ethyl alcohol glass at 0° K. have been calculated.
4. Regularities in the thermal data for the normal saturated aliphatic alcohols have been discussed.

CATALYTIC EFFECT OF RUTHENIUM SALTS ON THE REDUCTION OF PERCHLORIC ACID BY HYDROBROMIC ACID

BY WILLIAM R. CROWELL, DON M. YOST AND JAMES M. CARTER

RECEIVED NOVEMBER 7, 1928 PUBLISHED MARCH 6, 1929

Introduction

It is well known that both dilute and moderately concentrated solutions of perchloric acid are remarkably unreactive with most reducing agents, although the thermodynamic tendency for the acid to act as an oxidizing agent is undoubtedly very great. Its great power as an oxidizing agent is shown only when the acid is hot and concentrated. Under such conditions the lower valence compounds of osmium and ruthenium are oxidized to the tetroxides.[1] In dilute solutions of perchloric acid the only reducing agents mentioned in the literature as reacting with it are trivalent titanium, trivalent molybdenum and bivalent chromium,[2] the reactions in all three cases being measurably slow. It is to be noted that these three reducing agents have not only a very high reduction potential but have also high reaction rates with most oxidizing agents.

It was found by Dr. Robert H. Dalton in this Laboratory that bromine is evolved on heating mixtures of perchloric and hydrobromic acids containing small amounts of ruthenium chloride, while in the absence of ruthenium no such effect is observed. Subsequent experiments showed that the

[2] Bredig and Michel, *Z. physik. Chem.*, **100**, 124 (1922).

catalyzed reaction takes place both at room temperature and at 100°, but much more slowly at the lower temperature.

In this paper are described the results of a research on the nature of the catalysis involved in this reaction. We take this opportunity to express our appreciation of the many helpful suggestions made by Professor A. A. Noyes during the investigation. The work was aided by funds granted to him by the Carnegie Institution of Washington.

The resultant reaction under consideration is

$$ClO_4^- + 8Br^- + 8H^+ = Cl^- + 4Br_2 + 4H_2O \quad (1)$$

The fact that eight equivalents of bromine are liberated in the catalyzed reaction per mole of perchlorate ion used up is of importance in discussing the results of rate experiments, since a considerable amount of bromine liberated may correspond to only a small change in the concentration of perchlorate ion.

Interpretation of the mechanism of the reaction involves a knowledge of the chemistry of ruthenium in its numerous oxidation states. Unfortunately this has not been completely investigated. It has been definitely established, however, that bi-, tri- and quadrivalent ruthenium compounds are capable of existing in acid solution. The bivalent compounds form deep blue solutions, which react slowly with atmospheric oxygen to form light yellow or pink solutions that are oxidized by chlorine and bromine, but not by iodine, to the dark orange-red solutions of the quadrivalent salts. The quadrivalent salts in acid solution are quantitatively reduced by iodide[3] or by sulfurous acid to the trivalent state.

The compounds of sexivalent and septivalent ruthenium, the ruthenates (M_2RuO_4) and perruthenates ($MRuO_4$), are rapidly reduced by the halogen acids to the trivalent and quadrivalent states,[4] while with non-reducing acids they are decomposed into the tetroxide and various forms of lower valence.[5]

Ruthenium tetroxide, not only in solution but also in the solid, liquid or gaseous form, is a very active and powerful oxidizing agent. It is not so powerful, however, as permanganic acid, as is shown by the fact that the tetroxide is formed by the action of permanganic acid on the compounds of lower valence. At ordinary temperatures ruthenium tetroxide reacts with hydrobromic acid with the formation of bromine and a mixture of trivalent and quadrivalent ruthenium,[3] the mixture resulting from the fact that trivalent compounds react with bromine to form the quadrivalent compounds.[6]

Preparation of the Solutions

A stock solution of ruthenium chloride was prepared from material purchased as ruthenium trichloride, but containing also some tetrachloride. The solution was made by dissolving the salt in **0.5** *N* hydrochloric acid. The color of this mixture is dark orange-red. A measured portion of the stock solution was treated with chlorine; and, after boiling to expel the excess of chlorine, it was titrated with standard titanous sulfate solution, the end-point being determined electrometrically.[6] The stock solution was found to contain **2.09** g. of ruthenium per liter.

Another ruthenium solution was prepared by treating a definite volume of the stock solution with a small excess of sulfur dioxide, expelling the excess by boiling and adding just enough water to replace that lost by evaporation. The resulting solution had a light orange-red color and it was shown by an electrometric titration with titanous sulfate to contain substantially all of the ruthenium in the trivalent state.

Standard solutions of perchloric acid, hydrobromic acid, potassium iodide and sodium thiosulfate were made up and standardized by the usual well-known methods.

Non-Formation of Bromine from Hydrobromic Acid with Perchloric Acid Alone or with Ruthenium Tetrachloride Alone

To make sure that no bromine is formed by the action of perchloric acid alone on hydrobromic acid or by a reaction between quadrivalent ruthenium and hydrobromic acid, the following experiments were made.

Ten cc. of a mixture which was **0.2905** M in $HClO_4$ and **0.871** M in HBr was heated at 98° in a sealed glass tube for three and one-half hours. The mixture was then diluted three-fold and treated with potassium iodide; no iodine was liberated.

A mixture of **10** cc. of **9** M HBr and **1.00** cc. of **1** M $HClO_4$ was heated for seventy-five minutes in a distilling flask through which a stream of carbon dioxide was passed; after five minutes **0.05** milliequivalent of bromine (due to free bromine originally present in the hydrobromic acid) was found in the receiver by iodimetric analysis, but no more was formed afterward.

A solution which was 8 M in HBr and **0.0246** atomic in ruthenium, present as a mixture of the quadrivalent and trivalent chlorides, was heated in a sealed tube at 98° for one hour, and the resulting mixture was cooled and treated with carbon tetrachloride; no bromine was found to be present.

Effects of Perchloric, Hydrobromic and Hydrochloric Acids and Ruthenium Salt on the Reaction Rate

Experiments were next made to determine the effects of perchloric acid, hydrobromic acid, ruthenium salt and hydrogen ion on the rate of liberation of bromine. In these experiments definite volumes of the reaction mixtures were heated in a water-bath at 98° in sealed glass tubes. The tubes were removed at suitable intervals, broken under solutions of potassium iodide and the liberated iodine was titrated with standard thiosulfate. The stock solution containing both tri- and quadrivalent ruthenium was used, but the iodine liberated by the quadrivalent ruthenium present was so small compared to the total iodine that it could be neglected. The results of typical experiments are shown in Table I. The "bromine formed" is the number of milliequivalents produced per liter.

In Expts. 1 and 2 the composition of the reaction mixtures differed

Table I

Effect of Perchloric Acid, Hydrobromic Acid, Total Acid and Ruthenium Salt on the Reaction Rate

Experiment no.	1	2	3	11	12

Bromine formed in 72 hours	188.9	...	159.7	141.2	178.7

initially only in the concentration of perchlorate, that in Expt. 2 being twice that in Expt. 1. Since the concentration of perchlorate decreased only 2% after two hours, the amounts of bromine liberated within this interval may be compared directly in determining the order of the reaction with respect to the perchlorate. It will be seen that in Expt. 2 the amount of bromine liberated was at first approximately twice that liberated in Expt. 1 in the same interval of time, but that this ratio decreases appreciably as the reaction proceeds. Therefore, at the beginning of the experiments the rate is directly proportional to the concentration of perchlorate.

By comparing in the same way the results of Expts. 1 and 3, the effect of the concentration of ruthenium may be determined. At first the rate of the reaction is directly proportional to the concentration of ruthenium, but as the reaction proceeds, this is no longer true. Thus after twenty-four hours the ratio of the amounts of bromine liberated is 1.3, although the initial ratio of the ruthenium concentrations was 2.0 and that of the perchlorate had decreased by less than 5%.

A comparison of the results of Expt. 3 with those of Expts. 11 and 12 shows that both the bromide and total acid influence the rate appreciably, but in neither case is the rate directly proportional to their concentrations. It is difficult to say whether their action is of a specific nature or is due to activity effects. It is also possible that the total acid and bromide govern to some extent the nature of the complex ions of ruthenium which are present in the solutions and in this way influence the reaction rate.

The Catalytically Active Form of Ruthenium

The fact that the rate does not remain directly proportional to the concentration of perchlorate and of the ruthenium indicates that the catalytically active form of the latter is decreasing in concentration as the reaction proceeds.

If trivalent ruthenium were more active catalytically than the quadrivalent form, the liberation of bromine would decrease the concentration of the former by oxidizing it to the quadrivalent state. The two experiments presented in Table II were made to determine whether this was true. In Expt. 4 the ruthenium was present initially in the trivalent form, while in Expt. 5 it was present in the quadrivalent state. The quadrivalent ruthenium was prepared by treating a definite volume of the stock solution at 98° with a large excess of bromine for forty-eight hours. The excess of bromine was expelled by boiling.

TABLE II

CATALYTIC EFFECTS OF TRIVALENT AND QUADRIVALENT RUTHENIUM

Initial concentrations: ruthenium, 0.00103 atomic; $HClO_4$, 0.3 molal; HBr, 0.5 molal; total acid, 1.5 molal.

Time, min.	Bromine liberated, milli equivalents per liter Expt. 4 Ru^{III}	Expt. 5 Ru^{IV}	Time, min.	Bromine liberated, milli-equivalents per liter Expt. 4 Ru^{III}	Expt. 5 Ru^{IV}
15	22.6	1.08	90	79.8	7.55
30	41.0	2.20	120	88.1	8.65
45	52.i	5.18	150	95.5	9.90
60	62.0	6.28	24 (hours)	154.2	62.10
75	72.1	7.10	72 (hours)	201.5	132.4

The results show definitely that the quadrivalent form is much less active as a catalyst than the trivalent.

Two other types of experiments were made to obtain further evidence regarding the active form of the ruthenium. In the first type the reaction was carried out in a special distilling flask provided with a short reflux condenser bent at an angle with the exit tube and having an inlet tube which could be used to introduce a current of carbon dioxide. The bromine was caught in an acidified potassium iodide solution, which was replaced by a fresh one at measured intervals of time. The liberated iodine was titrated with standard thiosulfate. The results of an experiment of this type and of a similar experiment carried out in sealed glass tubes are given in Table III.

TABLE III

EFFECT OF REMOVAL OF BROMINE ON THE REACTION RATE

Initial concn.: $HClO_4$, 0.3 *N*; HCl, 0.33 *N*; HBr, 1.0 *N*; Ru, 0.00103 at.

Time, hours		0	1	2	3	4	5	6
Bromine lib., milli-equiv. per liter	Dist. expt.	0	51.6	92.2	122.2	147.2	169.5	191.1
	Closed-tube expt.	0	60.7	86.8	103.2	114.5	121.5	130.0

In the distillation experiment the bromine formed was removed fairly rapidly by the stream of carbon dioxide and was thereby prevented from reacting with the trivalent ruthenium to form the less active quadrivalent form, for it is shown later that this reaction is a slow one. The result showed that the rate of formation of bromine is less rapid in the sealed-tube experiments and therefore less rapid with quadrivalent than with trivalent ruthenium.

In the second type of experiments potassium iodide was added to the reaction mixtures and these were heated in sealed tubes. The iodide by its rapid reducing action prevents the formation of much bromine and quadrivalent ruthenium and, consequently, the concentrations of trivalent ruthenium and of bromide are held constant so long as iodide is present. The results of four such experiments are given in Table IV and are shown graphically in Fig. 1. The quantities of iodide added and of bromine formed are expressed in milli-equivalents per liter, both in the table and on the chart.

TABLE IV

EFFECT OF IODIDE ON THE REACTION RATE

	Expt. 4	Expt. 8	Expt. 9	Expt 10
Ru, at. wts. per liter	0.00103	0.00103	0.00103	0.00103
HBr, mole per liter	.5	.5	.5	.5
$HClO_4$, mole per liter	.3	.3	.3	.3
HCl, mole per liter	.7	.7	.7	.7
KI, millimoles per liter	.0	12.0	30.0	60.0
Bromine formed in 15 minutes	22.6	27.5	27.9	29.5
Bromine formed in 30 minutes	41.0	50.6	52.4	55.5
Bromine formed in 45 minutes	52.1	66.6	73.8	79.0
Bromine formed in 60 minutes	62.0	79.2	91.9	99.0
Bromine formed in 75 minutes	72.1	91.0	104.2	118.5
Bromine formed in 90 minutes	79.8	98.5	114.6	132.4
Bromine formed in 120 minutes	88.1	104.0	131.0	158.0
Bromine formed in 150 minutes	95.5	119.7	140.7	173.2
Bromine formed in 24 hours	154.2	192.1	211.6	251.4
Bromine formed in 72 hours	201.5	228.8	258.0	283.0

The curves in Fig. 1 are straight lines and are nearly coincident until the bromine formed equals the iodide added. This shows that the rate of the reaction is maintained practically constant until the iodide is used up. After this point is reached the rate falls off. This is probably due to the oxidation of the trivalent form by the bromine, which begins to accumulate as soon as all of the iodine has been oxidized to iodine.

The results of all of the experiments described in this section show conclusively that the active form of the catalyst is the trivalent ruthenium, and that this active form reacts with the bromine to produce quadrivalent ruthenium, which is much less active catalytically. If, however, bromine reacted very rapidly with the trivalent ruthenium, a much greater decrease in the rate with time would result than was actually observed. It may be inferred, therefore, that trivalent ruthenium and bromine react at a slow but measurable rate to form the quadrivalent ruthenium. To determine whether this was really the case, experiments were carried out as described in the next section.

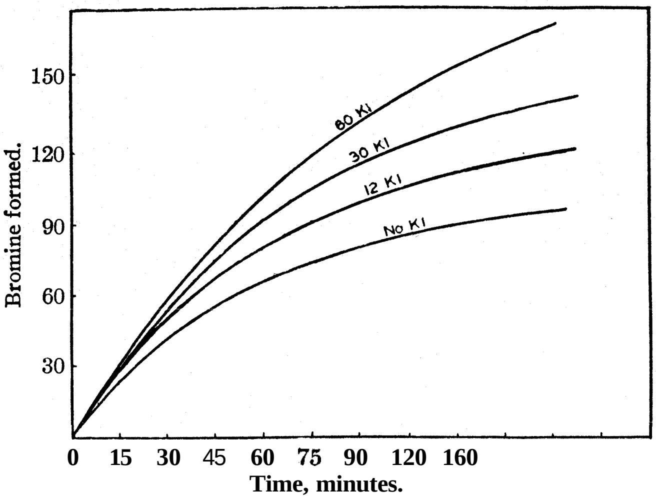

Fig. 1.—Effect of iodide on the reaction rate.

The Rate of the Reaction between Trivalent Ruthenium and Bromine

Stock solutions of bromine water, hydrobromic acid, hydrochloric acid and ruthenium trichloride were mixed and 20-cc. portions sealed in glass tubes. The tubes were placed in a water-bath whose temperature was maintained at 98°. The tubes were removed, one at a time, after measured intervals, cooled rapidly and emptied into a separating funnel. The bromine was extracted with ten 5-cc. portions of carbon tetrachloride. The carbon tetrachloride layer was treated with potassium iodide and the liberated iodine titrated with standard thiosulfate. The results of a typical experiment are shown in Table V.

TABLE V

RATE OF THE REACTION BETWEEN TRIVALENT RUTHENIUM AND BROMINE

Initial concn.: Ru^{III}, 0.00206 *M*; HBr, 0.5 *N*; HCl, 1.0 *N*; Br_2, 0.00850 N

Time	0 min.	30 min.	1 hr.	3 hrs.	5 hrs.	7 hrs.
Br_2 in CCl_4 layer (milliequiv. per l.)	8.5	7.6	7.1	6.8	6.6	6.3

The results, though not very accurate, show that the rate of the reaction between bromine and trivalent ruthenium is slow, as was inferred from the catalytic experiments. It was not practicable to make a complete investigation of this rate, since rather large quantities of ruthenium would have been required.

The Mechanism of the Catalyzed Reaction

Since hydrogen ion and bromide ion exert only secondary effects, the first step determining the rate of the catalyzed reaction might be that expressed by either of the equations

$$ClO_4^- + RuBr_5^{=} + 2H_2O = RuO_4^- + HClO_2 + 5Br^- + 3H^+ \qquad (2)$$

$$ClO_4^- + RuBr_5^{=} + 2H_2O = RuO_4^{=} + 5Br^- + ClO_2 + 4H^+ \qquad (3)$$

Either of these reactions would be in agreement with the experimentally established fact that the rate is directly proportional to the concentration of perchlorate ion and of trivalent ruthenium.

This first slow step might then be followed by the rapid reactions

$$RuO_4^- + 9Br^- + 8H^+ = RuBr_5^{=} + 2Br_2 + 4H_2O \qquad (4)$$

$$RuO_4^{=} + 8Br^- + 8H^+ = RuBr_5^{=} + 1^1/_2Br_2 + 4H_2O \qquad (5)$$

$$HClO_2 + 4Br^- + 3H^+ = Cl^- + 2Br_2 + 2H_2O \qquad (6)$$

$$ClO_2 + 5Br^- + 4H^+ = Cl^- + 2^1/_2Br_2 + 2H_2O \qquad (7)$$

The bromine that is thus formed would then slowly convert the trivalent ruthenium to the quadrivalent state. The fact that ruthenium tetroxide is formed by the action of hot concentrated perchloric acid on trivalent ruthenium compounds is not in disagreement with Reactions 2 and 3, since the ruthenates and perruthenates are decomposed by non-reducing acids into ruthenium tetroxide and ruthenium salts of lower valence. A detailed study of the very slow reaction between perchlorate ion and quadrivalent ruthenium was not made and therefore no data are available for determining its mechanism.

Summary

The reaction $ClO_4^- + 8Br^- + 8H^+ = Cl^- + 4Br_2 + 4H_2O$ is shown to be catalyzed by the presence of ruthenium salts. Its rate is found to be roughly proportional to the concentrations of perchlorate ion and of trivalent ruthenium salt, and to be considerably increased by increasing the concentrations of the bromide and of the acid.

It is shown that the bromine liberated by the reaction slowly converts the trivalent into the quadrivalent form and that removal of the free bromine by a current of carbon dioxide or by addition of an iodide maintains a larger reaction rate. These results, as well as those of comparative experiments in which the ruthenium salt was initially introduced in the trivalent and quadrivalent forms, respectively, show that trivalent ruthenium has a much greater catalytic effect on the reaction than quadrivalent ruthenium.

To explain the observed facts the following mechanism is suggested: the perchloric acid first slowly oxidizes the ruthenium from the trivalent to the sexivalent or septivalent state; the latter is then almost instantaneously reduced by the bromide to the trivalent state. The production of

quadrivalent ruthenium by oxidation of trivalent ruthenium by the liberated bromine accounts for the secondary effect produced by free bromine.

THE HEATS OF DILUTION AND SPECIFIC HEATS OF BARIUM AND CALCIUM CHLORIDE SOLUTIONS[1]

BY THEODORE W. RICHARDS AND MALCOLM DOLE

RECEIVED NOVEMBER 8, 1928 PUBLISHED MARCH 6, 1929

Introduction

The recent accurate and systematic investigations of the heats of dilution of various electrolytes carried out by Richards,[2] Lange[3] and their co-workers have been practically entirely limited to uni-univalent salts. The rise of the Debye and Hückel theory of complete dissociation has focused attention, however, on compounds with unsymmetrical valences, because, according to their ideas, the deviations of solutions from those predicted by the perfect gas laws are due partly to the electrical charges on the ions and when these are different the deviations are more marked. Hence a study of the heats of dilution of barium and calcium chloride solutions should prove of particular interest to the modern theories of solutions. Furthermore, one of us[4] had just completed electrochemical and viscosity experiments on barium chloride solutions and was therefore interested in this salt.

Determination of Specific Heats by the Direct Method

Introduction.—As in the previous papers of this series, the procedure in measuring the heats of dilution consisted in diluting a concentrated solution in several successive steps until the experimental errors became greater than the heat effect of the dilution. In addition to observing the rise in temperature of the calorimetric system, in order to calculate the amount of heat energy evolved it was necessary to know the heat capacity of the factors involved. The heat capacity of water and of the apparatus having been determined previously, the only factors remaining unknown were the heat capacities of the salt solutions. If the heat capacity at one

---

[1] On account of the death of Professor Richards on April 2, 1928, the work here described was completed and the manuscript was prepared by the junior author under the general direction of Dr. Lawrence P. Hall.

concentration is known, then the heat capacities of all the other concentrations may be found by performing the heat of dilution experiments at two temperatures and then calculating the change of the heat capacities of the factors by means of the Person–Kirchhoff equation. To find the heat capacity of the initial solution, a direct method must be used.

Review of **Previous** Values.—Specific heats of barium and calcium chloride have previously been measured by Thomsen,[5] Marignac[6] and Faasch[7] for barium chloride, and for calcium chloride by Thomsen,[5] Marignac,[6] Koch,[8] Dickinson, Mueller and George[9] and W. S. Tucker.[10] Of the data given by these investigators, Marignac's values would have sufficed for the present calculations since they were carried out at suitable concentrations, but although Richards and Gucker found Marignac to be an exceedingly accurate investigator,[11] it was decided to redetermine these values to a greater accuracy if possible.

The Apparatus.—Previous experimental methods of specific heat determinations have been reviewed recently by Richards and Gucker[11] and need not be considered here.

For this investigation the identical apparatus described by Gucker,[12] and further modified by Richards and Gucker,[13] was fortunately available. Many thanks are due to Dr. Gucker for so kindly lending the apparatus to us and for his interest and help in the carrying out of the experiments.

Materials **and** Solutions.—Commercial "C. P." barium chloride was dissolved, filtered, precipitated in freshly distilled alcohol, centrifuged, then again dissolved in water, recrystallized, centrifuged and dried in an oven at 120°. A spectroscopic test showed it to be free **from** strontium. For this direct determination of the specific heat, the solution used was that obtained by diluting the $BaCl_2 \cdot 50H_2O$ solution to $BaCl_2 \cdot 100H_2O$. It was analyzed gravimetrically and found to be $BaCl_2 \cdot 99.97H_2O$.

The calcium chloride was prepared by dissolving calcium nitrate in water, filtering, then precipitating the calcium as the carbonate, dissolving this in freshly distilled hydrochloric acid and finally recrystallizing from water, followed by drying in a centrifuge. A solution made up in the same way as the barium chloride solution proved to have the composition corresponding to $CaCl_2 \cdot 100.13H_2O$. All weighings throughout this paper were referred to the vacuum standard.

Experimental Procedure.—The experimental procedure was practically identical with that described by Gucker,[12] except that not so good

working conditions as he experienced can be claimed here. In his paper[14] he states that the two calorimeters never differed in temperature by more than 0.005° during the heating period. In the present investigation they differed greatly while being heated, probably by as much as 0.1°. The cause of this disconcerting inequality was different lags in the heating coils or in the calorimeters themselves which resulted, as far as could be told, from their being covered with spun gold. The standardization of the apparatus with water reduced this error appreciably; nevertheless, it must be admitted that the difficulty was present.[15] Separate check experiments showed the error of the procedure to be about 0.02% but, due to the uncertainties involved, the results might well be incorrect by as much as 0.05 or 0.1%.

Experimental Results.—In the actual procedure the temperature trends of the calorimeters before and after the heating period were plotted in order to insure that the trend had become constant before the reading was taken. Otherwise than this, the method was identical with that of Dr. Gucker. The experiments were carried out at two temperatures, from 19–21° and from 24–26°. The water standardization gave the same galvanometer deflections at both temperatures, but the barium and calcium chloride solutions were different. The results are summarized in the following tables.

Discussion of the Results.—From the viewpoint of F. Zwicky's theory,[12] the results are interesting because there is a decided increase in

TABLE I

WATER STANDARDIZATION DATA AT 20 AND 25°

Expt.	Av. temp. of heating period, °C.	Wt. of water *in vacuo*, g.	Galv. defl., cm.	Av. defl.
3	20.37, 25.01	245.26	9.00, 8.94	
4	20.12, 25.20	245.66	3.57, 3.57	3.57[a]
5	20.05, 25.01	245.26	8.52, 7.93	
6	19.67, 25.01	246.26	–4.20, –4.31	
12	20.01		–4.62	–4.38[b]
13	21.69	245.26	7.04	8.29[c]

[a] This value, which is intermediate between the two others, falls very near to a straight line drawn between the two other values when they all are plotted on a graph.

[b] The value –4.38 is the average of Expts. 6 and 12.

[c] The value 8.29 is the average of Expts. 3, 5 and 13. The total deflection due to one gram of water was taken as 12.67 cm. Expts. 12 and 13 were performed after the experiments on the salt solutions and constitute, therefore, a check on the constancy of the apparatus.

---

[14] Ref. 12, p. 1013.

[15] Inasmuch as this particular research, which was the last of the experiments here described, had to be carried out in the short time of twelve days (the only time the machine was available before the summer vacation), it was not possible to attempt to overcome this difficulty.

specific heat between 20 and 25°. This shows that the change of specific heat with temperature is quite noticeable and that it is a field of research which needs further development.

Heats of Dilution and Specific Heats

Review of Previous Investigations.—Heats of dilution of barium chloride have been measured by Magie,[16] Pratt,[17] and Smith, Stearn and Schneider.[18] The first two workers measured the temperature change only to 0.001° and obtained results which agree only in sign with those of this paper, while Smith, Stearn and Schneider determined the differential heat of dilution, in concentrated solutions only, by adding smaller and smaller amounts of water to a definite amount of solution and then extrapolating to zero amount of water added. The differential heats of dilution are not comparable to the total heats of dilution with which we are concerned in this research.

In addition to these heats of *dilution* might be mentioned the interesting work on the heats of *solution* of barium chloride in water by Lehtonen,[19]

and in water and mixtures of ethyl alcohol and water carried out by de Kolossowsky.[20]

The differential heats of dilution of calcium chloride solutions have been measured by W. S. Tucker[10] at 18°, and by Harrison and Perman[21] at 40, 50, 60, 70 and 80°. In neither research were smaller temperature changes than 0.001° measured, nor were measurements made in the range of low concentrations. Nernst and Orthmann[22] made one preliminary determination of the heat developed in the dilution of a moderately dilute solution of calcium chloride chiefly for the purpose of comparison with calcium nitrate, which at that concentration has a negative heat of dilution in contrast to calcium chloride, which has a positive heat of dilution. They were apparently solely interested in investigating the validity of the Debye and Huckel theory.

The Experimental Procedure.—The Richards adiabatic calorimeter method was used in this investigation for measuring the heats of dilution. The apparatus and the procedure have already been described in great detail by Richards and Rowe[23] and have been modified further by Richards and Gucker,[24] and improved by Richards, Mair and Hall.[25] The only variation of the procedure introduced in this investigation was to plot the temperature drifts of the calorimeter system before and after the solution and the water were mixed. The temperature readings were then made from the plot, thereby basing the final temperatures on several successive readings rather than on two. in this way there is no doubt that the temperature change of the system, in the most favorable cases, could be determined with an error of only 0.00001°. For example, in Fig. 1 are plotted the various temperatures of the system for Expt. 29 on calcium chloride. The total change was 0,00284" and agreed well with the temperature change in Expt. 30, which was 0.00285°. Needless to say, not all the experiments turned out as well as these two.

Experimental Results.—The method of calculating the results from the rise in temperature was practically the same as in the previous papers of this series. The temperature changes of the calorimetric system were corrected to 20 or 25° and then averaged before calculating any of the results. Since with two exceptions the heat capacities of the factors were used in the calculations, the temperature of the experiment was taken as the final temperature of the reaction. The two exceptions were the dilutions of $BaCl_2 \cdot 50H_2O$ to $BaCl_2 \cdot 100H_2O$ and $CaCl_2 \cdot 50H_2O$ to $CaCl_2 \cdot 100H_2O$, where the temperature of the reaction had to be the initial temperature

because the heat capacities of the products were the data from which the heat capacities of the factors had to be calculated.

The specific heats are the specific heats referred ta water over the same temperature range. They were calculated at **20** and 25° by using the value for the concentrated solution at 20° throughout **the** Person–Kirchhoff equation and the value at 25° throughout the equation. Heat capacities in mayers (joules per degree) at **20°** were found by multiplying the specific heat by 4.1805,[26] and at 25° by multiplying the specific heat by 4.1780.[26] For calculating the heats of dilution at **20** and 25° the average specific heat

over that range was used, since this involves no appreciable error. A negative sign for the heats of dilution means heat absorbed. The absolute value of the final temperature is the same as in the previous papers of this series (that is, the investigations which used the heat of dilution apparatus). The heat capacity of the apparatus devoid of water or solution was 76.4 mayers.

In all of the tables, a correction of −0.05° should be applied to all of the temperature readings. The absolute temperature is then correct to within ±0.02°.

Comparison with Earlier Data

In Table VI the data obtained in this research are tabulated with all other comparable values which are available in the literature. It might be mentioned that Pratt[17] published his values of the heats of dilution for barium chloride only in the form of a graph, which makes it impossible to obtain accurate values for comparison, In the specific heat column, (M.) stands for Marignac[6] and (T.) for Thomsen.[7]

Discussion of the Results

Although this is chiefly an experimental paper, it would not be amiss to draw a few conclusions from the results. In their investigation of the differential heats of dilution of barium chloride, Smith, Stearn and Schneider[18] made several measurements in the region of concentrated solutions, where the thermal effect on the addition of water is always negative. From this they concluded that the heats of dilution of barium chloride were always negative and so drew the curve on their graph. They also investigated strontium chloride, which they found to have just the opposite heat effect from barium chloride, *i. e.*, the differential heats of dilution were always positive. In both curves they found a sudden change in the region of 1.25 molal; they concluded from this that at that concentration the solutions of 1.25 molal strontium and barium chloride consisted chiefly of the intermediate ions $BaCl^+$ and $SrCl^+$. They explained the difference in the signs of the heats of dilution by the remarkable statement that the heat of hydration must be endothermic in one case and exothermic in the other.

In the light of modern theories of solutions, it is hardly necessary to explain the results in this way. In the first place, if there are complex ions, they are certainly not of the type $BaCl^+$, because the transference number of the barium ion in barium chloride solutions decreases with increasing concentrations, whereas if ions like $BaCl^+$ were present, the transference number would have to increase.[4] The complex ions, then, must be of the type $BaCl_3^-$ or $BaCl_4^{--}$ if they are present at all.

If we consider the very dilute solutions, we find excellent qualitative agreement with the Debye and Hückel theory. Both calcium and barium chloride have positive heats of dilution at very small concentrations, which the theory predicts.[27] The magnitudes of the thermal effects approach each other closely in dilute solutions, as would be expected from the complete dissociation theory. Hence in dilute solutions there is no need of assuming complex ions. Furthermore, in concentrated solutions there are so many effects such as heat of hydration, heat of polymerization of the water molecules, etc., that it is unnecessary if not actually unsound to explain any bend in the curve of the heat of dilution by merely *one* effect, such as that of the presence of complex ions. The heats of solution[19] of calcium, strontium and barium chlorides show a regular decrease in magnitude as the atomic weight increases, those for strontium chloride being half-way between those for calcium and barium chlorides; hence the different thermal effects of these solutions may be due to the intrinsic but regular difference in the atoms and not to any peculiarity of complex ions.

The authors take pleasure in acknowledging their indebtedness to the Carnegie Institution of Washington and to an anonymous benefactor of this Laboratory for essential financial assistance in carrying out this program of research.

Summary

1. The specific heats of a concentrated solution of calcium and barium chloride have been measured directly.

2. By the indirect method the specific heats and heat capacities of all the solutions have been determined.

3. The heats of dilution and the loss in heat capacity on dilution have been calculated from the observations.

4. Qualitative agreement with the Debye and Hückel theory has been found in dilute solutions.

REACTIONS IN LIQUID HYDROGEN SULFIDE. V. REACTION WITH FURFURAL

BY R. E. MEINTS AND J. A. WILKINSON

RECEIVED NOVEMBER 9, 1928 PUBLISHED MARCH 6, 1929

Cahours[1] treated furfuramide dissolved in alcohol with hydrogen sulfide gas and obtained a yellow crystalline substance which an analysis indicated was $C_{10}H_4S_2O_2$, thiofurfural. Baumann and Fromm[2] passed gaseous hydrogen sulfide into a solution of furfural dissolved in alcohol, saturated with hydrochloric acid, and isolated a similar body. Quam[3] has shown that furfural is soluble in liquid hydrogen sulfide and reacts with it. An endeavor has been made to prepare the compound mentioned above by the reaction between the two liquids.

The furfural was added to the liquid hydrogen sulfide contained in glass tubes cooled in a bath of solid carbon dioxide and ether. These tubes were then sealed; on coming to room temperature a reaction started and after a few days the whole mass became semi-solid and some yellow crystals formed. The tubes were opened after a week, the excess of hydrogen sulfide was allowed to evaporate and any furfural unacted upon was dissolved out with ether. The residue was soluble in hot ethyl acetate, from which solution yellow monoclinic needles separated. These blackened easily in the air, the black material being insoluble in hydrogen sulfide. When boiled with dilute sodium hydroxide solution the material turned brown but this was soluble in ethyl acetate and the yellow crystals reappeared on evaporating. These crystals softened at 80° and melted between 95 and 98°, which agrees very well with the data for the polymerized material prepared by Baumann and Fromm which softened at SO° and melted from 90–92°. Two samples on analysis were found to contain 28.74 and 28.57% of sulfur, while the theoretical for the compound C_5H_4OS is 28.6%. This indicates that the compound is a monosulfur derivative of furfural.

Furan, furfural alcohol, pyromucic acid, the ethyl ester and the nitroethyl ester of pyromucic acid were all treated in a similar manner but no reaction occurred. Therefore, with furfural it is not the oxygen of the ring that is replaced but the one in the aldehyde group.

Other work in this Laboratory has shown that the aldehydes as a class react with liquid hydrogen sulfide and substitute a sulfur for an oxygen in the aldehyde group, thus liberating water. Since the water is not entirely miscible with liquid hydrogen sulfide, it appears in a separate layer in the tube.

NOTE

A Modified Pirani Gage for Use in Corrosive Systems.—In studying reactions in gaseous systems at low pressures, frequent use has been made of the Pirani gage or some modification of it. If one of the gases involved is corrosive or if there is possibility of the reaction rate being affected by catalysis at a metal surface, the ordinary type of gage using a metal wire is unsatisfactory. In this Laboratory these difficulties have been eliminated by using a thin-walled glass capillary filled with mercury as the hot filament. The capillaries are drawn from ordinary 6-mm. Pyrex glass tubing and are usually made about 20 cm. long. These are then ring-sealed into a tube of about 1 cm. internal diameter. The resistance of such a gage varies from about 10 to 30 ohms depending on the size of the capillary.

The most satisfactory way to use this type of gage is to measure the current necessary to keep the temperature of the mercury thread constant. At low pressures the relation between the pressure and the heating current is linear, but at higher pressures the rate of increase of the current with increasing pressure falls off rapidly. These gages have been used with hydrogen and carbon monoxide and found to be quite satisfactory. The response to changes in pressure is so rapid that it does not cause any delay in taking readings. The maximum pressure readable with these gages varies with the accuracy of the current measurement. Using a milliammeter the practical upper limit is about 2 mm. of mercury, but by using a potentiometer this can be increased to several millimeters,

SOME MERCURY DERIVATIVES OF HALOGEN COMPOUNDS OF RESORCINSULFONEPHTHALEIN

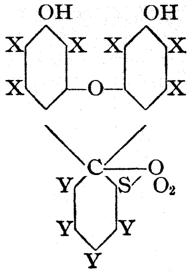
BY FITZGERALD DUNNING AND LARKIN HUNDLEY FARINHOLT

RECEIVED JUNE 14, 1928 PUBLISHED MARCH 6, 1929

For several years this Laboratory has been interested in the preparation of mercury derivatives of phthaleins and sulfonephthaleins and a study of their properties as therapeutic agents. In the course of this research we have had occasion to produce mercury derivatives of halogenated resorcinsulfonephthaleins. As many of the parent resorcinsulfonephthaleins, particularly those with halogen atoms present in the *o*-sulfobenzoic acid residue of the molecule, are unknown, we thought it advisable to make a brief report on the preparation of these compounds.

Results

The compounds which have been prepared may be represented in a general way by the following structural formula



Where X = H, Cl, Br, I, or HgOH and no more than two are halogen or mercury. Y = H, Cl, Br, I; all four being similar in individual compounds.

The following new halogenated resorcinsulfonephthaleins have been prepared: dichlororesorcinsulfonephthalein, resorcintetrachlorosulfonephthalein, resorcintetrabromosulfonephthalein and resorcintetra-iodosulfonephthalein. The mono- and dihydroxymercuri derivatives of all of these compounds have been prepared. In addition, the mono- and dihydroxymercuri derivatives of resorcinsulfonephthalein, dibromoresorcinsulfonephthalein and di-iodoresorcinsulfonephthalein have likewise been prepared.

These sulfonephthaleins show two color changes corresponding to the first formation of the mono- and then the disodium salts. They cannot be used as indicators, however, as they exhibit to a marked degree the phenomenon of dichromatism.

The preparation of resorcinsulfonephthalein has been described in the literature by Remsen and others.[1]

We have made use of the methods described by many of these investigators and with a modification in technique have been able to produce resorcinsulfonephthalein by condensing resorcinol with o-sulfobenzoic acid, o-sulfobenzoic anhydride, the acid ammonium salt of o-sulfobenzoic acid and saccharin. It was discovered that unless the condensation proceeded rapidly, a large amount of a by-product, probably a condensed polymer of resorcinol was formed. This may be separated from the resorcinsulfonephthalein by extraction with alcohol. Very pure resorcinsulfonephthalein can be obtained by any of these methods and, although no attempt was made to crystallize, the material obtained analyzed exactly as predicted by theory.

Preparation of Halogenated Resorcinsulfonephthaleins

Dichlororesorcinsulfonephthalein.—Fifty grams of resorcinsulfonephthalein was dissolved in 270 cc. of normal sodium hydroxide, forming the disodium salt, and 200 cc. of water was added. Fifteen grams of sodium chloride and 150 g. of Chloramine T (sodium salt of *p*-toluene chlorosulfonamide) were dissolved in water and added to the first solution. Concentrated hydrochloric acid (approximately 10 cc.) was added to start the reaction. The solution was allowed to stand overnight and a salmon-colored precipitate consisting mainly of *p*-toluene sulfonamide settled out. This mixture was made alkaline with sodium carbonate, to insure the solution of the dye. *p*-Toluene sulfonamide is only slightly soluble in sodium carbonate in the cold; therefore, the solution was cooled to 5–10° for several hours before filtering. The filtrate was acidified with hydrochloric acid and this precipitate was collected on a Büchner funnel. As the precipitate at this point is contaminated with the by-product, it was dissolved in sodium bicarbonate and reprecipitated with hydrochloric acid. This procedure was repeated several times. The final precipitate was collected on a Büchner funnel, washed with a small amount of cold water and then dried at 110°. No attempt was made to crystallize this compound. As obtained it is light red-brown in color, slightly soluble in water, alcohol, acetone and acetic acid. It dissolves readily in dilute sodium hydroxide, forming either a mono- or disodium salt. The solution of the sodium salt exhibits a marked fluorescence; yield, 65%.

Anal. Calcd. for $C_{19}H_{10}O_6Cl_2S$: Cl, 16.23; S, 7.33. Found: Cl, 16.28; S, 7.29.

Dibromoresorcinsulfonephthalein and di-iodoresorcinsulfonephthalein were prepared by the method of Orndorff.[2]

Preparation of Resorcin Halogenated Sulfonephthaleins.—Tetrachloro-, tetrabromo- and tetra-iodo-*o*-sulfobenzoic anhydrides were prepared by Dr. D. Twiss, of this Laboratory. These anhydrides were condensed with resorcinol to form the corresponding phthaleins.

The general method found to be satisfactory for preparing these compounds is as follows. The tetra-halogenated *o*-sulfobenzoic anhydride was mixed thoroughly with resorcinol, in the molecular proportion of 1:2. This mixture was heated in a flask in an oil-bath to 110–120° until the mass became very dark and solid. The temperature must be kept low as otherwise the yields will be poor. This melt was dissolved in 10% sodium hydroxide, the solution filtered and the filtrate precipitated with hydrochloric acid. It is necessary to use concentrated hydrochloric acid to precipitate both resorcintetrachlorosulfonephthalein and resorcintetrabromosulfonephthalein; the precipitates are tarry. These were dried, powdered, washed with hydrochloric acid and then dried. Both compounds are dark brown in color, strong dibasic acids in solution, soluble in water and dilute alkali and moderately soluble in alcohol and acetone. Resorcintetra-iodosulfonephthalein is not a very strong acid and may be precipitated with dilute hydrochloric acid. It is dark brown in color, slightly soluble in water, alcohol and acetone and readily soluble in dilute alkali. The yields were poor with resorcintetrachloro- and tetrabromosulfonephthalein. Resorcintetra-iodosulfonephthalein gave a yield of 80%.

Anal. Calcd. for $C_{19}H_8O_6Cl_4S$: Cl, 28.03; S, 6.34. Found: Cl, 28.24; S, 6.40. Calcd. for $C_{19}H_8O_6Br_4S$: Br, 46.75; S, 4.70. Found: Br, 46.18; S, 4.80. Calcd. for $C_{19}O_8O_6I_4S$: I, 58.23; S, 3.69. Found: I, 58.35; S, 3.70.

Preparation of Mercury Derivatives.—The mono- and di-mercury

---

[2] Orndorff and Vose, THIS JOURNAL, **46**, 1910 (1924).

derivatives of these halogenated resorcinsulfonephthaleins can be prepared by several of the known methods of mercuration.

A solution of molecular proportions of the disodium salt of a sulfonephthalein and of mercuric acetate will react readily on heating. No precipitate is formed by this reaction. The solution is filtered and then precipitated by dilute hydrochloric acid at 60°, with rapid stirring. This will avoid decomposition by loss of mercury. An alternate method is to boil an aqueous solution of the sodium salt of a sulfonephthalein with mercuric oxide in molecular proportions. This solution is filtered and can be taken to dryness on a water-bath or in vacuum and the sodium salt of the mercury derivative obtained immediately in very pure form.

The mercury compounds prepared were all insoluble in water and organic solvents. Both mono- and disodium salts can be readily formed. The solutions of these sodium salts show only a slight fluorescence, as compared with the parent phthalein.

TABLE I

COMPOUNDS AND ANALYSES

Sulfonephthalein	Formula	Mercury, % Calcd.	Mercury, % Found
Monohydroxymercuriresorcin-	$C_{19}H_{12}O_7SHg$	34.3	34.0

Dihydroxymercuriresorcintetrabromo-	$C_{19}H_8O_8Br_4SHg_2$	35.9	34.7

Analytical

Sulfur and the halogens were determined by the Parr bomb oxidation method. Mercury was determined by the ordinary method of decomposing with sulfuric acid and potassium permanganate, reducing manganese dioxide formed with oxalic acid and precipitating the mercury with hydrogen sulfide. However, when both iodine and mercury are present in the compound this method cannot be used to determine the latter, due to the formation of mercury iodide. The method used was devised by Mr. A. E. Stickels of this Laboratory and is as follows.

To a 0.3- to 0.5-g. sample in a Kjeldahl flask is added 25 cc. of concentrated sulfuric acid and the flask is heated until the material is dissolved. Powdered potassium permanganate is slowly added until the compound is entirely decomposed, taking care not to heat too high in order to prevent any mercury from volatilizing. The mixture is cooled, diluted with about 50 cc. of water and decolorized with oxalic acid or ammonium oxalate. It is diluted to about 400 cc. with water and if a precipitate forms it is heated until the precipitate is dissolved. The solution is cooled, 5 g. of potassium nitrite added and it is heated to boiling. About 2 g. of potassium bromide is added, the solution heated again to boiling, cooled and transferred to a separatory funnel. It is shaken out two or three times with chloroform in order to remove the free bromine. About 1 cc. of phenol is added and the shaking out continued with chloroform or carbon tetrachloride until all of the iodine is removed, which is evident when the chloroform has no color. From time to time more phenol may be required. The aqueous solution is filtered, heated to about 80° and the mercury precipitated with hydrogen sulfide. The precipitate is collected on a tared Gooch crucible, washed with alcohol, then carbon disulfide, again with alcohol and dried in an oven for an hour at 110°. The precipitate is weighed as mercuric sulfide.

This method has been used on known organic mercury compounds to which analyzed potassium iodide has been added with excellent results. Different experimenters have checked analyses with less then 0.3% error.

Summary

1. Several new halogen derivatives of resorcinsulfonephthalein have been made.

2. Mercury derivatives of a number of halogen compounds of resorcinsulfonephthalein have been prepared.

3. A satisfactory method for analysis for mercmy in the presence of iodine is included.

4. Work in this field is being continued.

POLARIZED LIGHT AND COCAINE DECOMPOSITION

BY H. T. DAILEY[1] WITH H. C. BENEDICT

RECEIVED JUNE 15, 1928 PUBLISHED MARCH 6, 1929

Introduction

Macht and Anderson[2] report that polarized light has a selective action on the decomposition of cocaine, digitalis and quinine as measured by their pharmacological effects. Other chemical effects attributed to polarized light have been reported.[3] Semmens and Baly and Semmens[4] have found that polarized light accelerates the hydrolysis of starch by diastase. Macht announced a substantiation of this work.[5] These reports have been ques-

[1] A portion of a thesis submitted to the Faculty of Northwestern University Dental School in partial fulfilment of the requirements for the degree of Master of Science in Dentistry.

tioned by Jones.[6] More recently the carefully controlled experiments of Bunker and Anderson[7] gave reason to doubt the validity of the conclusions of Semmens, Baly or Macht. In a note[8] Macht gave a preliminary report of the effect of polarized light on other alkaloids, all of which are optically active. Macht gives the work a practical turn by reporting that when a bottle of tincture of digitalis is wrapped in thin tissue paper the solution is more decomposed than that in an unwrapped bottle, due to the small amount of polarization of the light by the thin tissue paper.

He suggests as an explanation of this effect[2] that "if 'for every action there is a reaction' we may look at this phenomenon from the other end and argue that if a given solution can turn the plane of polarized light to the right or to the left, then *vice versa* we may expect polarized light also to react on the solution, and tend to produce some rearrangement in its molecules.''

It seemed that an investigation of the effect of polarized light on a substance which did not contain an asymmetric carbon atom would be a test of Macht's theory. Procaine (β-diethylamino-ethyl *p*-aminobenzoate hydrochloride) suggested itself, as it can be tested in much the same way as cocaine. This was also interesting from a practical point of view because procaine is frequently obtained in wrapped bottles or vials.

Before beginning the work on procaine it was considered desirable to attempt the work of Macht and Anderson on cocaine. From this attempt the contrary conclusion is drawn that polarized light does not cause greater decomposition of cocaine solutions than non-polarized light of the same intensity. Experiments in which procaine solutions are irradiated with polarized and non-polarized light of the same intensity do not show any selective effect (unpublished work).

Apparatus

Macht and Anderson[2] used an apparatus in which they obtained polarized light by transmission through a stack of twelve glass plates at the polarizing angle and also with large Nicol prisms, 2.5 and 3.5 cm. in diameter. As we were unable to obtain as large a Nicol prism as this, experiments were tried with a stack of twelve photographic plates (8 in. by 10 in.). These did not give very complete polarization, as tested by a Nicol prism for extinction. It can be computed that 18% of the light transmitted is non-polarized when using twelve plates. Why do Macht and Anderson make careful measurements of the absolute units of energy when they do not indicate how much of this is polarized? An apparatus was therefore built using a plane plate of black Carrara glass (17 by 24 cm.) obtained from Bausch and Lomb. They use this plate in their strain finder for glassware. The plate was adjustable to any angle by a three-point suspension to attain the maximum of polarization. When properly adjusted the center of the plate was completely extinguished by a crossed Nicol prism and the rest

[7] Bunker and Anderson, *J. Biol. Chem.*, **77**, 473 (1928).

[8] Macht, Science, 66, 653 (1927).

of the plate nearly so. The plate was inside a triangular blackened box (12 by 12 by $13^3/_8$ inches). In the two equal sides of the box six-inch holes were made to take the six-inch stove-pipe used to isolate the light system. In order to obviate any possible changes in the light by absorption in filters, the non-polarized end was balanced as to intensity with the polarized end by increasing its distance from the light source. At the end of each stove-pipe a removable upright was made, having a 0.75-inch hole to allow observation and to take a thermometer and having a shelf to hold the receptacle for the solution.

As a source of light a 400-watt tubular projection lamp rated at 9000 lumens was used. Because its filament lies in one plane, little light is wasted to each side. To diffuse the light a plate of ground glass was placed four inches from each side of the bulb. The intensity of the polarized and non-polarized ends was made the same within 3 or 4% by using a photometer made of two paraffin plates separated by a piece of tin foil. The experimental error of the photometer was determined on an optical bench before calibrating the apparatus. This photometer was placed in the position to be occupied by the receptacle on the polarized side and a 75-watt lamp was adjusted to balance. Holding the distance between the 75-watt lamp and the photometer constant, a position was found on the non-polarized side where a balance was attained. This was made the position of the non-polarized receptacle.

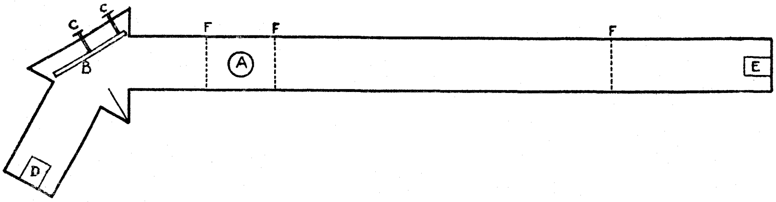

Fig. 1.—Diagram for irradiation device.

A, 400-watt projection lamp; B, black Carrara glass plate; *C*, screws to adjust angle of plate; D, shelf for receptacle on polarized side; E, shelf for receptacle on non-polarized side; *F*, ground plate glass.

The apparatus was so ventilated that the temperatures of the two ends were approximately that of the room, about **23–26**" depending on the day, and were always the same within a half degree throughout an irradiation. Our apparatus was so constructed that the receptacles were about one inch away from the black surface to prevent heating by absorption. From the description of the Macht–Anderson apparatus it seems that the receptacles were placed directly on the blackened surface. Also the distance from the light to the polarized end was less than half the distance to the non-polarized end (see diagram). Therefore, if heating effects came into play, they would be stronger on the polarized side and would if anything enhance the effect he described and which we were unable to obtain.

A few experiments were tried using an "Ahrens" prism of 13 mm. aperture as a polarizing device. The light source was a 15-watt microscope lamp. The heat was absorbed in one experiment by a water cell, in another by a Corning heat-absorbing glass filter.

No attempt was made to have a non-polarized control. The polarized light treated portion was compared with a portion which had been kept in the ice box during the irradiation. As the ice box was dark and cold and the polarized portion was warm (room temperature about **24°**) and light, this gives the greatest chance for the results to agree with those of Macht and Anderson. However, the goldfish anesthesia times are approximately the same (see Table II).

We also made a few tests with the light coming down perpendicularly to the surface of the solution. This is the manner in which many of the experiments of Macht and Anderson were run. It was suggested that we might not be obtaining the results they report because the decomposition was a surface effect, due to some sort of an oriented surface layer on which the polarized light would have a selective effect. The results of our tests do not bear out this suggestion, but may overcome an objection that we did not use the same apparatus as that of Macht and Anderson.

Methods of Testing the Solutions

The two methods used by Macht and Anderson[2] were used by us to determine the extent of decomposition of the cocaine; namely, the goldfish anesthesia time and the growth of *Lupinus albus*. They give no details of either method. We followed the technique given by Adams, Rideal, Rurnett, Jenkins and Dreger[9] on goldfish.

The goldfish were kept in Alberen sinks, the temperature of the water being 20" plus or minus 2". During a test the temperature of the solution was maintained at 20° plus or minus 0.2". Three goldfish were used in each experiment in 250 cc. of solution in a 600-cc. beaker. The time of anesthesia was taken as that given by Adams and co-workers.[9] "When no amount of pressure (on tail or fins) will cause the fish to move." At this point the fish were usually on their sides and had stopped breathing—to all appearances dead. If removed at once, 98% of the fish will entirely recover. Common goldfish about 2 to **3** inches long were used, as supplied by the Auburndale Goldfish Co., Chicago.

Whereas Adams and co-workers[9] found that with alkyl esters of ;b-aminobenzoic acid the goldfish could be used repeatedly after allowing a week for recuperation, we found that they could not be used a second time with cocaine. When the fish were used a week after one exposure no checks could be obtained. The time of anesthesia was longer by five to ten minutes and the individual times seemed to vary more. Fresh distilled water was made and a fresh supply of cocaine was obtained; neither of these changes gave any better results. A fresh supply of goldfish gave us checks and consistent results.

The following test was applied: two goldfish were anesthetized in a 1:5000 cocaine solution in about fourteen minutes. The fish were allowed to recuperate for two hours and again placed in a fresh 1:5000 cocaine solution. They were still swimming normally at the end of an hour. This suggests that unless fresh fish were used throughout, erroneous results might be obtained. It seems that goldfish develop a tolerance for cocaine and unless specially mentioned all the experiments reported were done on fresh fish.

To check our technique with that of Adams and co-workers,[9] tests were made on one of the anesthetics they used at two dilutions. The average

---

[9] Adams, **Rideal, Burnett,** Jenkins and **Dreger,** THIS JOURNAL, 48, **1758 (1926).**

anesthesia time of 8 and 9 fish checked their average time within 0.2 and 0.3 minute.

TESTS ON *n*-BUTYL *p*-AMINOBENZOATE

Concn., M	Time, minutes										Av.	Adams[9] Av.
0.0001	6	6.75	7.75	4.5	5.75	6.75	6.75	7	7	9	6.7	7.0
0.0005	16	16.5	26.5	17.5	23	20.5	21.0	22			20.5	20.7

We are thus reasonably certain that our technique of using the goldfish is essentially the same as theirs.

Another possible error may be introduced by the water used. If doubly distilled water is used, distilled the second time from alkaline permanganate as recommended by Adams and co-workers,[9] much longer times are required for cocaine anesthesia than when ordinary distilled water is used. That this was due to traces of tin from the block tin condenser was shown by boiling some of the doubly distilled water with a piece of cleaned block tin for two hours. A cocaine solution made with this water gave an anesthesia time nearly as short as that of ordinary distilled water and much shorter than the original water. Some of the doubly distilled water was boiled without the tin for two hours; a solution made with this water gave an anesthesia time the same as the original. We hope to look further into this effect.

The results of tests on 108 fish are tabulated in Tables I and II. About 50 more fish were used to obtain an anesthesia time for the non-irradiated solutions. As this time did not appreciably differfrom either the polarized or the non-polarized times for periods of irradiation up to three hours, and as it is not essential to the proposition, it is not necessary to include this data.

We were fortunate in having the assistance of Mr. V. F. Lang of Northwestern University Medical School in running tests on the *Lupinus albus,* as he has been using the method under Dr. C. A. Dragstedt for a year. The solutions were brought to him labeled A, B and C. This assured that the results obtained were not influenced by any preconceived idea of the results expected. The technique employed was that of Macht and Livingston.[10] All of the following steps are carried out in the dark at 20° plus or minus 1°. Seeds of *Lupinus albus* are sprouted in water overnight, and are then placed with the hilum down in moist sphagnum moss for three days. The roots are then measured from a characteristic brown ring to the tip. Seeds with roots of approximately the same length are placed in a series of three-inch test-tubes. The average of ten seedlings is considered a test. A standard is obtained by putting a half and half mixture of Shive's solution,[11] a nutrient solution containing $Ca(NO_3)_2$, $MgSO_4$ and KH_2PO_4 and distilled water

---

[10] Macht and Livingston, *J. Gen. Physiol*, 4, 573 (1922).

[11] Shive, *Physiol Research,* i, 327 (1915).

in the ten test-tubes containing the seeds. The average increase in length in mm. in twenty-four hours is considered 100% growth. The unknown solution is tested by mixing it with an equal volume of Shive's solution, treating ten plants with this mixture and comparing the average growth with that of the standard. Results are reported in percentage of standard growth. The concentrations of cocaine given are those of the original solution. The mixture used to grow the seedlings will thus be half as concentrated.

It should be noted that as the cocaine is decomposed it will have less anesthetic effect and the time of anesthesia for goldfish will be lengthened. On the other hand, as the cocaine has little effect on the growth of *Lupinus albus* and the decomposition products have a great effect,[10] the growth of the plants should be inhibited if there were appreciable decomposition.

In fact it can be computed from the data given by Macht,[10] on the relative growth of *Lupinus albus* in different concentrations of cocaine and its decomposition products, benzoic acid, methyl alcohol and ecgonine hydrochloride that, considering all the lethal effect to be due to the benzoic acid, 17% decomposition of a 1:1000 cocaine solution (0.0029 molar) would completely inhibit the growth and that 1.7% decomposition will give a growth index of 66–67%. Macht[2] finds an index of 75 after the solution has been irradiated for three hours. This would correspond to about 1% decomposition. Yet he obtains a change in the anesthesia time of about 400%.

Experimental Data

In Table I are given the results of the tests on cocaine solutions using the black Carrara glass plate as the polarizing device. Besides the individual times and the average times of anesthesia, the average deviation is included. The percentage increase in time of anesthesia due to the polarized light was obtained by subtracting the average non-polarized time from the average polarized time and dividing by the non-polarized time, results being expressed in percentage. If the non-polarized time is greater than the polarized, the results are negative.

The anesthesia time gradually increases with time of irradiation. This bears out the known fact that cocaine hydrochloride solutions are decomposed by light.

Table II is made up in the same form as Table I. It gives the results of experiments in which the polarized light was perpendicular to the surface of the solution and in which the polarized radiation was obtained by an "Ahrens" prism. In these experiments no non-polarized control was used but the results are compared with a portion of the solution which was kept in the ice box.

In the last experiment if the growth of one seedling which was obviously a "sport" had been omitted from the calculation, the growth index of the

10 hours	80	90	90	100	1:500

polarized side would have been 86.5% instead of 80%. It has been the experience of Dr. C. A. Dragstedt that variations of 10% or more are frequently obtained and that unless this difference is consistently obtained it is without significance.[12]

Table IV summarizes the results of Tables I and II, giving the average times of each experiment. We have included the average of the averages, regardless of time of irradiation or concentration. If there were a consistently longer time due to the polarized light, this should show up. However, this average shows a slightly longer time for the non-polarized light, and the average percentage increase in time due to the polarized light is −3.48%. These results are probably within the experimental error of the method.

TABLE IV

SUMMARY OF RESULTS

Radiation time	Concn.	Pol.	Non.	% Increase in time due to pol. light, %	Remarks
1	1:5000	11.29	11.2	0.8

6.5	1:5000	41.0	47.6	−13.8	Perpendicular light
7.0	1:5000	23.3	24.8	− 6.0	
12.0	1:5000	29.0	30.9	− 6.1	
5.0	1:5000	31.5	31.1	1.3	Perpendicular light
Average of av.		17.8	19.1 Total	−52.2	Av. −3.48

It will be noticed that in one or two experiments the solutions irradiated with polarized light have a slightly longer anesthesia time than the specimen treated with non-polarized light. However, these results are not obtained consistently, and as many or more tests are found which would reverse the conclusion.

---

[12] Personal communication.

Summary and Conclusions

1. A study of the relative effect of polarized and non-polarized light on the decomposition of cocaine has been made, in which (a) several concentrations of cocaine hydrochloride were used; (b) two methods of obtaining a polarized radiation were used; (c) the times of irradiation ranged from one to twelve hours; (d) the effect was tested on goldfish and *Lupinus* albus.
2. The conclusion is drawn that polarized radiations have no selective action in the decomposition of cocaine hydrochloride.
3. Cocaine is slowly decomposed by light.
4. Obvious sources of error which we have tried to eliminate are: the variability of individual goldfish, the tolerance that goldfish develop to cocaine and the effect of traces of impurity in the water.

THE SYNTHESIS OF CERTAIN ACRIDINE COMPOUNDS

BY KONOMU MATSUMURA

RECEIVED JUNE 22, 1928 PUBLISHED MARCH 6, 1929

In continuation of work on the preparation of certain acridine derivatives for bactericidal examination,' this paper deals with the preparation of the following compounds.

V. 9-Amino-3,6-dimethoxy-acridinium-methyl Chloride

9-Amino derivatives of acridine compounds are now attracting considerable interest in the field of medicine. Of these, Rivanol (2-ethoxy-6,9-diamino-acridine-hydrochloride) is the only product now employed in practice. The compound described here was prepared as a further contribution to the study of this kind of compounds.

Diphenylmethane, prepared from benzyl chloride, benzene and aluminum chloride by Radziewanowski's method,[2] was first converted into 3,6-diamino-acridone (I) by nitration, oxidation, and subsequent reduction by Schopff's[3] and Staedel's[4] methods, respectively, with a little modification. 3,6-Diamino-acridone was then converted into 9-amino-3,6-dimethoxy-acridine (IT) by hydrolysis with 50% sulfuric acid, methylation with dimethyl sulfate, chlorination with phosphorus pentachloride and subsequent amidation with ammonia. 9-Amino-3,6-dimethoxy-acridine on acetylation, treatment with *p*-toluene-methyl-sulfonate, and subsequent hydrolysis with hydrochloric acid, gave 9-amino-3,6-dimethoxy-acridinium-methyl chloride (IV).

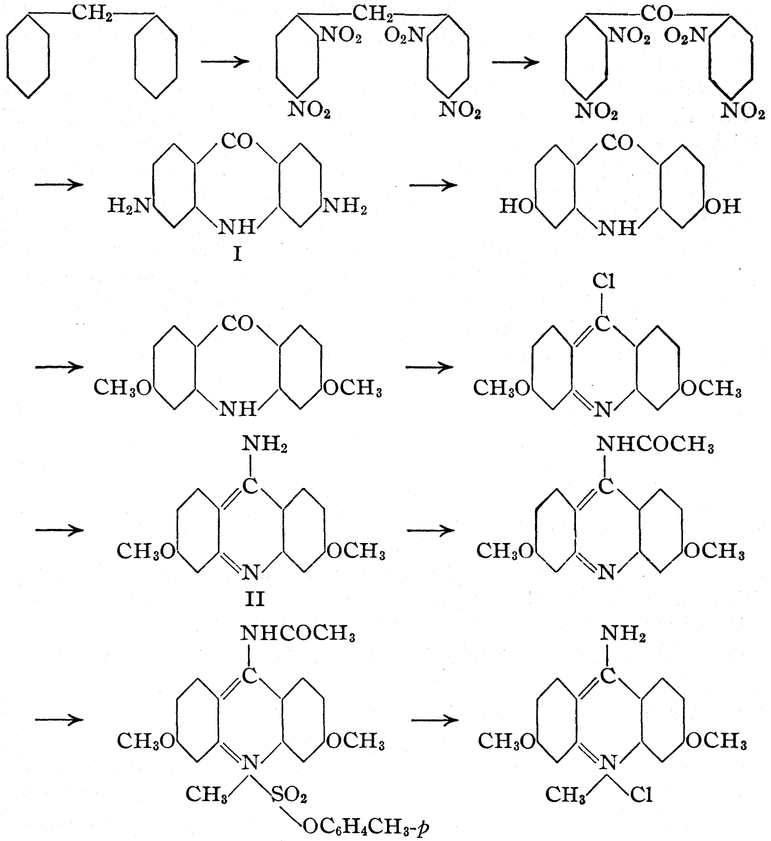
[3] M. Schopff, *ibid.,* 27, 2318 (1894).

[4] Staedel, *Ann* , **218,339** (1883)

The methyl iodide of 9-acetamino-3,6-dimethoxy-acridine (III) was obtained by direct combination of the components, but its scanty solubility in water made it disadvantageous in practice for physiological study.

The yields in all these steps of the synthesis are generally good enough for technical operation. The whole process of the synthesis is represented by the following scheme.



Experimental Part

2,4,2′,4′-Tetranitrodiphenylmethane.—The following modification of M. Schöpff's[3] method was used: 135 g. of finely powdered potassium nitrate was dissolved in 700 g. of concd. sulfuric acid below 30° during about three-quarters of an hour. 50 g. of diphenylmethane (b. p 260°) was introduced into the solution under constant stirring during one and one-half hours at 10–25°. The mixture was then gradually warmed to 70° on the sand-bath and kept at that temperature for half an hour under stirring and then allowed to stand. After being cooled, it was poured into 4 liters of ice water, when a light yellow precipitate was obtained which was filtered and washed.

After being dried, it was boiled with 200 cc of alcohol, filtered while hot and re-

crystallized from 400 g. of boiling glacial acetic acid, giving large prisms of light yellow color; m. p. 173°; yield, 81 g. (77%) after recrystallization.

2,4,2',4'-Tetranitrobenzophenone.—For the preparation of this compound by Staedel's method, the following procedure was found to be the best. To the boiling solution of 17 g. of tetranitrodiphenylmethane in 270 g. of glacial acetic acid, 25 g. of chromic oxide was gradually introduced from the upper end of the cooler during half an hour, and kept boiling for two and one-half hours longer.

Next day the separated crystals were filtered from glacial acetic acid, washed with glacial acetic acid, then with water and with alcohol, giving slightly yellowish prisms; m. p. 232°; yield, 16.5 g. (93%). The melting point is not in agreement with Staedel's and Schopff's descriptions (m. p. 225°). The lower melting point may perhaps be due to the presence of unaltered mother substance.

3,6-Diamino-acridone.—An attempt to reduce the nitro derivative to diamino-acridone by tin metal and concd. hydrochloric acid led to the formation of much tar, from which only a small amount of the diamino-acridone could be isolated. It was abandoned then and Schopff's method[3] was used in entirety. This process gave almost colorless needles, which are unaltered at 320'; yield, 10.7 g. (97%) from 18 g. of tetranitrobenzophenone.

3,6-Dihydroxy-acridone.—Attempts to convert the amine into the corresponding hydroxyl compound by the usual method of heating the diazotized solution of the amine led to the formation of much disagreeable black-violet coloring matter, from which only a small amount of dihydroxy-aaidone could be extracted, whereas the direct hydrolysis by sulfuric acid was found very satisfactory.

Twelve g. of 3,6-diamino-acridone, 50 cc. of water and 40 g. of concd. sulfuric acid were heated in an enameled autoclave at 195° for six hours. After being cooled, the contents consisted of a light brown colored cake and a slightly colored liquid. The cake was dissolved in an excess of dilute sodium hydroxide solution and after filtration precipitated again with dilute hydrochloric acid. It was recrystallized from boiling glacial acetic acid or better from boiling alcohol, giving almost colorless thin plates or columns of silky luster. It was unaltered at 320°.

The solution in conc. sulfuric acid gives pure blue fluorescence. It is fairly soluble in hot alcohol, in hot glacial acetic acid and acetone, very difficultly in nitrobenzene and insoluble in water, benzene and ether; yield, 10.2 g. (85%).

Anal. Subs., 0.0940: N_2, 5.2 cc. (16°, 760 mm.). Calcd. for $C_{13}H_9O_3N$: N, 6.17. Found: N, 6.44.

3,6-Dimethoxy-acridone.—To a boiling solution of 9 g. of 3.6-dihydroxy-acridone, 4.6 g. of potassium hydroxide and 5 cc. of water, in 50 cc. of alcohol, 12 cc. of dimethyl sulfate was added from the upper end of the cooler in three separated portions.

A violent reaction occurred at each addition and precipitate was produced. The mixture was boiled for an hour longer. On being cooled, it was made strongly alkaline by the addition of a solution of 4.5 g. of sodium hydroxide in 100 cc. of water. The precipitate of microscopic columns was filtered after standing for one night, washed with water and recrystallized from glacial acetic acid.

It gave almost colorless short needles or plates, unaltered at 320°; its concd. sulfuric acid solution shows a bluish-green fluorescence, and it is fairly soluble in hot alcohol and hot glacial acetic acid, but insoluble in benzene and ether; yield, 7.8 g. (77%).

Anal. Subs., 0.0937: N_2, 4.5 cc. (16°, 759 mm.). Calcd. for $C_{15}H_{13}O_3N$: N, 5.49. Found: N, 5.58.

9-Chloro-3,6-dimethoxy-acridine.—5.1 g. of 3,6-dimethoxy-acridone, 4.6 g. of phosphorus pentachloride and 12 cc. of dry toluene were well mixed into a homogeneous paste. The mixture was gradually warmed to 120–130° during an hour with occasional stirring and kept at that temperature for three hours longer. The toluene and phosphorus oxychloride were driven off by the current of dry air and the material was allowed to cool. The yellow mass thus obtained was treated with ice water, converted into a fine powder, and on making alkaline with dilute aqueous ammonia, free base was obtained; m. p. 152–8°; yield, 5.6 g. The product so obtained is good enough for use in the next step of the synthesis. For the further purification for analytical use, the crude product was dissolved in cold alcohol, and the filtered solution was concentrated in vacuum at room temperature. On addition of cold water to the concd. alcoholic solution, the chlorodimethoxy-acridine separated out as long needles of light yellow color; m. p. 184°. It was easily soluble in alcohol with green fluorescence, difficultly in benzene, almost insoluble in water and the solution in concd. sulfuric acid gave an intense green fluorescence.

Anal. Subs., 0.2833: AgCl, 0.1478. Calcd. for $C_{15}H_{12}O_2NCl$: Cl, 12.98. Found: Cl, 12.88.

The hydrochloride gave yellow needles and is very easily soluble in cold alcohol and rather difficultly in cold water.

9-Amino-3,6-dimethoxy-acridine.—A mixture of 70 cc. of absolute alcohol and 3 g. of copper acetate was strongly cooled by ice and salt and saturated with ammonia (dried through calcium oxide) at 0°. To this solution finely powdered, crude 9-chloro-3,6-dimethoxy-acridine prepared from 5.1 g. of dimethoxy-acridone was added and heated at 140° (24 atm.) in an autoclave for eight hours. After the evaporation of alcohol and excess of ammonia, the residual mass was extracted twice with hot dilute hydrochloric acid and then with hot water. The united hot extracts were made alkaline with dilute aqueous sodium hydroxide, when intensely yellow crystals separated and crystallized as yellow prisms from alcohol; m. p. 268°.

It is fairly soluble in ether, easily in acetone and hot nitrobenzene, sparingly in chloroform, benzene and hot water. The solution in concd. sulfuric acid gives a green fluorescence and on dilution with water a violet-blue fluorescence is shown. The alcoholic solution gives a green fluorescence and on dilution with alcohol a pure blue fluorescence. In dilute hydrochloric acid it is rather difficultly soluble, with violet-blue fluorescence, but is fairly soluble on warming; yield, 3.5 g.

Anal. Subs., 0.0570: CO_2, 0.1486; H_2O, 0.0302. Subs., 0.0796: N_2, 7.3 cc. (11.5°, 760.6 mm.). Calcd. for $C_{15}H_{14}O_2N_2$: C, 70.87; H, 5.51; N, 11.02. Found: C, 71.10; H, 5.89; N. 10.90.

The hydrochloride was obtained on addition of an excess of concd. hydrochloric acid to the hot alcoholic solution of the free base and subsequent cooling. It forms light yellow needles which begin to soften at 310° and melt at 315° (decomp.). It is fairly soluble in cold alcohol, rather difficultly in cold water but fairly soluble in hot.

Anal. Subs., 0.3152: 19.6 cc. $N/10$ NaOH. Calcd. for $C_{15}H_{14}O_2N_2 \cdot 2HCl$: HCl, 22.32. Found: HCl, 22.70.

The picrate forms yellow columns from alcohol, begins to decompose at 273° and sharply melts at 285° with foaming.

Anal. Subs., 0.0735: N_2, 9.0 cc. (13°, 770 mm.). Calcd. for $C_{15}H_{14}O_2N_2 \cdot C_6H_3O_7N_3$: N, 14.49. Found: N, 14.64.

9-Acetamino-3,6-dimethoxy-acridine.—9-Amino-3,6-dimethoxy-acridine and some excess of acetic anhydride, under the addition of sodium acetate, were kept for two hours at 100°. The reaction mixture was poured into water and warmed on the water-bath until completely dissolved. On treating the filtered liquid with aqueous sodium carbonate, the acetyl compound is precipitated as light yellow shining needles from alcohol; m. p. 277–278°.

Anal. Subs., 0.0836: 6.7 cc. (12°, 764 mm.). Calcd. for $C_{17}H_{16}O_3N_2$: N, 9.46. Found: N, 9.55.

9-Acetamino-3,6-dimethoxy-acridinium Methyl Iodide.—1.7 g. of 9-acetamino-3,6-dimethoxy-acridine, 5 cc. of methyl alcohol and 1 g. of methyl iodide were heated at 110° for one and one-half hours in a sealed tube. After evaporating the reaction mixture almost to dryness, the yellow mass was treated with boiling alcohol and filtered cold. It forms yellow plates, very sparingly soluble in hot water with blue fluorescence, and also in boiling alcohol; m. p. 310° (decomp.); the yield was the theoretical.

Anal. Subs., 0.2919: AgI, 0.1575. Calcd. for $C_{18}H_{19}O_3N_2I$: I, 29.00. Found: I, 29.15.

9-Acetamino-3,6- diiethoxy **-acridinium** Methyl-*p*-**toluenesulfonate.**—7.1 g. of 9-acetamino-3,6-dimethoxy-acridine was dissolved in 70 cc. of boiling nitrobenzene; 5 g. of p-toluene-methyl-sulfonatewas added to the solution at a time and allowed to cool. The separated mass was filtered, washed with benzene and then treated with boiling benzene. The benzene-insoluble matter was collected and washed with ether. It formed light yellow needles which began to soften at 250° and melted at 280°. It is fairly soluble in hot water, with blue fluorescence, easily in alcohol and fairly soluble in nitrobenzene; yield, 4.8 g.

Anal. Subs., 0.0859: N_2, 4.5 cc. (12.5°, 768 mm.). Calcd. for $C_{25}H_{26}O_6N_2S$: N, 5.81. Found: N, 6.26.

9-Amino-3,6-dimethoxy-acridinium Methyl Chloride.—A mixture of 4.2 g. of the acetaminodimethoxy-acridinium methyl toluenesulfonate, 15 cc. of water and 30 cc. of concd. hydrochloric acid was boiled for eight hours. After cooling, the separated crystals were filtered off and washed with a little water.

It forms yellow needles, unaltered at 315°, fairly soluble in cold water, with intense blue fluorescence, easily soluble in hot alcohol with violet-blue fluorescence, and concd. sulfuric acid solution gives a weak green fluorescence; yield, 2.7 g.

Anal. Subs., 0.0741: N_2, 5.6 cc. (15°, 766 mm.). Subs., 0.3439: AgCl, 0.1604. Calcd. for $C_{16}H_{17}O_2N_2Cl$: N, 9.20; Cl, 11.66. Found: N, 8.91; Cl, 11.53.

I hereby desire to express my hearty thanks to Professor Hata for the interest which he has kindly taken in this work.

Summary

The following compounds connected with the acridine syntheses have been characterized: 3,6-dihydroxy-acridone, 3,6-dimethoxy-acridone, 9-chloro-3,6-dimethoxy-acridine, 9-amino-3,6-dimethoxy-acridine, 9-acetamino-3,6-dimethoxy-acridine, 9-acetamino-3,6-dimethoxy-acridinium methyl iodide, 9-acetamino-3,6-dimethoxy-acridinium methyl *p*-toluenesulfonate and 9-amino-3,6-dimethoxy-acridinium methyl chloride.

THE REACTION BETWEEN AROMATIC NITRO COMPOUNDS AND ORGANOMAGNESIUM HALIDES

BY HENRY GILMAN AND ROY MCCRACKEN

RECEIVED JULY 19, 1928 PUBLISHED MARCH 6, 1929

Introduction

The reaction between aromatic nitro compounds and organomagnesium halides is complex and confusing. Earlier work by several others shows wide differences in the nature of the final products. The present results indicate that the course or courses of the reaction vary considerably with such conditions as temperature, relative quantities of reagents, type of Grignard reagent (alkyl or aryl MgX) and on whether the RMgX compound is prepared prior to or during the reaction with the nitro compound.

Historical Part

Yocich[1] obtained an unidentified hydrocarbon of the formula $C_{16}H_{10}$, melting at 87–88.5°, from the reaction between nitrobenzene and phenylacetenylmagnesium bromide, $C_6H_5C{\equiv}CMgBr$. We have repeated this work and have shown that his hydrocarbon was diphenyl-di-acetylene, $C_6H_5C{\equiv}C{-}C{\equiv}CC_6H_5$. Oddo[2] isolated a yellow compound from the reaction between nitrobenzene and ethylmagnesium iodide. This compound, to which he ascribed the formula $C_6H_5N({=}O)C_2H_5(OMgI)$, gave, on hydrolysis, ethylaniline and a red uncrystallizable oil that was not identified.

Pickard and Kenyon[3] in a short note containing the results of some preliminary experiments of the action of RMgX compounds on aromatic nitro compounds state that *p*-nitrotoluene reacts very vigorously with organomagnesium halides in ether solution, forming an amorphous yellow compound. This compound when hydrolyzed with acids yielded principally p-nitrosotoluene, p-tolylhydroxylamine, *p,p'*-azoxytoluene and *p*-toluidine. It is unfortunate that further details were not published because the products obtained by them have not been reported by others, unless we except the small quantity of the corresponding aniline obtained in some of our studies.

Schmidlin and Hodgson[4] obtained triphenylcarbinol from the reaction between *m*-nitrobenzaldehyde and triphenylmethylmagnesium chloride. They are inclined to attribute the formation of the carbinol to a splitting reaction of diethyl ether by the Grignard reagent. Straus[5] used *p*-nitro-

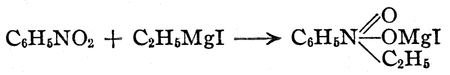
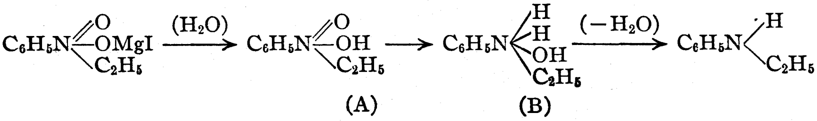
benzoyl chloride to characterize the -OMgX group in a substituted pentanol but instead of the expected *p*-nitrobenzoate he obtained a compound free of nitrogen and chlorine.

Hepworth[6] carried out a comprehensive investigation on the action of methylmagnesium iodide and ethylmagnesium bromide on nitrobenzene, *o*- and *p*-nitrotoluene and α-nitronaphthalene. In his experiments the Grignard reagent was prepared in the presence of the nitro compound by adding a mixture of the nitro compound and alkyl halide in ether to well-cooled ether containing powdered magnesium. By using about two moles of Grignard reagent per mole of nitro compound he obtained the respective alkylanilines and the azo compound corresponding with the nitro compound. Under the conditions of his experiments some unused nitro compound was generally recovered and he did not observe the formation of nitroso, hydroxylamine or azoxy compounds. He confirmed the formation of Oddo's[2] $C_6H_5N({=}O)C_2H_5(OMgI)$, but he disagrees with some of the following reactions proposed by Oddo.

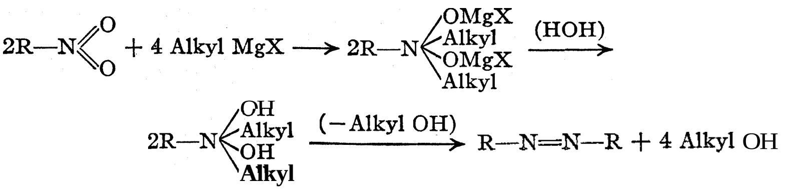


$$C_6H_5NO_2 + C_2H_5MgI \longrightarrow C_6H_5N\begin{cases}{=}O\\ -OMgI\\ -C_2H_5\end{cases} \qquad (I)$$



$$C_6H_5N\begin{cases}{=}O\\ -OMgI\\ -C_2H_5\end{cases} \xrightarrow{(H_2O)} \underset{(A)}{C_6H_5N\begin{cases}{=}O\\ -OH\\ -C_2H_5\end{cases}} \longrightarrow \underset{(B)}{C_6H_5N\begin{cases}-H\\ -H\\ -OH\\ -C_2H_5\end{cases}} \xrightarrow{(-H_2O)} C_6H_5N\begin{cases}-H\\ -C_2H_5\end{cases} \qquad (II)$$

Hepworth questions the intermediate formation of Compound (B), but sees no objection to postulating the direct loss of oxygen from Compound (A) to give ethylaniline. Admitting the difficulty of predicting the behavior of an unknown type like Compound (A), he suggests that "the loss of oxygen from such a compound is no more remarkable than the loss of carbon dioxide in the conversion of the simple monocarboxylic acid into the corresponding hydrocarbon, the more so if one accepts, what is probably the case, that Compound (A) is very unstable and just as likely to lose oxygen as Compound (B) is to lose water." He explains the formation of his azo compounds by the addition of two molecules of RMgX to his nitro compound to give an intermediate compound, two molecules of which, by the loss of four molecules of Alkyl OH compound, couple as follows



$$2R{-}N\begin{cases}{=}O\\ {=}O\end{cases} + 4\text{ Alkyl MgX} \longrightarrow 2R{-}N\begin{cases}-OMgX\\ -\text{Alkyl}\\ -OMgX\\ -\text{Alkyl}\end{cases} \xrightarrow{(HOH)}$$

$$2R{-}N\begin{cases}-OH\\ -\text{Alkyl}\\ -OH\\ -\text{Alkyl}\end{cases} \xrightarrow{(-\text{Alkyl OH})} R{-}N{=}N{-}R + 4\text{ Alkyl OH} \qquad (III)$$

Tanasescu[7] measured the volume of gas evolved in the Zerewitinoff analysis of o-nitrobenzaldehyde with methylmagnesium iodide. Gilman and Fothergill[8] then showed that Tanasescu was incorrect in attributing to o-nitrobenzaldehyde a cyclic hydroxy formula on the basis of gas evolved with methylmagnesium iodide, inasmuch as such gas evolution is an inherent property of aryl nitro compounds. Later, Gilman and Fothergill[9] extended their studies on the interference of nitro groups on the Zerewitinoff method for the quantitative estimation of active hydrogen.

Recent work by Mingoia[10] reports the formation of di-indyl-*m*-nitrobenzylidene from *m*-nitrobenzaldehyde and indylmagnesium bromide, and of di-α-methylindyl-*m*-nitrobenzylidene from the same aldehyde and a-methyl-indylmagnesium bromide. These results are somewhat surprising, for in view of the high reactivity of the aryl nitro group it might have been predicted that the nitro group would have been attacked at least concurrently with the action of the -CMgX compound on the aldehyde group.

Nitrosyl chloride (NO_2Cl) and nitrosyl bromide gave no nitrobenzene with phenylmagnesium bromide.[11] The products isolated were diphenyl and chlorobenzene or bromobenzene. References to reactions between the Grignard reagent and nitroparaffins, several oxides of nitrogen and a wide variety of compounds containing the nitroso group are to be found in a recent paper by Gilman and McCracken[12] on the reaction between nitrosobenzene and phenylmagnesium bromide.

Discussion of Reactions

Under the conditions of our experiments we have found-that about four moles of Grignard reagent are necessary for each mole of nitro compound before obtaining the positive color test described by Gilman and Schulze[13] for reactive organometallic compounds. In addition to the secondary amine and ROH compounds, there also was obtained *a* very large quantity of R-R compound, essentially equivalent to the amount of ROH compound formed. Other compounds formed in very small quantities were *p*-phenyldiphenyl (when phenylmagnesium bromide was used), di-p-tolyl (when benzylmagnesium chloride was used) and aniline (when nitrobenzene was used). No azobenzene was obtained nor did we succeed (under our conditions) in isolating any nitroso, hydroxylamine or azoxy compounds. Special efforts were made in some experiments to isolate nitroso compounds that may have been formed at an intermediate stage.

With alkylmagnesium halides the course of reaction appears to differ markedly from that when arylmagnesium halides were treated with the same nitro compound. For example, nitrobenzene with benzylmagnesium chloride gave 1,2-diphenyl-1,2-dibenzylhydrazine, $(C_6H_5)(C_6H_5CH_2)NN(CH_2C_6H_5)(C_6H_5)$. A special search for tetraphenylhydrazine that might have resulted from nitrobenzene and phenylmagnesium bromide failed to reveal any of this compound. Furthermore, it was shown that tetraphenylhydrazine underwent no noticeable reaction with phenylmagnesium bromide under conditions that simulated those used in the nitro reactions.

The equations proposed by Oddo[2] and by Hepworth[6] (see Reactions I, II and III) do not present a complete picture of the reaction. First, four and not one nor two moles of Grignard reagent are required for each mole of nitro compound; and, under the conditions of our experiments, when an insufficient quantity of Grignard reagent to complete the Reaction was added, small amounts of all of our end-products were isolated, together with unattacked nitro compound. In one of Hepworth's reactions between p-nitrotoluene and alkylmagnesium halides the use of four equivalents of Grignard reagent merely increased the quantities of alkyl-*p*-toluidine, and even with this ratio there was some unaltered nitro compound. This illustrates in a striking manner the different reactions that take place when the RMgX compound is formed in the presence of nitro compound. Second, neither of their explanations takes into consideration the formation of R-R compound by a coupling reaction of the organomagnesium halide. Third, Oddo's reaction scheme makes no provision for the formation of ROH compound, and Hepworth's interpretation correlates the formation of ROH compound (the isolation of which, by the way, was not described in his experiments) with azo compound, whereas in our studies large quantities of ROH compound were obtained when no azo compound was isolated.

Some support of the intermediate acidic compound (A in Reaction II) and its direct loss of oxygen to give the secondary amine may be found in related reactions. For example, it has long been known that oxygen and chloropicrin induce marked luminescence with Grignard reagents, particularly with p-chlorophenylmagnesium bromide. Unpublished studies show that such luminescence is an inherent property of nitro compounds. Quite likely the nitro compounds behave as oxidizing agents toward RMgX compounds and such oxidation in general is known to induce chemiluminescence.[14] Also, *p*-phenyldiphenyl has been obtained in small quantities by the oxidation of phenylmagnesium bromide.[15]

The formation of R-R compound may go hand in hand with the apparent absence of azo compound in our experiments, inasmuch as azo compounds

---

[14] Gilman and Adams, THIS JOURNAL, 47, 2816 (1925).

[15] Wuyts, *Compt. rend.*, 148, 930 (1909).

are known to react with Grignard reagents to give hydrazobenzene and R-groups which may couple to give R-R compounds or disproportionate to the corresponding olefinic and saturated hydrocarbons.[16] However, the R-R compound may also owe its formation to some other reaction or reactions, inasmuch as the reduction of azo compound should have yielded corresponding quantities of hydrazo compound. Hydrazo compounds have not as yet been identified and if such compounds were formed in appreciable quantities the method of working up the reaction products should have yielded large quantities of the corresponding azo compound as a consequence of the ready oxidation of hydrazo compounds.

For the present it may suffice to represent the reaction between nitrobenzene and phenylmagnesium hromide (a typical arylmagnesium halide) as follows

$$C_6H_5NO_2 + 4C_6H_5MgBr \xrightarrow{(H_2O)} (C_6H_5)_2NH + C_6H_5OH + C_6H_5C_6H_5 \qquad \textbf{(IV)}$$

At best such a representation is somewhat superficial and does not take into consideration the several concurrent and successive reactions that undoubtedly occur, the explanation of which must wait on an examination now in progress of the apparently intractable oils formed in these reactions. We have no experimental proof, at this time, for the mode of formation of the tetra-substituted hydrazines when alkylmagnesium halides are used. Alkylmagnesium halides are known to act in some cases as strong reducing agents, liberating olefinic hydrocarbons,[17] and we may be dealing here with addition of and reduction by the alkylmagnesium halide to give divalent nitrogen residues which then associate to tetra-substituted hydrazines.

Experimental Part

Details will be given here for a typical run between nitrobenzene and phenylmagnesium bromide. Table I contains an account of the several products obtained and their quantities. From the yields of phenol and diphenyl given in Table I there have already been deducted the quantities of these compounds present in the stock solution of phenylmagnesium bromide prior to reaction with nitro compound. In each 0.1 mole of this stock solution there were about 0.15 g. of phenol and 0.6 g. of diphenyl.

The nitrobenzene (24.6 g. or 0.2 mole) was dissolved in 200 ec. of dry ether in a one-liter three-necked flask provided with a mechanical stirrer, reflux condenser and a separatory funnel. Phenylmagnesium bromide was added dropwise with stirring and the reaction mixture was cooled with running water. After the addition of 0.4 mole of the Grignard reagent during one hour, a test[13] portion showed no RMgX compound; 0.2 mole more of phenylmagnesium bromide was added and the mixture gave no color

5	o-$CH_3C_6H_4NO_2$	13.7	.1	C_6H_5MgBr	.6
6	o-$CH_3C_6H_4NO_2$	13.7	.1	C_6H_5MgBr	.3
7	o-$CH_3C_6H_4NO_2$	13.7	.1	C_6H_5MgBr	.2
8	o-$CH_3C_6H_4NO_2$	13.7	.1	C_6H_5MgBr	.1
9	p-$CH_3C_6H_4NO_2$	13.7	.1	C_6H_5MgBr	.6

[a] In this experiment the phenylmagnesium bromide was prepared in the presence of nitrobenzene to simulate the conditions of Hepworth[a] in order to obtain, if possible, something like the relatively large amounts of azobenzene he secured. However, because it was impossible to make bromobenzene react with magnesium in the presence of nitrobenzene at low temperatures (−15°), the reaction was carried out without cooling, under which condition it proceeded smoothly. The mixture of bromobenzene and nitrobenzene in ether was added during three hours and after refluxing for two hours the mixture was hydrolyzed with 400 cc. of a saturated ammonium chloride solution. About 0.5 g. of aniline was obtained in this experiment but no azobenzene nor unaltered nitrobenzene. There was a large quantity of unidentified tarry product in this experiment.

[b] This experiment was carried out with the sole purpose of identifying Yocich's[1] hydrocarbon ($C_{16}H_{10}$) melting at 87–88.5°. Among the reaction products was 2 g. of diphenyl-di-acetylene melting at 88°. Its identity was confirmed by a mixed melting point determination and by the preparation of the picrate, which melted at 108°. In addition to 8.8 g. of recovered nitrobenzene, there was obtained one g. of phenylacetylene iodide ($C_6H_5CI{=}CHI$) melting at 76° and showing no depression in a mixed melting point determination with an authentic specimen. This di-iodo compound may owe its formation to a reaction between the small excess of phenylacetylene and some iodine resulting from the ethylmagnesium iodide used in the preparation of the phenylacetenylmagnesium iodide.

TABLE IB

PRODUCTS

	Amine	G.	Phenol, g.	Diphenyl, g.	p-$C_6H_5C_6H_4C_6H_5$, g.

8	$(o$-$C_7H_8)(C_6H_5)NH$	2.2[b]	3.52	..	...
9	$(p$-$C_7H_8)(C_6H_5)NH$	8.7	7.9	14.0	1.0

[a] The only product looked for here was the phenyl-α-naphthylamine in order to ascertain the value of this reaction for the preparation of some secondary aromatic amines.

[b] Expts. 5, 6, 7 and 8 are illustrative of the effects of varying quantities of Grignard reagent with a given quantity of nitro compound. No o-nitrotoluene was recovered in Expts. 5 and 6 but the quantities recovered in Expts. 7 and 8 were 2.7 g. (19.7%) and 7.6 g. (54.7%), respectively.

test[13] at the end of five hours; 0.1 mole more gave no test after twelve hours, and an additional 0.1 mole reacted within twenty-four hours. The total quantity of phenylmagnesium bromide added was about 0.8 mole or four equivalents per equivalent of nitrobenzene; the total time of reaction was forty-two hours. Several experiments showed that the addition of phenylmagnesium bromide in excess of four equivalents gave a color test that persisted, In some other studies on the rates of reaction of various compounds with the Grignard reagent, it has been shown that two equivalents of n-butyl- and of phenylmagnesiumbromide are used up almost at once (within five minutes) when added to 0.1 mole of nitrobenzene in an ether solution that is refluxed.

The reaction mixture was then decomposed in a few cases with cold, dilute hydrochloric acid or more generally by a saturated ammonium chloride solution. The ether layer was separated and extracted with two 100-cc. portions of 10% sodium hydroxide. The phenol obtained by acidification of this extract followed by ether extraction and distillation weighed 15.5 g. and boiled at 180–182°. In many experiments the phenol was recovered and weighed as tribromophenol. The reaction was carried out in an atmosphere of hydrogen because the extended time of reaction would have resulted in most of the Grignard reagent being oxidized to phenol by atmospheric oxygen.

The ether layer was dried with sodium sulfate, filtered and treated with hydrogen chloride to precipitate the hydrochlorides of the amines. The crude hydrochloride was filtered and treated with sodium hydroxide to liberate the amine, which was extracted with ether and purified by vacuum distillation. In this manner 19.5 g. of diphenylamine was obtained boiling at 176–178° (20 mm.) and melting at 50°. A mixed melting point determination with an authentic specimen of diphenylamine melted at 52°.

The ether filtrate from the hydrochloride precipitate was fractionally distilled. Redistillation of a first fraction (25.5 g. distilling between 240–275° and melting at 63–67°) gave 21 g. of diphenyl that distilled at 252–256° and melted at 69–70°. The residue of this first fraction was added to a second fraction (boiling between 275° (740 mm.) and 250° (30 mm.) and weighing 9.2 g.) and the combined portions were dissolved in benzene and treated with hydrogen chloride to assure complete removal of the amine. No amine hydrochloride precipitated on this treatment. This benzene solution, when distilled in a vacuum, gave an additional 3.5 g. of diphenyl (making a total of 24.5 g. of diphenyl), and one g. of *p*-phenyldiphenyl that melted at 203° after crystallization from alcohol. In every case, where possible, the identity of solids was confirmed by mixed melting point determinations made with authentic specimens.

Reaction between Nitrobenzene and Benzylmagnesium Chloride.—In view of the products obtained from the reaction between nitrobenzene and phenylmagnesium bromide, we expected the reaction between nitrobenzene and benzylmagnesium chloride to proceed after the general scheme represented in Reaction IV and to give, accordingly, benzylaniline, benzyl alcohol and dibenzyl. However, unusual difficulty was experienced in working up the basic fractions and the isolation of benzaldehyde prompted a number of experiments the object of which was to throw some light on the formation of the aldehyde and the difficulty of obtaining the expected benzylaniline. In view of the final identification of the 1,2-diphenyl-1,2-dibenzylhydrazine, it is unnecessary at this time to give an account of these several orienting experiments.

Thirty and eight-tenths g. (0.25 mole) of nitrobenzene was added slowly with stirring to one mole of benzylmagnesium chloride kept cool by running water. After allowing the reaction mixture to stand overnight, it was hydrolyzed by 100 cc. of water. The dark-colored oil obtained from the ether layer when fractionally distilled in a vacuum yielded 2.5 g. of aniline (identified,by the formation of benzanilide and *p*-nitrobenzanilide), 22.6 g. of dibenzyl (after deducting the quantity of dibenzyl formed in the preparation of benzylmagnesium chloride), 3 g. of *p*-ditolyl and a basic fraction which when treated in ether solution with hydrogen chloride gave 4.5 g. of a hydrochloride.

This hydrochloride was formed from 12.2 g. of a basic fraction that distilled over a wide temperature range, 150° (10 mm.) to 200° (5 mm.). After crystallization from an alcoholic hydrogen chloride solution, the salt melted at 213°. When refluxed with dilute hydrochloric acid it yielded benzaldehyde (identified by the phenylhydrazone), aniline (identified as tribromoaniline) and benzylaniline (identified as the hydrochloride). The derivatives of all three products of hydrolysis were identified in turn by mixed melting point determinations made with authentic specimens of the corresponding compounds.

Franzen and Zimmermann[18] first prepared 1,2-diphenyl-1,2-dibenzylhydrazine hydrochloride and found it to melt at 215.5°. On acid hydrolysis they obtained from it benzaldehyde, aniline and benzylaniline. Later, Wieland and Fressel[19] attempted to prepare the tetra-substituted hydrazine by the method used by Franzen and Zimmermann, by heating the corresponding tetrazene. However, they observed that the high temperature necessary to distil the hydrazine is sufficient to decompose this compound; and the distillation of the tetrazene yielded benzylaniline and benzalaniline. Acid hydrolysis would accordingly break down the benzalaniline to give benzaldehyde and aniline, so that the three products obtained by Franzen and Zimmermann from the hydrolysis of their supposed 1,2-diphenyl-1,2-dibenzylhydrazine would come, in reality, from the two decomposition products of their hydrazine, benzylaniline and benzalaniline. The high melting point (215.5') observed by Franzen and Zimmermann is explained by Wieland and Fressel as being due to rapid heating. However. it should be recalled that we identified our benzylaniline by the melting point of the corresponding hydrochloride and under our conditions of determining melting points it agreed with the correct point as given in the literature.

For our present purposes it does not make any difference whether we had in hand the hydrazine or its decomposition products (benzylaniline and benzalaniline), inasmuch as the compounds obtained by Franzen and Zimmermann and by Wieland and Fressel were prepared by a standard procedure for the preparation of such hydrazines and because Wieland and Fressel admit that their decomposition products (benzylaniline and benzalaniline) came from the tetra-substituted hydrazine.

Reaction between Nitrobenzene and Ethylmagnesium Bromide.—By analogy with the benzylmagnesium chloride reaction, one would expect to get 1,2-diphenyl-1,2-diethylhydrazine from the reaction between nitrobenzene and ethylmagnesium bromide. Experiment verified this. Wieland and Fressel[19] found this hydrazine to be unstable and to undergo considerable decomposition even when distilled in a high vacuum. The boiling point of their compound was 141° (1 rnm.). Our hydrazine boiled at 118–123° (0.5 mm. (or less)). Hydrolysis by heating with dilute hydrochloric acid gave the products described by Wieland and Fressel,[19] namely acetaldehyde, aniline and ethylaniline. However, our compound did not give the characteristic color reaction with acetic acid that they described. This was not wholly unexpected, inasmuch as Gilman and Pickens[20] prepared this hydrazine from azobenzene, phenylmagnesium bromide and diethyl sulfate, and found it to distil at 140–145° (1.5 mrn.), but not to give the color test. The reason for this discrepancy is to be found in the observation of Wieland and Fressel[19] that the tetrazene from which their hydrazine was prepared also gives the color test. Very probably their hydrazine was contaminated with some tetrazene.

[18] Franzen and Zimmermann, *Ber.*, 39,2566 (1906).

[19] Wieland and Fressel, *Ann.*, 392, 150 (1912).

[20] Gilman and Pickens, THIS JOURNAL, 47,2406,2412 (1925)

The formation of the hydrazine prompted a repetition of Hepworth's[6] experiment in which nitrobenzene and ethyl bromide were added to magnesium in ether to give ethylaniline and azobenzene. We found that the ethylaniline fraction boiled over a wide range (200–270°) when first distilled at atmospheric pressure. The fraction containing ethylaniline also gave qualitative tests for the hydrazine (acetaldehyde on acid hydrolysis) and for aniline. From this one may conclude that the hydrazine is one of the products of reaction and that a part, at least, of their and our ethylaniline may have resulted from the known course of thermal decomposition of the hydrazine to give ethylaniline.

Attempted Isolation of **Tetraphenylhydrazine** and its Treatment with **Phenyl-** and ***n*-Butylmagnesium** Bromides.—Several reactions were carried out between nitrobenzene and phenylmagnesium bromide with the express purpose of either identifying or isolating tetraphenylhydrazine or its rearrangement products. All of these unsuccessful experiments were made after it was shown that alkylmagnesium halides with nitrobenzene gave tetra-substituted hydrazines. The respective fractions that might have contained the tetraphenylhydrazine neither gave the characteristic color test[21] for the hydrazine nor did they yield the sparingly soluble diphenylbenzidine[21] that results from the rearrangement of tetraphenylhydrazine by concd. sulfuric acid.

Also, no reaction appeared to take place when 25.4 g. (0.08 mole) of tetraphenylhydrazine in 500 cc. of ether and 200 cc. of benzene was treated with 0.1 mole of phenylmagnesium bromide for fifteen hours at room temperature. On working up the reaction product in the customary manner, there was recovered 22.5 g. (85.2%) of the tetraphenylhydrazine. A less exact experiment with tetraphenylhydrazine (5 g.) and n-butylmagnesium bromide (0.05 mole) showed no evidence of reaction and most of the hydrazine was recovered.

Attempts to Isolate an Intermediate **Nitroso** Compound.—From 61.5 g. (0.5 mole) of nitrobenzene and 1.0 mole of phenylmagnesium bromide there was obtained 17.7 *g.* of phenol and 18 g. of unaltered nitrobenzene, but no nitrosobenzene. The high yield of phenol obtained here and the yields of phenol described in Expts. 6, 7 and 8 (Table I) indicate that the successive reactions leading to the formation of phenol proceed more rapidly than the initial reaction with nitro compound.

Equally unsuccessful attempts were made to isolate nitrosobenzene in several experiments in which the temperature and the ratio of nitrobenzene to RMgX were varied. In only one experiment was there a faint green color during the steam distillation procedure employed to remove any nitrosobenzene.

Attention was then directed to the possibility of isolating a more stable nitroso compound, p-nitrosodimethylaniline, when p-nitrodimethylaniline was used as the initial compound. However from 16.6 *g.* (0.1 mole) of *p*-nitrodimethylaniline and 0.1 mole of phenylmagnesium bromide there was recovered 7.8 g. (47%) of the nitro compound, but no p-nitrosodimethylaniline. From another experiment starting with 0.1 mole of p-nitrodimethylaniline and 0.4 mole of phenylmagnesium bromide there were isolated 4.4 g. of phenol, 5 *g.* of diphenyl and 5 6 g. of an intractable amino compound that may have been *p*-dimethylaminodiphenylamine.[22]

Reaction between Dimethylaniline Oxide and Phenylmagnesium Bromide.-—The $R(Alkyl)_2N(OH)_2$ intermediate postulated by Hepworth[6] (see Reaction III) might be expected to lose water and form a dialkylaniline oxide. For this reason, 27.4 g. (0.2 mole) of dimethylaniline oxide partially dissolved in 600 cc. of warm (40") benzene was treated with 0.4 mole of phenylmagnesium bromide. The following products were isolated: phenol (3.56 *g.*), diphenyl (8.6 g) and dimethylaniline (2 5 g). The am-

[21] Wieland and Gambarjan, Ber., **39,** 1499 (1906).

[22] Ref. 12, pp. 1060–1061.

moniacal solution obtained on hydrolysis yielded a very small quantity of a solid that dissolved readily in hydrochloric acid giving a purple color.

Reaction between Ethyl Nitrate and Phenylmagnesium Bromide.—This reaction was carried out at a very low temperature (about −80°) to determine whether nitrobenzene might be formed in accordance with the following reaction

$$C_6H_5MgBr + C_2H_5ONO_2 \longrightarrow C_6H_5NO_2 + C_2H_5O(MgBr) \qquad (V)$$

Kinkead[23] previously studied this reaction at about 0° and reported the production of a blue solution on extraction with chloroform, which had the properties of an indicator. **Hepworth**,[24] at −15°, obtained dimethylhydroxylamine, $(CH_3)_2NOH$, and diethylhydroxylamine from methyl- and ethylmagnesium halides, respectively.

When 0.2 mole of phenylmagnesium bromide was added dropwise and with stirring to 0.3 mole of ethyl nitrate cooled by a slush of carbon dioxide and acetone, diphenyl and phenol were obtained but no nitrobenzene.

Summary

The products obtained in the reaction between aryl nitro compounds and organomagnesium halides vary markedly with experimental conditions. Under the conditions of the experiments described here, the following general reaction takes place

$$C_6H_5NO_2 + 4C_6H_5MgBr \longrightarrow (C_6H_5)_2NH + C_6H_5OH + C_6H_5{\cdot}C_6H_5$$

With alkylmagnesium halides, tetra-substituted hydrazines are among the reaction products. Ethylmagnesium bromide and nitrobenzene, for example, give 1,2-diphenyl-1,2-diethylhydrazine, $(C_6H_5)(C_2H_5)NN(C_2H_5)(C_6H_5)$. The formation of alkylanilines in this reaction is due in part to the decomposition of such hydrazines.

THE PROPERTIES AND CHEMICAL CONSTITUTION OF GLUCIC ACID

BY E. K. NELSON AND C. A. BROWNE

RECEIVED SEPTEMBER 21, 1928 PUBLISHED MARCH 6, 1929

H. Winter,[1] while working in the laboratory of Fraser Eaton and Company, Soerabaya, Java, announced in 1894 that upon warming an aqueous solution of 1% invert sugar with 0.5% of calcium oxide in the form of calcium hydroxide at 66.5°, he obtained a voluminous, white flocky precipitate which redissolved on further heating. This precipitate turned brown on exposure to the air and because of its slimy character could not be filtered readily. Winter purified the precipitate, which he supposed to be a basic calcium salt, by decanting and washing five times with lime water, the settling of the precipitate being performed in a well-closed flask, filled

[1] Winter, *Z. Ver. Rübenzucker Ind.*, 44 (old series), 1049 (1894).

completely full in order to exclude the air. The unchanged white precipitate was then decomposed with dilute sulfuric acid and extracted with ether. Evaporation of the ether upon a watch glass left behind colorless, needle-like crystals of an organic acid in a yellow, sirupy mother liquor.

On repeating the experiment with 24 liters of invert sugar solution, Winter obtained a small amount of a yellow sirup filled with beautiful crystals 3–4 mm. long. After being placed in a desiccator over sulfuric acid the crystalline needles appeared in a few days to melt away and nothing was left in the sirup but some undeveloped crystals resembling cane sugar in appearance. After some time the sugar-like crystals also began to disappear with a darkening of color and a slight evolution of gas which ceased only after the residue had solidified to a dark resinous mass. The latter, upon distillation with water, yielded carbon dioxide and formic acid, leaving behind a residue of brown-colored flocks.

Winter's efforts to purify the substance by recrystallization from water, alcohol, ether or chloroform were unsuccessful. An aqueous solution of the crystals reduced Fehling's solution in the cold and precipitated black silver immediately from silver nitrate. From these results Winter supposed that the impure crystals of his experiment might be the so-called glucic acid, which Peligot,[2] Mulder,[3] Reichardt[4] and other investigators had never succeeded in isolating in the crystalline form, and which Winter further supposed to undergo on standing a slow transition into apoglucic acid with final decomposition into carbon dioxide, formic acid and other products. As much confusion prevails in the literature concerning the substance to which Dumas first gave the name of "glucic acid," the present study was initiated in the hope of determining more exactly the nature of the unstable acid compound that was obtained by Winter as a result of the action of calcium hydroxide upon invert sugar.

Experimental

The experiment of Winter was repeated except that dextrose (commercial "Cerelose") was used in place of invert sugar. In the preliminary test fifty grams of dextrose dissolved in five liters of water was heated at 67° with 25 g. of calcium oxide which had previously been well slaked in water. The precipitate which settled out on cooling was filtered, washed with lime water, decomposed with sulfuric acid and the calcium sulfate removed by filtration. The filtrate was thoroughly extracted with ether; on evaporation of the ether a small amount of crystalline material associated with a sharp-smelling liquid remained. The crystals were separated from the liquid on a porous plate.

[4] Reichardt, *Z. Ver. Rübenzucker Ind.*, 20 (old series), 529 (1870).

As Winter states that the precipitated calcium compound is somewhat soluble in water, it was thought that increasing the concentration might improve the yield. This proved to be the case and the following procedure was adopted. With further improvement in technique it is possible that the yield may be still further increased.

Four hundred grams of dextrose, 5 liters of water and **100** g. of calcium oxide (slaked) mere thoroughly mixed with a stream of illuminating gas in order to avoid oxidation by air and heated to 67°.

On cooling a voluminous precipitate (A) separated. This was filtered, washed with lime water and finally with alcohol and ether, care being taken to avoid the passage of air through the filter by keeping the precipitate covered with a layer of liquid.

The precipitate was dried in a vacuum desiccator, contact with air being avoided, and when dry it was kept in an atmosphere of illuminating gas.

A preparation of the calcium compound, dried in illuminating gas, rapidly rose in temperature from 20° to 48° when exposed to the air. After exposure to air overnight it yielded only a trace of crystalline substance, the resulting product appearing to be a mixture of formic acid and a liquid, oily acid. That the heating of the substance is due to absorption of oxygen was proved by the following experiment.

A quantity of the precipitate was placed in a flask attached to a train consisting of a U-tube containing liquid paraffin and a drying tube containing calcium chloride, the latter tube being connected with a supply of oxygen. The steady absorption of oxygen for many hours was noted by the bubbling through the U-tube.

The dried precipitate (A) weighed **118.6** g. and contained **30.3** g. of calcium oxide.

The calculated amount of sulfuric acid necessary to combine with the **30.3** g. of calcium oxide was diluted, cooled with ice and added to the ice-cooled suspension of the precipitate. The mixture was thoroughly agitated until the reaction was complete, when the calcium sulfate was removed by filtration and washed. The filtrate (B) was concentrated in a vacuum distillation outfit connected with a receiver cooled by ice and salt (in order to lower the temperature of distillation) and with a stream of carbon dioxide passing through a capillary tube into the distilling flask to prevent bumping and to exclude air. The distillation was conducted in a vacuum of **20–30** millimeters.

The concentrated solution was extracted with ether in an extractor designed for extracting liquids with ether, so long as crystals were obtained on evaporation of the solvent. The total yield of crystalline material (C) was **1.34** g. in this experiment. The oily product absorbed by the porous plates was recovered by extraction with ether and reserved for future investigation.

The distillate obtained in concentrating the acids in the filtrate (B) required 189.5 cc. of $N/10$ barium hydroxide for its neutralization, which yielded upon evaporation **2.1802** g. of barium salt. Since 189.5 cc. of $N/10$ barium hydroxide is equivalent to **2.1542** g. of barium formate, the volatile acid obtained by decomposition of the calcium precipitate (A) with sulfuric acid is almost entirely formic acid. The fact that no alcohol-soluble lead salt was found after conversion of the barium compound into the lead derivative indicated the absence of acetic acid.

The crystalline acid (C), Winter's "glucic" acid, is easily soluble in water and alcohol, but only moderately soluble in ether, chloroform or ethyl acetate.

The substance was freed from liquid impurities by wetting with a little ethyl acetate and spreading on a porous plate. If left in contact with the liquid acid which accompanies it, the substance is very unstable. When the crystals wet with the liquid acid were left overnight in a desiccator, the solid substance almost disappeared and a brown, pasty mass was left. This confirms Winter's observations. **An** optical examination[5] gave the following results.

In ordinary light: The material consisted of plates. Its indices of refraction were $N\alpha = 1.475$, $N\gamma = 1.734$, both ±0.002. Birefringence was extremely strong. Between crossed Nicols it showed anomalous blue and purple polarization colors due to peculiar dispersion This may be of use in recognizing the substance. An aqueous solution of the compound does not rotate the plane of polarized light.

The substance partially sublimes in beautiful crystals at the temperature of the water-bath. The unsublimed portion appears to have polymerized, as it no longer crystallizes from water.

The compound has no definite melting point. It turns brown and polymerizes at temperatures over 110°. Heated to 170° there was no evidence of melting in the dark colored transformation product.

An aqueous solution of the compound reduces silver nitrate, Fehling's solution and mercuric chloride at room temperature, the reductions taking place suddenly after an instant of time. The solution does not give a normal aldehyde reaction with Schiff's reagent. After treatment with this reagent, a solution of the substance gradually develops a violet-blue color. When a solution of ferric chloride is added to a solution of the compound, the ferric chloride is reduced and a faint blue color is developed which instantly disappears. The evanescent blue color is more marked if a solution of the substance is carefully added to a solution of ferric chloride. A very delicate and beautiful reaction is given by treating the substance in aqueous solution with a few drops of a solution of sodium nitroprusside, a drop of 10% solution of sodium hydroxide and finally a drop or two of acetic acid. An intense greenish-blue to blue color results and, on standing, a blue lake is deposited, leaving a nearly colorless supernatant liquid.

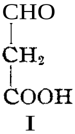
The substance is an acid and gives a sharp end-point on titration: 0.7333 g. = 16.27 cc. of $N/2$ NaOH. The neutralizing equivalent is therefore 90.

An analysis was made for carbon and hydrogen and the molecular weight was determined by the freezing-point method, using water as the solvent. The results obtained are as follows.

Anal. Calcd. for $C_3H_4O_3$: C, 40.89; H, 4.58; mol. wt., 88. Found: C, 40.53, 40.50, 40.66; H, 4.93, 4.73, 4.58; mol. wt., 88.4, 91.5, 94.9. The molecular weight appears to increase with the concentration, suggesting molecular aggregation.

A solution of the substance bleaches bromine water instantly; iodine absorption, calculated for one double bond, 288.3; found, 289, 285.

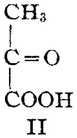
There are five possible constitutional formulas for an acid of the formula $C_3H_4O_3$.



$CHO-CH_2-COOH$

I

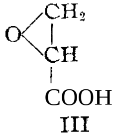
Semi malonic aldehyde



$CH_3-C{=}O-COOH$

II

Pyruvic acid



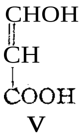
III

Glycidic acid

$CH_2{=}COH-COOH$

IV

α-Hydroxyacrylic acid



$CHOH{=}CH-COOH$

V

β-Hydroxyacrylic acid

The semialdehyde of malonic acid (I) should give an aldehyde reaction with Schiff's reagent, and should be oxidized easily into malonic acid, Pyruvic acid (11),a liquid, has properties altogether different from those of

---

[5] Made by G. L. Keenan, Food. Drug and Insecticide Administration, U. S. Department of Agriculture.

the acid under discussion. Moreover, when pyruvic acid is treated with sodium nitroprusside and alkali, a wine-red color is developed which is *discharged* on the addition of acetic acid. Glycidic acid (III) is a liquid, miscible with water, alcohol and ether. Its calcium salt readily takes up water, forming calcium glycerate, so that it could not be formed under the conditions of our experiments.

The ready absorption of bromine suggests the presence of a double bond as in IV and V, while the remarkable reducing properties indicate an aldehyde or an enolic form readily convertible into an aldehyde. These conditions seem to be best met by Formula V (β-hydroxy-acrylic acid), which is the enolic form of the semialdehyde of malonic acid.

Such a compound has been described by Pinner[6] under the name of "Acrolactic Acid," which was prepared by the action of barium hydroxide on monochloro-ethyl acrylate. The free acid was obtained as a sirup which showed a tendency to crystallize. On account of scarcity of material Pinner was unable to make an analysis. However, he states that acrolactic acid is extremely unstable, and, though not mentioning any direct experiments on its reducing properties, observes that its silver salt darkened at once.

The acid which we obtained appears to be fairly stable, if well separated from the liquid acid extracted with it and kept in a closed container in a cool place.

If the substance is acrolactic acid, it should yield formic and oxalic acids on gentle oxidation.

An excess of sodium hydroxide was added to an aqueous solution of 1 g. of the crystalline compound and the solution boiled for a short time. Sulfuric acid was added in slight excess and the solution was distilled. The distillate was neutralized with barium hydroxide and evaporated to dryness.

The barium salts weighed 0.6862 g., corresponding to 0.2781 g. of formic acid or 27.8% of the substance.

No acetic acid was found and optical examination showed the salt to consist entirely of barium formate.

One-half gram of the substance was oxidized with hydrogen peroxide in excess. After the addition of ammonia, ammonium chloride and calcium chloride, the solution was boiled. A copious precipitate resulted which weighed 0.3309 g., equivalent to 0.204 g. of oxalic acid, or 40.8% of the sample.

The precipitate was shown by optical methods to be calcium oxalate.

A preparation of Winter's glucic acid was hydrogenated, platinum dioxide and 0.0001 mole of ferric chloride being used. The absorption of hydrogen ceased after less than one-fifth of the calculated amount of gas necessary for completely hydrogenating a compound of the type of Formula

---

[6] Pinner, *Ber.*, 7,250 (1874); *Ann.*, **179**, 91 (1875).

V had been taken up. The substance recovered after hydrogenation was no longer crystalline and had the appearance of the polymerized product. It was thought that the ferric chloride might have caused polymerization and thus interfered with a normal hydrogen absorption.

The experiment was repeated, colloidal palladium being used as a catalyst: 0.3764 g. of substance absorbed 166 cc. of hydrogen at 25° arid 764.7 mm.; reduced to 0° and 760 mm. = 148.3 cc. or 0.01328 g. Calculated for two atoms of hydrogen absorbed by 0.3764 g. of mol. wt. 88, 0.00855 g.; and for three atoms, 0.01283 g. The product recovered after the reaction did not have an acid taste. It was highly soluble in water, very hygroscopic and scarcely soluble in ether. When dissolved in alcohol and precipitated with ether, an amorphous, very hygroscopic solid was obtained. It is evident again that a normal hydrogenation has not taken place, the product having probably suffered molecular change and polymerization.

It may be stated, finally, that the present investigation has not altogether confirmed the conclusion of Winter that his crystalline glucic acid undergoes first a transformation into apoglucic acid and then a further decomposition into carbon dioxide, formic acid and other products. No evidence was obtained in these experiments of the spontaneous decomposition of Winter's glucic acid into any such product as the apoglucic acid described by Mulder or into carbon dioxide, although abundant quantities of formic acid and of unidentified polymerization products were obtained.

The readiness with which glucic acid decomposes into formic acid leads to the conclusion that it may be a parent substance of the formic acid which occurs in the sirups and molasses of cane sugar factories, where the calcium hydroxide employed in clarification reacts with the reducing sugars of the juice. The instability of this compound in the presence of atmospheric oxygen and in contact with accompanying organic substances is no doubt the reason of its having escaped the attention of so many investigators.

The problem of the formation and decomposition of glucic acid under varying conditions is being subjected in this Laboratory to a further study in the hope that additional information may be secured upon some of the theoretical and practical questions involved.

Summary

1. The unstable calcium salt of an acid, originally described by Winter under the name of glucic acid, was prepared by the action of calcium hydroxide upon dextrose in aqueous solution at 67° in the absence of air. The precipitated calcium compound absorbed oxygen rapidly from the air with decomposition and evolution of heat.

2. The unstable calcium salt, after decomposing with sulfuric acid and extracting with ether, yielded a small amount of crystallizable unsaturated acid, corresponding to the formula $C_3H_4O_3$, which from its strong reducing

power, iodine absorption and other properties is in all probability the enolic form of the semialdehyde of malonic acid. The crystalline acid can be partially sublimed without decomposition but undergoes upon heating a considerable degree of polymerization. It yields formic and oxalic acids upon oxidation and is exceedingly unstable in the presence of organic impurities.

THE RATE OF HYDROLYSIS OF CASEIN IN ACID SOLUTIONS AS MEASURED BY THE FORMATION OF AMINO NITROGEN

BY E. S. NASSET AND DAVID M. GREENBERG

RECEIVED OCTOBER 3, 1928 PUBLISHED MARCH 6, 1929

Introduction

Greenberg and Burk[1] from their own measurements and such data as were available, calculated the order of the reaction of the hydrolysis of the proteins in solutions of acids. The hydrolysis for gelatin, silk fibroin and gliadin was found to conform to the equation of a second order reaction. A single series of measurements on casein by Dunn[2] apparently fitted a first order reaction best. This was in agreement with the findings of Carpenter,[3] who worked, however, under radically different conditions. It seemed worth while to check the order of the reaction of the hydrolysis of casein, since if a universal structural basis is common to all proteins, individual proteins would not be expected to show different orders of hydrolysis under the same fixed conditions. From the results given in the following, it is to be seen that casein conforms to the proteins already measured and that the hydrolysis reaction is of the second order under the conditions employed. Also, as was found for the other proteins, the effect of acids in accelerating the rate of hydrolysis is shown to be proportional to the hydrogen-ion activity of the acid solutions.

Experimental

The measurements were carried out at the temperatures of 127.5, 117.5 and 105.5°, employing the acids, hydrochloric, sulfuric and phosphoric. The hydrolyses were carried out in an autoclave with a steam line the pressure of which could be regulated by a reducing valve. The casein used was prepared according to the method, somewhat modified, of Van Slyke and Baker.[4] One-gram samples of thoroughly dried casein were placed in 50-cc. pyrex Erlenmeyer flasks, 40 cc. of the desired acid was added and

---

[3] D. C. Carpenter, J. *Biol. Chem.*, 67, 647 (1926).

[4] L. L. Van Slyke and J. C. Baker, *ibid.*. 35, 128 (1918); D. M. Greenberg and C. L. A. Schmidt, J. Gen. *Physiol.*, 7, 287 (1924).

then the flasks were sealed with a blast lamp. This made the casein concentration in the acids 2.5%. In a few instances large pyrex test-tubes were employed, using half the above amounts of casein and acid. A series of such sealed flasks or tubes was placed in the autoclave and the steam turned on. At appropriate intervals duplicate flasks were removed from the autoclave and immediately immersed in ice water. The removal of these flasks was accomplished in about eighty seconds, so that the temperature of the remaining flasks did not fall appreciably before the temperature was restored to the working level. As soon as the flasks were cool, the seal was broken and the contents neutralized to prevent further hydrolysis. With the gram samples the final volume was made up to 100 cc., with the half-gram samples up to 50 cc. One-cc. amounts of these solutions were used for analysis of amino nitrogen by the Van Slyke method.[5] Duplicate analyses were made on each sample. As in the previous work, the increase in amino nitrogen was taken as measuring the amount of hydrolysis. In calculating the percentage of hydrolysis, the figure taken for total amino nitrogen was that given by Dunn, namely, 70% of the total nitrogen of casein.

The experimental results are given in Tables I to V. The column headings in the tables require no further explanation.

Discussion

Order of the Reaction.—The constants of the order of the reactions are calculated, as in the former paper,[1] on the basis of the percentage of hydrolysis according to the formula

$$K = \frac{1}{t} \times \frac{X}{100 - x} \times \frac{1}{100} \qquad (1)$$

in which x represents the percentage of protein hydrolyzed in time t. The constants calculated according to this formula are in fair agreement with each other for each experimental condition of temperature and acid concentration. The reproducibility that can be expected for these experiments is shown in Table IV, in which are given the results of two experiments at the same temperature and acid concentration carried out at different times. The average results of the calculated constants of the two experiments agree within 10% of each other.

That the experimental results best fit the equation for a second order reaction is shown in Table I, in the experiment with 1.0 N hydrogen chloride. In the tabulated results for this experiment there are given the reaction constants as calculated for a first, second and third order reaction. It is to be seen that the first order constants regularly decrease in magnitude with time, while the constants for a third order reaction regularly increase in magnitude. This, in conjunction with the agreement of the second order constants, strongly favors the viewpoint that the hydrolysis of casein, as well as of gelatin, silk fibroin and wheat gliadin follows a second order reaction.

Catalysis by Acids.—In agreement with the previous results, the catalytic effect of acids on the hydrolysis of casein has been found to be proportional to the thermodynamic activity of the acids. The velocity constants at unit activity which are given at the foot of each column of velocity constants show good agreement among themselves at each temperature. In making the calculations, the values for the activity coefficients of hydrogen chloride and sulfate were taken from the tables of Lewis and Randall.[6] As a more rigid test of this relationship, two experiments were made using the comparatively weak acid, phosphoric. The unit activity constants obtained are in good agreement with those of sulfuric and hydrochloric acids. As we found no available data for activity coefficients of phosphoric acid in the concentrations employed, measurements of the hydrogen-ion activity of the solutions were made on the hydrogen electrode, using a 0.1 molal calomel hydrogen electrode and bridging across with a saturated KCl bridge. These measurements gave an activity of 0.137 molal for the 3.0 N and 0.123 molal for the 2.5 N acids.

Effect of Temperature.—As in the previous work[1] the mathematical relationship for the change of velocity constants with temperature was determined and the equation obtained by the same procedure as previously described is

$$\log \mathrm{Ka} = 0.0307T - 5.61 \tag{2}$$

in which Ka is the reaction rate constant at unit activity and the temperature T is in degrees centigrade. This gives the means of predicting the course of casein hydrolysis at a given temperature and acid of known activity. The constant, Ka, at any temperature can be obtained from Equation 2. This multiplied by the activity of the acid used gives the velocity constant for that particular acid concentration. The time required to effect a given degree of hydrolysis can be calculated by the use of Equation 1.

Summary

1. The rate of hydrolysis of casein by acids as measured by the increase in amino nitrogen has been found to conform to the equation for a second order reaction.

2. As was previously found for other proteins, the catalytic effect of acids on casein hydrolysis is proportional to the hydrogen-ion activity of the acids.

THE MECHANISM OF FORMATION OF BETA-ARYL-BETA-AMINO FATTY ACIDS BY THE CONDENSATION OF AROMATIC ALDEHYDES WITH MALONIC ACID AND ITS DERIVATIVES[1]

BY W. M. RODIONOW AND E. A. POSTOVSKAJA

RECEIVED OCTOBER 11, 1928 PUBLISHED MARCH 6, 1929

In our former investigations[2] we have found that the mechanism of Knoevenagel's synthesis of cinnamic acids[3] in the presence of ammonia is much more complicated than Knoevenagel himself and other authors assumed. We have discovered that besides cinnamic acid derivatives the corresponding amino acid is formed with a good yield, in accordance with the following equation

$$RCHO + NH_3 + CH_2(COOH)_2 = RCH(NH_2)CH_2COOH + CO_2 + H_2O$$

By replacing malonic acid by its esters, A. M. Fedorova[2b] obtained the esters of β-aryl-β-amino-isosuccinic acid

$$RCHO + NH_3 + CH_2(COOC_2H_5)_2 = RCH(NH_2)CH(COOC_2H_5)_2 + H_2O$$

After saponification with hydrochloric acid these derivatives give, quantitatively, the corresponding amino acids.

Two possibilities may be worthy of consideration in order to interpret the mechanism of this reaction

I (a) $RCHO + NH3 = RCH(OH)NH_2$
(b) $RCH(OH)NH_2 + CH_2(COOH)_2 = RCH(NH_2)CH(COOH)_2 + H_2O$
(c) $RCHNH_2CH(COOH)_2 = RCH(NH_2)CH_2COOH + CO_2$
11 (a) $RCHO + CH_2(COOH)_2 = RCH{=}CHCOOH + CO_2 + H_2O$
(The final result of Knoevenagel's reaction)
(b) $RCH{=}CHCOOH + NH3 = RCHNH_2CH_2COOH$

In favor of the second explanation and against the first may be cited the interesting investigations of Korner and Menozzi,[4] Engel[5] and of

many other authors, who have found that a certain yield of β-amino acids may be prepared by treatment of esters of unsaturated acids with ammonia.

The execution of this reaction is very difficult; it is necessary to warm both components many hours, often many days, under pressure in sealed tubes or in an autoclave. The yields are most unsatisfactory, only Engel having asserted that he obtained excellent yields in his preparations.

The formation of arylamino fatty acids in our case, especially with non-substituted malonic acid, goes very easily at moderate temperature not exceeding 90°, and generally under ordinary pressure. All the conditions of this reaction make the first explanation more probable and it seems that the first consideration is more nearly correct and corresponds better to all the facts.

In order to confirm this supposition, we have made our aldehyde condensations with mono-substituted malonic esters of the general formula $R'CH(COOC_2H_5)_2$, where R′ represents any aliphatic or fatty aromatic radical.

Substances of this type cannot give condensations with loss of water and formation of unsaturated acids capable of additional reactions with ammonia. It may also be mentioned that according to the researches of Claisen[6] the mono-substituted malonic acids in general do not condense with aldehydes.

We have carried out our condensations with methyl-, ethyl- and benzylmalonic esters. Benzaldehyde and piperonal were employed as second components.

It has already been mentioned that this condensation takes place under ordinary pressure, but with substituted malonic esters the yield increases generally, when the reaction is carried out in sealed tubes; but for this increase it is of much greater importance to have the correct temperature and particularly the correct time of heating.

In most cases the portion of the materials used which does not enter into the reaction remains unchanged; sometimes this condensation is contaminated with the formation of such by-products as diamides of the general formula $RCH(CONH_2)_2$, but we could never find any unsaturated compounds, which affirms the correctness of the first explanation of the mechanism of this interesting reaction.

We have extended our investigations to free methyl-, ethyl- and benzylmalonic acids and obtained the corresponding amino acids. It is evident that in this case the reaction takes more complicated paths, and as final substances the amino-*mono*-carbonic acids are formed according to the following equation

$$RCHO + R'CH(COOH)_2 + NH_3 = RCH(NH_2)CH(R')COOH + H_2O + CO_2$$

---

[6] Claisen and Crimson, *Ann.*, **218, 144 (1883)**.

The β-aryl-β-amino-α-alkylpropionic acid obtained is identical with the acid that can by prepared by saponification of the corresponding ester, $RCHNH_2C(R')(COOC_2H_5)_2$; R and R' must naturally be identical in ester and in acid.

The identity of both acids affirms again the correctness of our supposition. This is very important to note, since the use of free mono-substituted malonic acids makes possible many kinds of reaction and besides β-amino acids there also may be formed unsaturated substances, the constitutions of which have not yet been elucidated completely.

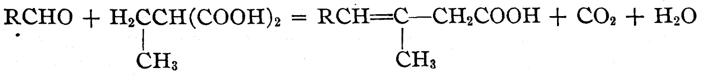
The formation of unsaturated acids may be explained in the following manner

$$\text{I}\quad RCHO + CH_3CH(COOH)_2 = RCH{=}CHCH_2COOH + CO_2 + H_2O$$

$$\text{II}\quad (a)\quad RCHO + CH_3CH(COOH)_2 = RCH(OH)CH(CH_3)(COOH)_2$$

$$(b)\quad RCH(OH)CH(CH_3)(COOH)_2 = RCH{=}C(CH_3)COOH + H_2O + CO_2$$

When a more complicated mono-substituted malonic acid is employed, that is, ethylmalonic acid, a third isomeride may be expected, as the possibility of an aldehyde condensation with the methyl group or with the methylene group of the ethyl radical is not excluded



$$RCHO + \underset{\displaystyle CH_3}{H_2\underset{|}{C}}CH(COOH)_2 = RCH{=}\underset{\displaystyle CH_3}{\underset{|}{C}}{-}CH_2COOH + CO_2 + H_2O$$

If the formation of amino acids may be ascribed to the addition of ammonia to the double linkage of unsaturated acids, we should expect in this case, in accordance with the investigations of Koerner, Menozzi, Engel and others, to obtain a-amino acids but our investigations show that this supposition is not justified.

The preparation of p-amino esters is a very simple operation. Equimolecular proportions of aromatic aldehyde, mono-substituted malonic esters and a little excess of alcoholic ammonia solution are heated on a water- or oil-bath until the alcohol is evaporated; the dry mixture is heated for three to four hours and then dissolved in ether and shaken with sodium bisulfite solution to remove any residue of unreacted aldehyde; the etheric solution is washed with water, dried with sodium sulfate and then treated with dry hydrogen chloride. The hydrochloride of the β-amino-ester separates as a heavy oil that solidifies not too rapidly and crystallizes from alcohol usually in snow-white needles. It is very easy to fix the end-point of the reaction with mono-substituted malonic acids. The mixture is heated until the development of carbon dioxide ceases. The *dry* residue is dissolved with addition of sodium carbonate in warm water (*ca.* 60°) and treated with ether in order to remove the unreacted aldehyde; the water solution is acidified with hydrochloric acid and the precipitated unsaturated acid is filtered off by suction and washed with water; the filtrate is shaken with ether to free it from unsaturated and fatty acids and then evaporated on the water-bath; it is finally dried in a desiccator over sulfuric acid in *vacuo.*

The resulting mixture, containing chlorohydrate of β-amino acid, common salt and ammonium chloride, is dissolved in absolute alcohol, filtered by suction from inorganic salts and evaporated on the water-bath. The chlorohydrate of the amino acid nevertheless usually is contaminated with small quantities of inorganic salts and must be twice recrystallized from absolute alcohol. The product is now pure and gives correct analytical results.

Experimental Part

Diethyl β-Phenyl-β-amino-α-methyl-ethane-α,α-dicarbonate Hydrochloride, C_6H_5-$CH(NH_2HCl)C(CH_3)(COOC_2H_5)_2$.—In a little, round-bottomed flask fitted with a direct condenser are placed 5 g. of methylmalonic ester, 3 g. of benzaldehyde and 1 g, of alcoholic ammonia solution (12 g. of ammonia in 100 g. of dry alcohol). After evaporating off the alcohol, the mixture is heated on a water-bath for five hours and then dissolved in 100 cc. of dry ether. Dry hydrogen chloride is then passed into the solution. The hydrochloride separates as a heavy oil. The flask is then tightly stoppered and allowed to stand until the oil sets to a mass of crystals, which usually requires one or two days. Double crystallization from hot, dry alcohol gives colorless needles, m. p. 158°; yield, 1.5 g. (about 16%).

A much better yield is obtained with modified conditions, as follows: 10 g. of methylmalonic ester, 6 g. of benzaldehyde and 15 cc. of alcoholic ammonia solution (10 g. of ammonia in 100 g. of alcohol) were heated in a sealed tube on a strongly boiling water-bath for seven hours. The mixture was then placed in a round-bottomed flask, the alcohol distilled off, the residue dissolved in dry ether, filtered from 0.6 g. of methylmalonyldiamide (m. p. 203") and the hydrochloride of the amino ester precipitated from the filtrate with hydrogen chloride. The product was crystallized from alcohol and dried in a desiccator. 2.8 g. of benzaldehyde and 4.6 g. of methylmalonic acid were recovered from the ethereal solution after filtering off the amino ester. The yield of the ester, calculated on the benzaldehyde actually combined, then increases to 96.6%.

Hydrochloride of Diethyl β-Piperonyl-β-amino-α-methyl-ethane-α,α-dicarboxylate, $CH_2O_2C_6H_3CH(NH_2HCl)C(CH_3)(COOC_2H_5)_2$.—Five g. of diethyl methylmalonate, 4.3 g. of piperonal and 20 cc. of 7% alcoholic ammonia solution were placed in a sealed tube and heated at 150° for five hours on an oil-bath. The mixture was evaporated to dryness, dissolved in dry ether and treated exactly as in the preceding preparation. The oil which separates solidifies very slowly and after several crystallizations the pure substance forms large plain needles. The ethereal solution from which the amino ester has been removed contains only unchanged piperonal and diethyl methylmalonate.

Hydrochloride of Diethyl β-Phenyl-β-amino-α-ethyl-ethane-α,α-dicarboxylate, $C_6H_5CH(NH_2HCl)C(C_2H_5)(COOC_2H_5)_2$.—Five g. of diethyl ethylmalonate, 2.8 g. of benzaldehyde and 1 g. of 12% alcoholic ammonia solution were heated in a sealed tube for five hours on a water-bath The alcohol was then evaporated, leaving in the flask a heavy oil. The oil was dissolved in 100 cc. of ether and filtered from 0.5 g. of an unknown substance, insoluble in ether, which was probably the diamide of ethylmalonic acid (m. p. 199°). The filtrate was treated with dry hydrogen chloride and an oil separated which solidified to fine, white needles. It was crystallized twice from alcohol. The best way of purifying the hydrochloride is by solution in alcohol and precipitation with dry ether. The ethereal alcoholic solution contains unchanged benzaldehyde

(1 **g.)**, diethyl ethylmalonate *(1.8* **g.**) and in small and varying quantities an unidentified substance melting at **74°.**

Hydrochloride of Diethyl **β-Piperonyl-β-amino-α-ethyl-ethane-α,α-dicarboxylate,** $CH_2O_2C_6H_3CH(NH_2HCl)C(C_2H_5)(COOC_2H_5)_2$.—Ten g. of diethyl ethylmalonate, 8 g. of piperonal and *20* cc. of 10% alcoholic ammonia solution were heated at 130–140° in a sealed tube for ten hours, with subsequent treatment as in the previous experiment. The **very** small yield of amino ester is explainable by the stability of the condensation product of piperonal with ammonia. The ester is insoluble in ether and may be isolated very easily.

Hydrochloride of p–Phenyl–8–amino–a–methylpropionic Acid, $C_6H_5CH(NH_2HCl)$-$CH(CH_3)COOH$.—**Five** g. of methylmalonic acid, *4.5* g. of benzaldehyde and *15* cc. of 10% alcoholic ammonia solution were heated on a water-bath until the evolution of carbon dioxide had ceased. The residue was dissolved in *20* g. of 15% soda solution at **60°.** The undissolved oil was extracted with ether *(0.2* g.). The alkaline solution was acidified with hydrochloric acid and again extracted with ether. This extract contains an unsaturated, nitrogen-free acid. After crystallization from alcohol it melted at 173° with decomposition. The water solution after treatment with ether was evaporated to dryness. The resulting hydrochloride of phenylaminomethylpropionic acid is contaminated with inorganic salts and must be crystallized from absolute alcohol.

Hydrochloride of **β-Piperonyl-β-amino-α-methylpropionic** Acid, $CH_2O_2C_6H_3CH$-$(NH_2HCl)CH(CH_3)COOH$.—Three and one-half g. of methylmalonic acid, *4.5* g. of piperonal and *15* cc. of 10% **alcoholic** ammonia solution were heated for six days on a water-bath until the evolution of carbon dioxide ceased. The residue was dissolved in *15* cc. of 15% soda solution and further treated as in the previous preparation. The first ethereal extract gave *0.9* g. of oil. The yield of unsaturated acid melting at 201–202° was only *0.8* g., about *13%* of the theoretical. It is either $CH_2O_2C_6H_3CH{=}CH$-CH_2COOH or $CH_2O_2C_6H_3CH{=}C(CH_3)COOH$. A molecular weight determination on the unsaturated acid gave *202.4;* calcd. for $C_{10}H_9O_4$, 206.

Hydrochloride of **β-Phenyl-β-amino-α-ethylpropionic** Acid, $C_6H_5CH(NH_2HCl)$-$CH(C_2H_5)COOH$.—Nine g. of **ethylmalonic** acid, *7.2* g. of benzaldehyde and 30 cc. of *10%* alcoholic ammonia solution were heated for five hours on a water-bath and then for three hours at **145°.** The mixture was dissolved in *30* cc. of 15% soda solution and

[b] 42.3 calculated on the basis of piperonal actually combined.

treated with ether. The ethereal solution gave **2.6** g. of oil (principally contaminated benzaldehyde). After acidifying with hydrochloric acid, the water solution gave **4** g. of unsaturated acid **(36%** of the theoretical) with a melting point of 107°. The hydrochloride of the amino acid was crystallized from alcohol. **A** molecular weight determination on the unsaturated acid gave **177.9;** calcd. for $C_{11}H_{12}O_2$, **176.**

Hydrochloride of β-**Piperonyl**-β-**amino**-α-**ethylpropionic** Acid.—Nine g. of ethylmalonic acid, **10.2 g.** of piperonal and **30** cc. of 10% alcoholic ammonia solution were heated for ten hours on a water-bath and then for eight hours at 145°, considerable tar being formed. Treatment with soda solution gave an oil insoluble in water, soda and ether. The water solution after acidification gave **4.3** g. (about 31% of the theoretical) of an unsaturated acid melting at 135° and, after evaporation, the amino acid, which may be crystallized from absolute alcohol. The molecular weight of the unsaturated acid was determined as **216;** calcd. for $C_{12}H_{12}O_4$, **220.**

Hydrochloride of β-**Phenyl**-β-**amino**-α-**benzylpropionic** Acid, $C_6H_5CH(NH_2HCl)$-$CH(CH_2C_6H_5)COOH$.—Ten g. of benzylmalonic acid, **5.4** g. of benzaldehyde and **20** cc. of 10% alcoholic ammonia solution were heated for one hour on a water-bath with a condenser and then for three hours at 145°. The mixture was dissolved in soda solution and treated with ether. On evaporating the ethereal solution an oil separated **(2.8 g.).**[7] The water solution was acidified with hydrochloric acid and gave 6.5 g. **(53%** of the theoretical) of an unsaturated acid, probably $C_6H_5CH{=}C(C_6H_5)CH_2COOH$, crystallizing from alcohol in snow-white needles with a melting point of **160".** After removing this substance, the water solution was shaken several times with ether, from which **0.5** g. of hydrocinnamic acid was isolated, m. p. 40° uncrystallized and 47° after crystallization. **A** mixed melting point with a known sample gave no depression. The solution was finally evaporated to dryness and the residue crystallized from alcohol. A molecular weight determination of the unsaturated acid gave **234.1;** calcd. for $C_{16}H_{14}O_2$, **238.**

Another Method of Preparation.—Five g. of benzylmalonic acid, **4** g. of benzhydramide and **20** cc. of alcohol were heated for eight hours on a water-bath and then at **120–125'** for six hours. The treatment of the mixture was carried out exactly as in the foregoing experiment and gave **1.6** g. of oil, **2.9** g. of unsaturated acid (m. p. 160–161°), **0.3** g. of hydrocinnamic acid and **3.9** g. of the hydrochloride of β-**phenyl**-β-**amino**-α-benzylpropionic acid (about 52% of the theoretical amount).

Hydrochloride of β-**Piperonyl**-β-**amino**-α-**benzylpropionic** Acid, $CH_2O_2C_6H_3CH$-$(NH_2HCl)CH(CH_2C_6H_5)COOH$.—Ten g. of benzylmalonic acid, **7.7** g. of piperonal and **30** cc. of 10% alcoholic ammonia solution were heated for twelve to thirteen hours on a water-bath. The mixture was dissolved in soda solution and filtered from **2.8** g. of crystalline material insoluble in cold soda solution (probably the diphenylaminopropane derivative), In order to remove the unchanged piperonal, the water solution was treated with benzene. The benzene solution was concentrated on a boiling water-bath to a thin sirup; crystallization usually began as soon as the sirup cooled, **4** g. of piperonal being separated in this way. The water solution was then acidified with hydrochloric acid and **2.8** g. of unsaturated acid melting at 205° separated. This yield was about 20% of the theoretical calculated for $CH_2O{=}C_6H_5CH{=}C(C_6H_5)CH_2COOH$. The acid solution was extracted with ether and gave **2.3** g. of unchanged benzylmalonic acid. Finally, the water solution was evaporated on the water-bath and the residual hydrochloride was crystallized from alcohol. **A** molecular weight determination of the unsaturated acid gave **284.9;** calcd. for $C_{17}H_{14}O_4$, **282.**

---

[7] The investigation of this substance has not been finished but it seems to he α,γ-diphenyl-α-aminopropane, $C_6H_5CH(NH_2)CH_2CH_2C_6H_5$.

Summary

The mechanism of formation of β-aryl-β-amino acids is explained; a general method of preparation of the diethyl esters of β-aryl-β-amino-α-alkyl-ethane-α,α-dicarbonic acids and also of the preparation of β-aryl-β-amino-α-alkylpropionic acids is worked out and many examples of this class of compound are described.

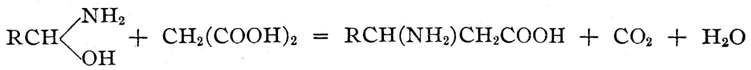
SYNTHESIS OF BETA-ARYL-BETA-AMINO-ETHANE-ALPHA, ALPHA-DICARBONIC ACIDS

THE MECHANISM OF KNOEVENAGEL'S SYNTHESIS OF CINNAMIC ACIDS

By W. M. Rodionow

Received October 11, 1928 Published March 6, 1929

For some time the writer and his collaborators[1] have studied Knoevenagel's synthesis of cinnamic acids[2] and have found that this reaction, in the presence of alcoholic ammonia solution as a catalytic agent, takes a more complicated path than is generally assumed. We have proved that in this reaction besides cinnamic acid derivatives β-aryl-β-aminopropionic acids also are formed in accordance with the following equation



$$RCH\begin{matrix}\diagup NH_2\\ \diagdown OH\end{matrix} + CH_2(COOH)_2 = RCH(NH_2)CH_2COOH + CO_2 + H_2O$$

In our paper with E. A. Postovskaja[3] we gave a satisfactory explanation of the mechanism of this reaction and could show that the formation of aryl-β-aminopropionic acids is a condensation reaction between aldehyde-ammonia and malonic acid and not an addition reaction of ammonia to the double bond of the corresponding cinnamic acid.

In our fundamental experiments we have first taken as condensing agent only alcoholic ammonia solution but later, with Mrs. Malevinskaja and Miss V. B. Zenkovich,[4] we replaced the ammonia with monomethylamine and monoethylamine and thus prepared with fair yields β-aryl-β-alkylaminopropionic acids

$$RCHO + NH_2R' + CH_2(COOH)_2 = RCHNHR'CH_2COOH + H_2O + CO_2$$

R' may be either methyl or ethyl.

We also tried to prepare β-aryl-β-dialkylaminopropionic acids and found that in this case the cinnamic acid derivatives are formed nearly

exclusively, accompanied by very small amounts of dialkylaminopropionic acids. We extended our preparations to other amines, especially to piperidine, which is, according to the investigations of many authors, the best catalytic agent for the synthesis of cinnamic acid, and we can state that in this case only cinnamic acids are formed and no traces of β-aryl-8-piperidylpropionic acids can be isolated.

This failure to prepare the piperidyl derivatives has induced us to modify the conditions of our condensations and we carried out this reaction at room temperature. Indications toward such modification had already been given in the very interesting paper of Mannich and Ganz.[5] These authors found that β-aminodicarbonic acids are formed when monosubstituted malonic acids, ammonia, or better still, methylamine or dimethylamine and formaldehyde are mixed together and allowed to stand at ordinary temperature or in ice. After ten to twenty hours a solid mass of crystals separates from the mixture and the corresponding aminodicarbonic acids are formed.

With Miss Holmogorzeva[6] we have worked out a method of preparation of such aryl-β-piperidylethane dicarbonic acids. It is very simple and consists in mixing piperidine and malonic acid at ordinary temperature in an alcoholic solution of the aromatic aldehyde. In the case of benzaldehyde the following reaction takes place

$$C_6H_5CHO + C_5H_{11}N + CH_2(COOH)_2 = C_6H_5CH(NC_5H_{10})CH(COOH)_2 + H_2O$$

and β-phenyl-β-piperidylethane-α,α-dicarbonic acid is formed (details in Experimental Part).

The replacement of benzaldehyde with piperonal gives with a good yield β-piperonyl-β-piperidylethanedicarbonic acid. The attempts to obtain β-aryl-β-amino-ethanedicarbonic acids were also crowned with success when an equimolecular mixture of benzaldehyde, malonic acid and a small excess of alcoholic ammonia solution was allowed to stand for some time. After five to ten minutes a reaction occurred with evolution of heat and on cooling the phenylamino-ethanedicarbonic acid separated as a white crystalline mass.

All compounds thus obtained are stable at ordinary temperature and may even be crystallized from alcohol and water, but on heating (above the melting or decomposition point) these substances undergo a decomposition with evolution of carbon dioxide and sometimes of ammonia.

It was proved further without difficulty that the heating of β-aryl-β-piperidylethanedicarbonic acids gives exclusively the corresponding cinnamic acid, but aryl-β-amino-ethanedicarbonic acids furnish a mixture of cinnamic acid and aryl-β-alanine.

---

[5] Mannich and Ganz, *Ber.*, 55, 3487 (1922).

[6] The unpublished thesis of Miss J. A. Holmogorzeva from the Laboratory for Alcaloid-Chemistry of the 2. State University of Moscow.

Further attempts were made in order to obtain β-alkylated β-aryl-β-amino-ethanedicarbonic acids. Two experiments, carried out by Miss Zenkovich, with alcoholic ethylamine solution proved that such condensations are possible, also with a fair yield, and two compounds of this type, β-piperonyl-β-ethylamino-ethanedicarbonic acid and β-phenyl-β-ethylamino-ethanedicarbonic acid are described in the Experimental Part.

It has already been mentioned that these condensations give an excellent yield (80–90% and more of the theoretical amount); but as the formation of β-aryl-aminopropionic acid is always accompanied by cinnamic acid and the maximum yield of either component seldom reaches 50%, it may be assumed that Knoevenagel's synthesis of cinnamic acid is a secondary process: first the formation of arylamino-ethanedicarbonic acid takes place and, second, this compound being unstable on heating, decomposes with evolution of carbon dioxide and ammonia and forms cinnamic acid.

The condensation of malonic acid with amine and aromatic aldehyde occurs then at room temperature or, better, on slight cooling, in the following way

$$RCHO + NH_3 + CH_2(COOH)_2 = RCHNH_2CH(COOH)_2 + H_2O$$

This compound may be isolated with an excellent yield; generally this process is not stopped at this point but the product is warmed further and the arylamino-ethanedicarbonic acid produced decomposes in two directions

$$RCH(NH_2)CH(COOH)_2 = RCH(NH_2)CH_2COOH + CO_2 \qquad (1)$$

$$RCH(NH_2)CH(COOH)_2 = RCH{=}CHCOOH + CO_2 + NH_3 \qquad (2)$$

The same products also may be obtained either by heating the isolated arylamino-ethanedicarbonic acid above its melting point or by dissolving it in hot water and acidifying with strong mineral acid.

The proportion of the mixture of both acids may be changed by many means: temperature, concentration of mineral acid, the nature of it and many other circumstances have a great influence on the course of this reaction and on the yield of each component.

It is interesting to note that β-aryl-β-amino-ethanedicarbonic acids readily undergo decomposition on heating and on boiling with mineral acids. The aryl-β-aminopropionic acids are more stable but in many cases the warming of their hydrochlorides with sodium acetate also causes elimination of the ammonia molecule and a corresponding cinnamic acid is formed with a fair yield. Another observation which was made is that the condensation with veratric aldehyde does not at ordinary temperatures give the dimethoxrphenylamino-ethanedicarbonic acid. Many attempts in this direction resulted only in the isolation of uninviting, resinous, tarry compounds from which with great difficulty were recovered the dimethoxycinnamic acids (probably a mixture of cis and *trans* isomerides).

Nearly all condensations with piperonal occur with a poorer yield than the same ones with benzaldehyde.

On summarizing all observations described in this paper and in our former investigations, the conclusion may be drawn that not only β-aryl-β-amino-ethanedicarbonic acids but also β-aryl-β-aminomonocarbonic acids are not so stable as the well-known a-amino acids. The existence of methoxy groups and also of methylene-dioxy groups in the benzene ring makes these compounds much more unstable, as was proved by unsuccessful attempts to obtain the dimethoxyphenylamino-ethanedicarbonic acid and smaller yields in many condensations with piperonal.

This work, as a whole, raises an interesting question from the biochemical standpoint. It is not impossible that the protein molecule contains not only a-amino acids but in certain, though indeed very small amounts, also β-amino acids; our methods for their isolation are too crude and the acid hydrolysis at comparatively high temperature decomposes β-amino compounds and leaves unchanged only the more stable a-amino acids.

The same decomposition can take place in living nature, where several enzymes can undertake the role of heat and transform β-amino acids and especially methoxylated compounds into cinnamic acid derivatives, and in this manner may be explained the fact that in many plant oils and drugs are found such acids as ferulic, isoferulic, coffeinic and many other styrolene derivatives.

Experimental Part

This part of the work was carried out by Miss V. B. Zenkovich and Miss J. A. Holmogorzeva; their shares are indicated with their initials (Z. or H.) at each preparation. For many of the analyses and constant assistance I am much indebted to Miss A. M. Fedorova (F.), to whom I also express my thanks in this place.

β-Piperonyl-β-ethylaminopropionic Acid (Z.), $CH_2O_2C_6H_3CH(NHC_2H_5)CH_2COOH$.—A mixture of 22 g. of piperonal, 70 cc. of 11% alcoholic ethylamine solution and 18 g. of malonic acid was heated on a boiling water-bath with the condenser set for distillation. The alcohol was distilled off and the yellowish residue dissolved in hot water and acidified with an excess of acetic acid. On cooling, the piperonylacrylic acid separated nearly quantitatively and was filtered off; 19.6 g. (70% of the theoretical). The filtrate was evaporated to dryness and crystallized from alcohol. The piperonylethylaminopropionic acid is insoluble in ether, sparingly soluble in alcohol and easily soluble in water, from which it crystallizes in fine, white needles.

The **nitrosamine** of this acid, $CH_2O_2C_6H_3CH(NNOC_2H_5)CH_2COOH$, may be prepared easily by treating the hydrochloride of the acid with sodium nitrite solution. It crystallizes very well from water and forms long, fine needles which melt at 136–138°.

Hydrochloride of β-Piperonyl-β-dimethylaminopropionic Acid (Z.), $CH_2O_2C_6H_3CH$-

$[N(CH_3)_2HCl]CH_2COOH$.—Twenty g. of piperonal, 40 cc. of 18% alcoholic dimethylamine solution and 16 g. of malonic acid were heated on a strongly boiling water-bath. After an hour 10 cc. of dimethylamine solution of the same strength was added and the whole warmed until the evolution of carbon dioxide ceased (nine to ten hours). The residue was dissolved in hot water, acidified with hydrochloric acid and the piperonylacrylic acid filtered off and dried; yield 14 g. (about 95% of the theoretical). The filtrate was evaporated to dryness, washed with chloroform and crystallized from alcohol. The acid has no melting point but seems to be chemically pure, as proved by its analysis.

All attempts to prepare in a similar manner the diethylamine compound were unsuccessful and only piperonylacrylic acid was obtained, in nearly quantitative yield.

β-Phenyl-β-amino-ethane-α,α-dicarbonic Acid (F.), $C_6H_5CH(NH_2)CH(COOH)_2$.—Twenty g. of benzaldehyde, 55 cc. of 6% alcoholic ammonia solution and 20 g. of malonic acid are mixed. The reaction occurs instantaneously; in order to prevent the raising of temperature the mixture is allowed to stand for twelve hours in ice water and then the solid is filtered off and washed with ether. The acid is sparingly soluble in cold water and alcohol and insoluble in ether. It crystallizes from alcohol in long lustrous needles.

On heating at 150° the acid decomposes with evolution of carbonic acid and ammonia and gives exclusively cinnamic acid; but on heating with hydrochloric acid 5 g. of the acid gave 2.50 g. of the hydrochloride of β-phenylalanine (ca. 50% of theoretical amount) and 1.65 g. of cinnamic acid (ca. 40%). The loss of the last compound is only to be explained with its volatility.

β-Phenyl-β-piperidylethane-α,α-dicarbonic Acid (F. and H.), $C_6H_5CH(NC_5H_{10})CH(COOH)_2$.—Four and nine-tenths g. of malonic acid was dissolved in 20 cc. of alcohol, 5 g. of benzene added and then 4 g. of piperidine. The reaction occurs with great evolution of heat and a white, crystalline mass begins to separate almost immediately. The mixture was allowed to stand for twelve hours and then the solid was filtered off and crystallized from alcohol. The acid is easily soluble in hot water, sparingly soluble in cold water and alcohol and insoluble in ether. It crystallizes from alcohol in lustrous plates and from water in long needles It is interesting to observe that only one carboxylic group of this acid is neutralized by alkali. Calcd. for one carboxyl group of 0.1 g. of acid: 3.6 cc. of 0.1 N sodium hydroxide. Found: 3.5.

Five grams of the acid was heated with water and hydrochloric acid; on cooling, 2.2 g. of cinnamic acid (m. p. 132–134°) separated (84.6% of the theoretical). From the filtrate were recovered the whole amount of piperidine and small amounts of cinnamic acid; no traces of β-phenyl-β-piperidylpropionic acid were found.

β-Piperonyl-β-piperidylethane-α,α-dicarbonic Acid (H.), $CH_2O_2C_6H_3CH(NC_5H_{10})CH(COOH)_2$.—Four and three-tenths g. of piperonal, 3 g. of malonic acid and 2.3 g. of piperidine were dissolved in 15 cc. of absolute alcohol and allowed to stand for twenty-four hours. The compound which separated off was crystallized from alcohol, giving lustrous plates. The acid is easily soluble in water, sparingly soluble in alcohol and insoluble in ether. Only one carboxyl group reacts with sodium hydroxide.

β-Phenyl-β-ethylamino-ethane-α,α-dicarbonic Acid (Z.), $C_6H_5CH(NHC_2H_5)CH(COOH)_2$.—Four and one-half g. of benzaldehyde, 13 cc. of 15% alcoholic ethylamine solution and 4.5 g. of malonic acid are mixed; reaction occurs instantaneously, the temperature rises to 50° and after a few minutes the aminodicarbonic acid begins to separate and is filtered off. After standing for some hours a small amount more of the compound may be recovered from the filtrate. The acid may be crystallized from hot alcohol. Lack of time made impossible the repurification and re-analysis of the substance.

TABLE I

ANALYTICAL AND OTHER DATA OP THE ACIDS

β-( )-β-( )-amino-propionicacids	Yield, g.	Yield, %	M. p., °C.	Formula	Analysis, N, % Calcd.	Analysis, N, % Found

[a] Hydrochloride. Calcd.: Cl, 12.95. Found: 13.09.

[b] With decomposition.

β-Piperonyl-β-ethylamino-ethane-α,α-dicarbonic Acid (Z.), $CH_2O_2C_6H_3CH(NHC_2H_5)CH(COOH)_2$.—Five and three-tenths g. of piperonal, 3.85 g. of malonic acid and 12 cc. of 15% alcoholic ethylamine solution were mixed and treated as in the previous experiment. The acid is easily soluble in hot water, less so in alcohol and insoluble in ether; it crystallizes from alcohol in little rods.

Summary

A new explanation of the mechanism of Knoevenagel's synthesis of cinnamic acids is proposed, a method of preparation of aryl-β-amino-ethanedicarbonic acids and their N-substituted derivatives is described and the specific preparation of some compounds of this type and the properties of these compounds are given.

REACTION OF CHLORO-ACETIC ACIDS WITH ZINC

BY HOWARD WATERS DOUGHTY AND DONALD A. LACOSS

RECEIVED OCTOBER 13, 1928 PUBLISHED MARCH 6, 1929

In previous contributions from this Laboratory[1,2] the reaction of trichloro-acetic acid with copper has been discussed and it has been shown that it affords an excellent method for the preparation of dichloro-acetic acid. The reaction is exothermic and the acid was used in benzene solution. During these investigations it was noted that the reaction of trichloro-acetic acid with zinc is also very vigorous, and the present authors, therefore, have studied this reaction. The work has been interrupted by change of residence of the junior author, so it seems advisable to make a brief statement of results so far obtained.

When zinc dust is added to a solution of trichloro-acetic acid in benzene,

[1] Doughty and Freeman, THIS JOURNAL, 44, 636 (1922).

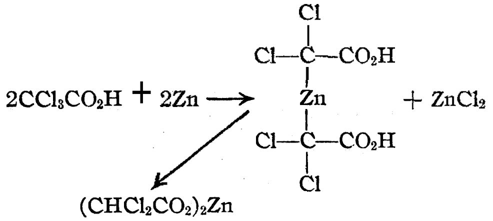
[2] Doughty and Black, *ibid.*, 47, 1091 (1925).

much heat is evolved and zinc chloride is formed, together with zinc dichloro-acetate and other products, depending on the relative quantities of acid and zinc. The reaction product is not easy to work with, owing apparently to the hygrosopic nature of the zinc chloride; the reaction was therefore studied in aqueous solution and it was found that it is not necessary to use zinc dust, as mossy zinc reacts very readily.

The least expected of the results obtained in these experiments is the fact that no hydrogen is evolved. When one mole of trichloro-acetic acid, dissolved in one liter of water, reacts with one gram atomic weight of mossy zinc, the zinc is dissolved very rapidly, the solution becomes neutral and contains zinc chloride and zinc dichloro-acetate, but no hydrogen is evolved. If more than this amount of mossy zinc is added the excess remains after the reaction is over. If zinc dust is added in excess, however, a white precipitate forms and part of the zinc dust is converted into zinc chloride. This white precipitate has not been identified. It contains zinc and is soluble in acids. The reaction of trichloro-acetic acid with mossy zinc is quantitative and the equation is

$$2CCl_3CO_2H + 2Zn = ZnCl_2 + (CHCl_2CO_2)_2Zn$$

The fact that no hydrogen is evolved in this reaction indicates that the mechanism of the reaction must be considered as similar to that of trichloro-acetic acid with copper. It has been suggested[1,2] that with copper an intermediate compound is formed in which the copper is joined directly to the carbon and that this is followed by a rearrangement in which hydrogen and copper exchange places. A similar mechanism for the reaction of trichloro-acetic acid with zinc would be expressed by the following



As in the corresponding reaction with copper, the hydrogen shifts from the labile or ionizable position in the carboxyl group to the very stable position in the dichloromethyl group. Apparently this reaction is very much more rapid than the more usual replacement of hydrogen ions by zinc ions as in the action of hydrochloric acid with zinc. The fact that a corresponding action takes place with copper and trichloro-acetic acid makes this explanation appear more probable than to assume that "nascent hydrogen" is formed which then reduces the trichloro-acetic acid to dichloro-acetic acid.

In a typical experiment, 32.8 g. (0.5 gram atomic weight) of "mossy" **zinc was** added to a solution of 81.7 g. (0.5 mole) of trichloro-acetic acid in 400 *cc.* of water and the mixture was stirred mechanically for three hours, when the zinc was completely dissolved and the solution was practically neutral, very slightly acid to litmus, but alkaline to methyl orange and lacmoid. In other experiments 10 g. of zinc in excess of the amount indicated by the equation brought the reaction to an end in one hour and a quarter, and the 10 g. of zinc remained.

The neutral solution resulting from the reaction was diluted to one liter and analyzed for chloride by the Mohr method and for zinc by titration with potassium ferrocyanide: calcd. for the equation given above: Cl, 0.500 gram atomic weight; Zn, 0.500 gram atomic weight. Found: Cl, 0.497; Zn, 0.480.

In another experiment, 53 g. of sodium carbonate (0.5 mole) was added to the neutral solution of zinc salts; the precipitated basic zinc carbonate was filtered off and the solution of sodium salts was evaporated to saturation and transferred to a distilling flask. An excess of concentrated sulfuric acid (75 cc.) was added and the mixture distilled at 25 mm. The fraction which distilled at 105° weighed 24 g. A portion of this distillate was dissolved in benzene and aniline was added. A white crystalline precipitate formed which, after recrystallizing, melted at 123–124°, which is the melting point of aniline dichloro-acetate. The product was further identified by a mixed melting point, using a sample of aniline dichloro-acetate prepared by the method of Doughty and Black.[2] Our acid boiled at 105° and 25 mm. Dichloro-acetic acid is reported[2] to boil at 102" and 20 mm.

In order to obtain some idea as to the energy of the reaction, which is strongly exothermic, 40.8 g. (0.25 mole) of trichloro-acetic acid was dissolved in 400 cc. of water in a thermos bottle which was provided with a one-holed rubber stopper through which passed a thermometer. "Mossy zinc," 16.4 g. (0.25 gram atomic weight) was added and the stopper with the thermometer was put in place. The bottle was shaken frequently and the time and temperatures were as follows.

Minutes	0	10	15	20	30	40	47	80
Temperature, °C	27	42	50	54	57	60	63	67

As in other cases, no hydrogen was evolved, and the solution was neutral (as defined above) at the end of the experiment, and all of the zinc was dissolved. The heat equivalent of the apparatus, as previously determined, was approximately 9.0 calories per degree. The specific heat of the substances present other than water is unknown, but an assumption of 0.25 seems reasonable. From these data we calculate the heat of the reaction as approximately 66,600 calories per mole of trichloro-acetic acid. Of this we can account for approximately 56,600 calories as the heat of formation of 0.5 mole of zinc chloride in solution, leaving approximately 10,000 calories per mole of trichloro-acetic acid for the other items involved in this reaction. No considerable accuracy is claimed for these figures, but they appear to us to have sufficient significance to justify us in mentioning the experiment.

The reaction in benzene is apparently the same as in water, and we have prepared aniline dichloro-acetate by this method also. There does not appear to be any advantage in this method of preparation of dichloro-acetic acid over that described by Doughty and Black.[2]

The corresponding reaction of dichloro-acetic acid with zinc is much less energetic. The amount of heat developed is not impressive, and it was necessary to heat, with stirring, for twelve hours on the water-bath to bring the solution to neutrality and to dissolve the zinc. There was some hydrogen evolved throughout the reaction and when the neutral solution was analyzed only 0.903 gram atomic weight of chlorine was found per mole of dichloro-acetic acid. Evidently in this case 90% of the reaction is similar to that of trichloro-acetic acid with zinc, while the other 10% takes the more usual course as when hydrochloric acid reacts with zinc.

The reaction of monochloro-acetic acid with mossy zinc is very slow, even on the water-bath or at boiling temperature. Time did not permit of a study of this reaction but it was noted that considerable hydrogen was evolved and the solution became neutral after about 100 hours. The analysis was not satisfactory, as apparently some acid was evaporated during the long period of heating. The solution also had some reducing effect on silver salts.

The marked difference in the speed of reaction of the chloro-acetic acids with zinc, and particularly the variation in the type of reaction as well, is interesting in connection with certain observations of one of us[3,4] concerning the reaction of compounds containing a trichloro- or tribromomethyl group with copper and with cuprous chloride in aqueous ammonia solution. It was shown that substances of this class (trihalogen methyl derivatives) are very much more reactive under the given conditions than those having fewer than three halogen atoms joined to one carbon atom.

Conclusion

When trichloro-acetic acid reacts with zinc in water solution, a neutral solution of zinc chloride and zinc dichloro-acetate is obtained. There is no evolution of hydrogen. The reaction is strongly exothermic.

With dichloro-acetic acid the corresponding reaction with zinc is much less exothermic, much slower and hydrogen is evolved to approximately 10% of the amount required by the equation $2HX + Zn = H_2 + ZnX_2$.

With monochloro-acetic acid the reaction is very slow and is to quite a large extent in accordance with the reaction just stated.

The reaction is similar to that in the case of trichloro-acetic acid and copper and an explanation of the mechanism is suggested.

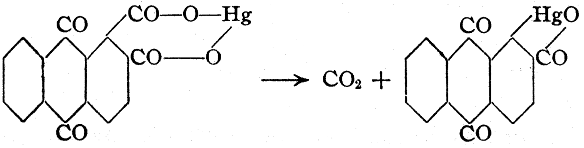
THE MERCURATION OF ANTHRAQUINONEDICARBOXYLIC ACIDS

By Frank C. Whitmore and F. L. Carnahan[1]

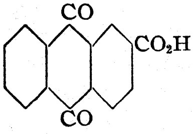
Received October 15, 1928 Published March 6, 1929

The purposes of the present research were to make available mercurated carboxylic acids of relatively high molecular weight and to study further the replacement of one of two ortho carboxyl groups by mercury.[2]

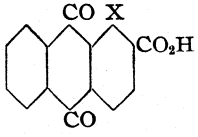
1,2-Anthraquinonedicarboxylic acid was converted to the mercury salt, which was heated dry until no more carbon dioxide was evolved and until ionizable mercury was absent.



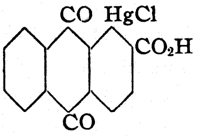
The position of the mercury was proved by treatment with acid, yielding pure anthraquinone-2-carboxylic acid (I) which was shown to be identical with some of the acid prepared by the oxidation of β-methylanthraquinone. Replacement of the mercury by halogen gave the known 1-iodo-anthraquinone-2-carboxylic acid (II) and the hitherto unknown 1-bromo-anthraquinone-2-carboxylic acid (II). The anhydro hydroxymercuri compound was also converted to 1-chloromercuri-anthraquinone-2-carboxylic acid (III).



I



II



III

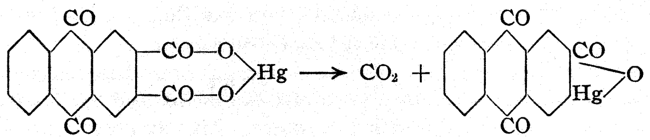
There was no evidence that any of the β-carboxyl was replaced by mercury with the formation of a derivative of anthraquinone-1-carboxylic acid. In other words, the carboxyl replaced was the one between the quinone group and the other carboxyl group.

2,3-Anthraquinonedicarboxylic acid was prepared from the 2,3-dimethyl compound obtained from o-xylene and phthalic anhydride. The mercury salt heated dry decomposed considerably more readily than that of the 1,2-acid.

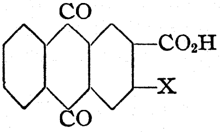
---

[1] Research Fellow in Chemistry, Northwestern University.

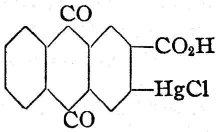
[2] This well-known method of introducing mercury into organic compounds was discovered by Pesci, *Atti accad. Lincei,* [5] **10,** I, 362 (1901).



Treatment of the mercurated product with acid and halogens gave anthraquinone-2-carboxylic acid (I), the known 3-bromo-anthraquinone-2-carboxylic acid (IV) and the new 3-iodo-anthraquinone-2-carboxylic acid (IV). The chloromercuri acid was also prepared (V).



IV



V

Experimental Part

Preparation of **Anthraquinone-1,2-dicarboxylic** Acid.—Naphthalene and phthalic anhydride were condensed in benzene solution in the presence of anhydrous aluminum chloride to form α-naphthoyl-*o*-benzoic acid. Through the elimination of water from this compound by means of concd. sulfuric acid benz-1,2-anthraquinone was obtained. The oxidation of the latter substance with potassium permanganate in strongly acid solution gave anthraquinone-1,2-dicarboxylic acid. Purification of the acid was effected by recrystallization from glacial acetic acid until the melting point was 270°.

Formation of the Mercury Salt of **Anthraquinone-1,2-dicarboxylic** Acid.—To a hot solution of 10 g. of the dibasic acid in 300 cc. of water and 5 g. of potassium hydroxide was added a solution of 7 g. of mercuric oxide in 40 cc. of 50% acetic acid. The resulting mixture contained a slight excess of the dibasic acid and was slightly acid with acetic acid. The mercury salt was immediately precipitated as a slightly yellow powder upon mixing the two solutions. It was filtered off, thoroughly washed with hot water, dried and pulverized. The yield was about 95%.

Establishment of a Carbon–Mercury Linkage in **Anthraquinone-1,2-dicarboxylic** Acid.—Refluxing of suspensions of the mercury salt in dilute acetic acid solution did not split out carbon dioxide to form a carbon–mercury linkage. Attempts were made under a wide range of conditions. To effect the desired result, it was found necessary to heat the dry mercury salt at 235°. No evolution of carbon dioxide was perceptible at lower temperatures.

The pulverized mercury salt was placed in a small flask which was immersed in a fused salt bath (potassium nitrate and sodium nitrite) held at 235°. A convenient amount of the mercury salt for a 200-cc. flask was 15 g. The material was frequently stirred in order to insure a uniform product. Small amounts of the material were tested from time to time for the presence of inorganic mercury by suspending in dilute acetic acid and adding a bright piece of copper wire. An amalgamation of the surface of the copper on heating the above mixture to boiling was taken to indicate the presence of inorganic mercury. This test was the most reliable one available. A minimum of eight hours' heating at 235° was required to obtain a product giving no test for inorganic mercury. The material thus obtained was almost entirely alkali-soluble, though long boiling with alkali was necessary to effect solution. Longer heating of the mercury salt gave a larger amount of alkali-insoluble material. The mercuration product as obtained in this way was a bright yellow powder. It did not melt and decomposed only on heating above 300°.

A suspension of 2 g. of the finely pulverized mercuration product in 400 cc. of water was boiled for five minutes with 25 cc. of concd. hydrochloric acid. The undissolved material was filtered and washed with hot water. It was then boiled with a dilute solution of ammonia for one minute. The material unchanged by this treatment was filtered and thoroughly washed with hot water. This treatment should suffice to eliminate both acidic and basic impurities. The material was then dried and analyzed.

Anal. Subs., 0.2517, 0.2310: Hg, 0.1128, 0.1030. Calcd. for $C_{15}H_6O_4Hg$: Hg, 44.5. Found: Hg, 44.8, 44.6.

Treatment of the Mercuration Product with Hydrochloric Acid.—A mixture of 10 g. of the mercuration product and 500 cc. of concd. hydrochloric acid was boiled for twenty-four hours. The reaction mixture was diluted with twice its volume of water and filtered. The residue was washed with warm water and extracted with dilute sodium hydroxide.

The alkali-insoluble material did not change on further boiling with concd. hydrochloric acid. It contained no mercury. On boiling with *aqua regia* anthraquinone was formed. The presence of this alkali-insoluble material was perhaps due to the action of hydrochloric acid on the monobasic anthraquinone acid. The 2-acid on boiling with concd. hydrochloric acid forms an alkali-insoluble product. Anthraquinone itself even on long boiling with concd. hydrochloric acid is unchanged.

The alkali-soluble material was precipitated from solution by the addition of hydrochloric acid. This material on drying weighed 4.25 g. (76.6% yield). It melted at 281–282° without further purification. The melting point after two crystallizations from glacial acetic acid was 285–285.5°. Investigation of the various fractions from the acetic acid crystallizations failed to show the presence of any other product.

Preparation of Anthraquinone-2-carboxylic Acid.—A solution of 40 g. of β-methylanthraquinone in 800 cc. of concd. sulfuric acid was added to 1600 cc. of hot water in a 3-gallon crock with vigorous mechanical stirring. To the suspension of β-methylanthraquinone thus produced was gradually added 60 g. of finely-powdered potassium permanganate. The reaction was allowed to continue with vigorous mechanical stirring for ten minutes after the addition of all of the permanganate. The mixture was then decolorized by the addition of a hot solution of oxalic acid. The insoluble material was collected on a filter and extracted with hot dilute ammonia solution. The insoluble residue from this treatment was unchanged β-methylanthraquinone. The ammoniacal solution was acidified with hydrochloric acid and the precipitated material filtered off. The crude acid was treated with decolorizing carbon in boiling glacial acetic acid. The solution was filtered and allowed to crystallize. The first crop of crystals melted at 285–286°. The melting point was unchanged by further recrystallization from glacial acetic acid. A mixed melting point of this acid with that obtained by the action of hydrochloric acid on the mercuration product was 285–286°, an indication of the identity of the two materials.

Formation of I-Iodo-anthraquinone-2-carboxylic acid.—The position of the mercury in the anhydro compound was further established by the formation of this acid on replacing mercury by iodine. A mixture of 6.75 g. (0.015 mole) of the mercurated product, 7.47 g. (0.045 mole) of potassium iodide and 3 81 g. (0.015 mole) of iodine and 200 cc. of water was heated at 70° for about three hours, or until the iodine was entirely used up. The presence of about 3 cc. of chloroform was found to be very helpful in the estimation of the amount of iodine present at any time. When the iodine had all reacted, the mixture was filtered while hot. The filtrate was acidified with hydrochloric acid and the deep yellow precipitate was collected on a filter. This was washed with a little potassium iodide solution and then with warm water. On crystallization from 95% ethyl alcohol the substance was obtained in very fine, deep yellow needle crystals which became orange colored on standing; melting point 266–268°. The melting point given in the literature is 266–267°.

Anal. Subs., 0.2518, 0.2606: 0.100 *N* $AgNO_3$, 6.72 cc., 6.94 cc. Calcd. for $C_{15}H_7O_4I$: I, 33.6; Found: I, 33.9, 33.8.

Preparation of 1-Bromo-anthraquinone-2-carboxylic Acid.—This previously undescribed acid was obtained in a fashion analogous to that used for the iodo acid. A suspension of 5 g. of the mercurated product in 500 cc of water was heated at 50° for three hours with an excess of bromine in sodium bromide solution At the end of this time the excess bromine was boiled off. The mixture was filtered while hot. The filtrate on acidification with hydrochloric acid gave a slightly yellow flocculent precipitate. This was filtered off, washed with warm water and dried, yield, 1.37 g. Apparently only a part of the mercury had been replaced, since 2.15 g. of the original material was recovered apparently unchanged. Crystallization from alcohol gave yellow needles, melting at 267–268°. As in the case of the corresponding iodo acid the needles were extremely fine.

Anal. Subs., 0.1589: 0.100 N $AgNO_3$, 4.80 cc. Calcd. for $C_{15}H_7O_4Br$: Br, 24.1. Found: Br, 24.2.

Preparation of 1-Chloromercuri-anthraquinone-2-carboxylic Acid.—A mixture of 5 g. of the mercurated product, 20 g. of sodium hydroxide and 500 cc. of water was heated just below boiling for twelve hours. The mixture was filtered hot and made barely acid with hydrochloric acid at the boiling point of the solution. After standing for a few minutes, it was made alkaline with 2 N sodium hydroxide solution and then just acid with hydrochloric acid. These operations were all carried out at the boiling point; otherwise filtration was very difficult and the precipitate likely to be very impure. The precipitated material was filtered off, washed thoroughly with hot water, dried and pulverized. The compound as thus obtained was a light yellow powder.

Anal. Subs., 0.2017, 0 2006: Hg, 0.0824, 0.0820. Subs, 0.1978, 0.2032: 4.00, 4.18 cc. of 0.100 N $AgNO_3$. Calcd. for $C_{15}H_7O_4ClHg$: Hg, 41.2; Cl, 7.28. Found: Hg, 40.9, 40.9; Cl, 7.16, 7.37.

Preparation of Anthraquinone-2,3-dicarboxylic Acid.—*o*-Xylene was condensed with phthalic anhydride in the presence of anhydrous aluminum chloride, high boiling naphtha being used as a diluent. The o-xyloyl-o-benzoic acid thus formed gave 2,3-dimethylanthraquinone on dehydration with 15–20% fuming sulfuric acid. Dimethylanthraquinone was oxidized to the dibasic acid as follows.

A solution of 40 g of 2.3-dimethylanthraquinone in 800 g. of concd sulfuric acid was added with vigorous mechanical stirring to 1600 g. of hot water in a 3-gallon crock. To the suspension of dimethylanthraquinone thus obtained was added in small portions 120 g. of finely-powdered potassium permanganate The addition was made at such a rate as to maintain the temperature at 90–95°. The reaction was allowed to continue for ten minutes with mechanical stirring after the addition of all the permanganate. The excess oxidizing agent was then removed by oxalic acid. The insoluble material was filtered off and washed with hot water It was transferred to a beaker and the acid dissolved in hot dilute ammonia solution. The residue of unchanged dimethylanthraquinone was removed by filtration. The dibasic acid was precipitated from the filtrate by the addition of hydrochloric acid. The material was filtered, thoroughly washed with hot water and dried; yield, 7.5 g. The amount of recovered dimethylanthraquinone was 21 g. The yield of the acid was 31.6%, based on the material which reacted. Purification was effected by crystallization from glacial acetic acid. The melting point of the material thus obtained was 340–342°.

Preparation of the Mercury Salt of Anthraquinone-2,3-dicarboxylic Acid.—To a hot solution of 7.5 g. of the acid in 500 cc. of water and 50 cc. of 2 N potassium hydroxide was added a solution of 5.25 g. of mercuric oxide in 30 cc. of 50% acetic acid. The mercury salt was immediately precipitated as a slightly yellow powder. The above procedure provided for a slight excess of the dibasic acid and the resulting mixture was slightly acid with acetic acid. The material was filtered off, washed with a large quantity of hot water, dried and pulverized. The yield was about 95%.

Establishment of a Carbon–Mercury Linkage in Anthraquinone-2,3-dicarboxylic Acid.—In a 200-cc. flask was placed 11 g. of the finely-powdered mercury salt of anthraquinone-2,3-dicarboxylic acid. The flask was heated in a fused salt-bath. The evolution of carbon dioxide was tested for from time to time as the temperature was raised. At 210–215" the evolution of carbon dioxide was first noticed. At this temperature the gas came off quite rapidly. The contents of the flask were stirred from time to time to insure uniform treatment of the material. At the end of four or five hours, no test could be obtained for inorganic mercury by the previously described copper wire method. The product was a bright yellow powder. Sublimed yellow needles and free mercury were evidence that some decomposition took place under the conditions used. The amount of material recovered was 8.72 g.

The mercurated product required purification before analysis, since it was not at all homogeneous. The possible impurities such as the original acid, anthraquinone and mercuric oxide are soluble in glacial acetic acid. Accordingly, 2 g. of the mercurated product was boiled for five minutes with 50 cc. of glacial acetic acid. The material undissolved by this treatment was filtered, dried and analyzed.

Anal. Subs., 0.2308, 0.2333: Hg, 0.1015, 0.1027. Calcd. for $C_{15}H_6O_4Hg$: Hg, 44.5. Found: Hg, 44.0, 44 0.

As in the case of the 1,2-dibasic acid, the formation of a mercuri-*bis* acid or a double mercuri-*bis* compound might be possible. No evidence was obtained for the formation of such products. The mercurated product after the above treatment was almost entirely soluble in alkali, though solution was very slow. The formation of two isomeric anhydro-*o*-hydroxymercuri acids was not possible here as in the case of the 1,2-dibasic acid.

Treatment of the Mercuration Product with Hydrochloric Acid.—A mixture of 3.00 g. of the mercurated product and 150 cc. of concd. hydrochloric acid was refluxed for fifteen hours. The reaction mixture was diluted with twice its volume of water, allowed to stand for a short time and filtered. The insoluble material was extracted with dilute ammonium hydroxide. The extract was acidified with hydrochloric acid. A slightly yellow flocculent substance was precipitated. The mixture was allowed to digest on the steam-bath for about an hour. The precipitated material was filtered off, washed with warm water and dried; yield, 1.49 g. The various filtrates were collected and evaporated to dryness together.

The material insoluble in ammonia was boiled with glacial acetic acid. Its original weight was 0.12 g. The amount soluble in acetic acid was 0.06 g. This was probably a substance formed by the action of hydrochloric acid on the anthraquinone acid. The insoluble material was probably unchanged mercury compound.

The material soluble in ammonia solution was the main product. It was dissolved in boiling glacial acetic acid and treated with decolorizing carbon and filtered. The filtrate on cooling deposited small felted crystals of a slightly yellow color; melting point, 280–281°. Further crystallization from the same solvent raised the melting point to 284–285°. A mixture with the 2-acid from the oxidation of β-methylanthraquinone melted at 284.5–285.5°.

The residue from the evaporation of the various filtrates was taken up in 25 cc. of water slightly acidulated with hydrochloric acid. The insoluble portion was collected on a filter. It weighed 0.10 g. It did not melt and seemed to consist largely of inorganic material.

The amount of the mercury compound reacting was 3.00 g. − 0.06 g. = 2.94 g. Assuming that the material insoluble in alkali but soluble in acetic acid is formed from an approximately equal weight of the 2-acid of anthraquinone, the amount of material accounted for is 1.49 g. + 0.06 g. = 1.55 g. The amount of the monobasic anthraquinone acid which would be formed from 2.94 g. of the anhydro compound is 1.65 g. The amount of material accounted for is thus about 94%.

Preparation of 3-Bromo-anthraquinone-2-carboxylic Acid.—A suspension of 2 g. of the mercury compound in 200 cc. of water was treated with an excess of bromine in potassium bromide. The mixture was heated at 50–60° for two hours under reflux to prevent the loss of bromine. The excess of bromine was then boiled off under a hood. The mixture was filtered and the filtrate acidified with hydrochloric acid. The mixture was allowed to digest on the steam-bath for about an hour. The product, after washing with warm water and drying, weighed 0.95 g. (yield 65%). After two crystallizations from 70% alcohol, it was obtained in very fine, almost colorless felted needles. These melted at 284–285.5°. The value given in the literature is 284°.

Anal. Subs, 0.1556: 0 100 *N* $AgNO_3$, 4.62 cc. Calcd. for $C_{15}H_7O_4Br$: Br, 24.1. Pound: Br, 23.7.

Preparation of 3-Iodo-anthraquinone-2-carboxylic Acid.—The previously undescribed iodo acid was prepared in a fashion analogous to that for the corresponding bromine compound. To a solution of 1.27 g. of iodine and 2.50 g. of potassium iodide in 200 cc. of water was added 2.25 g. (0.05 mole) of the mercury compound. The mixture was heated at 60° under a condenser until the iodine had all reacted (three to four hours). The insoluble material, usually small in amount, was removed by filtration. The filtrate was acidified with hydrochloric acid. The precipitated material was filtered after digestion on the steam-bath for about an hour, washed with a little potassium iodide solution to insure the removal of mercuric iodide, then with water at about 60° and dried. The crude yield was 1.37 g. or 72.5%.

On crystallization from alcohol the substance was obtained in extremely fine felted crystals of a bright yellow color. These melted at 289–290°.

Anal. Subs., 0.2042: 0.100 *N* $AgNO_3$, 5 36 cc. Calcd. for $C_{15}H_7O_4I$: I, 33.6. Found: I, 33.3.

Preparation of 3-Chloromercuri-anthraquinone-2-carboxylc Acid.—A mixture of 2 g. of the mercury compound, 50 cc. of 2 *N* sodium hydroxide and 450 cc. of water was refluxed for twelve hours. Any residue was filtered off. The filtrate was heated to boiling and made strongly acid with hydrochloric acid. A flocculent yellow precipitate was formed. After standing for three minutes the mixture was neutralized with 2 N sodium hydroxide. It was then made slightly acid with hydrochloric acid to precipitate the chloromercuri acid, the procedure again being carried out at the boiling point. The precipitation had to be made at the boiling point; otherwise the material precipitated was very difficult to filter and to wash free of the impurities which it contained. The product was filtered off and thoroughly washed with hot water. After drying it was pulverized and boiled for five minutes with 25 cc. of glacial acetic acid. It was washed and dried. The chloromercuri acid is a light yellow powder. Its alkaline solution is a deep red color.

Anal. Subs., 0.1996, 0.2488: Hg,[3] 0.0818, 0.1015. Subs., 0.2500: 5.32 cc. of

[3] In the usual gold crucible analysis an unusually high temperature was required for decomposition of this compound.

0.100 N $AgNO_3$. Calcd. for $C_{15}H_7O_4ClHg$: Hg, 41.2; Cl, 7.28. Found: Hg, 40.9, 40.8; Cl, 7.54.

All melting point temperatures given in this paper are uncorrected. The correction for temperatures used is about 4°.

All mercury analyses were made by the gold crucible method.[4]

In halogen analyses the materials were decomposed by the use of sodium peroxide as outlined in Kingscott and Knight, "Organic Analysis." The amount of halogen was then determined by the Volhard method.

Summary

1. The mercury salts of the 1,2- and the 2,3-dicarboxylic acids of anthraquinone lose carbon dioxide when heated above 200°. In each case a mercury–carbon linkage is established. In the 1,2-acid the replacement is limited to the carboxyl between the quinone group and the other carboxyl, that is, only the a-carboxyl is replaced.
2. The mercury salt of the 2,3-acid loses carbon dioxide more readily than that of the 1,2-acid.
3. The corresponding chloromercuri compounds have been prepared.
4. The mercury has been replaced by bromine and by iodine.
5. The following new compounds have been prepared: anhydro-1-hydroxymercuri-anthraquinone-2-carboxylic acid, 1-chloromercuri-anthraquinone-2-carboxylic acid, 1-bromo-anthraquinone-2-carboxylic acid, anhydro-3-hydroxymercuri-anthraquinone-2-carboxylic acid, 3-chloromercuri-anthraquinone-2-carboxylic acid, 3-iodo-anthraquinone-2-carboxylic acid.
6. A new method has been developed for preparing anthraquinone-2,3-dicarboxylic acid.

THE BROMINATION OF PYRIDINE[1]

BY S. MARY ELIZABETH ENGLERT AND S. M. MCELVAIN

RECEIVED OCTOBER 22,1928 PUBLISHED MARCH 6, 1929

The preparation of 3-bromopyridine and 3,5-dibromopyridine by the direct bromination of pyridine has long been known as a rather difficult reaction to carry out. Nevertheless, it appears to be the simplest method available for the preparation of these particular bromopyridines in quantity. Hofmann[2] was able to prepare 3,5-dibromopyridine by heating pyridine dibromide, $C_5H_5N\cdot Br_2$, in a sealed tube for one hour at 200°. He obtained the same product by heating pyridine hydrochloride and bromine together in a sealed tube. In neither reaction did he report the formation of 3-bromopyridine. Later, Ciamician and Silber[3] prepared 3-bromopyridine along with 3,5-dibromopyridine by heating pyridine hydrochloride and bromine in a sealed tube as Hofmann had done. They, however, heated their mixture for a longer time (twenty-four hours) and at a higher temperature (210–230°). Their combined yield of the mono- and dibromopyridines was only 21% of the theoretical. Blau[4] reported an improvement over the earlier sealed-tube methods, which consisted essentially of passing a mixture of bromine and carbon dioxide through molten pyridine hydrochloride. By this procedure the combined yield of the mono- and dibromopyridines was 42% of the theoretical.

This communication reports what seems to be a distinct improvement over all of the older methods of bromination of pyridine. The procedure consists of heating a perbromide of pyridine hydrobromide at 230–250° under ordinary pressure until the evolution of hydrogen bromide ceases.

There appears to be considerable variation in the composition of the perbromides of pyridine and pyridine salts as reported in the literature. Anderson[6] and Hofmann[2] treated pyridine and pyridine hydrochloride in aqueous solution with bromine and obtained crystalline precipitates which showed fair stability and to which they assigned the formula $C_5H_5N\cdot Br_2$. Grimaux[6] treated pure pyridine with bromine and obtained a compound that crystallized in thin, red plates and melted at 126°. To this compound he assigned the formula $(C_5H_5N\cdot Br_2)_2\cdot HBr$. Trowbridge and

[2] Hofmann, Ber., 12, 988 (1879).

[3] Ciamician and Silber, *Ber.*, 18,722 (1885).

[4] Blau, *Monatsh.,* 10, 372 (1889).

[5] Anderson, *Ann.*, 105, 341 (1858).

[6] Grimaux, *Compt. rend.,* 95, 85 (1882).

Diehl[7] were unable to obtain a definite compound from bromine and pyridine in aqueous solution but in chloroform solution they obtained a compound which appeared to have the formula $C_5H_5N{\cdot}Br_4$. On standing this tetrabromide lost bromine and passed into a compound which analysis showed to have the formula $C_5H_5N{\cdot}Br_2$. Barthe[8] obtained from pyridine and bromine a perbromide to which he assigned the formula $C_5H_5N{\cdot}Br$. Trowbridge and Diehl also prepared perbromides of salts of pyridine. By passing bromine into an aqueous solution of pyridine hydrobromide they obtained two perbromides, one of which contained 41.95% of bromine and the other 33.66% of bromine that was present as perbromide bromine. The latter compound melted at 93° and the formula $C_5H_5N{\cdot}HBr{\cdot}Br$ was assigned to it. The perbromide containing 41.95% of perbromide bromine was assumed to be a mixture of $C_5H_5N{\cdot}HBr{\cdot}Br_2$ and $C_5H_5N{\cdot}HBr{\cdot}Br$. These investigators also prepared a perbromide in aqueous solution to which they assigned the formula $C_5H_5N{\cdot}HBr{\cdot}Br_2{\cdot}H_2O$. It melted at 118–120° and contained 67.96% of perbromide bromine.

In the work which is reported here it was found that glacial acetic acid was a much better solvent than water for the preparation of these perbromides because both reactants (bromine and pyridine hydrobromide) were quite soluble in this medium and the perbromides which were formed, while very soluble in warm acetic acid, were quite insoluble in the cold acid. From one mole of bromine and one mole of pyridine hydrobromide in acetic acid solution there was obtained a perbromide that melted at 132–134". The yield was 95–97% of the theoretical based on the formation of $C_5H_5N{\cdot}HBr{\cdot}Br_2$. While this formula requires 50% perbromide bromine content, there was found only 47% of perbromide bromine in the product that melted at 132–134°.

One mole of pyridine hydrobromide and one-half mole of bromine in glacial acetic acid solution gave a perbromide that melted at 101–103° and had 39.7% of perbromide bromine. The perbromide bromine in the compound of the formula $C_5H_5N{\cdot}HBr{\cdot}Br$ amounts to 33.3%. The authors are not able as yet to assign satisfactory formulas to these perbromides but it is hoped that further work will throw some light on this subject.

An attempt was made to use pyridine hydrochloride instead of pyridine hydrobromide for the preparation of these perbromides but it was found that the yields from the hydrochloride were considerably lower than those from the hydrobromide and that the perbromides of pyridine hydrochloride were very deliquescent and quite difficult to handle.

When these perbromides were heated at 230–250" under a reflux condenser, there was a vigorous evolution of hydrogen bromide with the formation of 3-bromo- and 3,5-dibromopyridine. The perbromide containing 47%

---

[7] Trowbridge and Diehl, THIS JOURNAL, 19,558 (1897).

[8] Barthe, *Compt.* rend., 145, 75 (1907).

of perbromide bromine gave a 40% yield of 3,5-dibromopyridine but none of the 3-bromopyridine. A mixture of pyridine hydrobromide and this perbromide gave a 35% yield of 3-bromopyridine and a 10% yield of the dibromopyridine. 'She greatest yields of brominated pyridines were obtained when the lower perbromide was heated. In this case 36–38% yields of 3-bromopyridine and 30–36% yields of 3,5-dibromopyridine were obtained. The yield calculations were made on the basis of the bromine used in the preparation of the perbromides.

Experimental

Pyridine Hydrobromide Perbromide (47% Perbromide Bromine).—To a warm (60–65°) solution of 160 g. (1 mole) of pyridine hydrobromide in 240 g. of glacial acetic acid in a large beaker, a solution of 160 g. (1 mole) of bromine in 160 g. of acetic acid was added. The resulting solution was stirred thoroughly by hand and then allowed to cool. After two to three hours there was deposited a mass of large, orange-red, needle-shaped crystals. They were filtered off and dried in a desiccator. They were quite stable and when dry melted at 132–134°. The yield was 300–310 g. (95–97% based on the formation of $C_5H_5N \cdot HBr \cdot Br_2$). These crystals were analyzed for perbromide bromine by the method of Trowbridge and Diehl[7] and found to contain 47.0% of such bromine.

Pyridine Hydrobromide Perbromide (39.7% Perbromide Bromine).——This perbromide was prepared in exactly the same manner as the one described above except that 80 g. (0.5 mole) of bromine in 80 g. of acetic acid was added to the warm solution of 160 g. of pyridine hydrobromide in acetic acid. The crystals obtained melted at 101–103° and the yield averaged 205 g. Analysis showed 39.7% of perbromide bromine. There was no appreciable change in weight in either of these perbromides when they were allowed to stand in a vacuum desiccator over sulfuric acid for several days.

3-Bromopyridine and **3,5-Dibromopyridine.**—These products were prepared in better yields from the lower perbromide. The perbromide containing 39.7% of bromine as perbromide as obtained in the preparation described above was mixed with the residue left by the evaporation of the acetic acid mother liquors. The weight of this mixture amounted to approximately the sum of the weights of pyridine hydrobromide and bromine (that is, 240 g.) used in the preparation of the perbromide. This solid mixture was heated in a round-bottomed flask under a reflux condenser in a sodium nitrate–potassium nitrate bath that was maintained at 230–250°. The solid melted at about 100° and as the liquid reached the bath temperature there was a vigorous evolution of hydrogen bromide. The evolution of hydrogen bromide gradually subsided and at the end of six to eight hours had practically ceased. During the reaction there was considerable condensation of crystals of 3,5-dibromopyridine on the cooler parts of the flask and in the reflux condenser. When the evolution of hydrogen bromide had ceased, the reaction mixture was steam distilled until no more crystals of 3,5-dibromopyridine appeared in the condenser. The distillate consisted of an acid solution and suspension of 3,5-dibromopyridine which was completely precipitated out by the addition of alkali. The precipitate was filtered off and recrystallized from alcohol. The yield was 18–22 g. of a product that melted at 110–111°. The residue left in the flask after the removal of the 3,5-dibromopyridine by steam distillation was made strongly alkaline with sodium hydroxide and again steam distilled. The distillate consisted of water, pyridine and 3-bromopyridine and as it first came over was clear, but as the proportion of water increased it became turbid and when about 250 cc. of distillate had been collected, a layer of 3-bromopyridine and some pyridine was present in the receiver. This layer was separated, dried with solid sodium hydroxide and fractionated. The fraction that boiled at 160–175° amounted to 29–31 g. On redistillation practically all of this fraction boiled at 168–172°. The yield of the dibromopyridine was 30–36% of the theoretical and that of the 3-bromopyridine 36–38% of the theoretical based on the bromine used in the preparation of the perbromide.

The separation of 3,5-dibromopyridine from 3-bromopyridine by steam distillation of the former from acid solution was originally used by Ciamician and Silber[3] and is fairly satisfactory but not complete. There appears to be some of the di-substitution product left with the monobromopyridine even after prolonged steam distillation, and in the final distillation of the latter compound a small amount of the dibromopyridine usually crystallizes in the condenser.

When the perbromide of higher bromine content was heated under similar conditions, a 40% yield of the dibromopyridine was obtained but none of the 3-bromopyridine was found. It was thought that dilution of this higher perbromide with pyridine hydrobromide might increase the yield of the mono-substituted product but several runs in which 2 moles of pyridine hydrobromide was mixed with 1 mole of the higher perbromide gave an average of 10% yield of 3-bromopyridine and 30% yield of the 3,5-dibromopyridine.

Summary

A convenient method of brominating pyridine to 3-bromopyridine and 3,5-dibromopyridine has been described. It consists of the preparation of a perbromide of pyridine hydrobromide in glacial acetic acid solution and the transformation of this perbromide by heat into the bromopyridines.

SYNTHETIC GLYCERIDES. I. PREPARATION AND MELTING POINTS OF GLYCERIDES OF KNOWN CONSTITUTION[1]

BY H. P. AVERILL, J. N. ROCHE AND C. G. KING

RECEIVED OCTOBER 22, 1928 PUBLISHED MARCH 6, 1929

The isolation of pure triglycerides from natural fats and oils is an uncertain and laborious process because of the difficulty of complete separation. Even when pure triglycerides have apparently been obtained satisfactory evidence is not available to indicate which of the possible isomers has been found. It was thought that progress could best be made through the synthesis of glycerides of known constitution and the study of their chemical and physical properties. Data thus obtained will be valuable in the study of the components of naturally occurring fats and oils.

It seemed probable that definite relationships might be found between certain physical properties of the fats and their molecular structure if sufficient data were available to warrant conclusions. The three sets of isomers (only one having fatty acids) prepared by Fischer[2] indicated that

---

[1] This paper is based upon a part of the theses submitted by H. P. Averill and J. N. Roche to the Graduate School, University of Pittsburgh, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] E. Fischer, *Ber.*, 53, 1621 (1920).

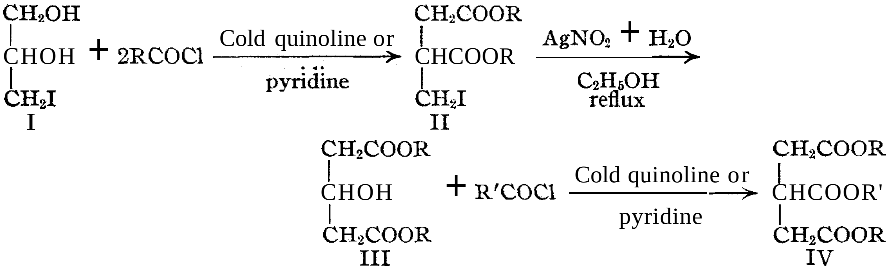
the unsymmetrical glycerides melt at a lower temperature than their symmetrical isomers and may differ somewhat in solubility, but much of the data in the literature is in conflict with this generalization.

A review of the literature on the synthesis of fats shows that there are seven general methods for preparing simple and mixed glycerides[3] Only two or possibly three of these methods, however, are found to be of value in the preparation of glycerides in which the position of the acyl groups can be stated with certainty. Four of the general methods are due to Griin and his co-workers and much of the data on synthetic glycerides found in the literature is based on these reactions. Three of Grüns' methods have been found to result in an unpredictable rearrangement of the acyl groups. It is found-that the replacement of an OH group in glycerol at elevated temperatures by an acyl chloride or the replacement of a halogen by an OH group-will always allow of a shifting of the acyl groups already present into their most natural positions. Not only is the separation of the individual components of such mixtures difficult to perform but they are further complicated because at the temperatures employed there can be reactions between two moles of the partly acylated glycerides.

The preparation of glycerides from halohydrins and soaps, a fourth method used extensively by Griin, while allowing of greater freedom from shifting, permits of side reactions of considerable magnitude.

Fischer, shortly before his death in 1920, devised an entirely new method for the preparation of unsymmetrical triglycerides and greatly improved the synthesis of symmetrical di- and triglycerides and by these methods glycerides can now be prepared whose chemical structure is reasonably certain.

The synthesis of symmetrical mixed glycerides by the Fischer method can best be shown by the following reactions



$$\begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2I \\ \quad I \end{array} + 2RCOCl \xrightarrow[\text{pyridine}]{\text{Cold quinoline or}} \begin{array}{l} CH_2COOR \\ | \\ CHCOOR \\ | \\ CH_2I \\ \quad II \end{array} \xrightarrow[\substack{C_2H_5OH \\ \text{reflux}}]{AgNO_2 + H_2O}$$

$$\begin{array}{l} CH_2COOR \\ | \\ CHOH \\ | \\ CH_2COOR \\ \quad III \end{array} + R'COCl \xrightarrow[\text{pyridine}]{\text{Cold quinoline or}} \begin{array}{l} CH_2COOR \\ | \\ CHCOOR' \\ | \\ CH_2COOR \\ \quad IV \end{array}$$

The synthesis of unsymmetrical mixed triglycerides can be shown by the following reactions

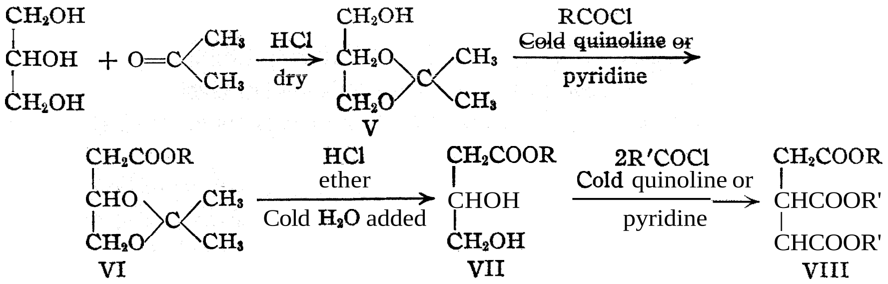
Foster, *J. Chem. Soc.*, *127*, 2760 (1925); E. Abderhalden and E. Eichwald, *Ber.*, **48**, 1849 (1915); E. Fischer, M. Bergwin and H. Barwind, *ibid.*, [2] 53, 1589 (1920); C. Amberger and K. Bromig, *Biochem. Z.*, 130,252 (1922).



No temperatures higher than 30–35° need be employed in these syntheses except for the conversion of the diacylated iodohydrin wherein the alcohol mixture is refluxed and the acyl group shifts from the β- to the a-position following hydrolysis of the halide. All intermediate compounds can be purified by crystallization or vacuum distillation before use in the next step.

Thus it is only within the last few years that a study of the physical properties of the isomeric glycerides has been possible. In view of the uncertainty of the data for many of the mono-, di- and triglycerides reported in the literature, this investigation was undertaken (a) to recheck many of the values given in the literature, (b) to synthesize other glycerides by methods which have been found satisfactory and (c) to find what relation exists between the constitution of the isomeric glycerides and their physical properties. Data are included in this paper only with respect to their melting points. Further data will be given in later papers.

Preparation of Acyl Chlorides.—Acyl chlorides were prepared by the use of oxalyl chloride and fatty acid according to the directions given by Adams and Ulich.[4] The following acyl chlorides were prepared: n-capryl, b. p. 104–105 (9 mm.); myristyl, b. p. 134° (2.5 mm.); stearyl, b. p. 165° (0.4 mm.); lauryl, b. p. 150° (22 mm.); caproyl, b. p. 138–140° (atmos.).

Stearyl chloride could only be distilled when the distilling flask was immersed up to the side arm in a special oil-bath. The top of the bath was heated by means of a hot-plate and the temperature maintained throughout the bath at 167'. All compounds of this type were kept in desiccators over phosphorus pentoxide.

Preparation of **α-Monoglycerides.**—The preparation of a-monomyristin will show the general procedure used in the preparation of monoglycerides.

To a mixture of 8.82 g. (1.1 moles) of acetoneglycerin and 8.85 g. (1.1 moles) of quinoline (pyridine used for low mol. wt. fatty acids) contained in a thin, glass-stoppered iodine flask, there was added, with cooling in an ice-bath, 15 g. (1 mole) of myristyl chloride. After standing at room temperature for two days, it was treated with 100 cc. of ether and 60 cc. of ice-cold, 0.5 N sulfuric acid. The mixture was shaken in a separatory funnel and the acid layer drawn off. After several washings with the ice-cold acid, no test for quinoline was found and the ether layer was then thoroughly

---

[4] R. Adams and L. Ulich, THIS JOURNAL, 42, 599 (1920).

shaken several times with 75-cc. portions of potassium bicarbonate and finally washed well with water. After drying over fused sodium sulfate, the ether was evaporated and the myristylacetoneglycerin purified.

The hydrolysis of the acetone compound was carried out by two different methods. (a) To the acetone compound obtained above dissolved in 75 cc. of th[illegible] 80 c[illegible] of concentrated hydrochloric acid was slowly added. The mixture was kept in a cold water-bath for half an hour and then treated with 300 cc. of water. The mixture was next placed in a freezing mixture and the monomyristin soon separated in the form of fine white crystals. After suction-filtering and washing with water, the crystals were dried over phosphorus pentoxide and crystallized from a 1:1 mixture of ether and petroleum ether. Lustrous plates or leaves separated which melted at 67.3'; the melting point did not change on repeated recrystallization.

(b) Ten grams of the myristylacetoneglycerin was shaken with 40 cc. of 0.25 *N* sulfuric acid at 45°. The mixture was left in a 40'-oven for twenty-four hours. It was then cooled to 0° and treated with a slight excess of barium hydroxide. The excess hydroxide was removed by carbon dioxide and the mixture evaporated without filtration at 40°. The residue was treated with chloroform and the chloroform solution filtered from the carbonate and sulfate and dried over fused sodium sulfate. After evaporation of the chloroform the monomyristin was crystallized from 1:1 ether and petroleum ether; melting point 67.2'.

The following a-monoglycerides were prepared according to the above method.

Compound	M. p., °C., found	Previously recorded
a-Monopalmitin	77.0	78–79 (a), 77.6 (d), 63 (h), 72 (g), 65 (e), 58 (i)
a-Monomyristin	67.3	68 (g), 68 (j)
α-Monocaprin	51.4	
a-Monolaurin	63.0	62-63 (a), 52 (b), 61 (c), 59 (b), 58 (c)
a-Monostearin	81.1	81–82 (a), 80.9 (d), 73 (e), 61 (f), 78 (g)
a-Monoacetin	Not distilled

Preparation of α,α-Diglycerides.—α,α-Diglycerides were prepared according to the following method, showing the preparation of a, a-dilaurin.

Ten and one-tenth g. (1 mole) of a-iodohydrin in 13.8 cc. (1 mole) of quinoline was cooled to 0° in ice water. To the mixture, which was kept cold, 22.0 g. (1 mole) of lauryl chloride in 42 cc. of chloroform was added in several portions. After standing at room temperature for forty-eight hours the red-colored reaction mixture was taken up with 400 cc. of ether and 100 cc. of ice-cold 0.5 N sulfuric acid. The washing with acid, bicarbonate and water was carried on in the same manner as for monoglycerides. After drying the solution the ether was evaporated and the a-iodo-dilaurin remained as a colorless oil. By dissolving in a mixture of ether and methyl alcohol (1:3) and cooling to −15° the iodine compound was obtained as white crystals melting at 23.5°.

Twenty-four grams of α-iodo-α,β-dilaurin was refluxed on a water-bath in a mixture of 150 cc. of ethyl alcohol, 21 cc. of water and 24 g. of silver nitrite for one hour. After the separation of silver iodide, the reaction mixture was filtered hot. The filtrate was evaporated on a water-bath and left behind an oil mixed with silver compounds. The oil was taken up with 100 cc. of absolute alcohol, filtered and again evaporated. This time it was boneblacked to clear it. By slow evaporation of the alcohol the α,α-dilaurin crystallized in shining plates. After drying over phosphorus pentoxide in a vacuum desiccator the α,α-dilaurin melted sharply at 56.6'. Repeated crystallization did not change the melting point. The mother liquor crystals of the second recrystallization melted at 56.4–56.6°.

The following α,α-diglycerides were prepared in the above manner.

Compound	M. p., °C., found	Previously recorded
a,a-Dilaurin	56.6	55 (d), 57 (c), liquid (e)
α,α-Distearin	79.1	78.2 (c), 76.5 (f), 74.5 (g), 76 (a), 78.5–9 (h)
α,α-Dipalmitin	69.5	70 (a), 69 (b), 69.5 (i)
α,α-Dimyristin	63.8–64.4	61 (c), 63 (d)

Synthesis of Triglycerides.—For the preparation of symmetrical mixed triglycerides the preparation of β-stearo-α,α-dilaurin is used as an example.

Four grams of α,α-dilaurin (1 mole) was dissolved in 5 cc. of chloroform and 1.42 g. (1.2 moles) of quinoline added. The flask containing this mixture was then placed in ice water and 2.9 g. (1.1 moles) of stearyl chloride in 2 cc. of chloroform was slowly added. After standing at room temperature for forty-eight hours, it was taken up with 300 cc. of ether and 100 cc. of ice-cold 0.5 N sulfuric acid and treated in the above manner for the separation of quinoline. After drying the solution over fused sodium sulfate, the ether was evaporated slowly, mostly at room temperature. The addition of alcohol to the chloroform remaining after evaporation of the ether caused a separation of the triglyceride. After drying over phosphorus pentoxide the glyceride melted at 49.8'. After two recrystallizations the melting point rose to 50.9' and was not changed by further crystallization.

For unsymmetrical mixed triglycerides, the monoglycerides were treated with two moles of an acyl halide and quinoline. The following triglycerides were prepared. Melting points and saponification numbers were taken as the best index of purity.

Compound	M. p., °C., found	Previously recorded
Trilaurin	45.6	45 (a), 45 (b), 46.4 (b)

Discussion of Results

It is evident from the above data that there was a considerable difference in the melting points of many of the compounds previously prepared and those described in this work.

In the case of the previously recorded isomeric stearodipalmitins mixtures of the mono- or dipalmitins and fatty acid were heated. The positions of acyl groups in a mixed glyceride cannot be stated with certainty when using this procedure. Both recorded compounds showed melting points of 60° when prepared by this method. The use of high temperatures also accounts for the faulty results recorded for the acetodipalmitins and the acetodistearins. The reaction between acetic anhydride and α,α-diglycerides can be accomplished in the cold if pyridine is added.

Symmetrical stearodilaurin as prepared by Grün melts 13° below the compound reported here. He prepared it by the same method used here except that in his method no quinoline was used for the removal of hydrogen chloride and the mixture was heated. This type of reaction is incomplete and extensive shifting of the acyl groups takes place, giving a mixture of triglycerides. The same criticism holds for his symmetrical laurodimyristin, which he prepared by the same method and found to be mixed with other unidentified substances.

Many of the unsymmetrical triglycerides previously recorded in the literature, prepared from diacylchlorohydrins and soaps, are in good agreement with those reported here. It is to be noted, however, that the replacement of the chlorine does not take place smoothly and considerable amounts of by-products form, giving low yields. The following compounds prepared by this method agree with those prepared during the present investigation: α-laurodistearin, α,α-dilaurin, a-stearodilaurin, β-stearodipalmitin, a-monostearin, and trilaurin.

The simple triglycerides, trilaurin and trimyristin, both of which were prepared from the α,α-diglycerides using acyl chloride and quinoline, agree very well with the melting points of the same compounds recorded in the literature and prepared by other methods.

In several cases the mono- and diglycerides which were used in preparing the triglycerides recorded in the literature were from 3 to 5° lower in melting point than those herein reported.

In the nine sets of isomeric glycerides reported here the symmetrical isomer in each case was found to have the higher melting point. This was not the case in three of the five sets of isomers for which values could be found in the literature (acetodipalmitins, stearodilaurins and stearodipalmitins). The average difference in melting points between the symmetrical and unsymmetrical isomers for the nine sets prepared is 4.7°.

Fischer's methods have been used for the first time in the preparation of a-monocaprin, a-monomyristin, α,α-dilaurin, α,α-dimyristin and for the following sets of isomers: the stearodilaurins, acetodipalmitins, caprodipalmitins, laurodipalmitins, myristodipalmitins and the laurodimyristins. The caprodipalmitins, laurodipalmitins and myristodipalmitins had not been prepared previously.

Summary

1. The methods devised by Emil Fischer for the synthesis of unsymmetrical and symmetrical mixed glycerides have been extended to the preparation of glycerides not previously synthesized and used to recheck many of the data reported in the literature.

2. In rechecking data available for eleven triglycerides, differences between the melting points of the compounds previously prepared and those described in this work have been found. The differences are shown to be due to the methods of preparation used and the reasons for these differences are indicated.

3. The following new triglycerides have been prepared: the isomeric caprodipalmitins, laurodipalmitins, myristodipalmitins and palmitodimyristins.

4. In the synthesis of triglycerides, the following new intermediate compounds have been prepared: caprylacetoneglycerin, a-monocaprin, a-iododilaurin, a-iododimyristin.

5. It was found that the symmetrical isomer in each of the nine sets of isomeric triglycerides made had a higher melting point than that of the unsymmetrical isomer.

RESEARCHES ON PYRIMIDINES. CIV. ISOURACIL AND ITS DERIVATIVES. A PRELIMINARY STUDY OF THE METHODS OF SYNTHESIS

BY TREAT B. JOHNSON AND W. T. CALDWELL[1]

RECEIVED OCTOBER 26, 1928 PUBLISHED MARCH 6, 1929

The Constitution of Orotic Acid

Various chemical aspects of the vitamin problem have stimulated an interest in the study of the chemistry of isouracil and its derivatives. Our interest in this type of pyrimidine compounds as possible vitamine constructions has been stimulated as a result of the continuation of some pyrimidine research which was inaugurated as early as 1907.[2] This research, which was of a preliminary nature, had to do with the question of determining whether orotic acid, $C_5H_4O_4N_2 \cdot H_2O$, is to be represented structurally as a pyrimidine compound.

Biscaro and Belloni[3] reported the isolation of this organic acid from milk whey in 1905 and described several of its derivatives. Sufficient experimental evidence was produced by these investigators to show that the acid is probably a heterocyclic compound having an ureide structure but insufficient data were obtained to enable them to draw a positive conclusion regarding its constitution.

The properties of orotic acid suggested the possibility of its being a pyrimidine having the constitution of one of the uracil-carboxylic acids represented by Formulas I and II, respectively. Wheeler, Johnson and Johns[2] prepared the compound represented by Formula I, and later Wheeler[4] made a careful study of the isomeric pyrimidine II. Neither of these two pyrimidines possessed the specific properties which characterized the orotic acid described by Biscaro and Belloni. The non-identity of the two pyrimidines I and II with orotic acid being established, there now remained to be considered the third pyrimidine possibility, namely, isouracil-carboxylic acid represented by Formula III. The further study of this

[4] Wheeler, *Am. Chem.* J.,38, 358 (1907).

interesting problem has now introduced us to many new features of pyrimidine chemistry which promise to become of immediate biochemical interest. It is not improbable that the easiest approach to isouracil, $\overline{\mathrm{NCONHCH{=}C(OH)CH}}$, which is the only 2-oxypyrimidine isomeric with uracil, $\overline{\mathrm{NHCONHCH{=}CHCO}}$, will be by decarboxylation of isouracil-carboxylic acid, III. Tafel and Houseman[5] described what they believed to be two isomeric modifications of this pyrimidine but state that, in consequence of the fact that all attempts to rearrange one form into the other were unsuccessful, the formulas assigned were given with reservation. No method has yet been developed for the synthesis of an isouracil of known structure. This paper contains a preliminary account of new work in this field.

It is of interest to note at this time that Biscaro and Belloni also made a preliminary study of the physiological action of orotic acid. Injection of an aqueous solution of the potassium salt into a frog produced a violent excitation followed by a complete paralysis of the central nervous system. The same experiment repeated on guinea pigs with corresponding body doses produced less violent results, indicating, therefore, that orotic acid is apparently tolerated in some degree by warm-blooded animals. A remarkable property reported as characteristic of orotic acid is its specific affinity for potassium. The acid is said to be able to liberate hydrochloric and nitric acids in aqueous solutions of their respective potassium salts. The Italian investigators postulated that orotic acid is possibly a natural factor influencing the relative proportions of sodium and potassium found in the different fluids and in muscular tissues of the animal body. To date no exhaustive physiological examination of any pyrimidine-carboxylic acids has been carried on. In the light of the known physiological activity of the different carboxyl derivatives of pyridine and quinoline, for example, it seems not improbable that some of the carboxyl derivatives of the reduced forms of pyrimidine may prove interesting pharmacologically.

Our present research has been confined to the study of two different methods proposed for synthesizing carboxyl derivatives of isouracil. Neither of the two procedures studied has led thus far to practical results. In method one we started with ethyl diethoxy-acetoacetate[6] IV, and prepared the mercapto-pyrimidine V. This proved to be a compound characterized by very desirable properties and was easily converted into the pyrimidine VI by interaction with phosphorus pentachloride. By reduction of this halogen compound we were also successful in synthesizing 2-ethylmercapto-4-ethoxymethyl-5-ethoxypyrimidine VII, which on hydrolysis apparently yields smoothly 2-oxy-4-ethoxymethyl-5-ethoxypyrimi-

[5] Tafel, *Ber.*, 34,258 (1901); Tafel and Houseman, *Ber.*, 40,8743 (1907).

dine VIII. The method of operating, involving as it does so many steps, does not yield this pyrimidine, however, in sufficient quantity to proceed through the last two steps of the synthesis represented by Formulas IX and III.

An interesting pyrimidine obtained in our research was the alcohol represented by either of the two formulas, X and XI. This proved to be very resistant to the action of hydrochloric acid, a result quite in accord with the behavior of other alcohols of this type in the uracil series.[7]

IV $C_2H_5OCH_2COCH(OC_2H_5)COOC_2H_5$

V $\overline{NHC(SC_2H_5){=}NC(CH_2OC_2H_5){=}C(OC_2H_5)CO}$

VI $\overline{NC(SC_2H_5){=}NC(CH_2OC_2H_5){=}C(OC_2H_5)CCl}$

VII $\overline{NC(SC_2H_5){=}NC(CH_2OC_2H_5){=}C(OC_2H_5)CH}$

VIII $\overline{NCONHC(CH_2OC_2H_5){=}C(OC_2H_5)CH}$

IX $\overline{NCONHC(CH_2OH){=}COHCH}$ X $\overline{NHCONHC(CH_2OH){=}C(OH)CO}$

XI $\overline{NHCONHCH(CH_2OH)COCO}$

In method two the starting point was the compound ethyl oxalo-ethoxyacetate, XII. This was found to interact with pseudo-ethylthiourea with formation of the pyrimidine XIII, but less favorably than the ketone ester IV under similar conditions. This observation is quite in accord with that of Wheeler,[8] who failed to obtain mercapto-pyrimidines by condensing pseudothioureas with ethyl oxalo-acetate. On the other hand, Johnson[9] found that ethyl oxalopropionate condenses smoothly with pseudothioureas. The pyrimidine XIII is converted by hydrolysis in hydrochloric acid solution into its corresponding diethoxy derivative, XIV, the mono-ethoxy compound, XV, and finally to isobarbituric acid XVIII with loss of carbon dioxide. It has been found also that the mercapto-pyrimidine XIII interacts normally step by step (XVI ⟶ XVII ⟶ III) up to the last stage of the synthesis, but not until we have found more favorable experimental conditions for the pseudothiourea condensation will it be practicable to apply this method of synthesis for the production of isouracil-carboxylic acid, III, in quantities needed for our researches.

XII $C_2H_5OOCCOCH(OC_2H_5)COOC_2H_5$

XIII $\overline{NHC(SC_2H_5){=}NC(COOC_2H_5){=}C(OC_2H_5)CO}$

XIV $\overline{NHCONHC(COOC_2H_5){=}C(OC_2H_5)CO}$

XV $\overline{NHCONHC(COOH){=}C(OC_2H_5)CO}$

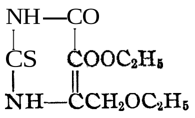
Biscaro and Belloni state that orotic acid fuses with decomposition at 260". As to whether this is a sharp and definite decomposition point we have no knowledge, but it is an interesting fact that the acid III, obtained by us according to the second outlined method of synthesis, melted with decomposition at the same temperature, 259–260°.

A complete record of our experimental work is given in the final section of this paper. This investigation is being continued by other co-workers in this Laboratory.

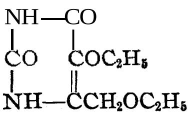
Experimental Part

2-Thio-4-ethoxymethyl-5-ethoxy-6-oxypyrimidine.—This pyrimidine was prepared by condensing thiourea with ethyl α,γ-diethoxyacetoacetate as follows: 7.6 g. of thiourea and 21 g. of ethyl α,γ-diethoxyacetoacetate were added to a solution of sodium alcoholate made by dissolving 2.3 g. of metallic sodium in 75 cc. of absolute alcohol. The resulting mixture was then refluxed in an oil-bath for eight hours, during which time the liquid changed in color from orange to dark red. On cooling, needle-shaped crystals separated from the solution. The alcohol then was distilled off under diminished pressure and the residue dissolved in 100 cc. of water and made acid to litmus with hydrochloric acid. Crystals of the pyrimidine separated and were purified by recrystallization from water after decolorizing with animal charcoal. The thiopyrimidine is practically insoluble in cold water and requires about 100 parts of boiling water for solution. It crystallizes in colorless needles, giving strong tests for nitrogen and sulfur, and melts at 178°.



Anal. Calcd. for $C_9H_{14}O_3N_2S$: N, 12.17. Found: N, 12.28, 12.29.

2-Oxy-4-ethoxymethyl-5-ethoxy-6-oxypyrimidine.—This pyrimidine was obtained from the corresponding thio-compound by the action of chloro-acetic acid. 2.53 g. of the above thiopyrimidine was treated with 3.16 g. of chloro-acetic acid in 60 cc. of distilled water and the mixture refluxed for five hours. On cooling, the 2-oxypyrimidine separated in large crystals and melted to a colorless liquid at 168°. The yield was 1.93 g., or 82% of the theoretical. The sulfur from the thiopyrimidine remained in the mother liquid combined in the form of thioglycolic acid, as shown by the characteristic and beautiful color test with ferric chloride and ammonia.



Anal. Calcd. for $C_9H_{14}O_4N_2$: N, 13.08. Found: N, 13.13.

2-Oxy-4-hydroxy-5-hydroxy-6-oxypyrimidine, IX.—0.92 g. of the above pyrimidine was placed in a pressure tube with 10 cc. of concentrated hydrochloric acid, sealed and heated for two hours at 120–140°. After cooling, the tube was opened and the gas which escaped burned with a green flame; the odor of ethyl chloride was noticeable. Before heating, the pyrimidine dissolved in the hydrochloric add, forming a clear solution; during the reaction the liquid became bright yellow and a yellow precipitate separated which was practically insoluble in water. This was digested with distilled water, filtered off and dried at 100°. The yield was 0.63 g., or 93% of the theoretical. The substance burned up completely when ignited on platinum foil. It did not melt when heated to 320'.

And. Calcd. for $C_5H_6O_4N_2$: N, 17.72. Pound: N, 17.61.

2-Ethylmercapto-4-ethoxymethyl-5-ethoxy-6-oxypyrimidine, V.—This compound was prepared by adding 20 g. of pseudo-ethylthiourea hydrobromide to a solution of 20 g. of ethyl α,γ-diethoxyacetoacetate in water containing 10 g. of sodium hydroxide. The mixture was then heated on the water-bath, upon which it became darker in color and ethyl mercaptan was evolved. After heating for eight hours the solution was cooled and acidified, giving a dark colored and rather oily mixture which was set aside to crystallize. This process was slow in starting but on long standing there separated dark colored, but very well formed, stocky crystals. These were purified by recrystallization from alcohol and decolorization with animal charcoal, when they were obtained in colorless crystals. The yield of the purified product was 4 g. The pyrimidine was practically insoluble in water but soluble in alcohol and acetone and gave good tests for nitrogen and sulfur. It melted at 123°.

Anal. Calcd. for $C_{11}H_{18}O_3N_2S$: N, 10.85. Found: N, 10.99, 10.91.

This compound was also obtained in the following way without first isolating the ketone ester; in general this latter method was preferable: 8.7 g. of metallic sodium in small pieces was added directly to 100 *g.* of ethyl ethoxyacetate in a dry flask connected with a reflux condenser. After cooling during the first stage of the reaction, the flask was suspended in a water-bath and heat applied until all of the sodium had dissolved. Then 70 g. of pseudo-ethylthiourea hydrobromide in absolute alcohol was added to the crude condensation product, the mixture warmed on the water-bath and then set aside to stand at room temperature. The formation of crystals in the dark-colored, viscous liquid was very slow in starting; alcohol and acetone were added in order to thin the material and the whole was then allowed to stand. During this time the crop of crystals gradually increased; after purification they were obtained in white, crystalline form, melting sharply at 123°. The yield was 14 g.

2-Ethylmercapto-4-ethoxymethyl-5-ethoxy-6-chloropyrimidine, VI.—9.53 *g.* of finely powdered phosphorus pentachloride was added to 11.7 g. of 2-ethylmercapto-4-ethoxymethyl-5-ethoxy-6-oxypyrimidine contained in a dry flask attached to a reflux condenser. After thorough mixing, no reaction was apparent after standing at room temperature for half an hour. The mixture was then moistened with *2* cc. of phosphorus oxychloride, forming a thick paste with a light yellow color but causing no further reaction. After half an hour the color was still unchanged, so the mixture was heated in a water-bath until the temperature rose to 80°, when the reaction started. With brisk evolution of hydrogen chloride an orange-red liquid was formed, but no odor of mercaptan was noticed. This liquid rapidly became darker in color; after fifteen minutes the water was raised to the boiling point and the heating continued for two hours. After the evolution of hydrogen chloride had ceased, the phosphorus oxychloride was distilled off on the water-bath under diminished pressure. The residue was treated with crushed ice, then warmed gently, neutralized with successive portions of ether and the solution placed over calcium chloride to dry.

The ethereal extract was then heated to remove ether and the residue of oil distilled under diminished pressure. It boiled at 165–166° under a pressure of 9–10 mm., distilling as a light yellow oil which did not solidify on cooling to 0°. The substance had an odor very suggestive of naphthalene. The yield was 7 g.

This pyrimidine also was prepared by allowing the reaction to take place in chloroform solution: 6.52 g. of the pyrimidine was dissolved in 50 cc. of chloroform and treated with 5.25 g. of phosphorus pentachloride dissolved in 66.7 cc. of chloroform. After refluxing for an hour the liquid changed from yellow to dark green in color. Five cc. more of the chloroform solution of phosphorus pentachloride was added in order to give a slight excess of this reagent and the heating continued for several hours, during which time the liquid became brown. The chloroform then was removed and the residue worked up from this point as in the previous case, the pyrimidine being obtained as an oil, insoluble in water.

Anal. Calcd. for $C_{11}H_{17}O_2N_2SCl$: Cl, 12.81. Found: Cl, 12.90.

2-Ethylmercapto-4-ethoxymethyl-5-ethoxypyrimidine, VII.—The 6-chloropyrimidine described above was dissolved in 115 cc. of alcohol and 75 cc. of water. This solution then was boiled under a reflux condenser with 35 g. of 87% zinc dust that was added in portions in the course of two hours. This liquid then was filtered from the residual zinc while hot, washing well with fresh alcohol. The solvent was removed by warming under diminished pressure until but a small quantity of water remained, containing a heavy red oil. This was extracted with ether and dried over calcium chloride.

The ether was distilled from the ethereal solution and from the residue there separated small crystals, which were first washed with alcohol to free them from adhering oil, finally with ether and petroleum ether and further purified by recrystallization from alcohol. The pyrimidine separated in the iorm of plates and gave good tests for both nitrogen and sulfur but not for chlorine and melted sharply at 167° to a clear oil.

Anal. Calcd. for $C_{11}H_{18}O_2N_2S$: N, 11.57. Found: N, 11.58. Mol. wt. (boiling point method using benzene as solvent). Calcd.: 242. Found: 244.

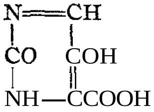
On hydrolysis of a small amount of the above pyrimidine with hydrochloric acid, ethylmercaptan was evolved and we obtained crystals of a substance which darkened very considerably at 281–284° with vigorous effervescence and decomposition. As little material was available this was not investigated but it was very probably 2-oxy-ethoxymethyl-5-ethoxypyrimidine.

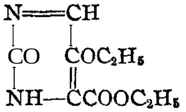
2-Ethylmercapto-4-ethylcarboxylate-5-ethoxy-6-oxypyrimidine, XIII.—Thirty-seven g. of freshly distilled ethyl oxalate and 33 g. of ethyl ethoxyacetate were dissolved in 100 cc. of anhydrous ether and placed in a dry flask attached to a reflux condenser. Then 5.75 g. of metallic sodium in wire form was added. After completion of the condensation with disappearance of the sodium, 41 g. of pseudo-ethylthiourea hydrobromide was added. The liquid emulsified and became yellow in color. It was warmed on the water-bath in order to distil off most of the ether, during which time the color became deeper; upon adding a solution of 14 g. of potassium hydroxide in alcohol to this, solid material began to collect in the flask and the liquid became darker in color. The mixture was then warmed on the water-bath for half an hour and in an oil-bath at 110–120° for two hours, during which time mercaptan was constantly evolved and the color became a deep brown. On cooling, a thick, almost solid, dark-colored mass remained. This was treated as follows: fifteen grams of glacial acetic acid was added in portions, the mixture warmed with 50 cc. of water and then cooled in ice. The crystals and semi-solid material which separated were filtered off and triturated with cold water. when we succeeded in obtaining a colorless product in the form of needles. This was purified by recrystallization from boiling water containing animal charcoal and dried in a vacuum desiccator. The substance gave strong tests for both nitrogen and sulfur and melted at 82–83°. The yield of this pyrimidine was small, but the condensation reaction leading to its formation is promising of further development and it will be studied exhaustively, as this combination would make possible many interesting syntheses if it were available in quantity. Its investigation will be continued.

Anal. Calcd. for $C_{11}H_{16}O_4N_2S$: N, 10.29. Found: N, 10.03.

That this pyrimidine behaves normally and is a stable construction was evidenced by its reactivity with phosphorus oxychloride: 0.5 g. was treated with 2 cc. of the oxychloride, whereupon the compound dissolved immediately. Hydrogen chloride was evolved and a clear solution was obtained after heating for half an hour on the water-bath. The excess of oxychloride then was removed by warming on the water-bath under diminished pressure. After adding ice and gently warming the mixture it was made neutral to litmus with dilute potassium hydroxide. On extracting with ether and evaporating the solvent, a red oil was obtained which contained both chlorine and sulfur and was undoubtedly mercapto-4-ethylcarboxylate-5-ethoxy-6-chloropyrimidine. As no micro-chemical apparatus was available it was impossible to obtain any analytical determinations confirming this constitution.

In order to determine whether this chloropyrimidine is easily reducible, all the material available was dissolved in 20 cc. of absolute alcohol and reduction applied by boiling with zinc dust under a reflux condenser for three hours after adding **10** cc. of water. The dark red color soon disappeared, the supernatant liquid becoming light yellow, almost colorless. After filtering off the zinc, the filtrate was evaporated and extracted with ether. On evaporating the ether a light yellow oil was obtained which finally solidified in the form of hexagonal plates melting at 55–56°. This compound was free from chlorine and its low melting point indicated that we were dealing with the new pyrimidine, 2-ethylmercapto-4-ethylcarboxylate-5-ethoxypyrimidine. It gave a strong test for sulfur. When this compound was heated at 120° with 10 cc. of hydrochloric acid, ethylmercaptan was evolved, showing that the original mercapto grouping had not been destroyed by the previous treatment with phosphorus oxychloride and zinc. The liquid in the bomb tube was yellow in color. On concentrating the acid solution and cooling, a beautiful crystalline substance separated in the form of prisms which melted at 259°. Whether we are dealing here with 2-oxy-4-carboxyl-5-hydroxypyrimidine (orotic acid?) or its corresponding diethyl derivative remains to be determined by further work.





2-Oxy-4-ethylcarboxylate-5-ethoxy-6-oxypyrimidine, XIV.—Thirty-six g. of ethyl oxalethoxyacetoacetate was mixed with a solution of **30** g. of pseudo-ethylthiourea hydrobromide in water. To this was added **15** g. of sodium hydroxide dissolved in water. After standing overnight the mixture was heated on the boiling water-bath, cooled and acidified with hydrochloric acid, whereupon a large amount of mercaptan was evolved from the dark-colored mixture. As it was difficult to stimulate crystallization of any of the products of the condensation, the material was set aside and allowed to stand. From the crystals that ultimately separated this pyrimidine was isolated and purified by several recrystallizations from water, in which it was only moderately soluble. After decolorizing with animal charcoal, it was obtained in the form of colorless needles. It gave no test for sulfur and melted at 230°.

Anal. Calcd. for $C_9H_{12}O_5N_2$: C, **47.36;** H, **5.3;** N, **12.28.** Found: C, 47.68; **H, 5.77; N, 12.07.**

2-Oxy-4-carboxylic **Acid** 5-Ethoxy-6-oxypyrimidine, **XV.**—This compound was obtained along with the pyrimidine just described, from which it was separated by fractional crystallization from alcohol and water. It is practically insoluble in cold water, from which it separates in hexagonal crystals melting sharply at 260° with decomposition. Some of the same pyrimidine was obtained in one experiment in which thiourea and oxalethoxyacetoacetic ester were allowed to react in alcohol containing sodium alcoholate. In this case the reaction product stood for a long time after acidification with hydrochloric acid before the pyrimidine was isolated.

Anal. Calcd. for $C_7H_8O_5N_2$: C, 42.0; H, 4.0; N, 14.0. Found: C, 42.18, 42.4; H, 4.51; N, 13.27, 13.18.

2,6-Dioxy-5-hydroxypyrimidine (Isobarbituric Acid), XVIII.—One g. of 2-oxy-4-carboxylic acid 5-ethoxy-6-oxypyrimidine was sealed in a tube with 10 cc. of concentrated hydrochloric acid and heated for two hours at 110°. Under these conditions no reaction took place. It was therefore heated again for ten hours at 160–165°. The reaction product was found to be insoluble in water and also difficultly soluble in alcohol. On recrystallization from alcohol it separated in the form of microscopic crystals arranged in clusters. These decomposed without melting at 350–355°. The compound was identified as isobarbituric acid. In other words, the carboxyl group is removed by intensive hydrolysis, the pyrimidine behaving in an entirely different manner than uracil-4-carboxylic acid,[2] which resists hydrolysis when heated with 20% sulfuric acid at 200°.

Anal. Calcd. for $C_5H_4O_5N_2$: N, 16.27; for $C_4H_4O_3N_2$: N, 21.87. Found: N, 21.71.

Summary

1. Isouracil-carboxylic acid can exist theoretically in several isomeric modifications and is isomeric with *orotic* acid, a substance stated to have been isolated from milk by Biscaro and Belloni.
2. Experimental evidence has been obtained indicating that isouracil-carboxylic acid may be identical with orotic acid.
3. Two different methods of synthesis have been applied for preparing isouracil-carboxylic acid. Only one thus far gives promise of leading successfully to this pyrimidine.
4. Several new derivatives of isouracil have been prepared.

THE SEPARATION OF THE SOLUBLE PROTEINS OF RABBIT MUSCLE

BY WALTER S. RITCHIE AND ALBERT G. HOGAN

RECEIVED OCTOBER 27, 1928 PUBLISHED MARCH 6, 1929

The earlier work on the separation of muscle proteins has been adequately reviewed,[1] so we will omit a detailed report of those investigations. Howe[2] has recently described a very ingenious procedure which deserves further study, in order to define more precisely the limits of its usefulness. There are several other recent papers[3] that have some bearing on the problem of extracting and separating muscle proteins, though they do not con-

tribute directly to our knowledge of the quantities that may be obtained. Lack of space, however, prevents more than mere mention.

Experimental

For our preliminary observations it seemed necessary to have samples that were as uniform as could be obtained. The material should be readily available, the tissue should be fresh and reasonably free from blood, so rabbits were chosen as experimental animals. They were killed by striking them a sharp blow on the back of the neck and the posterior portion of the animal was perfused with a Ringer-Locke solution until the perfusing liquid was free from color. At this point the rabbit was quickly skinned, the hind quarters removed and the tissue needed separated from the bone. We have assumed that complete removal of the soluble muscle proteins cannot be accomplished unless the tissue is finely subdivided, and have used two methods of grinding, either of which we regard as at least fairly satisfactory. When we first began, the samples were frozen with carbon dioxide and ground in a mortar. A somewhat higher percentage of extraction was obtained when samples were ground in this way but the procedure was tedious, and as the degree of extraction was not of primary importance at the time, this method of grinding was discontinued. Samples were next ground in a Nixtamal mill, which gives a very finely divided sample.

Methods of Extraction.—The samples, either 100 or 125 g. in size, were equally divided between four bottles of 200-cc. capacity and 100 cc. of the extracting solution was added to each bottle. These were gently shaken and allowed to stand for about an hour. The bottles were then centrifuged until the solid material had been thrown down making it possible to pour off the supernatant liquid without loss of tissue and the procedure was repeated until we were ready to discontinue extraction. When the extraction was complete the extract was made to volume, 2.0 liters for a 100-g. sample, 2.5 liters for a 125-g. sample, and filtered through a dry pad of cellucotton on a Büchner funnel. It has been reported frequently that muscle albumin rapidly changes its properties if allowed to stand at ordinary temperatures. For that reason the original samples, and all extracts, were constantly kept packed in a mixture of ice and salt. Nitrogen was determined in the original sample of muscle and in aliquots of the extract.

In studies such as we are reporting the choice of a solvent is of considerable importance, so we tried a large variety of solutions. Some of these were promising, but for various reasons we decided to use only 10% sodium chloride. It uniformly yielded a percentage extraction as high or higher than the other solutions, with the exception of ammonium chloride. In addition we had in mind the possibility of studying the separated proteins by the use of titration curves, and we wished to use a salt that has no buffer action. The hydrogen-ion concentration of the extracting solution was adjusted to a P_H value of about 6, varying between 5.9 and 6.1. The electrometric method was used almost exclusively in making hydrogen-ion determinations.

Separation of Protein.—In our studies of the forms of nitrogen present in muscle extracts, we have considered only three fractions, designated by us as albumin, globulin and non-protein nitrogen. In our preliminary observations various methods of precipitating the globulin were tried. Several of these offer promise but we are only reporting three in any detail: salting-out, dialysis and irradiation with a quartz mercury arc.

As to the salting-out process, several different salts seemed suitable for the purpose and our final choice of sodium chloride was based chiefly on convenience. An additional reason was that the same salt had been used as the solvent.

During our efforts to develop a satisfactory technique for precipitation by dialysis, we attempted the method of electro-dialysis. At first this procedure was regarded as very promising, but it was soon discarded, due to the difficulty of controlling the hydrogen-ion concentration. We finally decided to try dialysis by the usual method, taking such precautions as we might to prevent changes in the solubility of the protein. The dialyzing cell was immersed in ice water and toluene and thymol were added to prevent bacterial action. We believe these precautions are largely effective.

So far as we are aware, exposure to ultraviolet rays has never been used as a method of precipitating proteins quantitatively, though the effect of rays of short wave length on proteins has been reported by a number of investigators. Most of the publications have been reviewed by Clark[4] and by Stedman and Mendel[5] and we are omitting any discussion of individual reports. These contain many discrepancies but there is almost complete agreement on one point: protein solutions are rendered more unstable by irradiation. Some proteins are much more affected than others; for example, albumins are less readily coagulated by irradiation than are globulins. It occurred to us that if our muscle extracts contain two proteins, one might be coagulated more quickly than the other and so separated more or less quantitatively. We made no effort to determine whether or not the effects observed were due entirely to ultraviolet rays. The work of Young[6] suggests that visible rays also may bring about marked changes in the properties of protein solutions.

Precipitation of Muscle Globulin by Saturation with Sodium Chloride.—Since albumins in a concentrated salt solution are precipitated by the addition of acid, it seemed advisable first to determine within what range of hydrogen-ion concentration the globulin could be precipitated without contamination with albumin. Apparently the same amount of protein is precipitated at a P_H of 6, 7 or 8. Distinctly larger amounts are precipitated at a P_H of 5. Prom the standpoint of convenience in manipulation, a P_H of 6 is to be preferred, as the precipitate is always granular in character and easily washed on the filter. At a P_H of 7 the precipitate is slightly gelatinous at times, and at a P_H of 8 it is distinctly slimy and the washing process is very slow. The procedure of salt separation is well known, so we are omitting details of the technique we employed. Typical results are given in Table I.

Separation of Globulin by Dialysis.—Parchment chambers were used for dialyzing cells and in practically every case four aliquots were taken. They were dialyzed against tap water for twenty-four hours, against distilled water for twenty-four hours and then for another twenty-four hours against distilled water of a definite hydrogen-ion concentration. In terms of P_H units these were 4, 5, 6 and 7. After dialysis was complete, the precipitate was used for a nitrogen determination; also, an aliquot of the filtrate was saturated with sodium chloride and the nitrogen content of the precipitate was determined. The sum of these determinations was taken as representing the total globulin. We have explained the possible presence of globulin in the filtrate by assuming that it is held in solution by the albumin or by the non-protein constituents. After dialysis the solution does not give a test for chlorides.

The amount of protein precipitated seemed to be unrelated to the hydrogen-ion concentration of the dialysate, for the amount of protein precipitated in the four cells was approximately the same. There was considerable variation in individual determinations, however, as is shown in Table II.

TABLE II

PROTEIN IN EXTRACT PRECIPITATED BY DIALYSIS

Precipitation by Exposure to Ultraviolet Rays.—A preliminary trial made it quite evident that protein is precipitated from solution by irradiation with a quartz mercury arc, so we attempted to determine whether the method could be used for the quantitative estimation of muscle globulin. Our experience was that the hydrogen-ion concentration of the liquid had to be controlled quite rigidly if precipitation by irradiation was to be satisfactory. At a P_H of 4 or 5 the quantity of protein precipitated was definitely too high. Best results were obtained at a P_H of approximately 6, as precipitation was quite rapid and the precipitate was flocculent and easily washed. At a P_H of 7 or 8 a longer time was required for precipitation and the precipitates were too gelatinous to be filtered and washed satisfactorily. In order to obtain more definite information as to the time required for precipitation, extracts at a P_H of 5.8 were exposed for variable periods of time, one, two, four, six and eight hours. It developed that irradiation for four hours or less is too short a period, and that the quantity of protein precipitated during six or eight hours is about the same.

Determination of Albumin.—The filtrates obtained by the three different procedures for globulin precipitation varied widely in their salt content but all were treated alike for the precipitation of the albumin. They were heated to boiling and sufficient trichloro-acetic acid was added to make the final concentration 2.5%. The nitrogen content of the precipitate was then determined.

Determination of Non-Protein Nitrogen.—The filtrates from the albumin precipitates were taken for nitrogen determinations. This fraction was designated as non-protein nitrogen.

Comparison of Procedures.—Thus far our chief effort has been to obtain evidence that would justify the use of the three methods mentioned, saturation with sodium chloride, dialysis and irradiation with ultraviolet rays. A more critical test of the value of the procedures we have followed is to compare all three of them when applied to the same sample. Our data are tabulated to show such a comparison in Table III.

Inspection of Table III shows that the quantity of globulin precipitated by the three methods agrees within reasonable limits. At a P_H value of approximately 6 all methods give about the same result. Dialysis consistently gives slightly lower results than the other methods, possibly for the reasons mentioned in an earlier paragraph.

Little need be said concerning the albumin determinations, for they obviously depend on the amount of protein estimated as globulin. As a matter of fact the chief value of determinations of albumin and non-protein nitrogen is as a check on the accuracy of the analytical procedures.

We have not made an intensive study of the method of heat separation but, as this procedure may prove useful, we are including a statement of our experience.

Aliquots of the sodium chloride extract (usually 25 cc.) were transferred to 50-cc. centrifuge tubes, then placed in a water-bath maintained at 49°. When the protein solution reached this temperature it was allowed to

TABLE III

A COMPARISON OF THE PROCEDURES USED FOR THE SEPARATION OF MUSCLE PROTEIN

		Method of separation				
		Saturation with NaCl		Irradiation,	Dialysis,	Heat and trichloroacetic

Albumin	19.5	22.2	25.6	33.3	18.7	28.9
Non-protein N	24.1	19.0	13.7	9.8	15.5	16.5

The ratio of globulin to albumin as estimated by our methods is uniformly about 2.5 to 1 and is not in agreement with most of the earlier reports. Thus Streyrer[7] and Saxl[8] both reported considerably more albumin than globulin. Mann[9] in his discussion of this subject says that myogen (albumin) makes up about 80% of muscle albumin. On the other hand, Stewart and Sollman[10] report that paramyosinogen (globulin) is more abundant than myosinogen (albumin).

At various times measurements were made of the hydrogen-ion concen-

tration of the filtrates from the globulin precipitates. We regard these measurements, Table V, as of some interest though they may have no immediate application to our problem.

TABLE V

CHANGE IN HYDROGEN-ION CONCENTRATION AFTER PRECIPITATION OF THE GLOBULIN

Initial PH of extract	4	5	6	7
After saturation with NaCl	4.4 4.4 4.1	4.8 5.3 5.2	5.9 5.8 6.0	6.7 6.7 6.6
	4.3	4.6 5.1 4.8	5.7 5.7 5.7	6.5 6.4 6.7
		4.7 5.3	5.7 5.9	6.7
After dialysis	7.4 7.9 7.5	7.4 7.8 7.1	7.5 7.9 7.5	7.6 7.2 7.9
	6.4 7.0 7.5	6.4 8.4 8.0	6.6 8.3 7.6	6.7 7.6 6.9
	6.3	6.7	6.9	
After irradiation with ultra-violet rays	Ten filtrates shifted from a PH of approximately 5.7 to a PH that varied between 6.8 and 7.			

When globulin was precipitated by saturation with sodium chloride, the PH values were shifted in some cases toward a point between 4 and 5, in others toward a point between 5 and 6. After dialysis the solutions were practically always more alkaline than the distilled water against which they were finally dialyzed.

Measurements of the hydrogen-ion concentration of irradiated solutions were not made unless the globulin was precipitated in a flocculent condition. In such cases the initial PH value was usually a little less than 6, and such solutions always become more alkaline. Our experience agrees with that of Clark[11] who noted that the PH of irradiated solutions increased. Mond[12] observed that the PH shifted toward the isoelectric point. Stedman and Mendel[13] observed that their solutions always became acid, but suggested that this shift was due to the effect on the solvent rather than to any change that occurred in the protein.

Summary

A 10% solution of sodium chloride has been used to extract the soluble proteins of muscle tissue. If the extract is kept near the freezing point the solubility of the proteins changes very slowly.

When the extract is saturated with sodium chloride, irradiated with a quartz mercury arc or dialyzed, a portion of the protein is precipitated, to approximately the same extent by each method. We have assumed that this precipitate is a globulin fraction. Our results indicate that this extract contains about 2.5 times as much globulin as albumin.

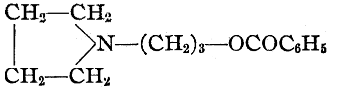
GAMMA-PYRROLIDINO- AND GAMMA-PYRROLINOPROPYL BENZOATES[1]

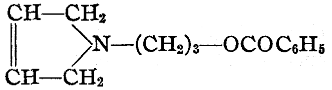
BY LESLIE H. ANDREWS AND S. M. MCELVAIN

RECEIVED OCTOBER 29, 1928 PUBLISHED MARCH 6, 1929

In a previous communication[2] the preparation of a number of substituted piperidino-alkyl benzoates was described. A preliminary pharmacological report on these substances indicated that they possessed local anesthetic action, the compounds in which a methyl group was substituted in the piperidine nucleus being the most efficient pharmacologically. The original purpose of the work which is reported in this paper was to prepare and submit for pharmacological study a corresponding series of compounds containing the pyrrolidine nucleus instead of the piperidine nucleus. However, on account of certain difficulties that are mentioned below, the substituted pyrrolidino-alkyl benzoates have not been prepared as yet, but two new substances, γ-pyrrolidinopropyl benzoate (I) and γ-pyrrolinopropyl benzoate (II) have been prepared and tested pharmacologically. It was thought that the latter compound would be particularly interesting as it would indicate the relative merits of an unsaturated structure in the production of local anesthesia.



I



II

These compounds were prepared by the condensation of γ-chloropropyl benzoate with the secondary amines, pyrrolidine and pyrroline, both of which were obtained by the reduction of pyrrole. Pyrrolidine was prepared by the catalytic reduction of pyrrole with Adams' platinum-oxide platinum black catalyst and pyrroline by the procedure of Knorr and Rabe,[3] which utilized zinc and hydrochloric acid as the reducing agent.

All attempts to reduce catalytically methyl and carbethoxy substituted pyrroles to the corresponding pyrrolidines were unsuccessful. While a small amount of reduction took place initially, the catalyst was soon poisoned and the reduction stopped. The catalyst could not be reactivated to any appreciable extent by shaking with oxygen. McCay and Schmidt[4] have reported a similar unsuccessful attempt to reduce the amide of pyr-

role-carboxylic acid. On account of the negative results obtained in these experiments, the work on the preparation of the substituted pyrrolidinoalkyl benzoates was abandoned for the present.

Pyrrolidine condensed very smoothly with γ-chloropropyl benzoate and the resulting γ-pyrrolidinopropyl benzoate was isolated as the hydrochloride, which melted at 125–126°. In the case of the pyrrolino compound, however, considerable difficulty was experienced in obtaining a pure hydrochloride. It was quite difficult to separate and crystallize this hydrochloride from a reddish oil that accompanied it. It was finally purified and found to melt at 136–138°.

Experimental

Pyrrole.—This compound was prepared by a procedure developed by Katherine Bolliger[5] which is as follows. In a twelve-inch evaporating dish 630 g. (3 moles) of mucic acid was treated with an excess of ammonium hydroxide (about 900 cc., sp. gr. 0.9) and quickly stirred to a smooth paste. It was then evaporated to dryness on a steam cone. The ammonium mucate thus formed was powdered, treated with 250–400 cc. of glycerol, allowed to stand for several hours and then distilled from a 5-liter flask. Distillation was continued until no more oily drops came over. At this point the residue in the flask foamed considerably. The upper layer of the distillate was separated in a separatory funnel and steam distilled until all of the oily, insoluble liquid had passed over. The distillate was washed with water, dried over solid sodium hydroxide and redistilled. It boiled at 128–132° The yield varied from 80-100 g. (40–50%).

The pyrrole so obtained could not be reduced catalytically, but when it was distilled from over sodium in an atmosphere of hydrogen according to the procedure of Willstatter and Hatt,[6] a water-white product with an odor suggestive of chloroform was obtained. There was hardly any loss of pyrrole in this distillation from sodium and the product so obtained yielded to catalytic reduction.

Methylpyrroles.—The α- and β-methylpyrroles were prepared by a modification of the procedure of Oddo and Mameli.[7] To 17 g. (0.7 mole) of magnesium turnings and 200 cc. of dry ether, a solution of 76 g (0.7 mole) of ethyl bromide in 100 cc. of ether was added After the Grignard reagent had formed, a solution of 33.5 g. (0.5 mole) of pyrrole in 100 cc. of ether was added slowly and with constant stirring. The reaction was quite vigorous and had to be carefully regulated. After all of the pyrrole solution had been added the mixture was refluxed for thirty minutes and then a solution of 63 g. (0.5 mole) of dimethyl sulfate in 100 cc. of ether was slowly added. The mixture was then refluxed for one hour, after which it was cooled by an ice and salt mixture. Cold water was then added with stirring until the white salt which formed was completely dissolved. The water and ether layers were separated and the aqueous layer was extracted with an equal volume of ether. The ether was distilled off from the combined ether extracts and the residue steam distilled The pyrrole layer was separated from the water and the latter extracted with ether. The ethereal extract and the pyrrole layer were mixed and the resulting solution dried with anhydrous sodium sulfate, after which the ether was removed by distillation and the basic residue fractionated There were obtained 13 g. of unchanged pyrrole (b. p 125–132°) and 19.5 g. of a fraction that boiled at 132–155°, which consisted of a mixture of α- and β-methylpyrrole This

[6] Willstätter and Hatt, *Ber.*, 45, 1471 (1912).

[7] Oddo and Mameli, *Gazz. chim. ital.*, 43, 504 (1913).

fraction was distilled twice over sodium in an atmosphere of hydrogen before **it was** further used.

α-Carbethoxypyrrole.—This ester was prepared by the procedure of Oddo[8] from pyrryl magnesium bromide and ethyl chlorocarbonate. Although Oddo reported yields of 85–90% of this ester, it was not possible to obtain over 20% yields of the ester that boiled at 130–138° (20 mm.) in this work. On cooling the ester solidified and the solid ester melted at 36–38°.

Pyrrolidine.—A solution of 18 g. of pyrrole (which had been twice distilled from sodium) in 60 cc. of glacial acetic was shaken with hydrogen in the presence of 0.5 g. of Adams' platinum-oxide platinum black catalyst. The absorption of hydrogen was at all times quite slow and would periodically stop, but by shaking the reduction mixture with oxygen the catalyst could be reactivated and the reduction caused to proceed. After forty-five hours an additional 0.3 g. of catalyst was added. After 96–100 hours of shaking the theoretical amount of hydrogen had been absorbed. The platinum was allowed to settle and the dark-colored solution decanted. The acid was neutralized under a reflux with a concentrated solution of sodium hydroxide and then an excess of the alkali added. The alkaline solution was then steam distilled until the distillate no longer gave an acid reaction to litmus paper. The distillate (about 1 liter) was acidified with hydrochloric acid and evaporated to dryness on a steam cone. A dark red, gummy residue remained. This residue was treated with 40% sodium hydroxide and extracted with ether. The ether solution was dried with anhydrous sodium sulfate and then distilled. There was obtained 12 g. of pyrrolidine (63% of the theoretical) boiling at 85–88°. A crystalline hydrochloride of pyrrolidine could not be obtained.

Willstatter and Hatt[6] reduced pyrrole catalytically in glacial acetic acid solution and stated that the solution became deeply colored during the reduction. Hess[9] described the reduction of pyrrole under similar conditions stating that the coloration was coexistent with inhibitory effect and was careful to exclude oxygen from the catalyst, in which cases there was no coloration of the solution. Later, Willstatter and Waldschmidt[10] found that frequent shaking of the catalyst with oxygen is absolutely essential in the reduction of pyrrole. With this latter finding the results of the present work are in agreement, for it was only by frequent shaking with oxygen that the reduction could be caused to proceed.

Pyrroline (Dihydropyrrole).—Ciamician and Dennstedt[11] report the reduction of pyrrole to pyrroline using zinc and acetic acid as the reducing agent. Knorr and Rabe[3] report a similar reduction of pyrrole with zinc and hydrochloric acid at a temperature sufficiently low to prevent the resinification of the pyrrole by the strong mineral acid. Both procedures were tried in this work and it was found that the procedure of Knorr and Rabe gave the better results. Ciamician and Dennstedt report yields of 20% of the theoretical by their method, but it has been possible in this work to obtain 56% yields of pyrroline using a modified Knorr and Rabe procedure, which is as follows.

[8] Oddo, *Gazz. chim. ital.*, 39, I, 649 (1909); *ibid.*, **42,** II, 244 (1912).

[9] Hess, Ber., **46,** 3120 (1913).

[10] Willstätter and Waldschmidt, *ibid.*, 54, 113 (1921).

[11] Ciamician and Dennstedt, *ibid.*, 15, 1831 (1882); *ibid*, **16,** 1536 (1883).

Five hundred cc. of 20% hydrochloric acid is placed in a flask fitted with a mechanical stirrer, dropping funnel and a thermometer, cooled to 0° by means of an ice and salt mixture, and 200 g. of zinc dust is added with vigorous stirring. Fifty g. of pyrrole is then added slowly from a dropping funnel. It is important that the temperature of the liquid be kept low (0–10") at the start, else the speed of reaction will cause the temperature to get out of control. After all of the pyrrole had been added (about one hour), 300 cc. of concentrated hydrochloric acid was added and the stirring continued for two hours longer. The temperature was kept at 15–25° during this time The cooling bath was then removed and the mixture stirred for four and one-half hours at room temperature. The remaining zinc was then filtered off and washed with a little water The filtrate was made sufficiently alkaline to dissolve the precipitated zinc hydroxide and then steam distilled until the distillate was no longer alkaline to litmus. The distillate was made acid with hydrochloric acid and evaporated on a steam-bath. The remaining gummy residue was treated with an excess of 40% sodium hydroxide and extracted twice with ether. This ether extract was dried with anhydrous sodium sulfate and distilled. The pyrroline fraction boiled at 89–92° and weighed 28.5 *g*. There was also obtained 6.5 **g.** of a fraction that boiled at 115–125° (20 mm.). The hydrochloride of pyrroline was obtained crystalline and melted at 162–163°.

Attempted Reduction of **Methylpyrroles** and **α-Carbethoxypyrrole.**—A solution of 8 g. of the methylpyrrole fraction, twice distilled from sodium and boiling at 132–155°, was subjected to catalytic reduction as described above in the preparation of pyrrolidine. In the first twenty minutes there was a rapid absorption of hydrogen amounting to approximately one-eighth of the theoretical amount, but after this initial absorption of hydrogen the reduction stopped and could not be induced to continue either by shaking with oxygen or by the addition of fresh catalyst. Several runs were made with samples of platinum catalyst of known catalytic activity with similar results.

α-Carbethoxypyrrole in acetic acid solution gave practically the same results as the methylpyrroles on catalytic reduction. On account of the extremely small amount of hydrogen that was absorbed, no attempt to isolate a reduction product was made in either case.

γ-Pyrrolidinopropyl Benzoate Hydrochloride.—A mixture of 20 g. (2 moles) of pyrrolidine and 28 g. (1 mole) of γ-chloropropyl benzoate was heated on a steam-bath for one and one-half hours. The reaction mixture, which had separated into two layers, was then diluted with 100 cc. of ether and the oily, insoluble layer of pyrrolidine hydrochloride separated by carefully decanting off the ether solution. The ?-pyrrolidinopropyl benzoate was precipitated from the ether solution as the hydrochloride, which was recrystallized several times from an alcohol–ether mixture. The purified product weighed 14 g. and melted at 125–126°.

Anal. Calcd.: Cl, 13.15. Found: Cl, 13.25, 13.26.

γ-Pyrrolinopropyl Benzoate Hydrochloride.—A mixture of 10 g. (2 moles) of pyrroline and 14 g. (1 mole) of γ-chloropropyl benzoate was heated on a steam-bath for half an hour. The reaction mixture was worked up as described above in the preparation of y-pyrrolidinopropyl benzoate hydrochloride. The hydrochloride of the pyrrolino derivative so obtained was quite difficult to crystallize and was found by analysis to contain a higher percentage (15.05%) of halogen than its formula required, which fact indicated that some pyrroline hydrochloride was mixed with it. Accordingly it was found advisable to shake the crude pyrrolinopropyl benzoate hydrochloride with 10% sodium hydroxide and benzoyl chloride. After this procedure the tertiary amine was reprecipitated from ether as the hydrochloride, which was recrystallized twice from an alcohol-ether mixture and twice from acetone. The product so obtained weighed **3.5** g. and melted at 136–138°.

Anal. Calcd.: 13.25. Found: Cl, 13.58, 13.58

The melting point of a mixture of the pyrrolidino and pyrrolino derivatives was depressed to 75° and it was completely molten at 120°. The latter compound when shaken with dilute potassium permanganate solution caused immediate decolorization, while the former reacted very slowly with this reagent.

Pharmacological Report

γ-Pyrrolidinopropyl benzoate hydrochloride (I) and γ-pyrrolinopropyl benzoate hydrochloride (II) are being studied pharmacologically by Mr. Charles L. Rose of the Lilly Research Laboratories, Indianapolis, Indiana. A preliminary report of this work, given in the table below, includes subcutaneous and intravenous toxicity determinations and measurements of the duration of anesthesia produced by the application of a 2% solution of the anesthetic to the rabbit's cornea. The corresponding values for γ-piperidinopropyl benzoate hydrochloride (III), cocaine and procaine taken from another paper[12] are included for comparison,

TABLE I

PHARMACOLOGICAL DATA

Compound	Av. dur. of anesthesia, min.	Subcutaneous toxicity to white mice (mg./kg.) M. T. D.	M. L. D.	No. of mice used	Intravenous toxicity to white rats (mg./kg.) M. T. D.	M. L. D.	No. of rats used
I	15	400	450	9	17.5	20	9
II	5	1000	1100	11	25	30	8
III	0	400	450	8	15	17.5	10
Cocaine	29	200	250	18	15	17.5	12
Procaine	0	900	1000	17	45	50	10

Discussion of Pharmacological Data

It is seen that the pyrrolidinopropyl benzoate (I) is a much more efficient anesthetic than the compound (III) that contains the piperidine nucleus instead of the pyrrolidine nucleus. This, it seems, would not have been expected, for practically all of the data which are available on the physiological behavior of various types of local anesthetic indicate that in a particular series[13] of compounds the substances of higher carbon content are more active physiologically (considering either toxicity or production of anesthesia or both) than those of lower carbon content. Compounds I and III have very similar structures, the only difference being that III contains one CH_2 grouping more in its cyclic structure than I. The effect of the double bond in II is quite marked, for when compared with I it is seen that

---

[12] McElvain, THIS JOURNAL, 49, 2839 (1927).

[13] For example, in the dialkylamino-alkyl-*p*-aminobenzoate series, an increase in size of the alkyl groups attached to the nitrogen atom causes an increase in both toxicity and anesthetic action [Schmitz and Loevenhart, *J. Pharm. Exptl. Ther.*, 24, 159 (1924)], and in the 1-alkyl-3-carbethoxy-4-piperidyl benzoates and *p*-aminobenzoates an increase in the size of the alkyl group causes an increased anesthetic action with a decreased toxicity [McElvain, THIS JOURNAL, 48, 2179, 2239 (1926)].

this change in structure causes a very great lowering in the physiological activity of the compound.

Summary

1. It has been found that while pyrrole can be reduced catalytically to the tetrahydro derivative, the methyl and carbethoxy substituted pyrroles could not be similarly reduced.

2. γ-Pyrrolidinopropyl benzoate and γ-pyrrolinopropyl benzoate have been prepared and tested pharmacologically as local anesthetics. It was found that the presence of the double bond in the latter greatly reduces its anesthetic activity. The pyrrolidino derivative was shown to have greater anesthetic action than the corresponding piperidino derivative. It is pointed out that this was an unexpected relationship, since data on other series of anesthetics indicated that the reverse should be true.

SOME DERIVATIVES OF TRIMETHYLETHYLSTANNANE

BY RALPH H. BULLARD AND RAYMOND A. VINGEE

RECEIVED OCTOBER 30, 1928 PUBLISHED MARCH 6, 1929

The study of the organic compounds of tin has been continued by investigating certain derivatives of trimethylethylstannane, $(CH_3)_3C_2H_5Sn$.

The hydride, dimethylethylstannane, $(CH_3)_2C_2H_5SnH$, derived from trimethylethylstannane by the substitution of a hydrogen atom for a methyl group, is of particular interest. It is oxidized by the air, being converted into the corresponding hydroxide. The reaction is represented by the equation $2(CH_3)_2C_2H_5SnH + O_2 = 2(CH_3)_2C_2H_5SnOH$. This oxidation is interesting in view of the fact that trimethylstannane, $(CH_3)_3SnH$, prepared by Kraus and Greer[1] is stable in the air, whereas triphenylstannane, $(C_6H_5)_3SnH$, prepared by Chambers and Scherer[2] oxidizes in the air to hexaphenylstanno-ethane, $(C_6H_5)_3SnSn(C_6H_5)_3$, with the formation of water.

Trimethylethylstannane, $(CH_3)_3C_2H_5Sn$.—This compound has been prepared by Cahours[3] from trimethylstannyl iodide and zinc diethyl, and also by Pope and Peachey[4] by the use of the Grignard reaction. The following method may also be used to advantage.

Trimethylstannyl bromide, $(CH_3)_3SnBr$, was dissolved in liquid ammonia and converted into the sodium salt by adding two atoms of sodium per mole of bromide. On adding ethyl bromide slowly the yellow color of the

---

[1] Kraus and Greer, THIS JOURNAL, 44, 2629 (1922).

[2] Chambers and Scherer, *ibid.*, 48, 1054 (1926).

[3] Cahours, Ann., 122, 48 (1862).

[4] Pope and Peachey, *Proc. Chem. Soc.*, 19, 290 (1903).

sodium salt was discharged and trimethylethylstannane was precipitated. The reaction took place as follows: $(CH_3)_3SnNa + C_2H_5Br = (CH_3)_3C_2H_5Sn + NaBr$. The ammonia was allowed to evaporate and water was added. The lower layer of colorless oil was separated, dried over anhydrous calcium chloride and distilled. That portion boiling at 107–108° was collected as the pure stannane; yield, 80%.

Mol. wt. Subs., 0.4158, 0.6448: C_6H_6, 21.30, 21.30; Δt, 0.515, 0.784. Calcd. for $(CH_3)_3C_2H_5Sn$: mol. wt., 192.7. Found: 189.5, 193.1; av. 101.3.

Anal. Subs., 0.3830, 0.5569: SnO_2, 0.2096, 0.4374. Calcd. for $(CH_3)_3C_2H_5Sn$: Sn, 61.60. Found: 61.61, 61.86.

Bromination of Trimethylethylstannane.—The stannane was cooled in running water and the calculated amount of a carbon tetrachloride solution of bromine was slowly added. Bromination took place readily. The reaction mixture was fractionally distilled and the portion coming over at 175–180° was collected.

Anal. Subs., 0.4890, 0.2321, 0.1091: AgBr, 0.3621, 0.1682, 0.0792. Calcd. for $(CH_3)_2C_2H_5SnBr$: Br, 31.02. Found: 31.51, 30.84, 30.85.

Ammonia gas was passed into a carbon tetrachloride solution of dimethylethylstannyl bromide. A white precipitate of the ammonia complex was obtained. This complex salt was not stable, for on standing it softened and the odor of the bromide became evident.

Dimethylethylstannane, $(CH_3)_2C_2H_5SnH$.—Dimethylethylstannyl bromide was dissolved in liquid ammonia and converted into the sodium salt by adding two atoms of sodium per mole of bromide. Excess ammonium bromide was then slowly added. The reaction proceeded as follows: $NaSnC_2H_5(CH_3)_2 + NH_4Br = (CH_3)_2C_2H_5SnH + NaBr + NH_3$. When the reaction was completed, the reaction tube was connected to a receiver immersed in liquid ammonia and the ammonia in the reaction tube was allowed to evaporate. The reaction tube was then warmed in a water-bath at 100° while a slow stream of ammonia gas was passed through the tube. The stannane was thus vapor-distilled from the reaction tube into the cooled receiver. The stannane boils at 90° under atmospheric pressure.

Anal. Subs., 0.4930: SnO_2, 0.4135 Calcd. for $(CH_3)_2C_2H_5SnH$: Sn, 66.42. Found: Sn, 66.07.

Mol. *wt.* Subs., 0.1290, 0.0843: 387 cc. (33.5 and 24.5 mm. at 22°). Calcd. for $(CH_3)_2C_2H_5SnH$: mol. wt., 178.7. Found: 182.9, 177.3; av., 180.1.

Oxidation of Dimethylethylstannane.—In order to preserve the stannane in the pure state it was found necessary to keep it sealed in tubes under nitrogen. The capillary at the end of the tube containing some dimethylethylstannane was broken, thus allowing the air to enter. After a few days the tube contained a mass of white, needle-like crystals which were found to be very hygroscopic.

Anal. Subs,, 0.0883, 0.1382: SnO_2, 0.0681, 0.1072 Calcd. for $(CH_3)_2C_2H_5SnOH$: Sn, 60.96. Found: Sn, 60.75, 61.10.

Dimethylethylstannyl hydroxide was also prepared from dimethylethylstannyl bromide by treating the bromide with 30% sodium hydroxide solution. The reaction mass was extracted with ether, the ether solution dried over anhydrous calcium chloride and the ether removed by boiling under reduced pressure at room temperature. There remained a mass of white crystals which, too, were hygroscopic.

Anal. Subs., 0.2492: SnO_2, 0.1926. Calcd. for $(CH_3)_2C_2H_5SnOH$: Sn, 60.96. Found: Sn, 60.88.

The authors wish to acknowledge their indebtedness to the Warren Fund of the American Academy of Arts and Sciences for a grant which assisted in defraying the expenses of the present investigation.

Summary

1. Trimethylethylstannane has been prepared in yields of 80% by treating sodium trimethyl stannide with ethyl bromide.

2. On brominating trimethylethylstannane a methyl group is removed and dimethylethylstannyl bromide is formed.

3. Dimethylethylstannane has been prepared by treating sodium dimethyl ethyl stannide in liquid ammonia with ammonium bromide.

4. On slow atmospheric oxidation of dimethylethylstannane there is formed dimethylethylstannyl hydroxide.

THE ACTION OF BASES ON CERTAIN MERCURATED ANILINES

BY FRANK C. WHITMORE, E. R. HANSON AND F. L. CARNAHAN[1]

RECEIVED NOVEMBER 2, 1928 PUBLISHED MARCH 6, 1929

A reaction which has received considerable study in this Laboratory is the conversion of mercury compounds of the type RHgX into the so-called "mercuri-bis" compounds of the type R_2Hg, in which both valences of the mercury are attached to carbon.

$$2\,RHgX \rightleftharpoons R_2Hg + HgX_2$$

This reaction readily goes to the left without any special precautions. It can be made to go to the right by a great variety of reagents, such as iodides, sulfides, thiosulfates, cyanides, sodium stannite and metals such as copper and sodium. For some time the working hypothesis in this Laboratory was that the formation of the mercuri-*bis* compounds could be brought about by "any reagent which removes mercuric ions more completely than does sodium hydroxide." This hypothesis proved useful but

---

[1] This work was carried on during the years 1923–1927 under grants from the Public Health Institute of Chicago.

was apparently contradicted by an observation of Pesci[2] that 3-acetoxymercuridimethyl-*p*-toluidine on standing with aqueous ammonia gives the corresponding mercuri-bis compound. After unsuccessful attempts to repeat this work, it was decided to use a more drastic treatment with potassium hydroxide. Indications early were found that certain mercurated dialkylanilines when treated with aqueous alcoholic potassium hydroxide gave traces of the mercuri-bis compounds. Great difficulty was found in applying this generally, however, even in this series. By the use of more concentrated solutions it has been possible to show that the reaction is general for the p-mercurated dialkylanilines. The *p*-acetoxymercuri compounds of dimethylaniline, diethylaniline, di-*n*-propylaniline, di-*n*-butylaniline, methylethylaniline and benzylethylaniline on refluxing with concentrated aqueous alcoholic solutions of potassium hydroxide give the corresponding mercuri-bis compounds.

The general method used in forming the mercuri-bis compound was to reflux for thirty minutes one mole of the mercurated aniline with 32 moles of potassium hydroxide in a solution of **100** moles of alcohol and **100** moles of water. In the case of p-acetoxymercuridiethylaniline only a trace of the mercuri-bis compound was obtained under these conditions. The use of 64 moles of potassium hydroxide gave the desired substance in small quantities.

The yields of the mercuri-*bis* compounds were small under the conditions of the experiments. Quantities large enough for separation and identification were all that were desired. It is no doubt possible to increase the yield greatly by proper variation of the conditions and concentrations.

The chief products accompanying the mercuri-his compounds were organomercuri oxides and hydroxides. The inorganic mercury produced as a result of the formation of mercuri-bis compounds appeared largely as mercurous and mercuric oxides. In the case of *p*-acetoxymercuridimethylaniline the formation of metallic mercury took place. The amount of insoluble material removed by hot filtration of the various reaction mixtures is consistent with the quantity of mercuri-his compound formed. The formation of ethane-hexamercarbide is also possible under the conditions. Mercuric oxide reacts with alcoholic alkali to form this substance. In the case of the action of p-acetoxymercuridimethylaniline with 32 moles of potassium hydroxide, the formation of a small amount of the mercarbide was proved.

The formation of the mercuri-bis compounds by means of aqueous alcoholic potassium hydroxide in the case of mercury compounds containing the $-NR_2$ group is probably very complex in mechanism. Undoubtedly the result is due chiefly to the existence of an alkaline reducing environment due both to the alkylated amines and the potassium ethylate present.

---

[2] Pesci, *Gazz. chim. ital.*, **28**, II, 106 **(1898)**.

The various steps in the reactions may be indicated as follows

$$RHgOCOCH_3 \longrightarrow RHgOH \rightleftharpoons (RHg)_2O \rightleftharpoons R_2Hg + HgO$$

The mercuric oxide is partly reduced to mercurous oxide or mercury and partly converted to the very insoluble ethane-hexamercarbide.

Experimental Part

Crystalline **p-Bromomercuri-aniline,** $BrHgC_6H_4NH_2$.—Five g. of *p*-acetoxymercuri-aniline was refluxed with a solution of 2 g. of sodium bromide in 1500 cc. of water for three hours. A small amount of undissolved material was removed by filtration. On cooling the filtrate deposited colorless, lustrous plates. When dried in air these became slightly greenish; yield, 1.8 g.; m. p. 181°.

Anal. Subs., 0.2112, 0.2206: Hg, 0.1147, 0.1202. Calcd. for C_6H_6NBrHg: Hg, 53.9. Found: Hg, 54.3, 54.4.

Crystalline **p-Iodomercuri-aniline,** $IHgC_6H_4NH_2$.—This substance was prepared similarly to the bromomercuri compound. The fine, flat plates which separated from the hot filtrate were crystallized from 250 cc. of hot alcohol. On drying the crystals assumed a slightly golden tint; yield, 1.2 g.; m. p. 165°.

Anal. Subs., 0.2023: Hg, 0.0971. Calcd. for C_6H_6NIHg: Hg, 47.8. Pound: Hg, 47.9.

Treatment of *p*-Acetoxymercuri-aniline with Potassium Hydroxide.—To a solution of 44.8 g. of potassium hydroxide in 35 cc. of water and 153 cc. of 95% alcohol was added 8.79 g. of *p*-acetoxymercuri-aniline (mercury compound 1 mole, potassium hydroxide 32 moles, alcohol 100 moles, water 100 moles). The mixture was refluxed for thirty minutes. A yellow precipitate was formed during the reaction. This was filtered off, washed with cold water and air dried. Its insolubility in alcohol, ether, chloroform, benzene and acetone, together with the fact that it decomposed on heating, proved that it was not the mercuri-*bis* compound. This is probably the usual compound formed by the action of concentrated alkalies on p-acetoxymercuri-aniline. Its true formula apparently is not known.

p-Acetoxymercuri-di-alkyl-anilines, $R_2NC_6H_4HgOCOCH_3$.—These substances were prepared by mercurating the N-di-substituted anilines with mercuric acetate in a mixture of water, 95% ethyl alcohol and acetic acid. With the last two the reaction mixtures gave no crystals until most of the acid had been neutralized by sodium hydroxide.

[a] Boiled for only ten minutes.

[b] Average of two or more analyses.

[c] Boiled for twenty minutes.

[d] The fact that this product was *p*-mercuri-*bis*-dimethylaniline was confirmed by

refluxing it with mercuric chloride in alcohol. The theoretical yield of *p*-chloromercuridimethylaniline was obtained; m. p., 225°; Hg calcd., 56.3; found, 56.2. Sodium hydroxide under similar conditions gave the same products.

[e] Treatment with mercuric chloride gave the chloromercuri compound; m. p., 164°; Hg calcd., 52.2; found, 51.8.

[f] Mercuric chloride gave the ClHg-compound; m. p., 171°; Hg calcd., 48.7; found, 48.5.

[g] The ClHg-compound was prepared as usual; m. p., 162–163°; Hg calcd., 45.6; found, 45.8.

[h] ClHg-compound, m. p., 165°; Hg calcd., 54.2; found, 53.0.

[i] ClHg-compound, m. p., 150–151°; Hg calcd., 45.0; found, 44.0.

Action of Sodium Ethylate on *p*-Acetoxymercuridiethylaniline.—(a) Four g. of sodium was dissolved in 54 g. of absolute alcohol. To the solution of sodium ethylate thus formed was added a solution of 2 g. of p-acetoxymercuridiethylaniline in 8 g. of absolute alcohol. The mixture was refluxed for twenty minutes. Metallic mercury separated from the reaction mixture. No mercuri-bis compound was obtained.

(b) Eight g. of sodium was dissolved in 94 g. of absolute alcohol and to the solution of sodium ethylate thus formed was added a solution of 2 g. of *p*-acetoxymercuridiethylaniline in 8 g. of absolute alcohol. The mixture was refluxed for twenty minutes. No mercuri-bis compound was detected in the reaction products.

(c) More vigorous treatment with sodium ethylate gave completely unmanageable products.

Preparation of Mercuri-*bis* Compounds from Acetoxymercuri Compounds and Sodium Iodide.—The reactions were carried out in cold acetone solution using an excess of the iodide.

TABLE IV

ANALYTICAL AND OTHER DATA

	Hg-*bis* compound		Mercury, %		
R	Yield. %	M. p., °C.	Calcd.	Found

[a] The melting point was not lowered by mixing with the Hg-*bis* compound obtained by means of alcoholic potassium hydroxide.

[b] The Hg-*bis* compound was further identified by conversion to the ClHg-compound, m. p. 170°.

[c] It was converted to the ClHg-compound, m. p. 161–165°. A 1:1 mixture of the Hg-*bis* and IHg-compounds melted at 100–122°.

[d] The ClHg-compound was obtained from it, m. p. 149–150°. A mixture of the Hg-*bis* and IHg-compounds melted at 110–120°.

Conversion of the Acetoxymercuri Compounds to the Mercuri–bis Compounds by Sodium **Thiosulfate** in cold concentrated aqueous solution.

TABLE V

MERCURI-*bis* COMPOUNDS

R	*Kg-his* compound Yield, %	M. p., °C.	Mercury, % Calcd.	Pound	
Di-n-propyl	**38**	**86**	..	..	..
Di-n-butyl	..	**80– 81**	**33.0**	**31.8**	**32.3**
Methylethyl"	..	132–133[b]	..	..	..
Benzylethyl[a]	**28**	125[b]	..	..	..

[a] The Hg-*bis* compound could not be obtained from the acetoxymercuri compound but was produced in small amount by treating an alcohol suspension of the hydroxymercuri compound with concd. aqueous sodium thiosulfate.

[b] The m. p. was not lowered by addition of known Hg-*bis* compound.

Formation of **Ethane-hexamercarbide.**—(a) A mixture of 7.96 g. of mercuric acetate, 44.8 g. of potassium hydroxide, 35 cc. of water and 153 cc. of alcohol (mercuric acetate 1 mole, potassium hydroxide 32 moles, water 100 moles, alcohol 100 moles) was refluxed for thirty minutes. The residue on hot filtration was washed with water and dilute alkali. It was then digested with 20% nitric acid until it became white. The solid was filtered off, washed with water and digested with potassium hydroxide solution. The residue was filtered, washed with water and air dried. The product was yellowish; yield, 0.64 g. It exploded violently at 230".

(b) p-Acetoxymercuridimethylaniline was treated with 32 moles of potassium hydroxide as above using four times the quantities listed. The residue from hot filtration was treated like that obtained in (a). Ethane-hexamercarbide was separated in a yield of 0.25 g. It exploded violently at 230°.

The formation of ethane-hexamercarbide is no doubt a secondary reaction. Mercuric oxide is set free by the formation of the mercuri-his compound. This reacts with alcohol in the presence of alkali to form ethane-hexamercarbide. No attempt to isolate the substance from other reactions in which mercuri-his compounds were formed was made. The conditions necessary for its formation, however, were satisfied in all cases.

Summary

1. Mercuri-bis compounds of the type R_2Hg have been obtained from six mercurated dialkylanilines by reaction with alcoholic potassium hydroxide, a new reagent for producing this change.

2. Crystalline p-bromomercuri- and *p*-iodomercuri-aniline have been prepared for the first time.

3. Earlier work on mercury derivatives of diethylaniline has been confirmed and extended.

4. Series of mercury derivatives have been prepared from di-n-propyl-, di-n-butyl-, methylethyl- and benzylethylanilines.

5. The conversion $RHgX \longrightarrow R_2Hg$ has also been accomplished in all these cases by means of sodium iodide.

A STUDY OF SOME OF THE REACTIONS OF 3-HYDROXY-6-AMINOTOLUENE AND OF CERTAIN OF ITS DERIVATIVES[1,2]

BY MARSTON TAYLOR BOGERT AND GEORGE HERBERT CONNITT

RECEIVED NOVEMBER 5, 1928 PUBLISHED MARCH 6, 1929

Since this o-amino-m-cresol is an industrial by-product, it seemed desirable to investigate it somewhat more fully as a possible source of useful intermediate or final products.

Because of its p-aminophenol structure, the first line of attack consisted in the synthesis of derivatives analogous to various well-known synthetic drugs, but none of these products have been subjected as yet to pharmacological examination. It is hoped that, since m-cresol is a somewhat stronger antiseptic than phenol, and the toluidines are less toxic than aniline, there may be some advantages in these new products, although Heubner[3] and Rhode[4] have pointed out that the analogous derivatives of *o,o*-dimethyl-p-phenetidine are all inferior therapeutically to those of p-phenetidine itself.

The simple phenacetin homolog, 3-ethoxy-6-acetylaminotoluene, is somewhat more soluble in water than phenacetin. The most soluble derivative of this type prepared in the course of the work was the 3-hydroxyethoxy-6-acetylaminotoluene, which structurally resembles "Pertonal," a drug stated by Cow[5] to be far less toxic than phenacetin, and as antipyretic to possess a much feebler but longer continued action. Like salicylyl-p-phenetidide, the corresponding salicylylaminocresol derivative was too resistant to hydrolysis to hold out much promise as a medicament. "Malakin" is the trade name under which salicylal-p-phenetidine has been marketed. It is stated to be a good analgesic, but too difficultly soluble in water. We synthesized the aminocresol analog and the corre-

sponding hydroxy derivative, but they are likewise but very slightly soluble in water.

Bender[6] and also Chattaway and Orton[7] have shown that acetylated anilines, when treated with hypochlorous acid, give chloro-amino derivatives which are unstable when the positions ortho or para to the nitrogen are either of them unoccupied, and that heating, alone or in solution, causes the halogen to migrate from the nitrogen to the ring. In the case of 3-ethoxy-6-acetyl-aminotoluene, when we applied Bender's method of treatment with hypochlorite, the product was a stable dichloride which lost no halogen when hydrolyzed by concentrated hydrochloric acid and was identified as the 2,4-dichloro-3-ethoxy-6-acetylaminotoluene by ethylation of the 2,4-dichloro-3-hydroxy-6-acetylaminotoluene. Further, the saponification product gave a stable hydrochloride, which would scarcely have been the case if the halogen had been adjacent to the amino group.

Staedel and Kolb[8] have shown that the action of hypochlorous acid on aminocresol hydrochloride yields the toluquinonechlorimide, but we found that excess of hypochorous acid converted the acetylaminocresol into 2,4-dichlorotoluquinone-6-acetimide, the structure of which was proved by its oxidation to 2,4-dichlorotoluquinone and its reduction to the 2,4-dichloro-6-acetylaminocresol, the structures of both of which have been established by Raiford.[9]

The reason for this 2,4-disubstitution is apparently the orienting influence of both the methyl and hydroxy (or ethoxy) groups toward these positions while only the acetylamino group tends to direct the halogen to Position 5. The chlorination thus follows the same course as in m-cresol itself.

Nitration of 3-hydroxy-6-acetylaminotoluene gave the 2,4-dinitro derivative. With the 3-acetoxy-6-acetylaminotoluene, nitration yielded the 5-nitro-acetylamino acetate, unless the reaction was carried out in such a way that some hydrolysis of the acetoxy group occurred, in which event the 3-hydroxy-2,4-dinitro derivative was also formed.

In the case of the 3-ethoxy-6-acetylaminotoluene, nitration in glacial acetic acid solution resulted in a mixture of approximately 85–90% of the 4-nitro derivative with 10–15% of the 5-nitro isomer. That the isomer formed in larger amount was the 4-nitro derivative was proved by the formation of 3-ethoxy-4-nitrotoluene by elimination of the acetylamino group, as well as by its other properties.

For these 6-acetylaminotoluenes, then, the hydroxyl group in Position 3 directs the entering nitro groups to 2 and 4. When the hydroxyl is ethylated, the 4-nitro is the chief product, with only a small quantity of

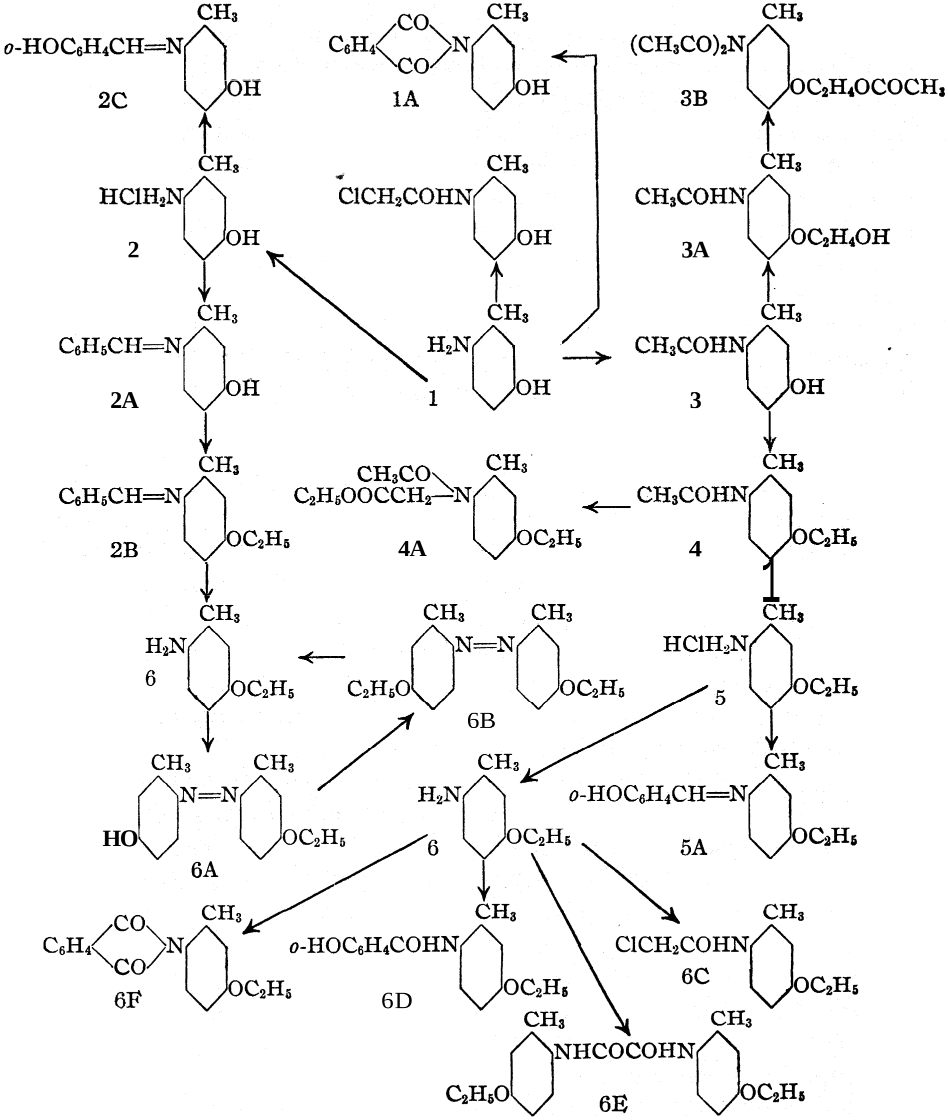
the 5-nitro isomer. But when the hydroxyl is acetylated, the nitro group enters Position 5 practically exclusively.

Nitration of 3-ethoxy-6-acetylaminotoluene with stronger acid, under the same conditions employed for the preparation of the 2,3-dinitro derivative from phenacetin,[10] gave similar results with the 3-ethoxy-6-acetylaminotoluene, the product being the 4,5-dinitro derivative.



Flow Sheet. General Products

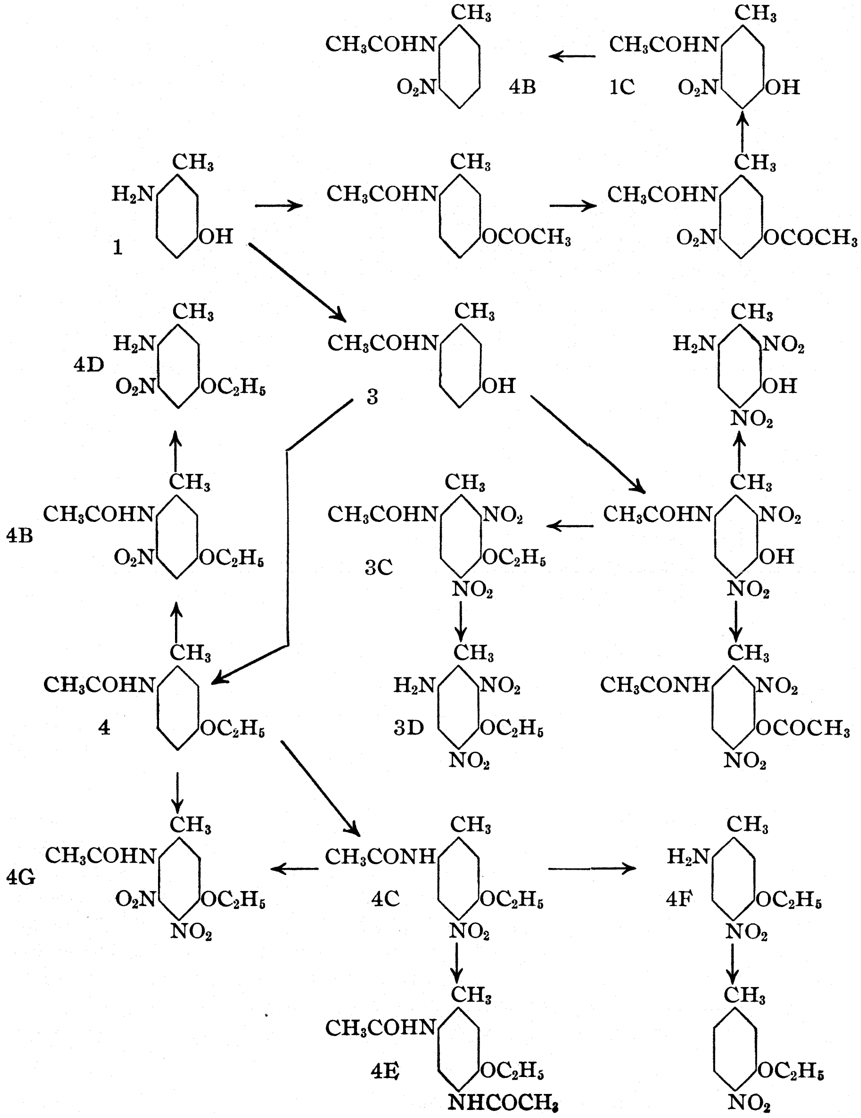
---

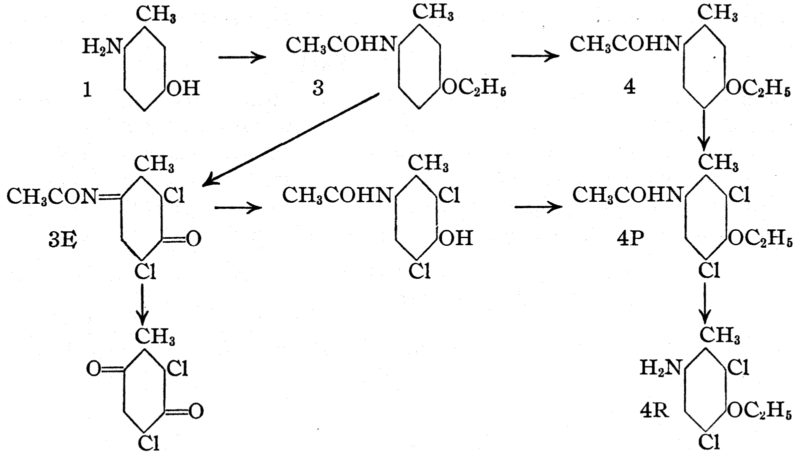
[10] Blanksma, *Rec. trav. chim.*, **27**, 49 (1908).

The synthetic work is presented diagrammatically in the Flow Sheets.

Experimental Part

3-Hydroxy-6-aminotoluene Hydrochloride.—After boiling the crude aminocresol (100 g.) with dilute hydrochloric acid (200 cc. of concentrated acid + 400 cc. of water) until dissolved, the solution was digested for an hour with Norite (40 g.) and filtered hot. As the clear red filtrate cooled, it deposited square, greenish plates whose color faded somewhat on drying. Recrystallized from dilute (1:2) hydrochloric acid, colorless plates were obtained, soluble in water or alcohol, which began darkening above





Flow Sheet. Substituted Products

250° and decomposed at about 290° (uncorr.); yield, about 80%. It was prepared first by Staedel and Kolb,[11] by the reduction of the nitrocresol with tin and hydrochloric acid.

This salt was used as our initial material, rather than the free base, because of its greater stability and the ease with which it could be obtained practically pure.

3-Hydroxy-6-benzalaminotoluene.—To a solution of the aminocresol hydrochloride (10 g.) in water (100 cc.), containing some sodium bisulfite (0.1 g.) to prevent oxidation, there was added an equimolar amount (6.62 g.) of benzaldehyde and slightly more (105%) than the calculated quantity of an aqueous solution of sodium acetate. The mixture was shaken vigorously and frequently during two hours. The pale, tan-colored flocculent precipitate of the crude benzal derivative was crystallized from benzene, alcohol or dilute acetic acid. From benzene it separated in needles, from the other solvents in blades, both forms melting at 135.5° (corr.); yield, practically that calculated.

Anal. Calcd. for $C_{14}H_{13}ON$: C, 79.60; H, 6.20. Found: C, 79.45; H, 6.02.

It proved to be easier to get a pure benzal derivative from the hydrochloride of the aminocresol than from the aminocresol itself. Fusion of this benzal derivative with sulfur gave a resin from which no thiazole could be isolated.

3-Hydroxy-6-salicylalaminotoluene.—When a mixture of 10 g. of 3-hydroxy-6-aminotoluene hydrochloride, 0.5 g. of sodium bisulfite, 7.6 g. of salicylaldehyde and 200 cc. of water was vigorously shaken, a voluminous yellow precipitate separated. An aqueous solution of sodium acetate (6 g. of $C_2H_3O_2Na$) was added and the mass again vigorously agitated, when its color changed rapidly from yellow to a reddish orange. The precipitate was collected, washed with water and dried; yield, practically that calculated. Recrystallized from 60% alcohol, it formed red blades, m. p. 92.5" (corr.), soluble in alcohol, ether, benzene or acetic acid, nearly insoluble in water.

Anal. Calcd. for $(C_{14}H_{13}O_2N)_4\cdot C_2H_6O$: C, 72.95; H, 6.13. Found: C, 72.97; H, 6.19.

---

[11] Staedel and Kolb, *Ann.,* 259, 217 (1890).

These analytical results indicate the presence of alcohol of crystallization. The product was therefore recrystallized from carbon tetrachloride until the m. p. remained constant at 111–111.5° (con.).

Anal. Calcd. for $C_{14}H_{13}O_2N$: C, 73.99; H, 5.77. Found: C, 73.35, 73.30; H, 5.75, 5.75.

Long drying of these crystals at 105° caused some decomposition. Fusion of this compound with sulfur failed to yield any thiazole.

3-Hydroxy-6-acetylaminotoluene.—A solution of 5 g. of the aminocresol in 150 cc. of water was added to one of 10 cc. of acetic anhydride in 2 cc. of glacial acetic acid, the mixture heated to boiling and filtered hot. Ten g. of Norite was added to the filtrate, which was evaporated on the steam-bath to half its volume, filtered and the filtrate allowed to cool. Radiating clusters of leaflets separated, m. p. 80.5° (corr.); yield, 65–70%. This is the mono-hydrate obtained previously by Staedel and Kolb,[11] who carried out the acetylation by the action of acetic anhydride upon the dry base, a less convenient method of preparation. It loses its water above 110° with formation of the anhydrous amide, m. p. 125°.

Its formation is in agreement with the observation of Lumière and Barbier[12] that the acetylation of aminophenols by acetic anhydride in the presence of water gives only the amide.

3-Hydroxy-6-chloro-acetylaminotoluene was prepared by following the procedure used by Jacobs and Heidelberger[13] for the production of the chloro-acetamide of *p*-aminophenol. The crude product (m. p. 121°; yield, 15%) was recrystallized from a benzene–alcohol (95:5) mixture, until the m. p. remained constant at 133–133.5° (corr.). The pure compound formed pale brownish, irregular plates, soluble in alcohol or hot water but only slightly soluble in benzene.

Anal. Calcd. for $C_9H_{10}O_2NCl$: C, 54.16; H, 5.05. Found: C, 53.91; H, 5.17

Phthal-*p*-hydroxy-*o*-tolil.—A mixture of 3-hydroxy-6-aminotoluene (10 g.), phthalic anhydride (12.1 g.) and benzene (100 cc.) was refluxed for an hour, the solvent then distilled off, the residual gummy mass dissolved in hot 95% alcohol (20 cc.) and the solution cooled. The crystals so obtained were recrystallized from 50% acetic acid, in the presence of Norite, and finally from 95% alcohol. The pure compound formed colorless, fine, short needles, m. p. 204° (corr.); yield, 33%.

Anal. Calcd. for $C_{15}H_{11}O_3N$: C, 71.14; H, 4.38. Found: C, 70.90; H, 4.48.

3-Acetyloxy-6-acetylaminotoluene.—After refluxing for an hour a mixture of 100 g. of the aminocresol with 100 cc. of glacial acetic acid, 10 g. of fused sodium acetate and 85 g. of acetic anhydride were added and the refluxing was continued for another hour. The excess of acid (100–125 cc.) was distilled off, 300 cc. of water and 20 g. of Norite added to the residue, the mixture boiled vigorously for a short time and filtered. As the filtrate cooled, long colorless needles separated which were purified by recrystallization from water and then melted at 127.5–128° (corr.); yield, 75%.

Anal. Calcd. for $C_{11}H_{13}O_3N$: C, 63.77; H, 6.28. Found: C, 63.96; H, 6.15.

Nitration of this compound yielded the 5-nitro-acetylamino acetate, unless the reaction was carried out in such a way as to cause some hydrolysis of the acetoxy group, when the 2,4-dinitro-acetylamino *m*-cresol was formed also.

---

[12] Lumière and Barbier, Bull. *soc. chim.*, [3] **33**, 783 (1905).

[13] Jacobs and Heidelberger, THIS JOURNAL, 41,458 (1919).

It dissolved in ether. In water it was less soluble than the hydroxyacetylaminotoluene, but more so than *m*-aminocresol itself. In dilute alkali it dissolved but slowly to a yellow solution which, when neutralized with hydrochloric acid and concentrated, gave the mono-acetyl derivative in a yield almost equal to that calculated. Its aqueous or alcoholic solution was not colored by the addition of ferric chloride.

The same product was obtained by the action of acetic anhydride upon the hydroxyacetylaminotoluene.

2,4-Dichlorotoluquinone-6-acetimide.—A cooled aqueous solution of calcium hypochlorite was poured into an ice cold solution of 3-hydroxy-6-acetylsminotoluene (20 g.) in glacial acetic acid (50 cc.) as long as it caused a precipitate. This yellowish-gray deposit, which gradually became brown and resinous, was collected, washed, dried and extracted with hot carbon tetrachloride. As these extracts cooled, crystals separated which, after repeated crystallization from ether, formed long, yellowish needles, m. p. 159–159.5' (corr.); yield of pure product, 25%.

Anal. Calcd. for $C_9H_7O_2NCl_2$: C, 46.59; H, 3.04. Found: C, 46.20; H, 3.03.

2,4-Dichlorotoluquinone.—The above toluquinone acetimide (1 g.), after standing for an hour with cold dilute chromic acid mixture, was distilled with steam. The quinone which passed over, when crystallized from 30% alcohol, formed golden scales, m. p. 104° (corr.), thus agreeing in crystalline form and m. p. with the reports of Southworth[14] and of Raiford,[15] who prepared the compound in other ways.

2,4-Dichloro-3-hydroxy-6-acetylaminotoluene.—Reduction of the dichlorotoluquinone acetimide was accomplished by passing a slow stream of sulfur dioxide through its suspension in dilute alcohol until the yellow color was discharged. The mixture was warmed with sufficient alcohol to effect solution and filtered hot. As the filtrate cooled, short, colorless needles separated, m. p. 212–212.5° (corr.). Raiford,[15] who prepared the compound by acetylation of the dichloro-aminocresol, found a m. p. of 204–207° (uncorr.) on an impure product.

Anal. Calcd. for $C_9H_9O_2NCl_2$: C, 46.20; H, 3.88. Found: C, 46.29; H, 3.92.

3-Hydroxy-5-nitro-6-acetylaminotoluene.—henitro-acetylaminocresyl acetate described beyond was warmed below 70° with a potassium carbonate solution (1 g. of anhydrous potassium carbonate to 20 cc. of water) until all was dissolved. The resultant red solution was neutralized immediately and carefully with acetic acid and the solution cooled. The greenish-yellow blades which separated were removed, and addition of a few drops of acetic anhydride to the red mother liquor discharged the color and separated a few more of the crystals; total yield, 62%. Recrystallized from 30% alcohol, this product formed greenish-yellow plates, m. p. 188.5° (corr.). Mixed with the initial nitro-acetate, the m. p. was lowered to 150–155°.

Anal. Calcd. for $C_9H_{10}O_4N_2$: C. 51.45; H, 4.80. Found: C, 51.24; H, 4.82.

Treated with strong mineral acids, this amide formed red, viscous oils and gums and no simple hydrolysis was realized.

The use of caustic in place of carbonated alkali in the initial hydrolysis caused deeper seated changes and decomposition, accompanied by the evolution of ammonia.

3-Acetyloxy-5-nitro-6-acetylaminotoluene.—The acetylaminocresyl acetate (15 g.)

---

[14] Southworth, *Ann.*, 168, 270 (1873).

[15] Raiford, THIS JOURNAL, 36, 670 (1914).

was added in small portions to a solution of 15 cc. of fuming nitric acid (sp, gr. 1.6) in 25 cc. of acetic anhydride, while the temperature was maintained below 5°. After the addition of all the acetate, the mixture was left in the freezing mixture for an hour. Crushed ice (300 g.) was then added and the mixture allowed to warm up gradually to laboratory temperature. The fine, yellow precipitate of crude nitro derivative amounted to a yield of 93%. Recrystallized from 50% acetic acid, it formed pale tan blades, m. p. 190–190.5° (corr.).

Anal. Calcd, for $C_{11}H_{12}O_5N_2$: C, 52.38; H, 4.76. Found: C, 52.52; H, 4 90.

The properties of this compound are quite different from those of the 3-acetyloxy-2-nitro-6-acetylaminotoluene described by Brand and Zoller.[16]

In the mother liquors some 3-hydroxy-2,4-dinitro-6-acetylaminotoluene was found, the amount being small unless the nitration was carried out in such manner as to cause considerable hydrolysis of the acetoxy group.

3-Hydroxy-2,4-dinitro-6-aminotoluene.—The dinitro-acetylaminocresol (1 g.) was boiled with concentrated hydrochloric acid (20 cc.) and water (30 cc.) until all was dissolved. The solution was decolorized with Norite, the filtrate from which yielded irregular, pale yellow plates on cooling. These plates lost hydrochloric acid gradually when heated and decomposed very rapidly at 200°.

Anal. Calcd. for $C_7H_7O_5N_3 \cdot HCl$: Cl, 14.20. Found: Cl, 14.34.

The free base was obtained by neutralizing with ammonia the mother liquors from the above hydrochloride and then adding a slight excess of acetic acid. The base precipitated as a red powder, which crystallized from 50% alcohol in blood-red blades, m. p. 166.5–167.5° (corr.). Nietzki and Ruppert,[17] who prepared this compound by the nitration of amino-cresotinic acid ($CH_3,OH,COOH,NH_2 = 1,3,4,6$), gave its m. p. as 160". It is but slightly soluble in water.

Anal. Calcd. for $C_7H_7O_5N_3$: C, 38.54; H, 3.24. Found: C, 38.57; H, 3.60.

3-Hydroxy-2,4-dinitro-6-acetylaminotoluene.—The acetylaminocresol (30 g.) was dissolved in the minimum quantity of glacial acetic acid and added dropwise to a well-cooled mixture of fuming nitric (sp. gr. 1.5) (45 g.) and glacial acetic (15 g.) acids, at such a rate that the temperature was maintained below 5°. After this addition had been completed, the mixture was left in the ice pack for two hours longer and was then poured upon 200 g. of crushed ice. The crude dinitro derivative separated as a yellow powder (yield, 50%), which was removed, washed with water and crystallized from glacial acetic acid, when it formed twinned orange-yellow plates, melting with decomposition at 231° (corr.), somewhat soluble in water.

Anal. Calcd. for $C_9H_9O_6N_3$: C, 42.37; H, 3.56. Found: C, 42.53; H, 3.62.

This method is a modification of that used by Reverdin and Crépieux[18] for the nitration of o-acetotoluidide.

By a different method, employing an acetylamino-m-cresotinic acid as initial material, Nietzki and Ruppert[19] have prepared this same compound and record an uncorrected m. p. of 225°.

---

[16] Brand and Zoller, *Ber.*, 40, 3332 (1907).

[17] Nietzki and Ruppert, ibid., **23,** 3479 (1890).

[19] Nietzki and Ruppert, *ibid.*, **23,** 3478 (1890).

3-Acetyloxy-2,4-dinitro-6-acetylaminotoluene.—After refluxing for four hours a solution of 0.7 g. of the dinitro-acetylaminocresol and a small amount of fused sodium acetate in 5 cc. of glacial acetic acid and 5 cc. of acetic anhydride, the mixture was cooled, diluted with 10 cc. of water, 0.5 g. of Norite added, the refluxing continued for another hour and the mixture filtered hot. As the filtrate cooled, yellowish-green needles separated which were crystallized from 50% alcohol and then melted at 170–170.5° (corr.); yield of pure product, 75%.

Anal. Calcd. for $C_{11}H_{11}O_7N_3$: C, 44.44; H, 3.73. Found: C, 44.40; H, 3.80.

The product was only slightly soluble in water, and its aqueous solution was not colored by the addition of ferric chloride. Nietzki and Ruppert[17] recorded a m. p. of 175° for a diacetyl derivative prepared by the action of acetic anhydride upon the dinitro-aminocresol but gave no analytical figures.

3-Ethoxy-4-nitrotoluene.—The ethoxynitrotoluidine (1 g.) was dissolved in boiling alcohol (20 cc.) and diazotized by adding slightly more than the calculated amount of sulfuric acid and then introducing slowly into the interior of the liquid, by means of a funnel tube, the calculated amount of nitrite dissolved in the minimum quantity of water. The mixture was boiled for five minutes, cooled, concentrated under reduced pressure and the gummy residue distilled with steam. The yellow solid carried over by the steam, crystallized from petroleum ether, gave tan needles (0.3 g.), m. p. 51–51.5°. Staedel and Kolb,[20] who prepared this compound from the silver salt of the nitrocresol and ethyl iodide reported a m. p. of 50–51°.

3-Ethoxy-6-aminotoluene.—When 3-ethoxy-6-benzalaminotoluene (100 g.) was mixed with dilute (50 cc. of concentrated acid to 600 cc. of water) hydrochloric acid. and the mixture distilled with steam as long as benzaldehyde came over, 70% of the calculated amount of aldehyde was collected. The red solution remaining in the distilling flask was neutralized with the calculated amount of sodium hydroxide and a red oil separated, which was collected and distilled, the major fraction coming over at 253–255° as a pale yellow oil which slowly darkened; yield, 83%.

Anal. Calcd. for $C_9H_{13}ON$: C, 71.50; H, 8.67. Found: C, 71.42; H, 8.46.

The compound was only very slightly soluble in water. Staedel and Kayser[21] obtained the same compound by reduction of the corresponding nitrocresyl ether, but merely stated that it resembled in general the corresponding *o*-cresol derivative and was volatile with steam. They also prepared and analyzed its oxalate.

Hydrochloride.—Colorless, large, flat plates, which began to decompose above 200° and melted finally at 212° (corr.); soluble in water or in alcohol.

Anal. Calcd. for $C_9H_{13}ON{\cdot}HCl$; Cl, 18.90: Found, 18.94.

3-Ethoxy-6-benzalaminotoluene.—One mole (10 g.) of 3-hydroxy-6-benzalaminotoluene was ground up with 1.05 moles (1.1 g.) of sodium hydroxide and 2.5 cc. of 95% alcohol. The heat evolved was sufficient to drive off the water and alcohol, leaving a greenish-gray powder. This powder was mixed with 20 cc. of 95% alcohol and 1.5 moles (7.8 cc.) of ethyl bromide, and the mixture refluxed for three hours, after which the alcohol and excess ethyl bromide were evaporated, 100 cc. of water was added to the residue, the heavy red oil which separated was removed and the residual liquid extracted with 20 cc. of benzene to recover the rest of this oil. The oil was washed carefully

---

[20] Staedel and Kolb, *Ann.*, 259,224 (1890).

[21] Staedel and Kayser, ibid., 217,219 (1883).

(to avoid emulsions) thrice with 0.5 N sodium hydroxide solution and then with water to remove the alkali. The washed oil was diluted with benzene (100 cc.), the solution dried over anhydrous sodium sulfate and distilled under diminished pressure, collecting the fraction of b. p. 212–217° (20 mm.); yield, 80%. The product was a bright yellow oil which gradually turned red on standing. It was soluble in alcohol, ether or benzene but not in water or alkalies.

Anal. Calcd. for $C_{16}H_{17}ON$: C, 80.30; H, 7.17. Found: C, 79.66, 79.58; H, 7.17, 7.15.

The same product was obtained when the ethylation was effected with ethyl sulfate instead of ethyl bromide.

The sodium salt of the aminocresol was dried thoroughly at 100–110°, the dry powder stirred slowly into the calculated amount of ethyl sulfate, the mixture heated at 100° for three hours, then diluted with water, the heavy oil separated and treated as described above; yield, 50%, of a product boiling at 210–217° (20 mm.). No thiazole was obtained when this benzal derivative was fused with sulfur.

3-Ethoxy-6-salicylaminotoluene.—When a mixture of 10 g. of 3-ethoxy-6-aminotoluene hydrochloride, 5 g. of sodium acetate, 100 cc. of water and 6.5 *g.* of salicylaldehyde was shaken vigorously, a heavy, yellow oil separated. This was removed and distilled under reduced pressure, collecting the fraction of b. p. 237–238° (16 mm.). On long standing this fraction crystallized in yellow blades which were purified by dissolving them in an ether--alcohol (4:1) mixture and allowing the solvent to evaporate spontaneously. The yellow solid obtained was readily freed from mother liquor by pressing and melted at 48.5° (corr.).

Anal. Calcd. for $C_{16}H_{17}O_2N$: C, 75.28; H, 6.72. Found: C, 75.50; H, 6.57.

Attempts to prepare a thiazole by fusion of this salicylal derivative with sulfur proved unsuccessful.

3-Ethoxy-6-acetylaminotoluene.—A mixture of 5 g. of the acetylaminocresol, 1.6 g. of sodium hydroxide, 3 cc. of ethyl bromide and 150 cc. of 95% alcohol was refluxed for ten hours, the alcohol then distilled off, the residue dissolved in the minimum quantity of hot 20% alcohol, the solution filtered and the filtrate cooled. The crystals which separated, after repeated recrystallization and decolorization, appeared as glistening, colorless needles, m. p. 118.5" (corr.); yield, 80–85%. Kayser[22] and Staedel and Kayser,[21] both of whom prepared it by direct acetylation of the aminocresol ethyl ether, gave the m. p. of this compound as 114°.

The solubility of phenacetin itself in 100 parts of water at 25" is stated as 0.077 part,[23] whereas this homolog dissolves to the extent of 0.28 part.

Anal. Calcd. for $C_9H_{11}O_2N$: C, 68.37; H, 7.83. Found: C, 68.36; H, 7.84.

Attempts to oxidize this toluene derivative to the corresponding benzoic acid by the action of potassium permanganate, either alone or in the presence of magnesium sulfate, proved unsuccessful; nor could we convert it into the corresponding benzaldehyde by Bornemann's[24] modification of the Étard reaction.

---

[22] Kayser, Ber., **15**, 1135 (1882).

[23] U. S. Pharmacopoeia, 10th Revision, **1926.**

[24] Bornemann, *Ber.,* **17**, 1462 (1884).

A similar lack of success attended our efforts to convert it into the 2-methyl-5-ethoxy-indole by the action of sodium ethylate or amylate in a reducing atmosphere, according to the method by which Madelung[25] obtained indoles from the acetyl, benzoyl and oxalyl derivatives of *o*-toluidine. Our products were only intractable tars from which no pure compounds were isolated.

3-Ethoxy-6-chloro-acetylaminotoluene.—To a solution of 15 g. of chloro-acetyl chloride in 30 cc. of benzene, there was added slowly 20 g. of 3-ethoxy-6-aminotoluene in 30 cc. of benzene. After a vigorous stirring of the crystal paste, the benzene (and hydrogen chloride) was evaporated, leaving a yield of crude amide about equal to that calculated. By crystallization from dilute acetic acid, the pure compound was secured in colorless, short, matted needles, m. p. 140.5–141° (corr.).

Anal. Calcd. for $C_{11}H_{14}O_2NCl$: C, 58.03; H, 6.20. Found: C, 57.87; H, 6.16.

When this compound was heated with aluminum chloride, following the method of Stollé,[26] no oxindole was obtained, although StollC accomplished this cyclization with **chloro-acetyl-o-toluidide.**

3-Ethoxy-6-salicylylaminotoluene.—When a benzene (20 cc.) solution of salicylic acid (4.6 g.) was added to a simple solution of 3-ethoxy-6-aminotoluene(5 g.) in benzene (30 cc.), and the flask shaken vigorously, the salt separated immediately. Phosphorus oxychloride (4 cc.) was added and the mixture refluxed as long as hydrogen chloride was evolved. The benzene was evaporated and the residue washed with hot water to remove the phosphoric acid. The soft, resinous mass remaining was dissolved in alcohol. Addition of water (50%) to this alcoholic solution, precipitated the crude amide (4 g.). As repeated crystallization from 75% acetic acid failed to give a colorless product, it was dissolved in 1 *N* sodium hydroxide, the alkaline solution digested with Norite for thirty minutes, filtered, the amide reprecipitated by saturating the filtrate with carbon dioxide, the precipitate washed. dried and recrystallized from alcohol. It was thus obtained in fine, colorless needles, m. p. 153.4–154° (corr.).

Anal. Calcd. for $C_{16}H_{17}O_3N$: C, 70.82; H, 6.32. Found: C, 70.74; H, 6.19.

Oxal-*p*-ethoxy-*o*-toluidide.—If a mixture of 10 g. of 3-ethoxy-6-aminotoluene with 5 cc. of ethyl oxalate was refluxed gently for two hours, or until no more condensate dripped back from the condenser, and was then cooled, it congealed to a cake of the crude toluidide (m. p. 200°); yield, 8.5 g., or 72%. Recrystallized from a 1:1 alcohol–benzene mixture, it yielded long, colorless needles, m. p. 205° (corr.), soluble in alcohol, benzene or ether, but not in water.

Anal. Calcd. for $C_{20}H_{24}O_4N_2$: C, 67.39; H, 6.79. Found: C, 67.45; H, 6.95.

As a by-product there was isolated what appeared to be the substituted oxanilic acid ester but the amount was too small for satisfactory purification and identification.

Experiments designed to transform this toluidide into the 5,5′-diethoxydiindyl, by the method of Madelung,[25] yielded only decomposition products.

Phthal-*p*-ethoxy-*o*-tolil.—A solution of 5 g. of 3-ethoxy-6-aminotoluene and 5 g. of phthalic anhydride in 25 cc. of benzene was refluxed for an hour. As the solution

---

[25] Madelung, Ber., 45, 1128 (1912).

[26] Stollé, J. prakt. *Chem.,* [2] 105, 137 (1923).

cooled, crystals separated which were recrystallized from 80% alcohol until colorless needles were obtained of the constant m. p. 140.5° (corr.); yield, 75%.

Anal. Calcd. for $C_{17}H_{15}O_3N$: C, 72.57; H, 5.38. Found: C, 72.07; H, 5.27.

Ethyl (2-Methyl-4-ethoxyphenyl)-acetylglycinate.—To a solution of 12 g. of 3-ethoxy-6-acetylaminotoluene in 50 cc. of dry benzene, there was added 1.5 g. of metallic sodium and the mixture was refluxed until the sodium had all reacted. At thirty to sixty-minute intervals three portions of ethyl chloro-acetate were added, amounting in all to 10 g., after which the mixture was refluxed for two to three hours longer, cooled, 10 cc. of water added to dissolve the salt formed, the benzene layer separated, the aqueous layer extracted twice more with benzene, the benzene extracts united, dried with anhydrous sodium carbonate and distilled, at first under atmospheric and finally under reduced pressure. A yellow, viscous oil was obtained, b. p. about 210° (15 mm.) which, after repeated rectification, yielded a fraction, b. p. 210–212.5° (22 mm.); yield, 10 g. or 60%.

Anal. Calcd. for $C_{15}H_{21}O_4N$: C, 64.51; H, 7.58. Found: C, 64.25; H, 7.34.

The above procedure is similar to that employed by Paal and Otten[27] for the production of ethyl acetanilido-acetate.

According to a recent German patent,[28] it should be possible to condense such a glycine to an indoxyl and to oxidize this indoxyl to the corresponding indigo but, although we followed the patent specifications closely, this result could not be realized.

2,4-Dichloro-3-ethoxy-6-aminotoluene.—The acetyl derivative (10 g.) was hydrolyzed by refluxing it for four hours with 2 N hydrochloric acid. There resulted a yellow, granular precipitate with red supernatant solution. Sufficient hot water was added to bring all into solution and the color was removed by digesting the solution with Norite. As the filtrate from this Norite cooled, it deposited long, colorless blades of the hydrochloride, which lost hydrochloric acid slowly and turned pinkish. They began to darken at 220° and melted at 244° (corr.).

Anal. Calcd. for $C_9H_{11}ONCl_2 \cdot HCl$: Cl, 13.82. Pound: Cl, 13.78.

The free amine was obtained by the addition of solid ammonium carbonate to a solution of the above hydrochloride and was purified by crystallization from 20% alcohol. It formed irregular plates and scales, m. p. 83° (corr.).

Anal. Calcd. for $C_9H_{11}ONCl_2$: C, 49.11; H, 5.04. Found: C, 49.44, 49.43; H, 5.18, 5.16.

2,4-Dichloro-3-ethoxy-6-acetylaminotoluene.—Bender's[6] procedure for the chlorination of acetanilide was modified as follows.

A hypochlorite solution was prepared from 127 g. (one mole) of calcium hypochlorite and 84 g. (one mole) of sodium bicarbonate in 1 liter of water, which was agitated frequently during three or four hours, then left overnight and finally filtered. This filtrate was added gradually to a cold solution of 10 g. of 3-ethoxy-6-acetylaminotoluene in 30 cc. of glacial acetic acid as long as it caused a precipitate. This required about 200 cc. The amorphous precipitate was crystallized from 50% acetic acid until its

[27] Paal and Otten, *Ber.*, 23, 2594 (1890).

[28] Badische Anilin- und Soda Fabrik, German Patent 188,436 (1907); *Friedlander*, 4, 514.

m. p. remained constant at 162.5–163° (corr.); yield, 10 g. or 75%. The product was soluble in alcohol, benzene or acetic acid, but dissolved very slightly in water.

Anal. Calcd. for $C_{11}H_{13}O_2NCl_2$: C, 50.40; H, 5.00. Found: C, 50.23; H, 5.08.

The same product was obtained by the action of sodium ethoxide and ethyl iodide upon 3-hydroxy-2,4-dichloro-6-acetylaminotoluene.

3-Ethoxy-4-nitro-6-aminotoluene.—When the acetyl derivative of this compound (1 g.) was boiled in 6 *N* hydrochloric acid until solution was complete and this solution was then allowed to cool, colorless plates of the hydrochloride separated which began to darken at 240° and decomposed at 249'. This salt was better defined and more stable than the 5-nitro isomer.

Anal. Calcd. for $C_9H_{12}O_3N_2 \cdot HCl$: Cl, 15.24. Pound: Cl, 15.28.

Neutralization of the mother liquors yielded the free base, which crystallized from 30% alcohol in dark red, columnar form, m. p. 86–87" (corr.).

Anal. Calcd. for $C_9H_{12}O_3N_2$: C, 55.09; H, 6.17. Found: C, 54.91; H, 6.23.

3-Ethoxy-4-nitro-6-acetylaminotoluene.—A solution of 20 g. of the acetylamino cresyl ether in the minimum amount of glacial acetic acid was added very slowly to a well-cooled solution of 20 g. of fuming (sp. gr. 1.5) nitric in 20 cc. of glacial acetic acid, so that the temperature never rose above 0°. After standing for two hours at 0°, the mixture was poured upon 200 g. of crushed ice, the yellow precipitate collected (yield, 55%), washed, dried and recrystallized from 95% alcohol, when it formed yellow plates, m. p. 192.5–193° (corr.).

Anal. Calcd. for $C_{11}H_{14}O_4N_2$: C, 55.47; H, 5.93. Found: C, 55.62; H, 5.93.

The mother liquor from these crystals contained also the 5-nitro isomer (m. p. 160°) to the extent of 10–15% of the total yield. It was separated from the 4-nitro form by fractional crystallization from 20% alcohol, in which solvent the 4-nitro derivative is the less soluble.

The 5-nitro derivative separated in this reaction was identical in all respects with that prepared by the ethylation of the 5-nitro-acetylaminocresol.

3-Ethoxy-5-nitro-6-aminotoluene.—The acetyl derivative of this base was hydrolyzed easily by concentrated hydrochloric acid, forming a red solution from which but little of the hydrochloride separated. The small amount obtained appeared in tan-colored fibers which began to darken above 200°, resinified at about 220°, and decomposed at about 240°.

Anal, Calcd. for $C_9H_{12}O_3N_2 \cdot HCl$: Cl, 15.34. Found: Cl, 14.87.

This salt was rapidly hydrolyzed by water to the free base, which crystallized from 30% alcohol in long orange-red needles, m. p. 101–101.5' (corr.).

Anal. Calcd. for $C_9H_{12}O_3N_2$: C, 55.09; H, 6.17. Found: C, 54.93; H, 6.31.

3-Ethoxy-5-nitro-6-acetylaminotoluene.—Metallic sodium (0.3 g.) was dissolved in absolute alcohol (20 cc.), the nitro-acetylaminocresol (1 g.) was added, followed by ethyl iodide (5 cc.), and the mixture was refluxed until its color changed from red to yellow (about two hours). Water (20 cc.) and Norite (1 g.) were added, the mixture boiled for ten minutes and filtered hot. As the filtrate cooled the crude ethoxy derivative separated in yellow needles which melted at 160° (corr.) after recrystallization from 50% alcohol; yield of crude product, 85%.

Anal. Calcd. for $C_{11}H_{14}O_4N_2$: C, 55.47; H, 5.93. Found: C, 55.56; H, 5.88.

By crystalline form, color and mixed m. p., this compound was proved to be identical with the 5-nitro derivative prepared by direct nitration of the ethoxyacetylaminotoluene.

The failure of our attempts to reduce this nitro derivative to the amine is in agreement with the observations of Bogert and Taylor[29] on the reduction of 3-nitro-4-acetylaminophenetole, and is in further support of the assumption that the nitro is adjacent to the acetylamino group.

3-Ethoxy-2,4-dinitro-6-aminotoluene.—The acetyl derivative of this compound (1 g.) was refluxed for three hours with 6 *N* hydrochloric acid (30 cc.) and Norite (1 g.), and filtered hot. The hydrochloride of the base separated, as the filtrate cooled, in pale yellow, rectangular plates which began to darken above 140° and decomposed at 195–197°.

Anal. Calcd. for $C_9H_{11}O_5N_3 \cdot HCl$: Cl, 12.77. Found: Cl, 12.85.

The mother liquors from the hydrochloride, when treated with ammonia, precipitated the free base as a yellow, flocculent solid which crystallized from 10% alcohol in short, yellow needles, m. p. 96–97" (corr.).

Anal. Calcd. for $C_9H_{11}O_5N_3$: C, 44.82; H, 4.60. Found: C, 44.70; H, 4.70.

3-Ethoxy-2,4-dinitro-6-acetylaminotoluene.—The dinitro-acetylaminocresol (5 g.) was ground in a mortar with anhydrous sodium carbonate (2.5 g.) and a little water (0.5 cc.). The brownish red triturate, after thorough drying, was heated with ethyl sulfate (5 cc.) at 140° for an hour, then cooled, water (50 cc.), alcohol (20 cc.) and Norite (1 g.) were added, the mixture was boiled for a short time and filtered hot. As the filtrate cooled, the ethoxy derivative separated. It was collected and crystallized from 50% alcohol, when it appeared in long, pale yellow needles, m. p. 167–167.5° (corr.); yield, 76% (2.5 g.), calculated on unrecovered cresol, since 30% of the initial material was recovered by acidification of the mother liquors from the crude product.

Anal. Calcd. for $C_{11}H_{13}O_6N_3$: C, 46.65; H, 4.63. Found: C, 46.89; H, 4.74.

3-Ethoxy-4,5-dinitro-6-acetylaminotoluene was prepared by the direct nitration of the ethoxy-acetyltoluidide, by the method of Blanksma,[10] for the analogous phenacetin derivative, following the modifications later suggested by Bogert and Taylor;[29] yield 67%. It crystallized from 95% alcohol in pale yellowish, fine needles, m. p. 257–258° (corr.).

The same product was obtained by subjecting the ethoxy-4-nitro-acetyltoluidide to a similar treatment; yield. 85%. It was insoluble in water and only slightly soluble in alcohol or glacial acetic acid.

Anal. Calcd. for $C_{11}H_{13}O_6N_3$: C, 46.68; H, 4.63. Pound: C, 46.54; H, 4.74.

3-Ethoxy-4,6-diacetylaminotoluene.—When 2 g. of the 4-nitro-ethoxyacetotoluidide was reduced with stannous chloride in hydrochloric acid solution until the yellow color of the solution was discharged, and the tin was then precipitated by hydrogen sulfide, the filtrate darkened so rapidly in the air that the excess of acid was neutralized with sodium carbonate and 5 cc. of acetic anhydride was added; yield of crude product, 57%. It crystallized from 10% alcohol in colorless, short, matted needles, m. p. 200–200.5° (corr.).

Anal. Calcd. for $C_{13}H_{18}O_3N_2$: C, 62.40; H, 7.25. Found: C, 62.09; H, 7.47.

3-Ethoxy-3'-hydroxy-6,6'-azotoluene.—To the solution of the diazonium chloride obtained by diazotizing at 0° 20 g. of 3-ethoxy-6-aminotoluene, there was added a cold

---

[29] Bogert and Taylor, THIS JOURNAL, **49,** 1578 (1927).

solution of 11.5 g. of m-cresol and 15 5 g. of hydrated sodium carbonate in 100 cc. of water. After standing overnight, the tarry precipitate became crystalline. It was removed, washed, dried and crystallized from benzene, when it appeared in long brownish spikes, m. p. 132.5° (corr.); yield, 60%.

Anal. Calcd. for $C_{16}H_{18}O_2N_2$: C, 71.09; H, 6.71. Found: C, 71.15; H, 6.71.

3,3′-Diethoxy-6,6′-azotoluene.—To 300 cc. of absolute alcohol in which 3 g. of metallic sodium had been dissolved, there was added 25.5 g. of 3-ethoxy-3′-hydroxy-6,6′-azotoluene, followed by 25 g. of ethyl bromide. The mixture was allowed to stand overnight and was then refluxed for six hours. The crystals which separated as the solution cooled were ground up in water, to remove all sodium salts, dried and crystallized from benzene. The compound separated in yellow, granular crystals, m. p. 149–149.5° (corr.); yield, 62%.

Anal. Calcd. for $C_{18}H_{22}O_2N_2$: C, 72.46; H, 7.44. Found: C, 72.61; H, 7.60.

3-Hydroxyethoxy-6-acetylaminotoluene.—After dissolving 5 g. of metallic sodium in 200 cc. of absolute alcohol, the solution was well cooled and 35 g. of the acetylaminocresol hydrate was gradually stirred in until all was dissolved. To this solution there was added 20 g. (125% of that calculated) of ethylene chlorohydrin. The mixture was left for twelve hours in a closed vessel at laboratory temperature and was then refluxed for six hours, the alcohol distilled off, 200 cc. of water added to the residue and the mixture again evaporated. A resinous oil separated and gradually congealed. It was treated with hot 95% alcohol, filtered from the sodium chloride and the filtrate as it cooled deposited crystals. By concentration of the mother liquor a second crop of crystals was obtained. Addition of acetone to this second mother liquor precipitated a third crop. These various lots of crystals were combined and recrystallized. From acetone small granular crystals were secured; from water rhomboidal striated plates and blades; yield of purified product, 25%. Both forms melted at 117–117.5° (corr.).

Anal. Calcd. for $C_{11}H_{15}O_3N$: C, 63.16; H, 7.23. Found: C, 62.92; H, 7.11.

In one hundred parts of water at 25° it dissolved to the extent of 4.35 parts.

3-Acetyloxyethoxy-6-diacetylaminotoluene.—The 3-hydroxyethoxy-6-acetylaminotoluene (3.5 g.) and a little sodium acetate were dissolved in acetic anhydride (3 cc.), the excess of anhydride distilled off, the residual solid dissolved in the minimum quantity of hot 30% alcohol, the solution cooled and the crystals which separated recrystallized from the same solvent. The product appeared as fine, colorless needles, m. p. 117° (corr.). Mixed with some of the initial hydroxyethoxy derivative (m. p. 117–117.5°, corr.), the m. p. was 95–109".

Anal. Calcd. for $C_{15}H_{19}O_5N$: C, 61.42; H, 6.52. Found: C, 61.52; H, 6.58.

Summary

1. 3-Hydroxy-6-aminotoluene has been studied as a possible source of useful intermediate or final products.

2. Since it is a homolog of *p*-aminophenol, various new derivatives have been prepared, analogous structurally to such well-known drugs as Phenacetin, Pertonal, Malakin and the like, but the pharmacological properties of these new products have not been determined as yet.

3. Chlorination and nitration of both the hydroxy and the corresponding ethoxy derivatives have been investigated, as well as the reduction products of the nitro derivatives.

4. In the course of the research many new compounds have been synthesized and many old ones prepared by new methods.

5. It was discovered that the benzalamino derivatives of these *p*-aminophenol types offered a very satisfactory form in which to ethylate the phenolic hydroxyl group.

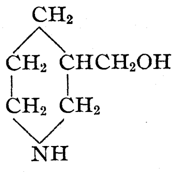
LOCAL ANESTHETICS DERIVED FROM 2-(BETA-HYDROXYETHYL)-PIPERIDINE

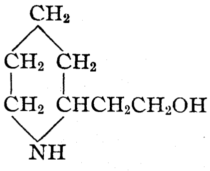
BY C. S. MARVEL AND R. S. SHELTON

RECEIVED NOVEMBER 5, 1928 PUBLISHED MARCH 6, 1929

Recently Sandborn and Marvel[1] have prepared the paminobenzoates of certain N-alkyl derivatives of β-piperidylcarbinol and have found that their monohydrochlorides have a strong local anesthetic action combined with a low toxicity. The close structural relation between β-piperidylcarbinol (3-hydroxymethylpiperidine) (I) and 2-(β-hydroxyethyl)-piperidine (II) suggested that similar derivatives of this second amino alcohol might have desirable pharmacological action.



I



II

The starting material for the preparation of these compounds is a-picoline. By the procedure of Ladenburg[2] this with formalin gave 2-(β-hydroxyethyl)-pyridine, which was reduced to the piperidine derivative by means of sodium and alcohol.[3] The nitrogen atom was alkylated by treatment with the corresponding alkyl halide, following the general method used to alkylate β-piperidylcarbinol.[4] These tertiary amino alcohols were treated with *p*-nitrobenzoyl chloride to give the corresponding ester hydrochlorides, which were in turn reduced catalytically by means of hydrogen and the platinum catalyst of Adams and Shriner[5] to the amino ester hydrochlorides. This reduction gave the best product when glacial acetic acid was used as a solvent. When alcohol was used as a solvent a colorless product was obtained at first but on standing it turned red. When

[5] Adams and Shriner, THIS JOURNAL, 45,2171 (1923).

the reduction was carried out in glacial acetic acid the product remained colorless.

The pharmacological tests were made by Messrs. H. J. Cannon and H. C. Spruth at the Abbott Laboratories,[6] using a 1% solution of the monohydrochloride of each amino ester on the cornea of a rabbit to determine the onset and duration times. Toxicity was determined by intravenous injection in rabbits.

TABLE I

PHARMACOLOGICAL PROPERTIES

Alkyl group	Ethyl	n-Propyl
Average onset, minutes	3	2.25–2.5
Av. duration of anesthesia, min.	15–20	35-40
M.F.D., mg. per kg. of body wt.	Not determined	14–15

It is interesting to note that the difference in structure between these derivatives and those from β-piperidylcarbinol is sufficient to reduce considerably their local anesthetic action. The α-derivatives are slower in their onset time and act for a shorter time than the β-derivatives.

Experimental Part

2-(β-Hydroxyethyl)-piperidine.—From 23 g. of a-picoline and 33 g. of technical formalin heated in sealed tubes at 135° for twelve to fourteen hours, there was obtained 6–7 g. of 2-(β-hydroxyethyl)-pyridine. Reduction of 23 g. of this pyridine derivative with 93 g. of sodium and 1 liter of absolute alcohol gave 13 g. of 2-(β-hydroxyethyl)-piperidine (b. p. 145–146° at 36 mm.). If care was not taken completely to remove the sodium hydroxide solution from the amino alcohol before distillation, there was considerable loss of material due to decomposition.

N-Alkyl 2-(β-Hydroxyethyl)-piperidines.—In a 250-cc. three-necked flask fitted with a condenser, a separatory funnel and a mechanical stirrer, was placed a benzene solution of the amino alcohol, and to it was added from the separatory funnel the alkyl halide. For the methyl derivative methyl iodide was used and the mixture was stirred

TABLE II

PREPARATION AND PROPERTIES OF N-ALKYL 2-(β-HYDROXYETHYL)-PIPERIDINES

Alkyl	Halide, g.	Amino alcohol, g.	N-alkyl yield, g.	B. p., °C.	d_4^{20}	n_D^{20}
Methyl	21	19.5	10	175–178 (35–40 mm.)	0.9840	1.4872
Ethyl	6	12.5	10	136 (27–28 mm.)	.9730	1.4885
n-Propyl	7.5	16	13.5	139–141 (27 mm.)	.9657	1.4905

Since the physical constants were not entirely in agreement with those reported by Ladenburg (ref. 3, pp. 133, 137, 140), the amino alcohols were titrated as a check on their purity.

at room temperature for two days. For the ethyl and *n*-propyl derivatives the alkyl bromides were used and the reaction mixtures were heated for eight hours on a steam-bath. A dark gummy material separated from the benzene in each case. The mixture was treated with excess 40% sodium hydroxide solution and the benzene layer was separated. The aqueous layer was extracted once with benzene and the benzene solutions were combined. The benzene was evaporated and the residue was distilled under reduced pressure. The results of the experiments are given in Table II.

N-Alkyl 2-(β-Hydroxyethyl)-piperidine *p*-Nitrobenzoate Hydrochlorides.—These compounds were prepared according to the usual procedure from the amino alcohols and p-nitrobenzoyl chloride in benzene solution.[1] The compounds separated from the solution as thick, gummy products. They were obtained crystalline by dissolving in absolute alcohol and precipitating with anhydrous ether. The methyl and n-propyl derivatives were especially difficult to obtain in a pure condition and the precipitation had to be repeated several times. The yields were about 55–60%. The results of these experiments are given in Table III.

TABLE III

PROPERTIES AND ANALYSES OF N-ALKYL 2-(β-HYDROXYETHYL)-PIPERIDINE *p*-NITROBENZOATE HYDROCHLORIDES

Alkyl group	M. p., °C.	Subs., g.	0.0549 N AgNO₃, cc.	Empirical formula	Chlorine, % Calcd.	Chlorine, % Found
Methyl	181–182	0.1075	5.88	$C_{15}H_{21}N_2O_4Cl$	10.78	10.66
Ethyl	198–199	.1155	6.13	$C_{16}H_{23}N_2O_4Cl$	10.35	10.34
n-Propyl	124–126	.1020	5.18	$C_{17}H_{25}N_2O_4Cl$	9.94	9.90

N-Alkyl 2-(β-Hydroxyethyl)-piperidine *p*-Aminobenzoate Hydrochlorides.—To a solution of 5 g. of the nitrobenzoyl ester hydrochloride in 200 cc. of solvent was added 0.25 g. of platinum oxide catalyst[6] and the mixture was shaken with hydrogen under about two atmospheres' pressure for about forty-five minutes. The drop in pressure indicated that reduction was complete in about seven minutes. The mixture was filtered to remove the catalyst and the solvent was evaporated. The residue was dissolved in about 75 cc. of absolute alcohol and then about 300 cc. of anhydrous ether was added to precipitate the product. This operation was repeated as often as was necessary to obtain a pure product. When the solvent was absolute alcohol, a nearly colorless product was obtained which turned red on standing. The ethyl derivative was made using this solvent. Glacial acetic acid was used as a solvent for the reduction of the propyl derivative and a better grade of material was obtained, although it was quite difficult to crystallize. The methyl compound has not been obtained in a crystalline form. The properties of the compounds are described in Table IV.

THE PREPARATION OF SYMMETRICAL METHYL ISOPROPYL HYDRAZINE AND METHYL ISOPROPYL DI-IMIDE

BY HERMAN C. RAMSPERGER[1]

RECEIVED NOVEMBER 5, 1928 PUBLISHED MARCH 6, 1929

The author has recently studied the rate of thermal decomposition of the gases of azomethane[2] (dimethyl di-imide) and azo-isopropane[3] (di-isopropyl di-imide). Their decomposition was found to be homogeneous and unimolecular. A study of the mixed azo compound methyl isopropyl di-imide would be valuable in indicating the mechanism of the decomposition and would provide a further test of various theories of unimolecular reactions. This compound had, however, never been prepared, nor had the corresponding hydrazine from which the azo compound could be prepared by oxidation. The preparation of these two new compounds is the first synthesis reported in the literature of a simple mixed aliphatic symmetrical hydrazine or of a mixed aliphatic azo compound.

A method of preparing the hydrazine derivative was suggested by Lochte, Bailey and Noyes.[4] By this method the hydrazone formed by treating methyl hydrazine with acetone would be reduced with hydrogen and colloidal platinum. This procedure was tried. An impure sample of the hydrazone was obtained but it could not be successfully reduced. In this connection it is significant that the reduction of the azine formed from hydrazine and acetaldehyde with hydrogen and platinum catalyst yields a gummy sirup from which no hydrazine derivative could be recovered. This method works well in the preparation of those symmetrical hydrazine derivatives having isopropyl or heavier radicals. It seems likely, therefore, that catalytic reduction will not succeed as a general method for the preparation of the simpler aliphatic hydrazines.

Preparation of Symmetrical Methyl Isopropyl **Hydrazine.**—The successful method is indicated by the following equations

$$C_3H_7(COC_6H_5)N-NH(COC_6H_5) + (CH_3)_2SO_4 + NaOH = C_3H_7(COC_6H_5)N-N(COC_6H_5)CH_3 + NaHSO_4 + CH_3OH \quad (1)$$

$$C_3H_7(COC_6H_5)N-N(COC_6H_5)CH_3 + 2H_2O = C_3H_7NH-NHCH_3 + 2C_6H_5COOH \quad (2)$$

Dibenzoyl isopropyl hydrazine was prepared by the procedure of Lochte, Bailey and Noyes.[4] This was methylated with methyl sulfate to give dibenzoyl methyl isopropyl hydrazine.

The dibenzoyl isopropyl hydrazine was dissolved in the smallest possible amount of 95% alcohol. To this was added with constant stirring equal molal amounts of

methyl sulfate and concentrated sodium hydroxide solution. One-fourth of the total amounts of each were separately added and when in about one hour the alkaline solution became acid, another fourth was added and so on, and finally an excess of 10 to 20% was added. A greater excess decreased the yield. The product was precipitated from solution by adding four volumes of water with constant stirring. The yield of crude product was 80% of that calculated. It melts at 63–6S°. It was purified by dissolving in alcohol and adding water, by crystallizing from ether or by dissolving in ether and adding petroleum ether. The yield was reduced to about 70% and the melting point was then 74–76". Several recrystallizations gave a melting point of 76.25 to 76.75'.

The once purified product was hydrolyzed by adding five times its weight of concentrated hydrochloric acid and heating on a steam-bath. Benzoic acid soon separated quantitatively. The benzoic acid was filtered off and the remaining solution was concentrated to a very small volume under reduced pressure. It was not possible to isolate the hydrochloride salt by taking up the sirupy residue with absolute alcohol. It was found later that this was due to the extremely hygroscopic nature of this salt. When pure symmetrical methyl isopropyl hydrazine was dissolved in dry ether and dry ether containing an equivalent amount of hydrogen chloride was added, a salt formed at once but became pasty due to the absorption of water while being rapidly filtered.

The sirupy residue was treated with concentrated sodium hydroxide solution (1 to 1) in the presence of pure nitrogen gas at reduced pressure (5 to 40 cm.). The methyl isopropyl hydrazine forms an upper layer which is distilled into a vessel containing sodium hydroxide sticks. The first container was then sealed off. After about twenty-four hours the upper liquid layer was distilled into a container with aluminum amalgam, after another twenty-four hours into another container with aluminum amalgam and finally fractionally distilled. The temperature and pressure of each distillation were carefully noted. The yield of pure product was 50%.

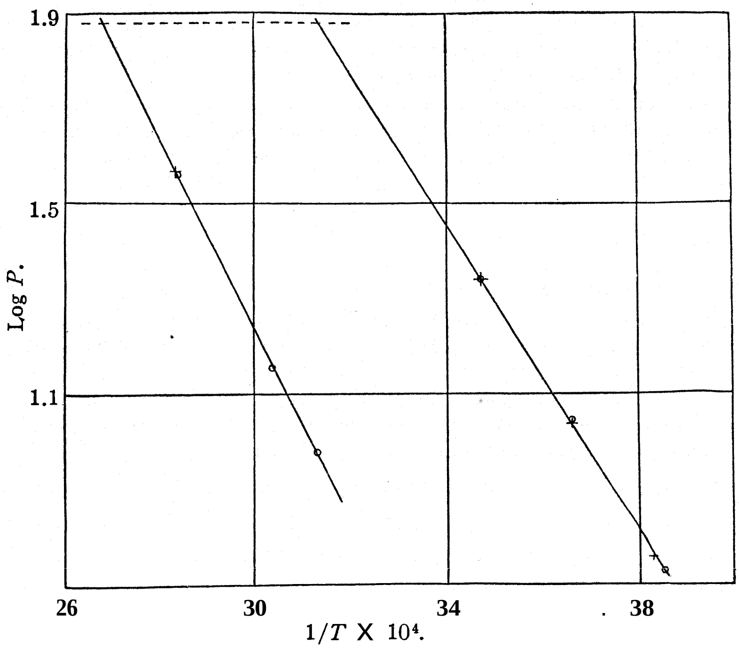
The fractional distillation showed that most of the material distilled between 79.5 and 79.7" at a pressure of 37.1 cm., but the first fourth of it distilled from about 78.0 to 79.5". The lower-boiling fraction probably contained some of the lower-boiling azo compound. Samples of the high-boiling fraction were distilled in vacuum into small bulbs which were used for density determinations and for titrations. Titrations with hydrochloric acid and with iodine by the method of StollC[5] both indicated a purity of 99.7 to 99.8%. The density was 0.7959 ± 0.0005. This value lies between that for symmetrical dimethyl hydrazine (0.8274) and that for symmetrical di-*iso*propyl hydrazine (0.7844). The boiling point under 76 cm. pressure was obtained from the various distillation temperatures and pressures. In Fig. 1 is plotted the logarithm of the distillation pressure in cm. as ordinate and the reciprocal of the absolute temperature of boiling as abscissa. The curve on the left is for methyl *iso*propyl hydrazine and that on the right for methyl isopropyl di-imide. The circles were taken from the data of the last two distillations and the cross is the value obtained from the fractional distillation. Since all of these points fall on the same curve, there was no change in the boiling point during the final treatment with aluminum amalgam. The points fall very nearly on a straight line as required by the Clapeyron equation (if A H is assumed

---

[5] Stollé, *J. prakt. Chem.*, [2] **66**, 332 (1902). See also ref. 4.

constant) and by extrapolation the boiling point at 76 cm. pressure is found to be 100.2 ± 0.5°. This boiling point falls between that of symmetrical dimethyl hydrazine (81°) and that of symmetrical di-isopropyl hydrazine (124.5"). The heat of vaporization as given by the slope of the curve of Fig. 1 is found to be 9150 cal. per mole.

This method of preparation should be applicable for other mixed symmetrical hydrazines.



Pig. 1.

Preparation of Methyl Isopropyl **Di-imide.**—Oxidation of the symmetrical methyl *iso*propyl hydrazine by cupric oxide in the presence of a small excess of concd. hydrochloric acid gave a rather poor yield of the azo compound which was probably contaminated by the higher-boiling isomeric hydrazone. Oxidation of the pure symmetrical methyl isopropyl hydrazine with 30% hydrogen peroxide was more successful. The oxidation was carried out on a vacuum line with about 20 cm. of nitrogen at the start. A 50% excess of hydrogen peroxide was added to the symmetrical methyl *iso*propyl hydrazine. The reaction mixture was surrounded by an ice-bath and allowed to remain for half an hour. Then the pressure was gradually reduced and the methyl isopropyl di-imide distilled out of the solution. The gas passed through a tube containing solid sodium bisulfate and calcium chloride, then through a stopcock and was condensed in a tube immersed in an ether–carbon dioxide snow mixture. The stopcock was closed and the liquid evaporated back and forth between two receivers with a calcium chloride tube between them. Non-condensable gases were pumped off several times. Finally the liquid was distilled through a long, upright tube which was cooled with carbon dioxide snow. The gas was allowed to escape very slowly through a stopcock and was condensed in ether-carbon dioxide mixture. The yield was only about

25%. This was due to the rather small quantities prepared and much was lost in the purification process just described.

The purity and boiling point of the liquid were determined from vapor-pressure data. Vapor pressures were determined at three temperatures before distilling one of the samples and then again after distilling about half of the sample. Two-thirds of the sample was collected for experiments on its thermal decomposition. The vapor-pressure data on this sample are plotted on the right part of Fig. 1. The circles represent the first vapor pressures and the crosses the later ones. It is apparent that there was practically no change in the vapor pressures during distillation, which indicates a pure sample. The boiling point was found by extrapolation to be 46.0 ± 0.5'. The heat of vaporization is 7350 cal. per mole.

Due to the explosive nature of aliphatic azo compounds no analysis was made. The identity of the compound was proved by its properties. It has a slight yellow color and its odor is similar to that of dimethyl di-imide. Its boiling point is between that for dimethyl di-imide (1.5') and that for di-isopropyl di-imide (88.5"). The isomeric hydrazone has a higher boiling point (about 90°). The distinguishing properties of azo compounds given by Lochte, Bailey and Noyes[4] are evidently found in this compound. In addition, its thermal decomposition is a very specific test for an azo compound. Preliminary measurements on its decomposition show that methyl isopropyl di-imide decomposes in a homogeneous, unimolecular manner, giving about two moles for each mole of azo compound. It decomposes at about the same rate at 300" as dimethyl di-imide does at 320° and di-isopropyl di-imide at 280". It deviates from the unimolecular rate constant only at pressures below several millimeters. Dimethyl di-imide deviates at pressures below several cm. while di-isopropyl di-imide does not show a reduction in rate even at 0.25 mm. This new mixed azo compound is therefore intermediate in its thermal decomposition.

The completed experiments on the thermal decomposition will be published later.

Summary

Symmetrical methyl isopropyl hydrazine has been prepared by methylating dibenzoyl isopropyl hydrazine with methyl sulfate and hydrolyzing the product in hydrochloric acid solution. The hydrazine derivative is obtained from the acid solution by adding concentrated sodium hydroxide in an atmosphere of nitrogen. It was dried with aluminum amalgam. Methyl isopropyl di-imide was prepared by the oxidation of this hydrazine derivative with hydrogen peroxide. It is a typical azo compound in physical properties and in its thermal decomposition.

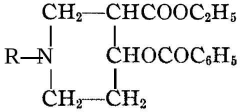
PIPERIDINE DERIVATIVES. VII. 1-ALKYL-4-PIPERIDYL BENZOATES AND PARA-AMINOBENZOATES[1]

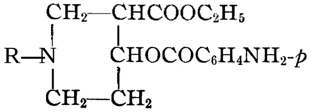
BY N. W. BOLYARD AND S. M. McELVAIN

RECEIVED NOVEMBER 5, 1928 PUBLISHED MARCH 6, 1929

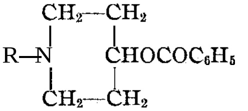
In previous communications[2] two series of piperidine derivatives, the 1-alkyl-3-carbethoxy-4-piperidyl benzoates (I) and the corresponding *p*-aminobenzoates (II) were described These substances are local anesthetics and it was shown that in both series an increase in size of the alkyl group attached to the nitrogen atom caused an increase in the anesthetic activity and a decrease in the toxicity of the compound.



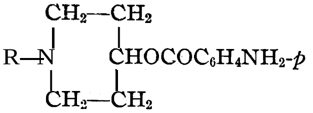
I



II

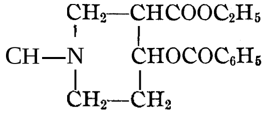


III

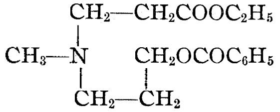


IV

It was desirable, it seemed, to continue the study of this type and to prepare two new series, the 1-alkyl-4-piperidyl benzoates (III) and p-aminobenzoates (IV). These compounds compared as to physiological activity with the former series would show the effect of the presence of the carbethoxy group in the molecule. They would also show whether or not the unusual relationship between the size of the alkyl group attached to the nitrogen and the pharmacological action of the compound that existed in Series I and II could be extended to another series of compounds. Still further relationship between structure and physiological action might be obtained by comparing the first member (where R is methyl) of Series III with 1-methyl-3-carbethoxy-4-piperidyl benzoate (V) and γ-(methyl-β-carbethoxy-ethyl)-aminopropyl benzoate (VI), which have already been described and studied pharmacologically.[3]



V



VI

---

[1] This paper is taken from the thesis submitted by N. W. Bolyard to the Graduate School of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

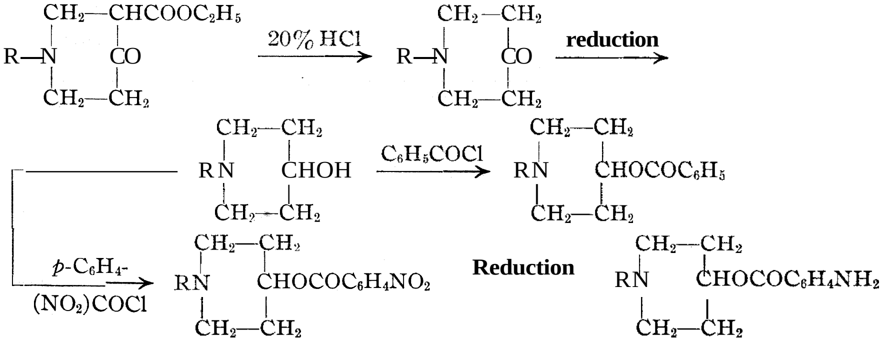
[2] McElvain, THIS JOURNAL, 48, 2179, 2239 (1926).

[3] McElvain, *ibid.*, 46, 1721 (1924).

The pharmacological data indicated that VI was very much less active physiologically than V, from the standpoint of both toxic and anesthetic effects. It was suggested at the time that this difference might be due to the presence of the cyclic structure in V, or to the fact that V contained two points of asymmetry while VI contained none. Consequently it seemed that a pharmacological comparison of these compounds with 1-methyl-4-piperidyl benzoate, in which there is the same cyclic structure that is present in V but no points of asymmetry, would indicate which of these two points of difference was the more fundamental.

In the Series III and IV those compounds in which R is methyl, ethyl, *n*-propyl, *n*-butyl, iso-amyl and phenylethyl have been prepared and submitted for pharmacological study. The phenylethyl derivative was included because it has been found[4] that when this group was attached to the nitrogen in Series II an extremely powerful anesthetic of relatively low toxicity resulted.

These members of Series III and IV were prepared from the corresponding 1-alkyl-3-carbethoxy-4-piperidones.[1] The carbethoxypiperidones were hydrolyzed and decarboxylated by treatment with 20% hydrochloric acid. The 1-alkyl-4-piperidones so obtained were catalytically reduced to the corresponding 4-hydroxypiperidines, which were acylated with benzoyl chloride and *p*-nitrobenzoyl chloride. The *p*-nitrobenzoates were catalytically reduced to the *p*-aminobenzoates. These reactions may be indicated thus



The hydrolysis and decarboxylation of the carbethoxypiperidones took place quite smoothly and yields of 70–92% of the theoretical for the 1-alkyl-4-piperidones were obtained. These piperidones were easily isolated and crystallized as the hydrochlorides. The reduction of these piperidones was carried out using Adams' platinum-oxide platinum black catalyst and proceeded much more rapidly than the reduction of the corresponding carbethoxypiperidones. The latter compounds required about fifty hours for complete reduction, while the 1-alkyl-4-piperidones were

[4] Thayer and McElvain, This Journal, 49, 2862 (1927).

completely reduced in six to eight hours. The resulting 1-alkyl-4-hydroxypiperidones were not isolated as such, but were directly acylated and obtained as the hydrochlorides of the benzoates and *p*-nitrobenzoates and as the monohydrochlorides of the p-aminobenzoates.

Experimental

1-Alkyl-3-carbethoxy-4-piperidone Hydrochlorides.—These compounds were prepared by the internal condensation of **β,β'-dicarbethoxydiethylalkylamines** by sodium in xylene.[1] Due to more careful manipulation of the reaction and isolation of the products, yields of 63–78% of the alkyl derivatives, as compared to 50–60% yields originally reported, and 50% yields of the phenylethyl derivative, as compared to a 40% yield reported by Thayer and McElvain, have consistently been obtained.

1-Alkyl-4-piperidone Hydrochlorides.—To 0.1 mole of the 1-alkyl-3-carbethoxy-4-piperidone hydrochloride was added 120 cc. of 20% hydrochloric acid and the resulting solution refluxed for one hour. At the end of this time no coloration was produced in a ferric chloride solution by a drop of the reaction solution. The latter was then evaporated to dryness under diminished pressure and the residue treated with a few small pieces of sodium hydroxide and just enough water to permit the decomposition of the piperidone hydrochloride. The free piperidone was extracted with three 75-cc. portions of ether and the combined extract dried over anhydrous sodium sulfate. The hydrochloride was then precipitated from the ether solution with dry hydrogen chloride and recrystallized from an alcohol–ether mixture. A summary of these piperidones is given in Table I.

TABLE I

1-ALKYL-4-PIPERIDONE HYDROCHLORIDES

1-*Substituent*	Formula	M. p. (corr.), °C.	Yield, %	Analyses, Cl, % Calcd.	Found
Methyl	$C_6H_{12}ONCl$	94– 95	84	23.71	23.25
Ethyl	$C_7H_{14}ONCl$	105–106	70	21.67	21.80
n-Propyl	$C_8H_{16}ONCl$	117–118	70	19.96	i9.67
n-Butyl	$C_9H_{18}ONCl$	178–180	70	18.50	14.62"
Iso-amyl	$C_{10}H_{20}ONCl$	183–185	70	17.24	17.24
Phenylethyl	$C_{13}H_{18}ONCl$	182–184	92	14.79	11.49[a]

[a] The analyses for the *n*-butyl and phenylethyl derivatives gave values for the percentage of chlorine that were considerably lower than the theoretical. Unusual care was exercised in their preparation and purification but no change in the analytical data could be obtained. The sharpness of their melting points suggested that the low analyses might be due to alcohol of crystallization, but drying in *vacuo* at 100° did not cause any change in weight of the material. The benzoyl derivatives obtained from the reduction products of these piperidones showed the calculated halogen content, so it was assumed that the cause of the abnormal halogen content in the case of the piperidones was not fundamental. .

1-Alkyl-4-piperidyl Benzoate Hydrochlorides.—A solution of 10 g. of the 1-alkyl-4-piperidone hydrochloride in 75 cc. of 95% alcohol was shaken with 0.3 g. of Adams' platinum-oxide platinum black catalyst and hydrogen under a pressure of 2–3 atmospheres. The reduction proceeded quite rapidly and at the end of six to eight hours the theoretical amount of hydrogen had been absorbed. The solution was then separated from the catalyst and the alcohol removed under diminished pressure. To the gummy residue which remained 20 cc. of benzoyl chloride was added and the mixture heated in an oil-bath at 150–165° for one hour. When the benzoylation had finished 25 cc.

of absolute alcohol was added to decompose the excess of benzoyl chloride. The resulting alcoholic solution was diluted with 300 cc. of ether and the precipitated hydrochloride of the 1-alkyl-4-piperidyl benzoate allowed to crystallize. These hydrochlorides were recrystallized from an alcohol–ether mixture. They are summarized in Table II.

TABLE II

1-ALKYL-4-PIPERIDYL BENZOATE HYDROCHLORIDES

1-Substituent	Formula	M. p. (corr.), °C.	Yield,[a] %	Analyses, Cl, % Calcd.	Found
Methyl	$C_{13}H_{18}O_2NCl$	219-220	64	13.87	13.75
Ethyl	$C_{14}H_{20}O_2NCl$	204-205	74	13.15	12.73
n-Propyl	$C_{15}H_{22}O_2NCl$	210-211	83	12.50	12.56

Iso-amyl	$C_{17}H_{26}O_2NCl$	199-200	50	11.38	11.60
Phenylethyl	$C_{20}H_{24}O_2NCl$	236-238	82	10.25	10.17

[a] Recrystallized product based on the piperidone hydrochloride used.

1-Alkyl-4-piperidyl-*p*-nitrobenzoate Hydrochlorides.—These substances were prepared in a manner similar to the benzoates described above except that an equivalent amount of p-nitrobenzoyl chloride was used instead of benzoyl chloride. Acylation took place at a lower temperature (130–145°) in this case. A summary of these p-nitrobenzoate hydrochlorides is given in Table III.

TABLE III

1-ALKYL-4-PIPERIDYL-*p*-NITROBENZOATE HYDROCHLORIDES

1-Substituent	Formula	M. p. (corr.), °C.	Yield, %	Analyses, Cl, % Calcd.	Found
Methyl	$C_{13}H_{17}O_4N_2Cl$	197-199	40	11.79	11.71
Ethyl	$C_{14}H_{19}O_4N_2Cl$	204–206	53	11.27	11.20
n-Propyl	$C_{15}H_{21}O_4N_2Cl$	219-220	48	10.79	11.01
n-Butyl	$C_{16}H_{23}O_4N_2Cl$	242-243	48	10.35	10.30
Iso-Amyl	$C_{17}H_{25}O_4N_2Cl$	243-245	52	9.94	10.15
Phenylethyl	$C_{20}H_{23}O_4N_2Cl$	242-244	55	9.08	9.08

1-Alkyl-4-piperidyl-*p*-aminobenzoate Hydrochlorides.—A solution of 5 g. of the nitrobenzoate hydrochloride in 75 cc. of 95% alcohol was shaken with 0.25 g. of Adams' platinum-oxide platinum black catalyst and hydrogen at 2–3 atmospheres' pressure. The absorption was so rapid that the theoretical amount of hydrogen was taken up in a few minutes. The shaking was continued for one hour to insure complete reduction. The catalyst was then filtered off and the solution evaporated nearly to dryness under diminished pressure. The aminobenzoate was precipitated as the monohydrochloride by the addition of 200 cc. of ether to the concentrated alcoholic solution and it was allowed to crystallize. These hydrochlorides were readily recrystallized from an alcohol–ether mixture. They are summarized in Table IV.

TABLE IV

Pharmacological Report

The 1-alkyl-4-piperidyl benzoates and p-aminobenzoates are being studied pharmacologically by Mr. Charles L. Rose of the Lilly Research Laboratories, Indianapolis, Indiana. A preliminary report of this work is summarized in Table V. The anesthetic efficiencies were determined in the usual way by application of a 2% solution of the hydrochloride to the rabbit's cornea and noting the duration of anesthesia. Both intravenous and subcutaneous toxicity measurements were made. For comparison the corresponding values that have been obtained for the 1-alkyl-3-carbethoxy-4-piperidyl benzoates and *p*-aminobenzoates with the same 1-substituent are given in parentheses in the table. The data for procaine and cocaine are also included.

TABLE V

Discussion of the Pharmacological Data

It will be seen from the data in Table V that the 1-alkyl-4-piperidyl benzoates as a group show a greater anesthetic effect and have very much lower toxicities than the corresponding p-aminobenzoates, while in the series in which there is a 3-carbethoxy substituent in the piperidine nucleus the *p*-aminobenzoyl derivatives show a greater anesthetic effect than the benzoyl derivatives. The carbethoxy group apparently is responsible for this variation in physiological effect.

The 1-alkyl-4-piperidyl benzoates and *p*-aminobenzoates also show the unusual relationship between the size of the alkyl group attached to the nitrogen and toxicity of the compound that was observed in the series containing a 3-carbethoxy substituent. Although the differences are not so great in the new series, it is evident from the data in Table V that in both series an increase in the size of the alkyl group attached to the nitrogen causes an increase in anesthetic effect and a decrease in subcutaneous toxicity.

Particular attention is called to the phenylethyl derivatives, especially 1-phenylethyl-4-piperidylbenzoate. This compound possesses about seven times the anesthetic power of cocaine, a subcutaneous toxicity approximately equal to procaine and an intravenous toxicity intermediate between that of cocaine and procaine. So far as the authors know there is no local anesthetic that approaches this substance in its ability to produce and sustain anesthesia of the rabbit's cornea.

A comparison of the pharmacological data for 1-methyl-3-carbethoxy-4-piperidyl benzoate with those for 1-methyl-4-piperidyl benzoate indicates that there is no apparent connection between the physiological action and the points of asymmetry which are present in the molecule. The latter compound has no asymmetric carbon atoms and is more active than the former which has two such carbon atoms. It would seem, therefore, that one possible explanation that was advanced[3] for the difference in the physiological activity of 1-methyl-3-carbethoxy-4-piperidyl benzoate and γ-(methyl-β-carbethoxy-ethyl)-aminopropyl benzoate (V and VI) was of little or no significance. Such a conclusion, however, is not entirely justified when 1-methyl-3-carbethoxy-4-piperidyl-*p*-aminobenzoate and 1-methyl-4-piperidyl-p-aminobenzoate are considered, for in this case the former with two points of asymmetry is much more active than the latter with no such points of asymmetry. This variation may be due to the presence or absence of the carbethoxy group or to the points of asymmetry in the molecule which the presence of the carbethoxy group causes. The greater the number of different series of compounds that are considered, the more difficult it appears to attribute physiological action to any particular point of structure. Generalizations which fit one series may be quite inapplicable to another. It is probable that the entire molecule functions in producing a certain physiological effect, and what appear to be important structural groupings so modify the effect of each other when they are present in the same molecule that generalizations are extremely difficult, if not impossible.

Summary

1. Two new series of piperidine derivatives, 1-alkyl-4-piperidyl benzoates and *p*-aminobenzoates, have been prepared and described.

2. The members of these series are local anesthetics and show the same relationship between the size of the alkyl group and pharmacological action of the compound as was found to exist in the 1-alkyl-3-carbethoxy-4-piperidyl benzoates and *p*-aminobenzoates.

3. The phenylethyl-4-piperidyl benzoate is a very potent local anesthetic, possessing about seven times the anesthetic power of cocaine and considerably less toxicity.

4. The relationship between physiological action and certain types of structure is discussed.

IMPROVEMENTS IN THE METHOD FOR THE PREPARATION OF MERCURY DIALKYLS FROM ORGANOMAGNESIUM HALIDES

BY HENRY GILMAN AND ROBERT E. BROWN

RECEIVED NOVEMBER 9, 1928 PUBLISHED MARCH 6, 1929

One of the best methods for the preparation of mercury dialkyls is the reaction between mercuric chloride and the Grignard reagent. Marvel and Gould[1] have described the preparation of several mercury dialkyls by this general reaction. They added the powdered mercuric chloride (about 100 g.) through a condenser in 5- to 10-g. lots over a period of about forty-five minutes and found that a large excess of Grignard reagent and long heating were apparently necessary in order to obtain good yields.

Having a need for large quantities of some mercury dialkyls in connection with studies of magnesium dialkyls, we found that a few variations markedly improved the yields and made the method somewhat more convenient. First, the extra manipulation involved in finely powdering the mercuric chloride and adding it in small portions can be obviated by the use of a Soxhlet extractor. Second, the time of heating was extended from ten to twelve hours to twenty to twenty-four hours. Third, a larger volume of ether was used. These alterations in procedure reduced the tendency of caking and they can be applied to similar reactions involving reactants that are sparingly soluble in ether.

Experimental Part

The reactants were used in the proportions described by Marvel and Gould.[1,2] The Grignard reagent, prepared in 500 cc. of ether, was carefully decanted from the excess magnesium into a two-liter, three-necked flask fitted with an efficient stirrer and a Soxhlet extractor, on top of which was connected a long condenser provided with a drying tube filled with a mixture of calcium chloride and soda lime. The stirrer used was of the

---

[1] Marvel and Gould, THIS JOURNAL, 44, 153 (1922). This article contains a review of earlier work. The authors are indebted to Dr. C. S. Marvel for the suggestion that extended heating would improve the yields. Marvel and Hager, *ibid.*, 48, 2689 (1926) obtained a 90% yield of mercury di-n-heptyl from mercuric chloride and n-heptylmagnesium bromide after a four-day period of refluxing. Marvel and Calvery, ibid., 45,820 (1923), extended the method to the preparation of branched-chain mercury dialkyls.

[2] Although an excess of Grignard reagent is desirable for higher yields, it is possible that the liberal excess used in these experiments can be reduced.

centrifugal type.[3] It consists of a section of glass tube **0.75** inch in diameter and 1.25 inches long with a hole about **0.5** inch in diameter in the center. This is fused opposite the hole onto a glass rod.

The unpowdered mercuric chloride was placed in an extraction thimble and the Grignard reagent was diluted to one liter with anhydrous ether. The flask was warmed by a water-bath until gentle boiling started. The ether solution of mercuric chloride siphoned over into the reaction flask. Care was taken that the ether solution of mercuric chloride did not strike the side of the flask.[4] When all the mercuric chloride had dissolved, usually after about four hours with **100** g. of material, the extractor was removed and the condenser was attached directly to the flask.[5] The temperature of the water-bath was increased to 55–60° and refluxing was continued for an additional eighteen to twenty hours. The reaction mixture was then cooled by an ice-bath and **400** cc. of water was slowly added from a dropping funnel. The ether layer was separated and the water layer was extracted with **50** cc. of ether. After drying the combined ether extracts with calcium chloride, the ether was removed by distillation and the mercury dialkyls fractionally distilled in *vacuo.*

In the following table the time of refluxing includes the four-hour period generally required to extract the mercuric chloride.

TABLE I

MERCURY DIALKYLS

Alkyl bromide	G.	Moles	Magnesium G.	Magnesium Atoms	Mercuric chloride G.	Mercuric chloride Moles	Reflux, hours	Mercury dialkyls, G.	Mercury dialkyls, yield[b] %
Ethyl[a]	125	1.15	30	1.23	97	0.32	22	80	86.5
Ethyl	125	1.15	30	1.23	97	.32	24	82	88.7
Ethyl	250	2.30	60	2.46	194	.64	24	164	88.7
Ethyl	250	2.30	60	2.46	194	.64	24	162	87
n-Butyl[c]	134	0.98	25	1.03	97	.32	16	58.5	52
n-Butyl	134	.98	25	1.03	97	.32	28	75	66.7
n-Butyl	134	.98	25	1.03	97	.32	28	74	66

[a] The mercury diethyl distilled at 65–66° (**18** mm.) uncorrected.

[b] Marvel and Gould (ref. **1**) obtained yields of mercury diethyl ranging from **61** to 75% and their yield of mercury di-n-butyl was 47%. Dr. Marvel has recently carried out some promising experiments on mercury di-n-butyl by first preparing the butyl-mercury halide and then treating this with an excess of Grignard reagent. Also, Mr. Hager obtained excellent yields of mercury di-n-butyl by using a special apparatus for the addition of mercuric chloride. The advantage of the Soxhlet extractor is its general availability.

[c] The mercury di-n-butyl was distilled twice from a Claisen flask provided with a specially indented fractionating side-arm of about **6** inches height to separate the mercury n-butyl halides, of which a considerable quantity was recovered in the distilling flask. The mercury di-n-butyl distilled at 116–118° (**18** mm.). It is probable that the yield of mercury dialkyls can be increased significantly by a more protracted period of refluxing.

---

[3] "The Preparation of Synthetic Organic Chemicals at Rochester," Eastman Kodak Co., see Fig. **21,** p. **26.**

[4] If this solution strikes on or close to the side of the flask, caking may result.

[5] It is probably not necessary to remove the Soxhlet extractor but this was always done. A second condenser may be attached to the other neck of the flask if this is necessary to condense all of the ether vapor.

Summary

Improved directions are given for the preparation of mercury dialkyls from organomagnesium halides.

THE SUPPOSED ALPHA,BETA,BETA-TRIMETHYLGLUTARIC ACID OF NOYES AND SKINNER

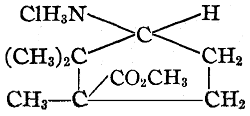
BY FRANCIS EARL RAY

RECEIVED NOVEMBER 15, 1928 PUBLISHED MARCH 6, 1929

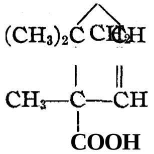
Introduction

In a previous paper[1] an attempt was made to elucidate the course of the reaction which occurs when the methyl ester of iso-aminocamphonanic acid, I, is decomposed by nitrous acid.

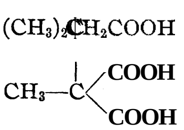
It was thought by Noyes and Skinner[2] that the reaction gave, in part, the unsaturated compound, II, because on oxidation of this product with alkaline permanganate and decomposition with heat, an acid was obtained which was considered to be α,β,β-trimethylglutaric acid, IV.



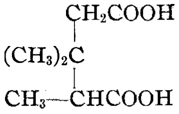
I



II



III



$$\begin{array}{l} \quad CH_2COOH \\ (CH_3)_2C \\ CH_3{-}CHCOOH \end{array}$$
IV

It was shown[1] that the acid obtained was not α,β,β-trimethylglutaric acid. The suggestion that α,β,γ-trimethylglutaric acid might be formed by the migration of one of the 0-methyl groups was also disproved.

As it then seemed probable that IV was α,α,β-trimethylglutaric acid, Dr. Skinner suggested[3] that a methyl group might migrate from the β- to the a-position when carbon dioxide is liberated by heat from III. It is this possibility with which the present investigation deals.

Discussion

Perkin and Thorpe[4] had obtained α,β,β-trimethylglutaric acid by decomposing the ethyl ester of α,β,β-trimethyl-α-cyanoglutaric acid with hydrochloric acid in a sealed tube at 200° without isolating the intermediate α,β,β-trimethyl-α-carboxyglutaric acid. It seemed possible that this vigorous treatment might prevent a migration that would take place under the influence of heat alone.

---

[1] Ray, THIS JOURNAL, 50, 558 (1928).

[2] Noyes and Skinner, *ibid.*, 39, 2692 (1917).

[3] Private communication.

[4] Perkin and Thorpe, J. *Chem.* Soc., 75, 65 (1899).

Accordingly, the a,β,β-trimethyl-α-carboxyglutaric acid was prepared after many attempts and decomposed by heat. It gave, however, the α,β,β-trimethylglutaric acid, showing no evidence of the migration of a methyl group.

An examination of Dr. Skinner's analytical data[2] for the tricarboxylic acid shows that they correspond to an acid of molecular weight 193 or 194. As trimethylcarboxyglutaric acid has a molecular weight of 218, the explanation of the reaction was based on an error in the interpretation of the analytical data.

The analytical data of Noyes and Skinner seem to indicate that their tribasic acid was a carboxydimethylsuccinic acid, but the melting point of their dibasic acid does not correspond to the melting point of either the unsymmetrical or the fumaroid or maleinoid form of the symmetrical dimethylsuccinic acid. The nature of their acid, and of the unsaturated isomer of lauronolic acid from which it was obtained, must be considered uncertain.

Experimental Part

Diethylacrylic Ester.—This ester was prepared from *iso*-amyl alcohol by oxidation with dichromate, bromination, esterification and removal of hydrobromic acid by boiling with quinoline; b. p. 60–65" (5 mm.).

β,β-Dimethyl-α-cyanoglutaric Ester.—Fifty-four g. of dimethylacrylic ester, 60 g. of cyanoacetic ester, 12 g. of sodium and 200 cc. of absolute alcohol dried with magnesium methylate were boiled for fifteen hours; 75 g. of methyl iodide was added and the mixture heated for five hours. In other experiments the mixture with methyl iodide was heated in a pressure flask from six to twenty-four hours. On saponification with potash and decomposition an acid was obtained that melted at 99–100°.[5] The analysis showed that the third methyl group did not enter the molecule.

Anal. Subs., 0.2002: H_2O, 0.1364; CO_2, 0.3853. Calcd. for $C_7H_{12}O_4$: H, 7.50; C, 52.50. Found: H, 7.62; C, 52.49.

This difficulty was finally overcome by methylating in an'alcohol-free ether or in a benzene solution.

α,β,β-Trimethyl-α-carboxyglutaric Acid.—This acid was not isolated by Perkin and Thorpe.[4] They obtained only compounds containing nitrogen on heating the ester with potash. In a previous paper[1] it was shown that prolonged boiling with strong potash is necessary to obtain the acids from these esters. In this case, after boiling the ester for twenty hours with 50% potash, the solution was evaporated to dryness and heated to 120° for ten hours. The dry salt was washed with ether, dissolved in water, acidified and extracted with ether. On spontaneous evaporation of the ether the mass crystallized. It was recrystallized, first from hydrochloric acid and then from benzene. After nine recrystallizations it melted at 189–190° with evolution of carbon dioxide.

After heating for thirty minutes at 200°, the mass was recrystallized four times from benzene; m. p. 86°. Perkin and Thorpe[4] give 86–87° for α,β,β-trimethylglutaric acid.

Anal. Subs., 0.0587: Ag, 0.0325. Calcd. for $Ag_2C_8H_{12}O_4$: Ag, 55.64. Found: Ag, 55.40.

---

[5] Perkin and Goodwin give 101° for β,β-dimethylglutaric acid, *J. Chem. Soc.*, ***60***, 1472 (1896).

The writer expresses his thanks to Professor W. A. Noyes for advice and help during the progress of this investigation.

Summary

The explanation given by Noyes and Skinner for the formation of the unsaturated acid obtained by the decomposition of iso-aminocamphonanic acid with nitrous acid is shown to be based on an erroneous interpretation of the analytical data.

No member of the trimethylglutaric acid series is formed on oxidation of this unsaturated acid.

The decomposition of α,β,β-trimethyl-α-carboxyglutaric acid proceeds normally, giving α,β,β-trimethylglutaric acid whether decomposition is effected by heat alone or by heating the ester with hydrochloric acid in a sealed tube at 200".

SYMMETRICAL DIPHENYL-TETRA-TERTIARY-BUTYLETHYNYLETHANE

BY S. S. ROSSANDER AND C. S. MARVEL

RECEIVED NOVEMBER 16, 1928 PUBLISHED MARCH 6, 1929

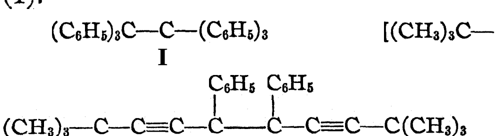
As the first step in a study of the effect of acetylenic groups on the stability of the ethane linkage in a hexa-substituted ethane, Salzberg and Marvel[1] have prepared hexa-*tert.*-butylethynylethane (II). This hydrocarbon was found to be stable toward oxygen and in this respect to differ very markedly from the hexa-aryl ethanes. However, it did react with 1% sodium amalgam to give tri-*tert.*-butylethynylmethyl sodium. This reaction indicates that this hexa-substituted ethane has a central linkage that is about as easily ruptured with metals as that in hexaphenylethane (I).

$(C_6H_5)_3C-C-(C_6H_5)_3$

I

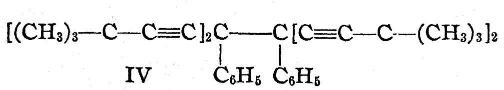
$[(CH_3)_3C-C\equiv C]_3C-C[C\equiv C-C-(CH_3)_3]_3$

II



$$(CH_3)_3-C-C\equiv C-\underset{C_6H_5}{\overset{C_6H_5}{C}}-\underset{C_6H_5}{\overset{C_6H_5}{C}}-C\equiv C-C(CH_3)_3$$

III



$$[(CH_3)_3-C-C\equiv C]_2\underset{C_6H_5}{C}-\underset{C_6H_5}{C}[C\equiv C-C-(CH_3)_3]_2$$

IV

For further information concerning these acetylenic derivatives a study of the compounds intermediate between hexaphenylethane and hexa-*tert.*-butylethynylethane has been made. **A** hydrocarbon $C_{38}H_{38}$, which may be *sym.*-tetraphenyl-di-*tert.*-butylethynylethane (III), was described

---

[1] Salzberg and Marvel, THIS JOURNAL, 50, 1737 (1928).

by Salzberg and Marvel.[2] This hydrocarbon was much more stable than was expected for one with the structure represented by Formula III.

In the present paper the preparation and properties of *sym.*-diphenyl-tetra-*tert.*-butylethynylethane (IV) are described. This hydrocarbon was produced by the action of silver on phenyl-di-*tert.*-butylethynylbromomethane. It is stable in oxygen and shows no tendency to form a peroxide. When a solution is heated, color develops and this color does not disappear when the solution is cooled. It is changed by heat but apparently does not rearrange to a solid stable compound as does hexa-*tert.*-butylethynylethane. It reacts with 40% sodium amalgam and with liquid sodium–potassium alloy to give the alkali metal derivative of phenyl-di-*tert.*-butylethynylmethyl. It does not react with 1% sodium amalgam.

There is little doubt concerning the structure of this hydrocarbon, since the alkali metal derivatives obtained by splitting the ethane can be converted into phenyl-di-*tert.*-butylethynylacetic acid. For comparison this acid was prepared from phenyl-di-*tert.*-butylethynylbromomethane by the Grignard reaction.

If the reaction between silver and phenyl-di-*tert.*-butylethynylmethyl bromide is carried out in the presence of oxygen, the ethane is not produced. Instead, oxygen is absorbed and only tarry products are left when the solvent is removed. The amount of oxygen absorbed is greater than would be needed for the formation of a peroxide. This absorption of oxygen is similar to that observed in the cask of diphenyl-*tert.*-butylethynylbromomethane. It is especially interesting in this connection to note that in the reaction of tri-*tert.*-butylethynylbromomethane with silver no oxygen is absorbed.

Experimental Part

Phenyl-di-*tert.*-butylethynylcarbinol.—The Grignard reagent was prepared from 20 g. of *tert.*-butylacetylene by adding it from a separatory funnel to 75 cc. of a 4.116 N ether solution of ethylmagnesium bromide. The heat of the reaction caused the ether to reflux and an efficient condenser filled with water at about 5° was needed to avoid loss of the acetylene. To the ether solution of the Grignard reagent was added 23 8 g. of ethyl benzoate. The best results were obtained by adding half of the ester, stirring for three or four hours and then adding the second half of the ester over a period of two hours. The mixture was stirred for two hours longer and then it was decomposed by pouring into an ice-cold solution of saturated ammonium chloride. The ether layer was separated, dried over anhydrous sodium sulfate, filtered and the solvent evaporated. The residue was distilled under reduced pressure. The product boiled at 135–139° (1.5 mm.). This product solidified after standing at 0° for about ten days. The material was recrystallized by dissolving in petroleum ether and cooling the solution in carbon dioxide snow. The yield of recrystallized carbinol was 10–12 g. (55–64% of the theoretical amount); m. p. 46–47°.

Anal. Subs., 0.2182: CO_2, 0.6788; H_2O, 0.1745. Calcd. for $C_{19}H_{24}O$: C, 85.02; H, 9.03. Found: C, 84.84; H, 8.96.

---

[2] Salzberg and Marvel, THIS JOURNAL, 50,2840 (1928).

This carbinol was rearranged to the α,β-unsaturated ketone by dissolving 1 g. in 6 cc. of glacial acetic acid and adding to the solution 1 cc. of concentrated sulfuric acid. The mixture was poured into cracked ice and the ketone was extracted with ether. The ether was concentrated to about 10 cc. and cooled in carbon dioxide snow. The ketone was separated as yellow crystals. After four recrystallizations a product was obtained which melted at 108–110°. An ether solution of this product did not react with sodium. The yield was only 0.5 g.

Anal. Subs., 0.1074: CO_2, 0.3346; H_2O, 0.0865. Calcd. for $C_{19}H_{24}O$: C, 85.02; H, 9.03. Pound: C, 84.96; H, 9.00.

Phenyl-di-*tert*.-butylethynylbromomethane.—Three g. of the carbinol was dissolved in 20 cc. of dry ether and the solution was cooled to 0°. Then 1 g. of phosphorus tribromide was added and the solution was stirred at 0° for one-half hour. To the mixture was added 100 cc. of 10% sodium bicarbonate solution and stirring was continued for ten minutes. The ether layer was separated, dried over sodium sulfate and evaporated under reduced pressure. The residue was dissolved in the least possible amount of absolute ether and 8 cc. of absolute alcohol was added. This solution was again evaporated under reduced pressure until crystals appeared and was then allowed to stand at about 0° overnight until the bromo compound had crystallized. It was collected on a filter and then again crystallized from ether and alcohol. After drying in a vacuum desiccator there was obtained 2.4 g. (60% of the theoretical amount) of a white crystalline product; m. p. 58–59°.

Anal. Subs., 0.2431: CO_2, 0.6152; H_2O, 0.1502. Subs., 0.2011: 3.9cc.of0.1540 N $AgNO_3$. Calcd. for $C_{19}H_{23}Br$; C, 68.85; H, 6.99; Br, 24.13. Found: C, 69.00; H, 6.91; Br, 24.15.

The filtrates from this bromo compound were evaporated to dryness and the residue was heated with acetone and then recrystallized. A few colorless crystals melting at 169–174° were obtained. The product contained bromine but not enough material was isolated for further identification.

***Sym*.-diphenyl-tetra-*tert*.-butylethynylethane.**—A solution of 2.048 g. of phenyl-di-*tert*.-butylethynylbromomethane in 10 cc. of absolute ether was shaken with 2 g. of molecular silver for twenty-four hours. The solution was filtered and evaporated under reduced pressure almost to dryness. To the residue was added 8 cc. of absolute alcohol and the evaporation was continued until crystals began to form. The mixture was cooled to 0° for a few hours and filtered. The yield of hydrocarbon was 0.75–0.9 g. (40–50% of the theoretical amount). After recrystallization from ether and alcohol it melted at 98–99°.

Anal. Subs., 0.2010: CO_2, 0.6700; H_2O, 0.1670. Calcd. for $C_{38}H_{46}$: C, 90.85; H, 9.24. Found: C, 90.91; H, 9.22.

A solution of 0.4 g. of the ethane in 15 cc. of bromobenzene at about 100° was shaken in an atmosphere of oxygen for six hours. No absorption of oxygen was observed. The solution did turn yellow at 100° but the color did not disappear on cooling.

Effect of Heat on the Hydrocarbon.—A solution of 0.2 g. of the ethane in 4 cc. of hexane was heated in a sealed tube at 100° for one hour. The solution became light yellow and the color remained when the solution was cooled.

A solution of 0.22 g. of the ethane in 4 cc. of absolute alcohol was heated in a sealed tube to 100° for one hour. The solution became intensely yellow. The color did not disappear on cooling. On working up the solution 0.14 g. of the ethane was recovered.

A solution of 0.4 g. of the ethane in 15 cc. of xylene was refluxed gently for one hour. The solution turned dark red in color. When the solution was evaporated and the residue crystallized from alcohol and ether, 0.19 g. of the ethane was recovered. There was some oily residue which did not crystallize. A solution of 0.2 g. of the ethane in xylene was heated in a sealed tube to 140° for one hour. The color was yellow when air was thus excluded. From this reaction 0.1 g. of the ethane was recovered.

Cleavage of the Ethane with Alkali Metals,—A solution of 0.55 g. of the ethane in 10 cc. of dry ether was shaken with 5 cc. of liquid sodium–potassium alloy in an atmosphere of *dry* nitrogen. The solution turned red in about thirty seconds and was very deeply colored in one and one-half minutes. After twenty-four hours an excess of moist carbon dioxide was passed in until the solution became clear. The mixture was heated with 50 cc. of water containing 5 g. of potassium hydroxide. The mixture was heated to evaporate the ether and then cooled and filtered. The solution was cooled to 0°, acidified with dilute hydrochloric acid and a white precipitate of organic acid separated. After repeated crystallization from petroleum ether and methyl alcohol (using Norite to decolorize each solution), there was obtained a small amount of acid, m. p. 154-156". This was found to be identical with phenyl-di-*tert.*-butylethynylacetic acid described below.

A solution of 1 g. of the ethane in 10 cc. of dry ether was shaken with 8 cc. of 40% sodium amalgam in an atmosphere of dry nitrogen. After about twenty seconds the surface of the alloy was tinged with red and the solution was yellow. After about eighty seconds the solution turned red. After shaking for twenty hours the mixture was decomposed with moist carbon dioxide and the acid isolated as described above. The yield of crude acid, which was still yellow in color, was 0.73 g. (56% of the theoretical amount). The recrystallized material melted at 154–156°. In the crystallization it was found that much of the yellow color was absorbed on the filter paper on allowing the crude material to stand in a funnel.

Anal. Subs., 0.2031: CO_2, 0.6040; H_2O, 0.1467. Calcd. for $C_{20}H_{24}O_2$: C, 81.08; H, 8.17. Found: C, 81.11; H, 8.08. *Neutral equivalent.* Subs., 0.1025: 2.85 cc. of 0.1215 N NaOH. Calcd. for $C_{20}H_{24}O_2$: 296.2. Found: 293.4.

When a solution of 0.1 g. of the ethane in 10 cc. of ether was shaken with 3 cc. of 1% sodium amalgam in an atmosphere of dry nitrogen for three days, no color was developed. Practically all of the ethane (0.082 g.) was recovered on evaporation and crystallization of the residue.

Phenyl-di-*tert.*-butylethynylacetic acid.—To prove the structure of the acid obtained by splitting the ethane with alkali metals, phenyl-di-*tert.*-butylethynylacetic acid was prepared from phenyl-di-*tert.*-butylethynylbromomethane. This was accomplished by the action of 40% sodium amalgam on the bromide to give the sodium derivative of phenyl-di-*tert.*-butylethynylmethyl which, with carbon dioxide, gave the acid and also by the action of magnesium and carbon dioxide on the bromide.

A solution of 1 g. of phenyl-di-*tert.*-butylethynylbromomethane in 10 cc. of dry ether was shaken with 4 cc. of 40% sodium amalgam in an atmosphere of dry nitrogen for twenty-four hours. The solution was then treated with moist carbon dioxide as described under the splitting of the ethane. The acid was isolated as before and the yield was 0.6 g. (66% of the theoretical amount). This product after several recrystallizations from petroleum ether and methyl alcohol melted at 154–156° and showed no depression in melting point when mixed with the acids obtained by splitting the ethane with sodium–potassium alloy or 40% sodium amalgam.

Anal. Subs., 0.1890: CO_2, 0.5606; H_2O, 0.1344. Calcd. for $C_{20}H_{24}O_2$: C, 81.08; H, 8.17. Found: C, 81.05; H, 7.95. *Neutral equivalent.* Subs., 0.1006: 2.8 cc. of 0.1215 N NaOH. Calcd. for $C_{20}H_{24}O_2$: 296.2. Found: 295.0.

The same acid was obtained by the action of carbon dioxide and magnesium on the bromide. To a solution of 2 g. of phenyl-di-*tert.*-butylethynylbromomethane in 10 cc. of dry ether was added 0.15 g. of magnesium and about 0.01 g. of iodine. The mixture was stirred and a slow current of dry carbon dioxide was passed over the surface of the ether. More ether was added from time to time as it evaporated. After about five hours the mixture was decomposed with dilute hydrochloric acid and the organic acid was extracted from the ether with a solution of 5 g. of sodium hydroxide in 50 cc. of water. The acid was reprecipitated and the yield of crude acid was about 1 g. After recrystallization it melted at 154–156° and showed no depression in the melting point when mixed with the acid prepared from the ethane by splitting with alkali metals and treating with carbon dioxide.

When an attempt was made to prepare the Grignard reagent from the bromide first, and then to convert it to the acid by the action of carbon dioxide, only the ethane was obtained.

Reaction of Phenyl-di-*tert.*-butylethynylbromomethane and Silver in an Atmosphere of Oxygen.—A solution of 0.5 g. of the bromide in 5 cc. of ether was treated with 0.5 g. of molecular silver in an atmosphere of dry oxygen. The reaction mixture was shaken by hand from time to time. In about ten hours the reaction mixture had absorbed the theoretical amount of oxygen (18.4 cc. at 25° and 745 mm.) for the formation of a peroxide. In twelve hours a total of 25.5 cc. of oxygen was absorbed. No further absorption occurred in four hours more. The solution was evaporated under reduced pressure but only oily products were obtained.

Another run of 0.2 g. of the bromide was made and the reaction was discontinued when the theoretical amount of oxygen had been taken up by the reaction mixture. No crystalline products were isolated on evaporation of the solution.

Summary

1. *Sym.*-di-phenyl-tetra-*tert.*-butylethynylethane has been obtained by the action of silver on phenyl-di-*tert.*-butylethynylbromomethane.

2. The hydrocarbon reacts with 40% sodium amalgam or with liquid sodium–potassium alloy to give the alkali metal derivative of phenyl-di-*tert.*-butylethynylmethyl. The ethane does not react with 1% sodium amalgam.

3. The properties of this hydrocarbon are intermediate between those of hexa-*tert.*-butylethynylethane and of the hydrocarbon $C_{38}H_{38}$ obtained by the action of silver on diphenyl-*tert.*-butylethynylbromomethane.

NITROGEN TRICHLORIDE AND UNSATURATED ACIDS

BY GEORGE H. COLEMAN AND GEORGE M. MULLINS[1]

RECEIVED NOVEMBER 17, 1928 PUBLISHED MARCH 6, 1929

The addition of nitrogen trichloride to unsaturated hydrocarbons,[2] unsaturated ketones,[3] and diphenylketone[4] has been reported previously.

Nitrogen trichloride also reacts with unsaturated acids to form small yields of stable addition products and large amounts of nitrogen and chlorine. The chlorine is taken up in part by the excess of unsaturated acid present. Very small amounts of ammonium chloride are formed and in this respect the reaction differs from most of the other reactions of nitrogen trichloride with unsaturated compounds.

The reaction was studied with crotonic acid and cinnamic acid. With crotonic acid the α-chloro-β-dichloro-aminobutyric acid first formed is converted by the hydrochloric acid produced in the solution to β-amino-α-chlorobutyric acid, which precipitates slowly from the carbon tetrachloride solution as the hydrochloride. A similar precipitation of the hydrochloride has been observed with benzalacetone,[3b] methylpropene[2b] and toluene,[5] although this is not characteristic of many of the reactions of nitrogen trichloride with unsaturated compounds. At 20° ten days or longer is required for the complete precipitation of the hydrochloride. It seems probable, however, that the primary addition takes place more rapidly than this. At lower temperatures a longer time is required for the completion of the reaction, but the yields are better and the product slightly purer. The free aminochloro acid was prepared from the hydrochloride and its structure established by reduction to β-aminobutyric acid.

In the case of cinnamic acid the limited solubility of the compound in carbon tetrachloride made it necessary to use a suspension of the finely powdered acid and required the separation of the product from the excess cinnamic acid. Carbon tetrachloride is probably the best solvent for use with nitrogen trichloride, particularly when the reaction mixture is to stand several days. The reaction rate of cinnamic acid is not far different from that of crotonic acid. The dichloro-amino group again enters the β-position. The structure of the product was established by reduction to β-amino-β-phenylpropionic acid.

Experimental

The Reaction of the Crotonic Acid

The Preparation of the Hydrochloride of β-Amino-α-chlorobutyric Acid.—Nitrogen trichloride was prepared and analyzed as described in previous papers.[2b] Solutions containing about 1.5 mg. moles of nitrogen trichloride per gram of solution were used. The crotonic acid was dissolved in enough carbon tetrachloride for complete solution, the nitrogen trichloride was added and the apparatus arranged for collecting the gas evolved. Eighteen runs were made using varying proportions of crotonic acid and nitrogen trichloride and carrying out the reaction at different temperatures. It was found that about 1.5 moles of crotonic acid was required for each mole of nitrogen trichloride. Very little increase in yield was observed when a larger excess of acid was used. In the following table several representative yields obtained at different temperatures are given. For each mole of nitrogen trichloride 1.5 moles or more of crotonic acid was used.

TABLE I

PERCENTAGE YIELDS OF β-AMINO-α-CHLOROBUTYRIC ACID PROM NITROGEN TRICHLORIDE AND CROTONIC ACID

Yields at 0°, %	14.6	9.3	14.6
Yields at 13°, %	18.4	16.4	19.7
Yields at 20°, %	10.5	13.1	12.8

The solutions remained clear for a short time after mixing but soon became opalescent and a slow precipitation of the hydrochloride of the aminochloro acid continued for some days. At 20" ten days or longer was required for complete precipitation. The rate of evolution of nitrogen indicated, however, that the primary reaction was more rapid than this. At the lower temperatures a longer time was required. The product obtained at 0 and 13° was soluble in absolute ethyl alcohol and analysis indicated that it was the hydrochloride with only traces of impurities. The reaction product at 20° contained a small amount of ammonium chloride. For analysis the slightly impure product was purified by dissolving in absolute n-propyl alcohol, filtering and reprecipitating with anhydrous ether. If necessary this was repeated.

Anal. Subs., 0.1355, 0.1285: 15.38, 15.03 cc. of 0.1008 *N* $AgNO_3$. Subs., 0.0629, 0.0126: 35.75, 7.21 cc. of 0.01 N HCl. Calcd. for $C_4H_9O_2NCl_2$: Cl, 40.80; N, 8.05. Found: Cl, 40.61, 40.75; N, 7.96, 8.01.

β-Amino-α-chlorobutyric Acid.—The free aminochloro acid was prepared by dissolving the hydrochloride in absolute methyl, ethyl or n-propyl alcohol and adding pyridine[6] or by adding the calculated amount of lithium hydroxide to an aqueous solution of the hydrochloride, evaporating until crystals formed and adding ten volumes of alcohol.[7] The highest yields obtained by each method were as follows: CH_3OH and C_5H_5N, 63%; C_2H_5OH and C_5H_5N, 70%; C_3H_7OH and C_5H_5N, 80%; LiOH and C_2H_5-OH, 60%. After several recrystallizations from 80% ethyl alcohol, the acid was obtained as white needles melting at 161–161.5° (uncorr.).

Anal. Subs., 0.1229, 0.1673: 8.61, 11.85 cc. of 0.1032 N $AgNO_3$. Subs., 0.3818, 0.0905: 28.32, 6.88 cc. of 0.0964 *N* HCI. Calcd. for $C_4H_8O_2NCl$: Cl, 25.82, N, 10.18, Found: Cl, 25.66, 25.95; N, 10.00, 10.25.

Benzoyl-β-amino-α-chlorobutyric Acid--0.3 g. of the purified hydrochloride was dissolved in 10 cc. of water, three times the theoretical amount of benzoyl chloride

---

[6] "Organic Syntheses," John Wiley and Sons, Inc., New York, 4, 31 (1924).

[7] Fischer and Raske, *Ber.*, 40, 3720 (1907).

and 5 cc. of a 45% solution of sodium hydroxide were added and the mixture was thoroughly shaken. After several hours the solution was acidified and the precipitate filtered off and dried. When the precipitate was thoroughly dry the benzoic acid was removed by repeated extraction with boiling petroleum ether (b. p. 120–140°). After several recrystallizations from water the product melted at 174–174.5° (uncorr.).

β-Aminobutyric Acid.—Several attempts were made to reduce the aminochloro acid to the amino acid with sodium amalgam in both acid and alkaline aqueous solution at room temperature and at 0°. The chlorine was not completely removed. The reduction was finally carried out in an alkaline methyl alcohol solution. The hydrochloride was dissolved in about 20 times its weight of methyl alcohol and several times the theoretical amount of sodium amalgam (2.5%) added very slowly with constant stirring. When the reaction was complete the alcohol was evaporated on a water-bath. The residue was taken up with water and concentrated hydrochloric acid added. The solution was evaporated to dryness as before and the residue extracted with n-propyl alcohol. Pyridine was then added and the product thus obtained was recrystallized from 80% ethyl alcohol. After several recrystallizations the compound melted at 184–185° (uncorr). The melting point recorded for β-aminobutyric acid is 184° and that for α-aminobutyric acid 292° (decomp.). The product gave no test for chlorine by the Beilstein method.

Anal. Subs., 0.0167, 0.0204: 16.07, 19.51 cc. of 0.01 N HCl. Calcd. for $C_4H_9O_2N$: N, 13.59. Found: N, 13.50, 13.39.

The Reaction with Cinnamic Acid

Preparation of the Hydrochloride of β-Amino-α-chloro-β-phenylpropionic Acid.—The reaction with cinnamic acid was carried out in much the same manner as that with crotonic acid. The limited solubility of cinnamic acid in carbon tetrachloride made it necessary to use the acid partly dissolved and partly suspended in finely powdered form in the solution. The reaction mixtures were allowed to remain at room temperature for two weeks. Dry hydrogen chloride was then passed into the solution and the product, together with some unchanged cinnamic acid, was filtered off. This was shaken several times with anhydrous ether to free it from the cinnamic acid. The yields of crude product varied from 5 to 8.5%, calculated from the nitrogen trichloride.

The crude hydrochloride was purified by a method similar to that used by Posner[8] with β-phenylalanine. The crude product was treated with a little concentrated hydrochloric acid and the mixture evaporated to dryness on a water-bath. The residue was taken up with methyl alcohol, the solution decolorized with charcoal and the hydrochloride reprecipitated by the addition of five volumes of ether. The product melted at 228–230° (uncorr.).

Anal. Subs., 0.1365, 0.1706: 5.86, 7.35 cc. of 0.0983 N HCl. Subs., 0.2037, 0.1422: 17.07, 11.94 cc. of 0.1008 N $AgNO_3$. Calcd. for $C_9H_{11}O_2NCl_2$: N, 5.93; Cl, 30.08. Found: N, 5.91, 5.85; Cl, 29.99, 30.05.

β-Amino-α-chloro-β-phenylpropionic Acid.—The free aminochloro acid was prepared by dissolving 0.77 g. of the hydrochloride in 15 cc. of methyl alcohol and adding 4 cc. of pyridine; 0.40 g. of white precipitate formed on standing. After recrystallizing from 80% ethyl alcohol, the product melted at 199–200° (uncorr.).

Anal. Subs., 0.0202, 0.0514: 10.10, 25.63 cc. of 0.01 N HCl. Subs., 0.1157, 0.0551: 5.70, 2.73 cc. of 0.1008 N $AgNO_3$. Calcd for $C_9H_{10}O_2NCl$: N, 7.01; Cl, 17.79. Found: N, 7.00, 6.98; Cl, 17.60, 17.69.

Benzoyl-β-amino-β-phenylpropionic Acid.—The hydrochloride of the aminochloro

---

[8] Posner, *Ber.*, 38, 2321 (1905).

acid was dissolved in a small amount of water and six times the theoretical amount of sodium amalgam added very slowly with constant stirring. When the reaction was complete the solution was acidified with hydrochloric acid and evaporated to dryness on a water-bath. The residue was taken up with methyl alcohol, the solution filtered and evaporated as before. The product was weighed and the calculated amount of 0.1 N sodium hydroxide added to free the acid from the hydrochloride. This was evaporated until crystals began to form and then allowed to stand at 0° for twenty-four hours. This method was used since β-amino-β-phenylpropionic acid is soluble in alcohol and the methods used for the other acids were not applicable. A 65% yield of crude product was obtained which contained no chlorine. The melting point was, however, too low and the compound could not be readily purified. The benzoyl derivative was prepared as described for β-amino-α-chlorobutyric acid. The melting point of the purified product was 194–195° (uncorr.). A mixed melting point was taken with the known compound prepared by another method.

Anal. Subs., 0.0200, 0.0201: 7.65, 7.66 cc. of 0.01 N HCl. Calcd. for $C_{16}H_{15}O_3N$: N, 5.21. Found: N, 5.36, 5.34.

Summary

Nitrogen trichloride reacts with crotonic acid to form, among other products, α-chloro-β-dichloro-aminobutyric acid, which is changed by hydrochloric acid to β-amino-α-chlorobutyric acid. The structure of the compound was established by reduction to the corresponding amino acid.

A similar reaction occurs with cinnamic acid. The dichloro-amino group again enters the 8-position.

[Contribution from the Chemical Laboratory of Bryn Mawr College]

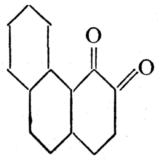
SOME DERIVATIVES OF 3,4-PHENANTHRENEQUINONE

By Louis Frederick Fieser

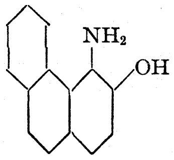
Received November 17, 1928 Published March 6, 1929

In the belief that a knowledge of the reduction potentials of ortho- or para-quinones derived from phenanthrene, but isomeric with 9,10-phenanthrenequinone, would throw some additional light on the general problem of the relationship between the oxidizing power and the structure of the various quinones, the author undertook to prepare one or two compounds of the isophenanthrenequinone type, and to compare them, by the potentiometric method, with the corresponding naphthoquinones. In the course of this work it soon became evident that the isophenanthrenequinones, which have received scarcely any attention up to the present time, are interesting from several points of view other than that of the original problem, and the work has thus developed into a rather extensive study of the general chemistry and the methods of obtaining various isophenanthrenequinones and compounds derived from them. The presentation of the results of investigations which are concerned solely with the chemistry of phenanthrene derivatives will be followed with an account of the electrochemical data which have accumulated.

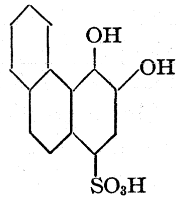
3,4-Phenanthrenequinone (I).—This is the only one of the isophenanthrenequinones of the type indicated which has been described up to the present time. Barger[1] obtained the quinone by oxidizing morphol with silver oxide; the morphol which he employed was prepared by converting 3-phenanthrol into an ortho-aldehyde and oxidizing the latter substance with hydrogen peroxide, A more convenient method was suggested by an unexplained observation of Werner and his students.[2] These investigators, in the course of a careful study of 3-phenanthrol, converted this compound into an amino-3-phenanthrol by coupling with a diazonium salt and reducing the azo dye. When they attempted to diazotize the amino-3-phenanthrol hydrochloride, as the first step in the proposed conversion of the compound into a dihydroxyphenanthrene, they were surprised to find that nitrous acid converted the salt into a sparingly soluble, easily decomposed, yellow substance. Since the substance was obviously not a diazonium salt, their original plan was abandoned, though it is now clear that they were very close to achieving one of the aims of the extensive studies on phenanthrene undertaken by Werner, namely, the preparation of morphol from the hydrocarbon. It appeared probable to the author that the colored substance was a quinone, produced by the oxidizing action of nitrous acid, and investigation has shown that this is the case and that the substance is 3,4-phenanthrenequinone. On reduction it yields morphol, while morpholquinone may be obtained from it by known methods. It is thus clear that 3-phenanthrol couples in the 4-position and that the amine has the structure of II.



I



II



III

It has been found possible to carry out the preparation of 4-amino-3-phenanthrol hydrochloride on a large scale in a simple manner. The dyestuff formed on interaction with diazotized sulfanilic acid is reduced, without being isolated, by means of sodium hyposulfite. The oxidation of the amine hydrochloride is best accomplished by adding an aqueous solution of chromic acid to a suspension of the salt in glacial acetic acid. The yields in all of these reactions are good.

3,4-Phenanthrenequinone is characterized by the brilliant red color of its crystals and by a beautiful color reaction with concentrated sulfuric acid. Though certain precautions must be observed in order to prevent

Barger, *J. Chem. Soc.*, 113,218 (1918).

Werner, Löwenstein, Wack and Kunz, Ann., 321,297 (1902).

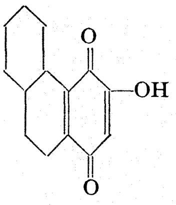
the destruction of a considerable quantity of the material during the course of its preparation, the pure quinone is a quite stable substance. Like other ortho-quinones it adds a molecule of sodium bisulfite with the formation of a sulfonic acid derivative of the hydroquinone. In consideration of the nature of this reaction, the substance must have the structure of 3,4-dihydroxy-phenanthrene-1-sulfonicacid, III, and this is confirmed by the conversion of the substance into the para-quinone described below. The sulfonic acid was isolated in the form of the *p*-toluidine salt and was converted into the corresponding quinone by oxidation.

3-Hydroxy-1,4-phenanthrenequinone.—A fairly satisfactory method of preparing this compound, which is the first representative 1,4-phenanthrenequinone to be described, was found in the oxidation of 3,4-dihydroxyphenanthrene-1-sulfonic acid in alkaline solution with hydrogen peroxide. The quinone separates in the form of a sparingly soluble sodium salt. Much poorer yields of the hydroxyquinone were obtained by the addition of acetic anhydride to 3,4-phenanthrenequinone and by hydrolyzing and oxidizing the 1,3,4-triacetoxyphenanthrene produced, or by hydrolyzing 3,4-phenanthrenequinone-1-sulfonic acid, though these methods are serviceable in several other instances.

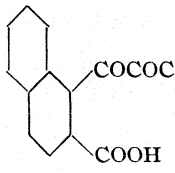
3-Hydroxy-1,4-phenanthrenequinone is very similar in properties to other compounds of the same type, such as hydroxynaphthoquinone or 2-hydroxy-1,4-anthraquinone. Thus the methyl ether may be obtained by the Fischer method of esterification, while interaction of the silver salt of the quinone with allyl bromide yields a mixture of the C-alkylation product, 2-allyl-3-hydroxy-1,4-phenanthrenequinone (63%) and the ortho-quinone ether, 1-alloxy-3,4-phenanthrenequinone (17%).

The Cleavage of 3-Hydroxy-1,4-phenanthrenequinone by Alkali.—While the above-mentioned reactions of the isophenanthrenequinones all belong to well-known types, an entirely novel behavior was discovered when 3-hydroxy-1,4-phenanthrenequinone was subjected to the prolonged action of dilute alkali. The red sodium salt of this quinone is only moderately soluble in water, but when a suspension of the salt in very dilute sodium hydroxide solution was boiled for a few hours in an open beaker the material all dissolved and gave a dull brown-red solution. On acidification a substance separated which dissolved readily in water and crystallized in the form of colorless plates.

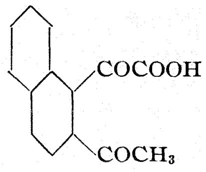
The empirical formula of this compound corresponds to that of 3-hydroxy-1,4-phenanthrenequinone plus the elements of water. The substance displaces carbonic acid from its salts, it may be esterified with an alcohol and hydrogen chloride and titration reveals the presence of a single carboxyl group. From these facts it would appear that the quinonoid ring of the hydroxyquinone, IV, has suffered cleavage by the action of a molecule of water. The nature of this cleavage is further elucidated by the fact



IV



V



VI

that the acidic substance yields naphthalene-1,2-dicarboxylic acid on oxidation in alkaline solution by means of hydrogen peroxide. From this it may be concluded that the cleavage of the hydroxyquinone has occurred between the carbon atoms at positions 1 and 2 or at the 2- and 3-positions, or at the 3- and 4-positions. A distinction among these three possibilities is furnished by a consideration of other properties of the cleavage product. This acid melts at 195° and at that temperature loses carbon dioxide; it is not affected by prolonged boiling of its solutions either in dilute acids or alkalies. It is conceivable that the quinone, reacting in a tautomeric, ortho-quinonoid form, might undergo ring rupture at the 1,2-bond, giving V, but this formula is not consistent with the fact that the acid evolves carbon dioxide on melting. The possibility of cleavage between 3 and 4 is ruled out because this would give rise either to a β-keto acid or a β-keto aldehyde (or their enolic forms), and such substances would not possess the observed stability toward mineral acids and alkalies.

On the other hand, the rupture of the ring at the double bond between positions 2 and 3 would yield the α-keto acid, VI, and the properties of the cleavage product are entirely consistent with this formulation. A further confirmation of this structure is furnished by the application of a reaction typical of a-keto acids. It is known that aniline, at an elevated temperature, converts phenylglyoxylic acid into benzalaniline,[3] and α-naphthylglyoxylic acid into the anil of α-naphthaldehyde.[4] In the present instance the cleavage product reacts with one equivalent of aniline at 180° to give a substance having the analysis and properties to be expected for the anil of 2-aceto-1-naphthaldehyde, which indicates that the reaction has followed the normal course

$$C_{10}H_6(COCH_3)(COCOOH) + C_6H_5NH_2 \longrightarrow C_{10}H_6(COCH_3)(CH{=}NC_6H_5) + CO_2 + H_2O$$

A further reaction of 2-aceto-1-naphthylglyoxylic acid (VI) follows a course which is probably novel. While oxidation in alkaline solution yields naphthalene-1,2-dicarboxylic acid, the action of hydrogen peroxide in glacial acetic acid solution, or of chromic acid in dilute sulfuric acid solution, yields 1,2-naphthindandione, VIII. The identity of this product was established by comparison with an authentic sample prepared by

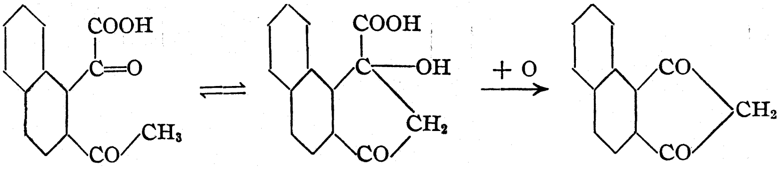
[4] Rousset, *Bull. soc. chim.*, [3] 17, **303** (1897).

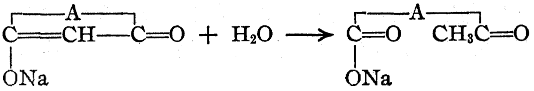
Noto's method.[5] A possible explanation of this rather surprising reaction is given in the following



VI VII VIII

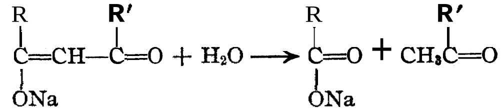
The known ability of the carbonyl group of a-keto acids to enter into aldol condensations lends some plausibility to the hypothesis that the a-keto acid, VI, exists in solution in equilibrium with a small amount of the α-hydroxy acid, VII, while there are many parallels to the conversion of VII into VIII. Thus a-hydroxy-isobutyric acid yields acetone on oxidation,[6] benzilic acid yields benzophenone[7] and a-phenyl-lactic acid, which is the most closely related to the hypothetical acid VII, yields acetophenone.[8]

Only further investigation can determine whether the alkaline cleavage of hydroxyquinones with the production of a carboxyl group and a ketone group in the same molecule is a general reaction, though results to be published shortly demonstrate that at least one other phenanthrene derivative, namely, 2-hydroxy-1,4-phenanthrenequinone, reacts with alkali in the manner indicated with particular ease. It will be noted that these reactions may be represented as follows



$$\overbrace{\underset{\text{ONa}}{\underset{|}{\text{C}}}{=}\text{CH}{-}\text{C}}^{\text{A}}{=}\text{O} + \text{H}_2\text{O} \longrightarrow \overbrace{\underset{\text{ONa}}{\underset{|}{\text{C}}}{=}\text{O}\quad \text{CH}_3\text{C}}^{\text{A}}{=}\text{O}$$

from which the similarity to the alkaline cleavage of a β-diketone, reacting in its enolic form is apparent.



$$\underset{\text{ONa}}{\underset{|}{\overset{\text{R}}{\overset{|}{\text{C}}}}}{=}\text{CH}{-}\overset{\text{R}'}{\overset{|}{\text{C}}}{=}\text{O} + \text{H}_2\text{O} \longrightarrow \underset{\text{ONa}}{\underset{|}{\overset{\text{R}}{\overset{|}{\text{C}}}}}{=}\text{O} + \text{CH}_3\overset{\text{R}'}{\overset{|}{\text{C}}}{=}\text{O}$$

The similarity between the two classes of compounds is not limited to the alkaline hydrolysis; it is quite generally true that hydroxyquinones yield C-alkylation products when the alkylation is carried out with certain particularly reactive alkyl halides9 and 3-hydroxy-1,4-phenanthrenequinone forms no exception to this rule.

In connection with a recent study of the alkaline hydrolysis of β-diketones, Bradley and Robinson[10] have advanced a theory of the mechanism

of the reaction based upon the assumption that the cleavage is a reaction characteristic of the ketonic modification, even though the concentration of this form in an alkaline solution is very small, and without regard to the possible mechanism, or the rate, of the formation of the ketonic modification from the enol. In order to apply these ideas to the cleavage of a hydroxyquinone, one would have to suppose that the salt of this strongly acidic substance undergoes hydrolysis even in the presence of alkali, that the free enol or its ion rearranges into a triketone, and that the latter, purely hypothetical, substance undergoes cleavage. There is little justification for such a view. At the time of the publication of the paper by Bradley and Robinson, their statement that "substances having fixed keto–enolic structures and related to β-diketones are relatively stable to hydroxyl ions," which they cite as evidence in support of their hypothesis of ketonic cleavage, was doubtless justified; but the discovery of the ready cleavage of compounds of fixed enolic structure lends support to the alternate view that it is the enolic modification which suffers cleavage in those cases in which the existence of such a modification is possible.

Experimental Part[11]

4-Amino-3-phenanthrol Hydrochloride.—The amine was prepared by Werner and his students[2] by coupling 3-phenanthrol with diazotized sulfanilic acid and reducing the azo compound with stannous chloride. The process was tedious and in order to convert the aminophenanthrol, which they isolated by extraction with ether, into the hydrochloride, it was necessary to use small quantities of the material. It has now been found that much better results may be obtained by reducing the un-isolated dyestuff with sodium hyposulfite, and that the amine hydrochloride may be prepared on a large scale if proper precautions are taken to prevent oxidation.

Ninety-seven grams of 3-phenanthrol[12] was dissolved in a warm solution of 60 g. of sodium hydroxide in 1.5 liters of water and the solution was cooled by the addition of about 500 g. of ice. A suspension of the diazonium salt was prepared by dissolving 105 g. of crystalline sulfanilic acid in 500 cc. of water and the requisite quantity of alkali, adding 37 g. of sodium nitrite, and pouring the solution into a mixture of 127 cc. of concentrated hydrochloric acid, 200 cc. of water and 500 g. of ice. When diazotization was complete the suspension was poured into the well-stirred phenanthrolate solution. The thick, bright-red solution of the azo compound was allowed to stand for one-half hour, when some solid matter separated, and then a solution of 230 g. of 85% sodium hyposulfite was added and the mixture heated and stirred until the red color disappeared and the aminophenanthrol which separated became very nearly colorless. The product sometimes separated in the form of colorless needles which became slightly yellow on drying and which melted with decomposition at 162° (Werner, 159–161°).

---

[11] The melting points recorded below are all uncorrected. Difficulty was experienced in the analysis of several phenanthrene derivatives, the values for carbon often being as much as 1% too low. This trouble was completely eliminated by the use of a Dennstedt contact star, as recommended by Scholl, *Ber.*, 43, 342 (1910).

[12] New observations concerning the preparation and the alkali fusion of the sulfonates of phenanthrene will be reported in a future communication.

In order to obtain the hydrochloride, the moist amine was made into a fine paste with 2.5 liters of water containing a little sulfur dioxide, 95 cc. of concentrated hydrochloric acid was added and the mixture was heated and stirred until all but a very small quantity of black, tarry material dissolved. On adding hydrochloric acid to the filtered solution, while still hot, 4-amino-3-phenanthrol hydrochloride separated in the form of pale gray needles; yield, 113 g. (92%).

The material prepared in the manner indicated may be preserved indefinitely without undergoing any change, but a less pure product rapidly becomes green. The free amine is very sensitive to the oxidizing action of the air and to heat and it is largely destroyed if an attempt is made to dissolve the dry material in water containing just one equivalent of hydrogen chloride. A considerable excess of acid is required to prevent hydrolysis. These facts may serve to explain Werner's difficulty in preparing the pure salt in quantity.

3,4-Phenanthrenequinone.—Oxidation of 4-amino-3-phenanthrol hydrochloride with chromic acid in aqueous solution or suspension gave a product which was contaminated by considerable black, insoluble material. Though this may be removed by extracting the quinone with alcohol and precipitating it with water, the following method of oxidation gives a product which is practically pure at the outset, provided that the amine salt is pure and that the conditions are carefully controlled as specified.

Twelve grams of 4-amino-3-phenanthrolhydrochloride was made into a fine paste with 120 cc. of glacial acetic acid at room temperature. A thermometer was placed in the mixture, an ice-bath was made ready and a solution of 5 g. of chromic anhydride in water was added all at once. The mixture was stirred vigorously and the temperature was not allowed to rise above 40°. The salt rapidly dissolved and formed a deep red solution. After ten minutes the solution was poured into 500 cc. of water, thus precipitating the quinone in the form of *a* very fine, orange-red suspension which soon coagulated to a spongy precipitate which was easily collected and washed free of acid. The yield was 8.9 g. (87%) and the quinone was very nearly pure.

Slight variations from these conditions, such as a change in the initial or the maximum temperature or the gradual addition of the oxidizing agent, gave, in poorer yield, a darker product which was collected and washed with great difficulty, for a very fine, black substance partially clogged the filter paper and rendered the filtrate black. The quinone is also produced by the action of nitrous acid on a suspension of the amine hydrochloride but it rapidly undergoes decomposition to a black tar.

3,4-Phenanthrenequinone is best crystallized from a mixture of benzene and ligroin. On rapid cooling the solution deposits a spongy product; excellent, long, brilliant red needles are produced on cooling slowly. In agreement with the observation of Barger,[1] the substance was found to melt with decomposition at 133°.

Anal. Calcd. for $C_{14}H_8O_2$: C, 80.76; H, 3.88. Found: C, 80.35; H, 4.06.

The reaction of this quinone with sulfuric acid constitutes a highly characteristic test, for a solution of the substance in the concentrated acid at first has a beautiful Prussian blue color which changes in a few minutes to a clear, chrome green. The rate of the change is dependent upon the purity of the sample and also upon the amount of acid employed. Mixed with a very small quantity of acid, the pure quinone gives a blue color which lasts less than one minute; using a large volume of acid, it persists for several minutes. When the uncrystallized quinone is added to a large volume of acid, the blue stage has only a momentary existence.

Morphol is conveniently prepared by reducing the quinone with an aqueous solution of sodium hyposulfite or sulfur dioxide, while diacetylmorphol is best obtained by boiling a mixture of 10 g. of the quinone, 10 g. of zinc dust, 10 g. of fused sodium acetate and 80 cc. of acetic anhydride until no further color change occurs. The mixture is then diluted with glacial acetic acid, filtered and cautiously treated with water. Crystallization from benzene gives a pure product (10.8 g.) melting at 158° (Barger, 158°). Vongerichten has described the conversion of this substance into diacetylmorpholquinone.[13] The author's experiments confirmed his statement regarding the yield and the pure material was found to melt at 197° (Vongerichten, 196°).

The Addition of Sodium Bisulfite to 3,4-Phenanthrenequinone.—This reaction, which proceeds so readily in the case of β-naphthoquinone, at first presented some difficulties. Since the phenanthrenequinone is very easily destroyed by acids, much of the material is converted into an insoluble, black substance unless the bisulfite solution is concentrated enough so that the addition reaction becomes very rapid. Thus, while the quinone dissolves only partially in dilute bisulfite solution, it is almost completely soluble in a saturated solution and, after time has been allowed for the rearrangement of the primary addition product, the sulfonic acid formed may be isolated in the form of an amine salt or else oxidized to a sulfonated quinone.

Ammonium 3,4-Phenanthrenequinone-1-sulfonate.—Twenty and eight-tenths grams of uncrystallized 3,4-phenanthrenequinone was ground to a fine paste with 150 cc. of water and 41.6 g. of sodium bisulfite was added all at once while the mixture was stirred thoroughly. Nearly all of the quinone dissolved, giving a thick, dark-brown solution. After standing for a few hours, it was diluted with water to a volume of 250 cc., 8.5 cc. of concentrated sulfuric acid was added cautiously, together with a few drops of caprylic alcohol to disperse the foam, and the solution was heated until the sulfur dioxide had been driven off. The solution was then filtered through a folded paper in order to remove a little dark material, cooled to room temperature and treated with a chromic acid solution containing 15 g. of the anhydride and 15 cc. of concentrated sulfuric acid. To the deep-red solution of the quinone a saturated solution of sodium chloride was added, causing the separation of a partially gelatinous precipitate of sodium 3,4-phenanthrenequinone-sulfonate. In spite of the dispersed character of the precipitate, no difficulty was experienced in collecting it and in pressing it free of most of the water, though it was not obtained in a condition satisfactory for analysis. The ammonium salt, although it is rather unstable, forms good crystals. It was prepared by adding saturated ammonium chloride solution to a hot solution of the sodium salt and cooling the solution rapidly. Small, glistening, dark red plates were thus obtained; yield: 18.5 g. (about 53% of the theoretical amount).

The salt is not easily crystallized. A hot solution in pure water turns dark before crystals begin to separate and even when an ammonium salt is added to decrease the solubility, a dark red, insoluble substance is formed unless the solution is cooled rapidly and unless the crystals are separated from the solvent without delay. The air-dried material contained about 13% of water and the anhydrous salt is very hygroscopic.

Anal. Calcd. for $C_{14}H_{11}O_5NS$: S, 10.50. Pound: S, 10.58.

p-Toluidine Salt of 3,4-Dihydroxyphenanthrene-1-sulfonic Acid.—The sodium and potassium salts of the acid are extremely soluble in water, but the p-toluidine salt crystallized readily on adding a solution of the amine hydrochloride to the solution of the dihydroxyphenanthrene-sulfonate obtained by the addition of sodium bisulfite to 3,4-phenanthrenequinone or by the reduction of the sulfonated quinone. The compound dissolves readily in water and crystallizes in the form of colorless needles which become slightly gray on drying and which decompose at about 182".

And. Calcd. for $C_{21}H_{19}O_5NS$: C, 63.45; H, 4.82. Found: C, 63.44; H, 5.03.

1-(p-Toluidino)-3,4-phenanthrenequinone.—This compound soon precipitated when aqueous or alcoholic solutions of equivalent quantities of ammonium 3,4-phenanthrenequinone-1-sulfonate and p-toluidine were combined and heated for a short time. A brick-red product was thus obtained in 60% yield. It is sparingly soluble in alcohol; somewhat more so in glacial acetic acid or toluene. It dissolves in alcoholic sodium hydroxide solution with a red color but it is insoluble in aqueous alkali. Crystallized from xylene the substance formed a crust of small, dark red crystals which melted with decomposition at 260°.

Anal. Calcd. for $C_{21}H_{15}O_2N$: C, 80.48; H, 4.83. Found: C, 80.29; H, 5.01.

1-(p-Toluidino)-3,4-diacetoxyphenanthrene was prepared by the reductive acetylation of the above quinone with zinc dust, sodium acetate and acetic anhydride. It is only sparingly soluble in alcohol, but readily soluble in benzene or glacial acetic acid. The benzene solution is fluorescent and it deposits short, colorless needles melting at 208°.

Anal. Calcd. for $C_{25}H_{21}O_4N$: C, 75.16; H, 5.30. Found: C, 75.09; H, 5.60.

3-Hydroxy-1,4-phenanthrenequinone.—Several methods of hydroxylating 3,4-phenanthrenequinone were investigated and the less successful procedures may be mentioned briefly. The Thiele reaction, which involves the addition of acetic anhydride to the quinone molecule under the influence of sulfuric acid, gave very poor resuits, probabiy because the quinone is extremely sensitive to the action of mineral acids. Even at room temperature the reaction yielded only a black, tarry product which gave a certain amount (30%) of the hydroxyquinone on hydrolysis, air oxidation and purification through the sodium salt, but from which pure 1,3,4-triacetoxy-phenanthrene could not be isolated.

A second method, which has given good results with similar compounds,[9b,14] consisted in the conversion of ammonium 3,4-phenanthrenequinone-1-sulfonate into 3-methoxy-1,4-phenanthrenequinone (see below), and hydrolyzing this ether. Thus a suspension of 5 g. of the ammonium salt in 25 *cc.* of methyl alcohol was treated with 4 cc. of concentrated sulfuric acid, while shaking, and the mixture was then allowed to cool. The ether which separated, washed with water and with a little alcohol, was nearly pure, and it gave a 97% yield of the pure hydroxyquinone on hydrolysis. The yield was only 2 g., or 59% of the theoretical amount, so that the overall yield of the hydroxy compound from 3,4-phenanthrenequinone was only 30%.

---

[14] Fieser, THIS JOURNAL, 48,2929 (1926).

A much simpler process, which gave a better yield of material, consisted in oxidizing 3,4-dihydroxyphenanthrene-1-sulfonic acid in alkaline solution with air or, better, with hydrogen peroxide. It is convenient to start with 4-amino-3-phenanthrol hydrochloride and not to isolate any of the intermediates in dry form.

Twelve grams of this amine salt was oxidized in the manner indicated above and the 3,4-phenanthrenequinone (average dry weight, 8.9 g.) was made into a paste with 100 cc. of water; 16 g. of sodium bisulfite was added and, after one-half hour, 4 cc. of concentrated sulfuric acid was added cautiously; the sulfur dioxide was boiled off and the filtered solution of sodium 3,4-dihydroxyphenanthrene-1-sulfonate was treated with 70 cc. of 6 *N* sodium hydroxide solution and 100 cc. of 3% hydrogen peroxide solution. A red precipitate of the sodium salt of 3-hydroxy-1,4-phenanthrenequinone soon began to separate and it was collected after a few hours. The addition of more peroxide to the filtrate usually gave a further quantity of the salt. The combined product was dissolved in boiling water, the red solution was quickly filtered from a small amount of black material and acidified, when the hydroxy compound separated in the form of a very fine yellow suspension. This material is very pure. The yield was 5.6 g., or 58% of the theoretical amount based on the weight of aminophenanthrol hydrochloride.

3-Hydroxy-1,4-phenanthrenequinone is only very sparingly soluble in water; it dissolves readily in alcohol or benzene and very readily in glacial acetic acid. The solution in concentrated sulfuric acid is brown-red, while the alkaline solution is red. The sodium salt is very sparingly soluble in the presence of an excess of alkali. The hydroxy compound is a strong acid, being soluble in sodium acetate solution. It was crystallized repeatedly from benzene and from dilute acetic acid, when it formed small, orange-yellow needles which sintered at 200° and melted, with some decomposition, at 230".

Anal. Calcd. for $C_{14}H_8O_3$: C, 74.99; H, 3.60. Found: C, 74.87; H, 3.67.

3-Methoxy-1,4-phenanthrenequinone.—The preparation of this ether from ammonium 3,4-phenanthrenequinone-1-sulfonate has been described above. It was also obtained by boiling a solution of the hydroxy compound in methyl alcohol containing a little hydrogen chloride. The ether soon separated in crystalline condition. It was crystallized from alcohol and from benzene-ligroin, forming light yellow needles melting at 170".

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.61; H, 4.23. Found: C, 75.69; H, 4.40.

3-Methoxy-1,4-diacetoxyphenanthrene was obtained in 91% yield by the reductive acetylation of the above ether. Crystallized repeatedly from benzene–ligroin, it formed clusters of stout, colorless needles, m. p. 168.5".

Anal. Calcd. for $C_{19}H_{16}O_5$: C, 70.35; H, 4.98. Found: C, 70.14; H, 5.15.

An attempt to obtain a pure oxidation product of this substance was unsuccessful, though there were indications of the formation of a small amount of a phenanthrenequinone.

The Allylation of 3-Hydroxy-1,4-phenanthrenequinone.—The hydroxy compound was converted into its dark red silver salt by adding silver nitrate to a neutral solution of the ammonium salt at 60°.

Anal. Calcd. for $C_{14}H_7O_3Ag$: Ag, 32.59. Found: Ag, 32.60.

A suspension of 6.7 g. of this salt in 100 cc. of benzene was treated with 2.7 g. of allyl bromide and heated to boiling for forty-five minutes, when the reaction was complete. Only two products were isolated: 1-alloxy-3,4-phenanthrenequinone and 2-allyl-3-hydroxy-1,4-phenanthrenequinone. The former crystallized on concentrating the benzene solution, whiie the latter was extracted from the benzene solution with ammonia solution; yields: 63 and 17%, respectively. A *p*-quinone ether appeared to be present in small quantity, but it was not obtained in pure form.

1-Alloxy-3,4-phenanthrenequinone is readily soluble in alcohol or benzene and crystallizes in the form of brilliant orange needles melting at 161°. While it is not soluble in bisulfite solution, it is completely hydrolyzed by dissolution in alcohol containing a little hydrochloric acid, a reaction characteristic of o-quinone ethers of this type.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 77.10; H, 4.56.

2-Allyl-3-hydroxy-1,4-phenanthrenequinone dissolves readily in glacial acetic acid or alcohol but it does not crystallize well from these solvents. The solution in ligroin deposits light sponges of small, orange needles, m. p. 155°.

And. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 77.22, H, 4.60.

This C-alkylation product may also be prepared in good yield by heating 1-alloxy-3,4-phenanthrenequinone to a temperature just above the melting point. Like other substances of this type the compound dissolves in alkali with a red color and it is converted into the following heterocyclic derivative by sulfuric acid.

1-Methyl-5,6-(1,2-naphtho)-3,4-quinone resulted when 1 g. of the above quinone was dissolved in 5 cc. of cold, concentrated sulfuric acid and the solution poured into a large volume of water. The flocculent, red precipitate was crystallized several times from benzene–ligroin with the use of animal charcoal and it was thus freed of a little tar and obtained in the form of brilliant red, flat needles melting at 198–199°. It is insoluble in bisulfite solution.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 76.98; H, 4.56.

The **Action of Alkali on 3-Hydroxy-1,4-phenanthrenequinone.**—The hydrolytic cleavage of this quinone may be accomplished by prolonged boiling of a solution of the sodium sait in water, but the reaction is hastened by the presence of an excess of alkali. Thus a suspension of 8 g. of the pure sodium salt in 3 liters of water containing 20 cc. of 6 N sodium hydroxide solution was boiled gently in an open beaker until all of the solid had dissolved, the clear red color had given place to a dull red-brown and the volume had been dimished to about 400 cc. This required about four hours. A small amount of dark material was then separated by filtration and the solution was acidified with hydrochloric acid while still hot. A part of the material separated in the form of an oil which soon solidified, while part formed large plates. Concentration of the mother liquor yielded an additional quantity of this substance. The combined product, on crystallization from dilute hydrochloric acid with the use of animal charcoal, yielded 5.7 g. (82%) of slightly brown, but essentially pure, material.

This substance, which has been identified as 2-aceto-1-naphthylglyoxylic acid (VI), was freed of all traces of coloring matter only after repeated crystallization from acidified water, though this process did not alter the melting point. The pure material melts at 196° with the rapid evolution of carbon dioxide and passes into a glassy substance. It dissolves readily in hot water and crystallizes, best in the presence of a mineral acid, in the form of large, colorless plates. The solubility in cold water is quite appreciable. On acidification of a dilute aqueous solution of the sodium salt the compound separates very slowly but in the form of excellent crystals. The acid decomposes sodium carbonate; it is very sparingly soluble in benzene, moderately soluble in ether and very readily soluble in alcohol.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.41; H, 4.16. Found: C, 69.41; H, 4.26. *Neut. Equiv.* Subs., 0.1716: 5.74 cc. of 0.1242 N $Ba(OH)_2$. Calcd. for $C_{14}H_{10}O_4$: mol. wt., 242.1. Found: 240.7.

The methyl ester was easily obtained by boiling a solution of the acid in methyl alcohol containing hydrogen chloride. After removal of most of the alcohol the addition of water caused the separation of an oil which soon solidified. The ester dissolves readily in benzene and only sparingly in ligroin; it crystallizes well from a mixture of the two solvents, forming small, colorless prisms melting at 181". It does not react with sodium bisulfite to any appreciable extent and it is indifferent toward bromine or ferric chloride.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.29; H, 4.72. Found: C, 70.56; H, 4.88.

Oxidation of the Cleavage Product in Alkaline Solution.—A solution of 0.5 g. of 2-aceto-1-naphthylglyoxylic acid in 4 cc. of 5% sodium hydroxide was treated with 2 cc. of perhydrol and the solution was kept at a temperature of 60° for several hours. The oxidation was not complete, for some of the unchanged acid separated in the form of a dark tar on acidification. After this had been removed and the solution boiled with animal charcoal and well concentrated, small, colorless crystals of naphthalene-1,2-dicarboxylic acid melting at 175° were obtained. The material was purified by crystallization of the sparingly soluble acid potassium salt and then crystallized from water. The acid melted at 175° with loss of water; the anhydride so produced melted at 165". These properties agree with Cleve's description[15] of naphthalene-1,2-dicarboxylic acid.

Anal. Calcd. for $C_{12}H_8O_4$: C, 66.66; H, 3.73. Found: C, 66.46; H, 3.76.

Oxidation of the Cleavage Product in Acid Solution.—To a boiling solution of 1 g. of 2-aceto-1-naphthylglyoxylic acid in a mixture of 75 cc. of water and 4 cc. of concentrated sulfuric acid, a solution of 0.4 g. of potassium dichromate was gradually added. Oxidation took place rapidly with the evolution of carbon dioxide and the separation of a yellow substance which was found to be 1,2-naphthindandione (VIII). After one crystallization from alcohol, long, slender, yellow needles melting at 174–175° were obtained; yield, 0.6 g. The same substance was obtained, though in poorer yield, by boiling a solution of 2 g. of the glyoxylic acid in 12 cc. of glacial acetic acid with 5 cc. of perhydrol for one hour.

Samples of 1,2-naphthindandione were crystallized from a variety of solvents such as alcohol, glacial acetic acid and benzene-ligroin; the melting point always remained constant at 174–175° and the crystals were distinctly yellow. On solution of the crystallized material in alkali, however, a small amount of colored impurity remained undissolved and the material precipitated by acidification and crystallized from benzene–ligroin was now only very faintly yellow but still melted at the same temperature.

Anal. Calcd. for $C_{13}H_8O_2$: C, 79.57; H, 4.02. Found: C, 79.45; H, 4.18.

The alkaline solution of the compound is deep red; the solution in concentrated sulfuric acid is yellow. It reacts with benzaldehyde in the presence of a trace of pyridine to give a product which forms small, lemon-yellow needles melting at 179°. The properties of the diketone correspond very closely with the description of 1,2-naphthin-

---

[15] Cleve, Ber., 25, 2475 (1892).

dandione given by Noto,[5] who synthesized this compound from naphthalene-1,2-dicarboxylic acid, except that the melting point of 174–175° is lower than the figure of 180° recorded by the Italian investigator, and that the benzal derivative was found to melt at 179°, instead of at 190°. The identity of the two compounds was definitely established, however, by comparing the material obtained in the present research with a sample prepared by Noto's method. Each sample, as well as a mixture of the two, melted at 174–175°.

The Action of Aniline on 2-Aceto-1-naphthylglyoxylic Acid.—Two and one-half grams of the acid was dissolved in ether, 0.98 g. of aniline added and the solution evaporated to dryness. The solid residue was transferred to a small flask and this was evacuated with the use of an oil pump and heated in an oil-bath. At 175° the material commenced to fuse with the evolution of gas and a thick, dark-brown liquid soon resulted. After heating at 175–180° for ten minutes, the flask was cooled and the product crystallized from benzene. The dark-brown impurities are largely retained in the mother liquor, for clean, yellow crystals of the nearly pure reaction product separated from the solution on cooling and a further quantity was obtained on concentrating the mother liquor; yield, 1 g.

2-Aceto-1-naphthalaniline is readily soluble in benzene, moderately soluble in alcohol or ether and sparingly soluble in ligroin or water. A sample for analysis, crystallized from benzene and from ethyl acetate, formed small, yellow needles melting at 202°.

Anal. Calcd. for $C_{19}H_{15}ON$: C, 83.48; H, 5.53. Found: C, 83.14; H, 5.72.

The compound is insoluble in alkali; it dissolves in concentrated sulfuric acid to give a solution exhibiting an intense green-yellow fluorescence. On addition of a small amount of water, the fluorescence disappears and a colorless salt soon crystallizes from the clear solution. The salt decomposes on further dilution with the formation of the yellow anil.

The author takes pleasure in acknowledging a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences for the purchase of the phenanthrene used in this investigation and in other studies to be reported shortly.

Summary

1. 3,4-Phenanthrenequinone may be obtained in quantity and in good yield by converting 3-phenanthrol into an azo dye, reducing the azo compound and oxidizing the 4-amino-3-phenanthrol so produced. The quinone adds a molecule of sodium bisulfite and the resulting product may be converted into 3-hydroxy-1,4-phenanthrenequinone. The alkylation of this hydroxyquinone follows the normal course.

2. When 3-hydroxy-1,4-phenanthrenequinone is boiled with dilute alkali, the quinonoid ring suffers hydrolytic cleavage in a manner entirely analogous to the cleavage of β-diketones.

PHOSPHORIC ACID ESTER DERIVATIVES OF CHOLINE. BASIS FOR THE PHYSIOLOGICAL ACTIVITY OF -ONIUM COMPOUNDS. VIII[1]

BY R. R. RENSHAW AND C. Y. HOPKINS

RECEIVED JANUARY 24, 1929 PUBLISHED MARCH 6, 1929

The phosphoric acid ester of choline and its derivatives are of interest not only because of their relationship to lecithin and because of a possible utilization of them in the synthesis of the latter substance, but also on account of the pharmacological properties that some of them may have.

Our earlier work on attempts to prepare phosphoric acid ester derivatives of choline[2] convinced us that these could not be obtained readily by double decomposition reactions with iodo- or bromo-ethyltrimethylammonium salts, nor by the action of phosphoric halides on choline. Much better prospects for obtaining these products as well as for the synthesis of the structure usually assigned to lecithin seemed possible by starting with β-chloro-ethyl phosphoryl dichloride $ClCH_2CH_2OPOCl_2$. This product was obtained in coöperation with Mr. Shott in this Laboratory in 1926, and during the winter of 1927–1928 the products herein described were prepared. We expected to extend this work before publishing, but since others have entered the field[3] it seems desirable to present the material at this time.

β-Chloro-ethyl Phosphoryl Dichloride, $ClCH_2CH_2OPOCl_2$.—A mixture of 80.5 g. (1 mole) of ethylene chlorohydrin and 100 cc. of dry carbon tetrachloride was stirred vigorously while 153.5 g. (1 mole) of phosphoryl chloride was added through a dropping funnel over a period of one and one-half hours. The stirring was continued while the flask was heated on the water-bath for three hours. The mixture was then distilled very carefully under diminished pressure, with the temperature being kept below 60° until the carbon tetrachloride was removed and hydrogen chloride no longer was evolved. The product distilled at 108–110° (15 mm.) in a yield of 91 to 93 g. (46 to 47% of the theoretical). It is a colorless, mobile liquid of suffocating odor.

Anal. Calcd. for $C_2H_4O_2Cl_3P$: Cl, 53.86. Found: CI, 54.14, 53.89.

This dichloride condensed readily with trimethylamine under anhydrous conditions to form a very hygroscopic product which was probably dichlorophosphato-ethyltrimethylammonium chloride, isomeric with the product isolated by the action of phosphoryl chloride on choline.

Dimethyl (3-Chloro-ethylPhosphate, $ClCH_2CH_2OPO(OCH_3)_2$.—To a rapidly stirred mixture of 29.5 g. (0.15 mole) of β-chloro-ethyl phosphoryl dichloride and 50 cc. of dry

---

[1] This problem is being carried on in cooperation with Dr. Reid Hunt of the Harvard Medical School. The physiological data are the basis of another series of papers published elsewhere by him.

[2] Renshaw and Ware, THIS JOURNAL, 47, 2993 (1925).

[3] Our attention has just been called to a report of a paper on "Esters of Phosphoric Acid," presented before the Biochemical Society by Plimmer and Burch, in which they describe (3-chloro-ethyl phosphoryl dichloride.

carbon tetrachloride contained in a flask surrounded by cold water, there was added drop by drop 12 g. (0.37 mole) of absolute methyl alcohol. The reaction mixture was refluxed gently for one to two hours until no more hydrogen chloride was evolved. The solvent was then removed by evaporation under a vacuum and the remaining liquid fractionated at a pressure of 4 mm. Considerable decomposition resulted at higher pressures. There was finally obtained 7 g. (25% yield) of the desired ester boiling at 95–96° (4 mm.). Dimethyl β-chloro-ethyl phosphate is a colorless, mobile liquid having a faint ester odor.

Anal. Calcd. for $C_4H_{10}O_4PCl$: Cl, 18.79. Found: Cl, 18.94, 18.70.

Dimethylphosphato-ethyltrimethylammonium Chloride (Choline Ester of Dimethyl Phosphoric Acid), $(CH_3O)_2OPOCH_2CH_2N(CH_3)_3Cl$.—A toluene solution of 3.0 g. (0.05 mole) of trimethylamine and 9.4 g. (0.05 mole) of dimethyl β-chloro-ethyl phosphate was allowed to stand overnight in a pressure bottle. The product was filtered off and washed with toluene and dry ether. It crystallized from a small volume of chloroform in fine needles, m. p. 136.5–137° (corr.). It is somewhat soluble in chloroform and acetic anhydride, very soluble in water and in ethyl alcohol, nearly insoluble in ether, toluene, petroleum ether and carbon tetrachloride. It is very hygroscopic.

Anal. Calcd. for $C_7H_{19}O_4NClP$: Cl, 14.32. Found: Cl, 14.42, 14.37.

Dr. Reid Hunt has found this compound to have little muscarine action. It does have, however, a powerful stimulating nicotine action.

Conclusion

β-Chloro-ethyl phosphoryl dichloride has been prepared. It condenses with trimethylamine to form a quarternary salt. From it, too, dimethyl β-chloro-ethyl phosphate has been obtained. This forms with trimethylamine the choline ester of dimethylphosphoric acid. Hunt has found that the latter compound has the interesting property of giving a powerful stimulating nicotine action and yet has little muscarine action.

NEW YORK, N. Y.

NEW BOOKS

College Chemistry. BY NEIL E. GORDON, Professor of Chemical Education, Johns Hopkins University. World Book Company, Yonkers-on-Hudson, New York, 1928. ix + 516 pp. 88 figs. 14 X 21 cm. Price $2.96.

The book is written especially for students who have had high-school chemistry and therefore omits much of the descriptive material found in ordinary texts. It is divided into two general parts, the non-metals and the metals. Under each head certain units are taken up, since it is the idea of the author that for students who already have a reasonable amount of chemical information, the more advanced viewpoint is best given by the study of topics rather than by a description of the properties of individual elements. Like other Gordon texts, the subject is presented by means of laboratory exercises, on which the discussion is based. While this may make the book less generally useful than if it were cast in the usual form, yet it has advantages for those who wish to follow Dr. Gordon's methods exactly. In general, standard methods of presentation have been used. The author should be commended for his practice of presenting problems without excessive use of formulas. It is doubtful, however, whether the terms electronization and deëlectronization will ever take the place of the historical reduction and oxidation. The book is carefully written and well arranged and undoubtedly is a real addition to the texts available for the teaching of chemistry.

P. A. BOND

Anleitung zur Chemischen Gesteinsanalyse. (Introduction to Chemical Rock Analysis.) By PROF. DR. J. JAKOB. Gebriider Borntraeger, W 35 Schöneberger Ufer 12 a, Berlin, Germany, 1928. vii + 81 pp. 3 figs. 16 × 24.5 cm. Price, bound, R. M. 7.

This "Biichlein" attempts to instruct the student in the making of the complicated chemical analysis of rocks, by which igneous rocks are mostly meant, within the compass of 79 pages. There is no general discussion of apparatus, reagents, methods or sources of error, and much of the matter is relegated to the footnotes. The student is assumed to have some knowledge of general quantitative analytical procedure or to work under the supervision of an instructor.

The methods, in general, follow those of Hillebrand and of the reviewer, but there are many complications and variations, and several of these differences in procedure are wide and unexpected, some of them not for the better. The treatment is very unbalanced: some of the descriptions are ultra-detailed, while again an important determination is dealt with much too briefly. Thus, only one page is devoted to the method for FeO, while two pages are given to the unimportant Li_2O. The reviewer differs with the author as to many particulars, such as the use of a porcelain basin ("which should not be much attacked") for treating the sodium carbonate melt; the advocacy of the old and very inaccurate and tedious Cooke method for FeO instead of the rapid and accurate Pratt method; the use of H_2SO_4 instead of HCl in several processes; the inordinate quantities of hydrofluoric acid that are recommended; the non-use of molten pyrosulfate for bringing the ignited Al_2O_3, etc., precipitate into solution; and the details of many other procedures too numerous to be mentioned here. The author advocates the determination of several constituents in aliquot parts of a filtrate. This is usually quite unnecessary, for the amount of rock powder available is, or should be, sufficient to make many of the author's material-saving procedures uncalled for, although they may often be necessary in analyzing a mineral of which there may be only a gram or so. The author lays much stress on accuracy, but the attainment of this is, in many cases, rendered difficult by the elaborate and complicated precautions that are taken especially to ensure it. The book, on the whole, is distinctly disappointing and, as a modern textbook, does not compare favorably with the earlier ones by Dittrich and by Jannasch.

The reviewer takes this opportunity to deplore the very inadequate and unsatisfactory way in which the quantitative analysis of silicates, including rocks and minerals, is treated in the standard manuals of quantitative analysis, such as those of Fresenius and of Treadwell-Hall.

HENRY S. WASHINGTON

Physikalisch-chemische Praktikumsaufgaben. (Experiments in Physical Chemistry.) By DR. ARNOLD EUCKEN, Professor and Director of the Physical-Chemical Institute of the Technical High School of Breslau, and Dr. Rudolf Suhrmann, Lecturer at the Technical High School of Breslau. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 4, Leipzig C 1, Germany, 1928. xii + 240 pp. 103 figs. 16 × 23 cm. Price, unbound, M. 13; bound, M. 14.

This Laboratory manual is undoubtedly the best that has so far been published. The experiments are, in the main, well chosen to illustrate the principles of physical chemistry, and are sufficient in number to allow the instructor considerable latitude in the way of choice of the experiments to be assigned. The directions, while brief, are sufficiently explicit, and an abundance of references are given so that the student who has a real curiosity (and some do exist) can easily learn more concerning the subject. The typography and binding are both excellent.

Part I is an introduction to the various methods of physico-chemical measurement and includes 24 experiments. Part II is devoted to physico-chemical analyses by mechanical, optical, thermal and electrical methods. Fourteen well-chosen experiments illustrate the use of such methods for quantitative analytical work. Doubtless some will consider that much of this should be given in a course entitled, say, "Quantitative Analysis by Instrumental Methods." The important point is that it be given somewhere. Part III is devoted to the determination of physical chemical constants and includes 59 experiments grouped under the general headings: thermal constants (26 experiments), calorimetric measurements (6 experiments), reaction velocity (4 experiments), electrolytic constants (8 experiments), surface phenomena (7 experiments), and the constitution of matter (8 experiments). Among these many experiments are a considerable number which are essentially new, and while the reviewer has not had an opportunity to try them out in the laboratory, he sees no reason why they should not work out satisfactorily. Part IV is an Appendix in which ten additional experiments are suggested. The student is expected to work out his own details of procedure from the literature references and hints given.

A laboratory course based on the performance of all of the experiments given would probably run through a period of two years, which is more time than can usually be devoted to this subject. However, with such an excellent assortment from which to choose, the instructor should be able to plan assignments of 30 to 40 experiments for a year's course for each student, and at the same time to vary the assignments so as to have most of the experiments going on in the laboratory. Students learn much by association, and the reviewer believes that nothing is more deadly than to have each student in a class perform exactly the same list of experiments. Such a system savors too much of machine production. The greater the variety of the experiments going on in the laboratory, the more interest on the part of the students (and instructor).

J. H. MATHEWS

Das Gesetz der chemischen Massenwirkung. Seine Thermodynamische Begründung und Erweiterung. (The Law of Chemical Mass Action. Its Thermodynamic Basis and Development.) By RICHARD LORENZ, Dr. Phil., Dr. Ing. E.H., Professor and Director of the Physical Chemistry Institute of the University of Frankfort. Leopold Voss, Solomonstrasse 18 B, Leipzig, Germany, 1927. x + 176 pp. 13 figs. 16 × 23.5 cm. Price, unbound, R. M. 12.50; bound, R. M. 14.50.

This monograph presents the results of the experimental work of the author and his collaborators on the equilibrium between molten metals and their salts (chlorides), all being of the type $Pb + CdCl_2 = Cd + PbCl_2$, in which there are two immiscible liquid phases. A thermodynamic development of a mass action law for such condensed systems is given, using van Laar's and the author's equations for the chemical potential of gases in gas mixtures.

The classical mass action law of Guldberg and Waage is discussed at length, giving the van't Hoff derivation and several applications. The chemical potential of a gas in a mixture of ideal gases is next developed and the "ideal mass action" law again derived by use of the general equilibrium relation $\Sigma\ (\nu_1\, \mu_1) = 0$. An equation for the chemical potential of a gas in a mixture of gases obeying van der Waals' equation is then obtained by use of the thermodynamic potential $F_{V,T}$, and applied to condensed (liquid) systems by replacing the volume of the gas by the van der Waals' B constant for the mixture. The "new mass law" deduced in this manner is applied to some nine equilibria between molten metals and their chlorides with fair success. Finally a discussion of the Duhem–Margules relation and the electromotive force of cells composed of molten salts and metals is given.

The logic of the treatment of mixtures of gases obeying van der Waals' equation is not satisfying, although the expression given for the chemical potential can be deduced by use of the more rigorous methods developed by Gillespie and others. The author's derivation is not made with a minimum of assumptions and in fact those assumptions which are used are not clearly stated. Since the treatment of condensed systems requires an integration along the van der Waals' isotherm into the liquid phase, the new mass action law so obtained can hardly be considered as resting on a firm thermodynamic basis and must stand or fall on its simplicity and reproduction of the experimental data.

The monograph contains a wealth of historical information, especially that derived from German sources. Much material which does not bear on the author's main thesis and which is to be found in textbooks on physical chemistry is included.

JAMES A. BEATTIE

Atomic Structure as Modified by Oxidation and Reduction. By WILLIAM COLEBROOK REYNOLDS, D.Sc. (Lond.), **F.I.C.,** A.R.C.S. **Longmans, Green and Company, 55 Fifth Avenue, New York, 1928. viii + 128 pp. 11 figs. 14 × 22.5 cm. Price, $3.00.**

This book presents a scheme of electron distribution in atoms which is at variance with those now considered generally useful or probable. The author shows a hearty indifference to spectroscopic or other verifications of his proposed structures, but applies these to the "explanation" of a wide variety of facts of inorganic and organic chemistry. As the rules of the game are not very clearly stated, it is hard to appraise the theory's triumphs in these fields. The sections on the" emission and absorption of radiation, the structure of solid conductors and magnets, are entirely qualitative and vague, and appear to offer no advantages over treatments based on quantum theory. No book of this type can be complete without a little something about the ether, and accordingly we learn that "the chemistry of the ether has been neglected" and come to know "the properties of ether particles," and that "on account of these," e. g., it is not m but e which varies at high electronic speeds. Stress and strain, dielectric constants, photoelectricity, gravitation, special and general relativity and many other topics are one by one seized, licked into shape in a few terse sentences and returned to their guardians, the physicists, with a grave word or two of warning or encouragement. It seems a pity that a book of such wide scope should bear *a* title which might mislead a prospective purchaser into expecting another mere Sommerfeld or Andrade. The reviewer begs to take as his motto a clause from page 123 "At present we must try and appraise aberrations correctly."

NORRIS F. HALL

Lumineszenz-Analyse im filtrierten ultravioletten Licht. (Analysis by Means of Luminescence in Filtered Ultraviolet Light.) By PROFESSOR DR. **P.** W. DANCKWORTT, **Hannover. Akademische Verlagsgesellschaft m. b. H., Leipzig, Germany, 1928.** vii **+ 106 pp. 39 figs. 16 × 23.5 cm. Price, unbound, M. 6.50; bound, M. 7.80.**

Inorganic and organic substances in truly great variety fluoresce in that part of the invisible radiation of the quartz mercury vapor lamp which is transmitted by nickel oxide glass, Differences in color and intensity including, of course, absence of fluorescence, lead to qualitative identifications and even to quantitative data. It is evident that comparisons involving several monochromatic and widely separated spectral bands would be even more highly informative. The book outlines microscopic as well as macroscopic procedures, and does not neglect photographic possibilities. Gems, minerals, fossils, textiles, rubber, dyestuffs, foods, drugs, anatomical preparations and bacteria are examples of the materials discussed. The section on criminal investigation ought to provide plots for a wealth of detective stories involving secret writings, counterfeited or altered money, stamps, checks and other documents, finger prints, physiological secretions and the like. Some two hundred selected references are given in conclusion. The author, enthusiast though he is, stresses the uncertainties of his art, especially in inexperienced hands. The general interest of the book will amply repay the reader, even if it touches upon none of his scientific or personal problems.

G. S. FORBES

Chemical Publications, their Nature and Use. By MELVIN GUY MELLON, Ph.D., **Associate Professor of Analytical Chemistry, Purdue University. McGraw-Hill Book Company, Inc., 370 Seventh Ave., New York, 1928. viii + 253 pp. 14.5 × 21 cm. Price, $2.50.**

About a year or so ago, Crane and Patterson published their "Guide to the Literature of Chemistry," intended for the student in college as well as for the chemist of wider experience; this, however, is more of a reference book than a textbook. In "Chemical Publications" Mellon has presented a real textbook, based upon his undergraduate course in chemical literature.

The object of the book is stated to be three-fold: first, to sketch briefly the general trend of events giving rise to and accompanying the development of chemical publications; second, to present an outline of the present sources of published chemical information, with a consideration of the general nature of each class and of typical examples in the various classes; and third, to suggest certain exercises indicating possible laboratory work for class use.

The book opens with a discussion of original sources: periodicals, institutional publications (covering mainly Federal documents), patents and their literature, dissertations and manufacturers' bulletins. Then follows a discussion of the so-called secondary sources: abstract journals, review serials, bibliographies, general works of reference and textbooks.

This material, comprising the first eight chapters, covers in an abbreviated form the material previously covered by Crane and Patterson, but it is felt that it is presented in such a way as to be more useful to the group for which it is intended. The real purpose of the book will be found in the last two chapters, which discuss "Making Searches in Chemical Literature" and "Library Problems." After introducing the student to the methods of classification used by libraries, the card catalog and indexes, directions are given for making a short and an exhaustive search of the literature. Finally, there is presented a series of fourteen problems, sufficient for a semester of sixteen weeks. These are of increasing complexity, starting with data regarding a given journal, institutional publication or patent, then going to data regarding a given chemical, chemical system, apparatus or process and concluding with the preparation of a bibliography and a critical report.

The reviewer has had ample opportunity to observe the need of this kind of training for our chemical students. For example, many of the questions which come to the Research Information Service of the National Research Council could be answered by the inquirer by consulting the standard textbooks or the indexes of *Chemical Abstracts.* Another point which should be emphasized by the instructor in such a course is accuracy in literature citations. When one finds a bibliography with from ten to fifty per cent. of errors, one cannot but wonder at the accuracy of the body of the paper to which the bibliography is appended. While much of this is due to the inexcusable habit of copying citations from published papers without first verifying them, it in no way relieves the author of his responsibility.

Professor Mellon has presented a very helpful book and it is to be hoped that the appearance of this work may stimulate the chemical departments of many universities to introduce a course on "Chemical Literature" as a part of their regular curriculum.

CLARENCE J. WEST

Chemical Patents Index. A Comprehensive and Detailed Index of the Subject Matter of Specification and Claims of United States Patents and Patent Reissues Granted during the Decennial Period 1915–1924 Inclusive, Covering the Entire Field of Chemical Technology. By EDWARD CHAUNCEY WORDEN, FIRST. Ph.C., B.S., M.A., F.C.S., F.L.S. Volume I. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1927. 904 pp. 17 × 25 cm. Price, $25.00.

This is the first of five volumes which will contain a detailed and comprehensive index of the United States Patents during the decade 1915–1924. During this period 398,377 patents were issued, of which 22,882 dealt with some branch of chemical technology. 14,526 names are recorded as sole or joint inventors in these patents. The chemical patents were examined in detail and an index card prepared for every chemical substance or class or process mentioned. It is stated that in one extreme case 2756 cards were prepared from a single patent. The work will obviously be extremely useful to anyone who has to deal with chemical patents in any way. Its usefulness is, however, limited by the fact that it covers only a single decade. Therefore the index can supplement, but not replace, the older and more cumbersome method of making a patent search. Fortunately the author announces that he and his staff are now engaged in extending the work to cover the decade 1905–1914 and the period 1925–1926. It is to be hoped that the work will receive sufficient support to make possible its extension backward and forward.

It may be of interest to append the first dozen names of inventors in order of number of chemical patents issued during this decade, together with a few other well-known names: C. Ellis, 237; W. Snelling, 67; W. Lindsay, 47; S. Peacock, 47; A. Backhaus, 46; H. Dreyfus, 41; W. Kempton, 40; L. Barton, 39; R. Benner, 38; S. Carroll, 38; R. Price, 38; T. Edison, 37; L. Baekeland, 28; H. Howard, 27; H. Dow, 24; G. Claude, 20.

GRINNELL JONES

L'État Colloidal et l'Industrie. (The Colloidal State and Industry.) By W. KOPACZEWSKI, **M.D., Sc.D., Professor at l'Institut des Hautes Études, Belgium. Vol. II. Librairie Polytechnique. Ch. Béranger, 15 Rue des Saints Pères, Paris, France, 1927. viii + 344 pp. 68 figs. 16 × 25 cm. Price, fr. 70.**

Vol. I appeared in 1925, and in response to the criticism it drew that the treatment of many industries was summary, the author in his present preface points out that these books are meant to serve as a complement to existing technologies, supplying missing colloidal data.

Vol. II is divided into three parts: (1) applications dealing with the mechanical properties of colloids (including decantation, filtration, centrifugation, ultrafiltration, dialysis, diffusion, adsorption, catalysis and its applications); (2) applications of the electrical properties of colloids (including sorption and its applications and electrophoresis); **(3)** equilibrium conditions of the colloidal state (including stabilization and labilization of hydrosols, swelling and syneresis of gels). The indexes and tables of contents of both volumes are included, and each chapter is followed by a bibliography, which does not, however, enable the reader to locate the source of each statement directly.

The author has compressed into this book a large amount of useful information and his references indicate that he has not confined his wide reading within national or linguistic lines, so that there is hardly anyone who will not get much good of it. All told, however, one receives the impression that some of the information comes directly from patents, books or journal articles, and expresses points of view rather than commercially and technically accepted procedure. Few will agree to placing the lower colloidal limit or size at 20 $m\mu$; but then, one does not have to agree with everything an author says to profit by his labors.

JEROME ALEXANDER

Pharmaceutical and Medical Chemistry. By SAMUEL P. SADTLER, Ph.D., LL.D., late Professor Emeritus of Chemistry in the Philadelphia College of Pharmacy, Virgil Coblentz, Ph.D., F.C.S., Professor Emeritus of Chemistry and Physics in the Department of Pharmacy of Columbia University, and Jeannot Hostmann, Ph.G., late Associate Professor of Chemistry and Director of the Analytical Laboratory in the Department of Pharmacy of Columbia University. Sixth edition, revised and rewritten by Freeman P. Stroup, Ph.M., Professor of General Chemistry, Philadelphia College of Pharmacy and Science. J. B. Lippincott Company, Philadelphia and London. **15** X **23.5** cm.

As stated in the preface to the present edition, "The appearance of the United States Pharmacopeia X, the National Formulary V, and the 1926 edition of New and Non-official Remedies has made it essential that a new edition of this book be prepared. Besides, many manufacturing chemical processes have undergone change and many new substances have come into more or less general medicinal and pharmaceutical use in recent years." A comparison of past editions with the present one reveals no material change in the general character of the book, although the authors have striven to bring the text up to date and to amplify certain portions obviously needing such attention. Revision of both the inorganic and organic sections has been thoroughly effected. The section on chemical physics is omitted from the present edition owing to the fact that in most college courses in pharmacy today more elaborate courses in physics are available than formerly. This saving in space is taken advantage of by the introduction of entirely new matter of a purely chemical character, as also by materially enlarging the index, thus rendering the present edition more desirable both as a textbook and reference work. Serious errors are few as will be readily apparent to the reader. A typographical error has, however, apparently crept into the periodic system of the elements, p. 208, Period E, Column V, Se should read Sb.

W. O. EMERY

Glycerol and the Glycols. Production, Properties and Analyses. By JAMES W. LAWRIE, Ph.D., Research Chemist, E. I. DuPont de Nemours and Co. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., **419** Fourth Avenue, New York City, **1928.** 447 pp. 81 figs. **15.5** × **23.5** cm. Price **$9.50.**

This book is an interesting and valuable addition to our knowledge of industrial aliphatic chemistry, containing as it does a very thorough review of the subject and many new and otherwise inaccessible data.

The first four chapters give a review of the sources, methods of production and manufacture of glycerol from soap lyes.

In Chapter V the synthesis of glycerol by fermentation is described at length and in Chapter VI the physical properties and constants of glycerol and its aqueous solution are given. For the latter it is evident that the author has drawn freely on the valuable data in the DuPont files, which are otherwise inaccessible.

The chemistry and reactions of glycerol, its detection, analysis, specifications and commercial utilization are discussed in a thorough manner, while chapters on the manufacture of glycerol trinitrate, glycol dinitrate and the methods of production of the glycols also contain much valuable information.

While the text is printed in the customary clear type the same cannot be said of the numbering of the footnotes.

The subject matter has been carefully corrected, to judge from the few misspelled words noted, *e.* g., p. 206, hypochlorus; p. 224, pyrocatechic, isophorn; p. 314, glycerite; p. 348, labil; p. 388, difficient; p. 371, internals.

Formula II on p. 387 is incorrectly given, as is also the formula for ethylene on p. 363. Table 113 on p. 381 is incorrectly given as Table 112. A few other points calling for comment are the following: The statement (p. 44) that propylene chlorohydrin can be hydrolyzed to glycerol is obviously incorrect. The same remark also applies to the statement that glycerol is a triose. The boiling point of di-iso-amylin calls for correction, as well as the spelling of the word. It would seem advisable to insert in a footnote to Table 113 the significance of the letters used. The term "artificially" (p. 220) should be replaced by "synthetically."

In Table 98 the melting points of the two forms of the trinitrate are given as 2.2 and 12.2" and in Table 99 as 2.5 and 13.5". The values obtained by the reviewer and co-worker in a carefully conducted research were 2.0 and 13.2" and so far as is known represent accurate data.

The author (p. 212) gives the number of theoretical oxidation products of glycerol as eleven but overlooks hydroxymalonic acid (tartronic acid).

The latent heat of fusion is given in a clear-cut statement (p. 348) as 23.1 calories per gram, while on p. 391 attention is drawn to the probable incorrectness of the figures by quoting the same author's own attitude.

This value was carefully determined by the reviewer and co-worker and there is no doubt as to the inaccuracy of Nauckhoff's figures. As given in the text it would seem that the doubt is on the side of Hibbert and Fuller's results. The description of the apparatus, Fig. 70, p. 359, does not correspond with the text; at least it is difficult to recognize in the sketch a graduated centrifuge tube of the dimensions given.

One point which calls for criticism (and for which the editors of these Monographs must also be held responsible) is the careless use of the terms nitro and nitrate. The author repeatedly speaks of nitro glycerol and nitro glycols when obviously glycerol and glycol nitrates are meant. Thus nearly all of the names used in Table 99, and in much of the text, are scientifically inaccurate and misleading. It is to be hoped that this nomenclature will be carefully revised in any subsequent edition.

The author's views on the future of glycerol and the possibility of its synthesis are of interest. The fermentation process would seem to hold, at present, far greater possibilities than the synthesis from petroleum.

In tabulating the various factors which have led to the recent slump in the price of glycerol the most important is omitted, namely, the commercial development of the manufacture of ethylene glycol at a competitive price.

In the opinion of the reviewer, who has devoted a number of years of his scientific career to the possibility of the synthesis of glycerol and glycols, there are few basic organic raw materials which offer more wonderful possibilities than glycerol.

The makers of this product need not necessarily be at all pessimistic about its future, for if they are willing to spend on scientific and technical research only a fraction of the total sum expended on the commercial development of synthetic glycols, there is reason to believe that they will find other more highly profitable outlets and thus render themselves more independent of its present restricted commercial application.

Dr. Lawrie's book can be strongly recommended as a valuable and authoritative work to all interested in the future development of industrial organic chemistry.

The dedication of it to Professor Julius Stieglitz is an admirable and charming tribute to an investigator who has contributed much to the advancement of organic chemistry.

THE OXIDATION OF BENZOYL-ORTHO-TOLUIDINE AT A BENZENE–WATER INTERFACE WITH SPECIAL REFERENCE TO THE TEMPERATURE COEFFICIENT OF THE REACTION RATE

BY LOUIS S. KASSEL[1] AND NORWOOD K. SCHAFFER

RECEIVED JULY 9, 1928 PUBLISHED APRIL 5, 1929

In a recent paper, R. P. Bell[2] has reported some reaction rate measurements for the system aqueous potassium permanganate–benzoyl-o-toluidine dissolved in benzene. Oxidation occurs at the interface and the solubility relations at 25°, according to Bell, are such that an appreciable amount of homogeneous oxidation of A[3] cannot occur. Bell finds that the rate of this reaction is independent of the rate of stirring of the benzene layer over a four-fold range, and that the 10° temperature coefficient for the range 15–25° is 13, corresponding to an energy of activation of 43,700 cal. He finds that the reaction is of the first order with respect to the permanganate, and that the rate increases with the concentration of *A* for low concentrations; but becomes independent of concentration at about 5–6 grams/liter. This suggests the formation of a saturated film at this concentration, and since the same conclusion is reached from an application of the Gibbs-Helmholtz equation to the interfacial tensions for the system water–benzene–A, this conclusion is probably correct. The permanganate is almost certainly negatively adsorbed and the reaction may well occur upon the impact of permanganate ions on the adsorbed film of A. It is this mechanism which Bell has proposed.

Our attention was directed to this work by the extremely large temperature coefficient which Bell found. Few reactions have temperature coefficients greater than 4, and none, so far as we are aware, in excess of 7, at temperatures where their rates are appreciable. No mechanism which we could construct was capable of accounting for the magnitude of the observed rate; the discrepancy in all cases amounted to a factor of at least

[2] Bell, *J. Phys. Chem.*, 32, 882 (1928).

[3] Hereafter, for brevity, benzoyl-*o*-toluidine will be designated by A, and benzoyl anthranilic acid, one of the oxidation products, by B.

10^{20}. It thus seemed that, if this value 43,700 calories was in any way related to an actual energy associated with the reaction, some new ideas would have to be introduced into reaction rate theory to account for the speed of this reaction. Before this was attempted, however, it appeared desirable to verify the experimental results, and this we have attempted to do. Our work disagrees with that of Bell in three particulars.

1. Bell gives a list of desirable characteristics for an interfacial reaction, to which the one selected presumably conforms. One of these characteristics is that no solid should separate out. He states especially that although B is rather insoluble in benzene and but slightly soluble in water, his rates apply to the initial part of each run, during which it all remained in solution. He makes no statement about manganese dioxide, but by implication one would suppose that it is not formed. Since the reaction is started in a neutral solution and since this solution can scarcely avoid becoming alkaline as the reaction proceeds,[4] the formation and precipitation of manganese dioxide is to be expected. It actually occurred in all of our experiments, and we cannot see how it could have been absent in Bell's.[5]
2. Bell varied the rate of stirring of the benzene layer by a factor of 4, keeping the rate of stirring in the water layer constant, and found no change in the rate. He therefore concluded that the rate of reaction was independent of the rate of stirring. We found that when the rate of stirring in both layers was increased, the rate of reaction increased markedly.
3. We did not verify Bell's value of 13 for the temperature coefficient, but instead found a value of about 2.

Experimental Part

A was prepared by benzoylation of technical o-toluidine in benzene solution. The resulting material was filtered hot and A separated out upon cooling. It was then recrystallized from benzene. Three separate preparations were used during the work. The first (Sample I) was not washed with hydrochloric acid at any stage. Sample II was washed with dilute hydrochloric acid and then with water after recrystallization and Sample III with the same reagents before recrystallization. Samples I and II melted at 139–140° and Sample III at 142°. The value given by "International Critical Tables" is 143°.

The reaction was carried out in a five-liter bottle of brown glass. The area of the

---

[4] The equation $2KMnO_4 + A \longrightarrow 2MnO_2 + B + 2KOH$ certainly would lead to increased alkalinity. So would $6\ KMnO_4 + 5A + 4H_2O \longrightarrow 6Mn(OH)_3 + 5B + 6KOH$. Any further reaction which took place could only increase the alkalinity.

[5] Since the submission of this paper, we have been informed by Bell (private communication) that in the initial parts of his runs the manganese dioxide did not separate out, but that on standing this did take place. It appears that it is formed as a colloid. Our own observations on this point are incomplete, since we could not examine the surface closely until after the reaction was stopped, but we have some reason to believe that in our experiments also the initial stage does not involve precipitation. though the colloid does not appear to have been as stable as in Bell's experiments.

interface was 220 cm.^{2}. A single stirrer was used for both solutions, with three paddles in the water layer and one in the benzene. A protecting tube of about 5 cm. length surrounded the portion of the stirrer which passed through the interface, so that the disturbance produced would be confined to a small region, but the alignment was good enough so that even that small part of the interface was not noticeably agitated. The paddles were perfectly straight horizontal rods, about 8 mm. in diameter and 20 mm. long. The three paddles in the water layer were mounted at angular intervals of 120° and vertical intervals of 10 mm. The chief reason for the rather inefficient design was that otherwise it would have been almost impossible to give even a crude idea of the amount of stirring produced.

The course of the reaction was followed by withdrawing 10-cc. samples of the permanganate solution from time to time and titrating with freshly prepared ferrous ammonium sulfate solution; this seemed preferable to the oxalic acid which Bell used, since it was unnecessary to heat the solution during the titration and the chance of reaction between B and the permanganate in the hot acid solution was thus avoided. The pipet with which the solution was withdrawn passed through a protecting tube which contained no benzene layer; since almost all of the manganese dioxide collected at the interface, this made the sampling more reliable than it would have been otherwise.

The thermostatic regulation was entirely adequate. Fluctuations as great as 0.05" did not occur.

Altogether 20 runs were made. The first five were preliminary and since they were made with a different stirrer or in a different reaction vessel than the others the results will not be reported. Run 6 was made with 1400 cc. of benzene solution, containing 5.36 grams/liter of A, and 1750 cc. of about 0.035 N permanganate. All of the following runs were made with 1000 cc. of benzene containing 6 g. of A, and 1750 cc. of about 0.005 N permanganate. Runs 6–10 were made at 25.0° using Sample I. In each of these runs one or more changes was made in the rate of stirring during the run, and with a single exception each change resulted in a perfectly definite change in the rate of reaction. The exception was in run 9, which showed no abrupt change when the rate of stirring was increased from about 20 r.p.m. to 80; the measurements were not continued a sufficiently great time after the change to make the results definite and the run could never be duplicated. In general it may be said that at rates of stirring of 80 or more the results are reproducible with quite fair accuracy, but that at lower rates they are erratic. For example, in run 4, with a different stirrer, no reaction was observed in five hours at 20 r.p.m., nor in one hour at 33, but a rapid reaction set in at 160; in run 9, as has been said, a slow reaction occurred at 20 r.p.m.; in run 10 no reaction had occurred after eight hours at speeds of 10–45 r.p.m.; run 11, with Sample II, gave reaction at 20–50 r.p.m., while run 12, with the same sample but at 27.9°, showed no reaction in three hours at 20–40 r p.m. Since the time available for these experiments was limited, we were forced to abandon this part of the investigation without reaching a definite conclusion as to the relation between the rate of reaction and the rate of stirring at rates less than 50 r.p.m. Between 50 and 250 r.p.m., however, there is a very definite and marked dependence on the rate of stirring. This is shown by Pig. 1, in which the observed rates in runs 6, 7, 9 and 10 (run 8 gave about 100 times the normal rate, but it also showed dependence on the stirring) are plotted against the rate of stirring. The rates are given in moles of permanganate per hour per cm.^{2} of surface per unit molarity. The general trend of the points is quite obvious except at low rates, The rather considerable scattering is attributable mainly to two causes; it was not always possible to keep the rate of stirring quite constant, and some of the abscissas represent mean values which may not be accurate. Most of the points at higher rates were obtained from the later parts of runs, when varying amounts of manganese dioxide were present; this, or some other reaction product, appears to have a poisoning effect on the surface, so that rates which were not obtained under **exactly** corresponding conditions should not be expected to agree perfectly. The best evidence that between **50** and **250** r.p.m. the rate does depend on the stirring is obtained from the single runs. The complete data for run **7,** which is fairly typical, are shown in **Fig. 2.** We did not work at greater rates than **250** r.p.m. because at that rate the stirring had become rather violent; it is scarcely possible to suppose that such agitation is not much more than is needed to keep a fresh supply of reactants at the surface and the increase in rate which occurs with increased stirring in this region is probably due to a breakdown in the oriented absorption of *A*, giving a condition more favorable to reaction, or to incipient emulsification, with a consequent increase in the area of the interface; that this last suggestion is not unreasonable follows from the fact that visible emulsification occurs at rates of about **500** r.p.m.

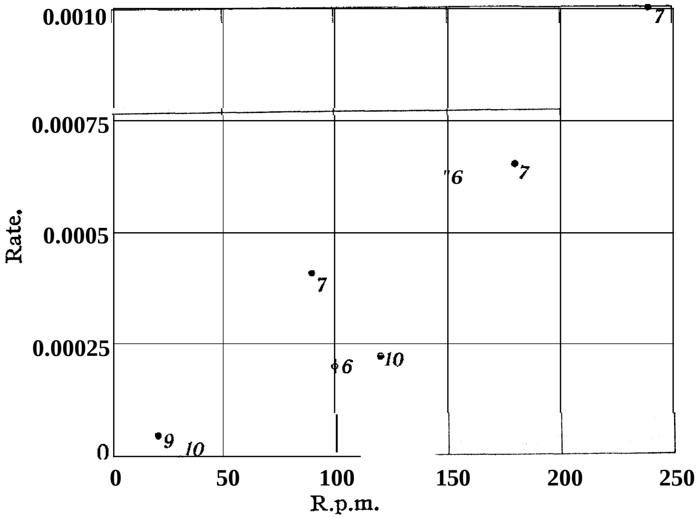

Fig. **1.**

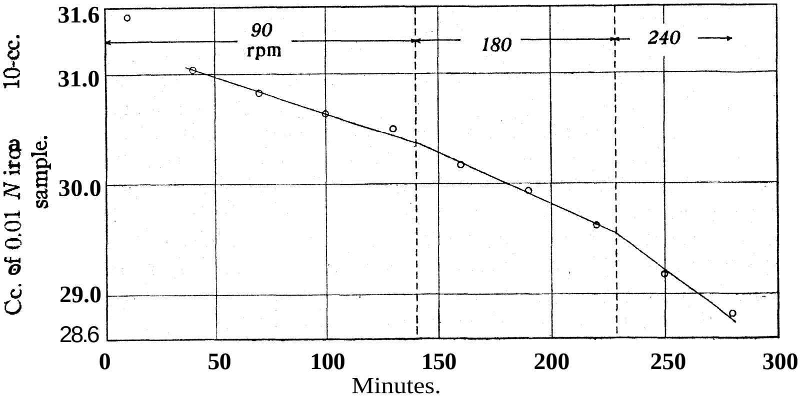

Fig. 2.

The remaining runs were devoted to a determination of the temperature coefficient of the reaction rate at about **120** r.p.m. Runs 13–16 were made with Sample II and runs **17–20** with Sample III. The temperature range of the former series was only 30–40° and the stirring was somewhat erratic. The results confirm those of the latter series but cannot be regarded as very reliable. Runs **17–20** were all very good and the technique of regulating the stirrer had been mastered by then. The sample used was the best of the three; it reacted more slowly than did Sample II, and the rates, therefore, apply to the initial part of the reaction when only a small amount of manganese dioxide was present. The separate titrations with few exceptions were in good agreement and the determination of the rate from the slope of a straight line drawn through the experimental points was subject to an uncertainty of not more than 5%. The complete data for run 18 are shown in Fig. **3,** and the results for the entire series are listed in Table I.

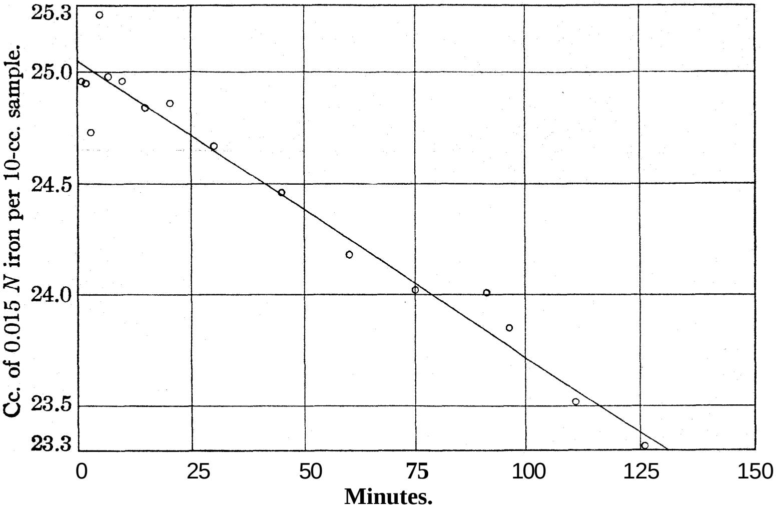

Fig. 3.

TABLE I

RESULTS FOR THE SERIES

Run number	17	18	19	20
Temperature, °C.	25.6	45.3	35.16	15.3
k	0.00025	0.00120	0.00052	0.000126

In this table k is the number of moles of permanganate reduced per hour per cm.^{2} of surface per unit molarity of the permanganate, with 6 g./liter of A in the benzene solution, at **120** r.p.m. with the stirrer described.

In Fig. 4 is shown a plot of ln k against $1/T$ for these values. The four points lie on a smooth curve which, however, is not a straight line. The curvature is not great but is far from negligible, as a calculation of the energy of activation E_0 for various intervals shows.

TABLE II

VALUES OF E_0

Temperature interval, °C.	15.3–25.6	25.6–35.15	35.15–45.3
E_0	11,500	14,100	16,200

These values are all subject to a correction of $RT/2$ if the reaction is bimolecular, but this is in any case negligible.

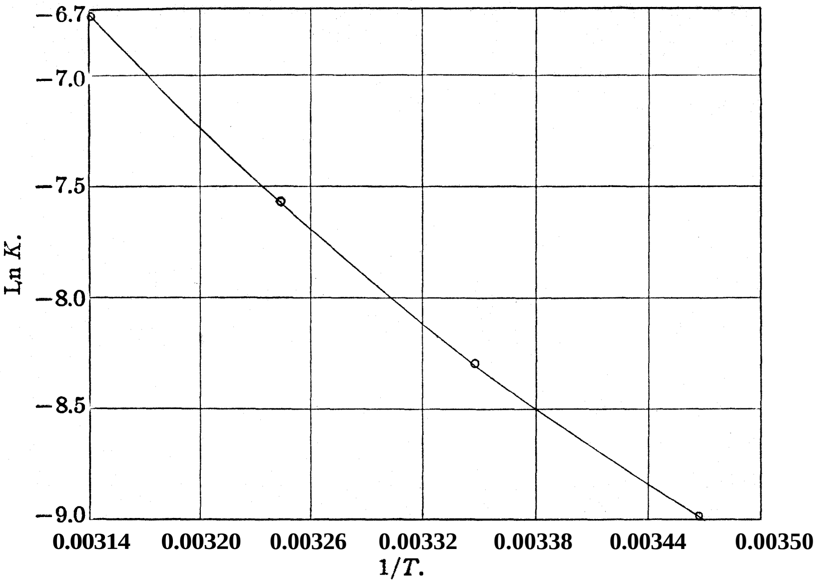

Fig. 4.

Discussion

If this trend in the value of E_0 is real, as we believe it to be, there are a number of possible explanations for it. The reaction product, B, is not perfectly stable to permanganate, and there may be a slow but appreciable homogeneous reaction occurring, particularly at the higher temperatures. This could result in a trend of the sort observed if the homogeneous reaction had the larger temperature coefficient. Or, since A is distinctly soluble in boiling water, it may not be quite insoluble at 35–45°. Thus, there may be a certain amount of homogeneous oxidation of A in addition to the main heterogeneous part of the reaction. This would lead to a trend of the type observed, regardless of which reaction had the greater temperature coefficient, but it would seem very likely, if this explanation is correct, that the larger one belongs to the homogeneous reaction, first because that is the normal situation, and second because in this case the temperature coefficient for the homogeneous reaction would include the temperature coefficient of solubility. Then the energy of activation for the interfacial reaction would be less than 11,500, and that for the homogeneous reaction greater than 16,200. Other explanations for this trend in E_0 are possible; in fact, any two or more reactions, either simultaneous or successive, both leading to a reduction of permanganate, are capable of accounting for it.

It is not possible from the results of our work to assert definitely what the cause of the disagreement between our results and those of Bell is, but we believe that the following reason will probably account for it. Bell says (p. 883), "One preparation was recrystallized from alcohol and one from benzene. . . . Both were therefore considered pure and were used indifferently in the subsequent work." The first series of Bell's runs (Runs 5–16) is devoted to a determination of the dependence of the reaction rate on the concentrations. The first three of these, taken alone, show the reaction to be first order with respect to the permanganate; the last six, made at approximately constant permanganate concentration, give a smooth curve when the rate is plotted against the concentration of A. The velocity read from the curve for 4.55 g./liter of A is 3.3 cc./hour. The first three runs of the series were made at 4.55 g./liter of A, and when corrected to the same permanganate concentration as the other six give, in the same units, a rate of 0.56 cc./hour. The discrepancy, a factor of 6, is scarcely assignable to experimental error in view of the good agreement within each of the two groups. Bell does not mention this disagreement at all; since our own three samples showed considerable differences in rate, we consider it probable that the same is true of the two Bell used, and that the first three runs of this series were made with the less active sample. It is worth noticing that if his temperature coefficient, 13, be divided by this ratio, 3.3/0.56, the result is 2.2 in very good agreement with our own value of 2.0 for the same temperature interval. If this suggestion as to the cause of his error is correct, then he must have made Runs 5, 7, 8 of Series 1 and all those of Series 3 with a single sample, the less active one; and must have made the remaining runs of Series 1 and all those of Series 2 with the more active sample.[6]

With regard to the actual nature of the catalyst responsible for the varying activity of the different preparations, we have no suggestion to

---

[6] Bell has informed us that the explanation we suggest is not acceptable. It seems that the runs for which the reported concentration of *A* was 4.55 g./liter were made at an actual concentration of 1.55 g./liter. This removes the factor of six pointed out above. Furthermore, all the runs on which the temperature coefficient was based were made with a single sample. Bell is willing, however, to accept our value for the temperature coefficient, since his study of this quantity was a minor point in his investigation. We wish to emphasize that the main thesis of his work, the verification of the Gibbs–Helmholtz equation, is not affected by our work.

make. Of our three samples, I was about twice as active as III and II 5–7 times as active.

It may be worth while to repeat the calculation which Bell has given for the fraction of fruitful collisions of permanganate ions at the interface. This is necessarily based on the unlikely assumption that the ions may be treated as a perfect gas. It is found that at 25°, making this assumption, 2.07×10^4 moles would strike per cm.^{2} per hour per unit molarity, and of these 0.00025 moles would react. The fraction of fruitful collisions is, therefore, 1.2×10^{-8}, about one-tenth that Bell found; in the absence of knowledge as to the rate of stirring that he used this is not very significant, though it points to a somewhat lower rate for our Sample III than for either of his. If we put $1.2 \times 10^{-8} = e^{-E_0/RT}$ and solve for E_0, we get 10,900 calories. This value is not very significant. The calculated number of molecules striking is quite possibly in error by a large factor, due to negative adsorption among other causes; the chances are that it is too large. This would mean that the true fraction of fruitful collisions is greater than that calculated, and the corresponding true value of E_0 would be smaller. However, the direct calculation of E_0 in this way is rather naive. It has been suspected for a long time, and the great mass of experimental data of Hinshelwood and others show it to be so, that the rate of a bimolecular gas reaction is calculable by multiplication of the number of collisions with the factor $e^{-E_0/RT}$; but there is no certainty that the actual mechanism of the reaction considered here is bimolecular (for example, it might involve the unimolecular breakdown of a complex formed between A and a permanganate ion) and furthermore the work of Norrish and Smith[7] shows that for reactions occurring in solution it is necessary to introduce a probability factor P, which may be very small. The omission of this factor, if it should be present, would make the calculated value of E_0 too large. There are thus at least two sources of error, both tending to make the calculated value of E_0 too large, so that the true value is probably less than 10,900 by a considerable amount, although some unsuspected error in the other direction may change this. The value with which this calculated quantity is to be compared is also uncertain. If, as has been said was possible, the trend in the observed temperature coefficient is due to two reactions occurring together, that with the lower temperature coefficient being heterogeneous, then the energy of activation for the heterogeneous reaction is less than 11,500. In fact, on this basis, we should be justified in applying the $RT/2$ correction mentioned before and saying that it was less than 11,200. It is quite possible for a number less than 10,900 to equal a number less than 11,200, but this possibility does not lend any weight to the vast number of assumptions made in arriving at these figures. There is no large obvious discrepancy,

---

[7] Norrish and Smith, *J. Chem. Soc.*, **1928,** 129.

such as Bell's work appeared to involve, but more than that cannot be said. It is, of course, needless to mention that the close agreement between the numbers 10,900 and 11,200 is to be regarded as a coincidence without significance. There are several other causes which contribute to the uncertainty of the foregoing calculations. Among these are a possible variation of the concentration of the absorbed film of A with the temperature and the effect of the catalyst. It would be possible to clear up some of these points by further experimental work, but many of them seem destined to remain obscure unless information can be obtained from other measurements than those of reaction rates.

Conclusion

The general impression given by Bell's experimental results is that his work is reliable. On the whole his data are more consistent than our own. We therefore have felt safe in accepting, without verification, his results on the order of the reaction. His interpretation of the main reaction as being due to collisions of permanganate ions on the adsorbed film of A is inherently reasonable, and is not in disagreement with the very uncertain calculations of the last section. There does not seem to us, however, to be any certainty that it is correct. The trend in the temperature coefficient which we found probably means that there is some additional reaction occurring, but it is not possible to assert anything as to its nature. Much could be done by varying the depth of the aqueous layer, keeping other conditions constant. If the disturbing reaction is the subsequent oxidation of B homogeneously, this should change the disturbance and the main reaction by the same factor, leaving their ratio unchanged, while if there is a homogeneous oxidation of A it would increase in importance with the depth of the layer. Also, of course, the homogeneous oxidation of A could be increased, if it occurs, by increasing the concentration of A, best at a fairly high temperature. It should be remembered too that none of the existing derivations of the equation $(d \ln k/dT) = E_0/RT^2$ is directly applicable to a system in which the rate depends on the stirring, and that possibly the trend in the value of E_0 is normal. It does not seem to us, however, that the reaction is one which would repay further study; its twofold dependence on stirring and on an unknown catalyst make it rather unpromising from **a** theoretical standpoint, and, therefore, we do not intend to study the system further.

This investigation was aided financially from a grant made to Professor A. A. Noyes by the Carnegie Institution of Washington.

Summary

1. The oxidation of benzoyl-o-toluidine by permanganate at a benzene–water interface is dependent upon the rate of stirring and upon the presence of some unknown catalyst.

2. The temperature coefficient of this rate does not appear to be 13, as Bell reported, but, when runs under comparable conditions are made, is about 2. It increases somewhat with the temperature, indicating that more than one reaction is occurring.

3. The mechanism suggested by Bell, impact of permanganate ions on an adsorbed film of benzoyl-o-toluidine, does not disagree with the data, but it is impossible to make any but the crudest sort of verification. Other mechanisms are possible.

A TEST OF THE RADIATION HYPOTHESIS OF CHEMICAL REACTION[1]

BY WILLIAM URE[2] AND RICHARD C. TOLMAN

RECEIVED JULY 17, 1928 PUBLISHED APRIL 5, 1929

The viewpoint that thermal unimolecular reactions are to be considered as photochemical reactions with the activating frequencies lying in the infra-red region should be susceptible of experimental test by subjecting a system to radiation from an outside source and determining whether or not the thermal reaction rate is thereby increased. The difficulties in such an experiment arise from two sources. First, there is the necessity of obtaining a high intensity of infra-red radiation, without at the same time raising the temperature of the reacting substance to such a point that the normal thermal rate is the preponderating effect. In the second place, the extreme opacity of almost all substances to all but the shortest of infra-red rays makes it difficult to find a window that will permit a high intensity over the wide range of frequencies which may be important in activating the molecules. For since we do not know in what part of the infra-red spectrum the activating frequencies might lie, a conclusive. test of the hypothesis should involve the use of all frequencies which are present to an appreciable extent in a hohlraum at the thermal reacting temperature.

Daniels[3] has shown that over a considerable range of frequencies the unimolecular rate of decomposition of N_2O_5 is not appreciably affected by radiation. In the present experiments the effect of infra-red radiation on the rate of racemization of d-pinene in the liquid state was studied.

---

[1] Presented before the regional meeting of the Pacific Division of the American Association for the Advancement of Science, June, 1928.

[2] This is part of a thesis submitted by William Ure to the Division of Chemistry, California Institute of Technology, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[3] Daniels, THIS JOURNAL, 48,607 (1926).

This reaction has been shown by Smith[4] to be unimolecular in the gas phase, in the liquid and in solution in various organic solvents. During the progress of the work Lewis and Mayer[5] and Mayer[6] published the results of a research also dealing with the activation of pinene by infra-red radiation. The conditions of their experiment were such that the molecules in the form of a molecular ray were subjected to an intense field of radiation for a very short length of time. Their method had the advantage of doing away with the necessity for any window and of eliminating collisions so that any effect noticed would be due to radiation. No racemization was detected.

It is to be observed, however, that in experiments in which the reacting substance is at a temperature much below that at which the thermal rate is appreciable, practically all of the molecules are in energy states which are very low compared to that of the energy of activation. Hence, since the energy per quantum of infra-red radiation is also small, only a few molecules will be in states from which they can become activated by absorption of a quantum, and thus the increase in rate brought about by the radiation may be unobservably small. This point will be considered in more detail later. For this reason the present experiments are of interest, since they differ from the work of Lewis and Mayer in that pinene was subjected to radiation while at a temperature at which the thermal reaction was just appreciable. The density of radiation in the shorter infrared has been increased by a large factor over that which prevails in a hohlraum at the reacting temperature of pinene. Thus if radiation of the frequencies over which it was possible thus to increase the density was active, a large increase in the already measurable rate should have been observed. This was not found and within the limits of error no increase in rate was observed.

Experimental Determination of the Rates

Apparatus.—The liquid pinene was contained in a vessel having a large window of very thin mica, which is highly transparent to the near infra-red, and was subjected to an intense beam of radiation from the open end of a cylindrical furnace kept at 850° which was situated just below the window. The vessel was cooled by air-blasts and the temperature of the liquid was maintained in the neighborhood of the boiling point, 156°.

The experimental arrangement is shown in Fig. 1. The reaction vessel A was a hemispherical glass vessel 5 cm. in diameter, the rim of which was flared out and ground flat, the mica sheet **0.04** mm. thick being clamped in place between two brass rings and a tight seal ensured by inserting cork gaskets. The cork was found to have no effect on pinene over a considerable period of operation.

It was found necessary to conduct the experiments in an atmosphere of nitrogen, since considerable oxidation of the pinene was found to take place in the presence of

air during the length of time and at the temperature necessary for the runs, and the construction of the reaction vessel made evacuation impossible. The reaction vessel was accordingly connected through the upright condenser B with a 5-liter bottle filled with dry nitrogen, and arrangement also made to bubble nitrogen through the liquid from the side-tube C. A tube D leading to within a few millimeters of the mica window and connected to a small reservoir E rendered filling and emptying the vessel an easy matter. The small reflux condenser B prevented the loss of pinene during the run. At F a thermocouple was inserted through a thin glass tube.

The radiator consisted of a cylindrical alundum tube 5 cm. in inside diameter and 25 cm. long, closed at the bottom end and wound with chromel wire No. 22 in the following manner. The tube was first completely wound in a spiral groove provided. The whole winding was then covered with a layer of "insalute" cement and the winding continued back over the upper half of the tube, giving a total length of about 65 ft. of wire. This allowed the upper end of the tube, which was left open, to attain more nearly the temperature of the lower end, which was closed and had better heat insulation. The lower end was closed by a disk of asbestos board, on the inside of which was attached a small helical coil containing about 6 ft. of No. 22 chromel wire. This was covered with a layer of "insalute" which then formed part of the inner wall of the furnace. The whole furnace was packed in asbestos, leaving the top open, except that this end was covered by a mica window 0.025 mm. thick to minimize cooling. A thermocouple junction was embedded in the wall of the furnace at approximately half-way along the tube. The interior walls of the furnace were coated with a mixture of powdered copper oxide with a small amount of "insalute" as a binder, thus giving a surface of a high degree of "blackness."[7] The furnace was operated at approximately 115 volts, A.C., and 2.2 amperes, the current being adjustable by hand in the body winding and in the end helix separately.

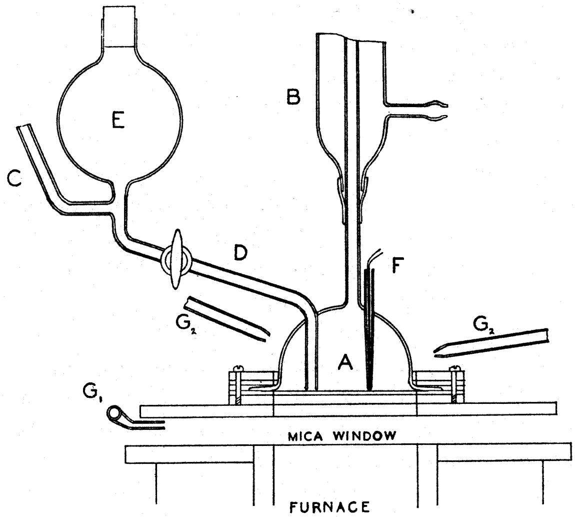

Fig. 1.

The reaction was followed by observing the optical rotation of the liquid, using a

---

polariscope reading to 0.01'. A 10-cm. tube was used for convenience in handling small quantities of liquid. It had a capacity of about 12 cc. and was enclosed in a water jacket through which water at 25° was pumped from a thermostat during measurements.

Material Used.—The pinene was obtained from Kahlbaum. It had an initial rotation at 25° (10-cm. tube) of +45.3° and was slightly yellowish in color. Fractionation under reduced pressure gave a colorless liquid of rotation +46.2 to +46.6° and $d_{4^\circ}^{25^\circ}$ of 0.857 to 0.855. Cildermeister and Hoffmann[8] record for *d*-α-pinene from Grecian turpentine $d_4^{25} = 0.854$. The thermal rate of samples of the same pinene was observed in the gas phase by a method similar to that used by Smith." The temperature was that of boiling *p*-nitrotoluene (237") and the values of k_1 obtained were 3.03×10^{-3} and 2.91×10^{-3} min.$^{-1}$, being in good agreement with Smith's value of 3.07×10^{-3} min.$^{-1}$.

Experiments.—About 20 cc. of pinene was placed in the reaction vessel, forming a layer over the mica window 1.2–1.4 cm. thick. A stream of dried nitrogen was then bubbled through the liquid through the tube C for about ten minutes to displace all of the air in the vessel. The stopcock was then closed and the system connected to the nitrogen reservoir. The furnace was moved up into a position with the open end 1.7 cm. from the reaction vessel window. A blast of air was passed between the two windows from the fan-shaped tube G_1 and two jets of air G_2 directed on the upper side of the reaction vessel for the purpose of regulating the temperature of the liquid. The temperature was allowed to rise to the neighborhood of the boiling point. The liquid was not allowed to boil vigorously in case sudden increase in pressure might rupture the window. Runs were carried on for from four to eight hours, the temperature of the liquid and that of the furnace being taken at frequent intervals. The current to the furnace was kept about 2.2 amperes by a hand-operated rheostat. The liquid varied in temperature 4–6° during a run and the furnace temperature 10–15°. At the expiration of a run the furnace was removed and the liquid cooled to room temperature by the air blast. It was then expelled into the reservoir E and removed from there to the polariscope tube.

Results.—The results of four experiments are shown in Table I. The fifth and sixth columns give the average of a number of polariscope readings, taken before and after the run, respectively, individual readings being reproducible to 0.03'. The seventh column shows the difference; it is to be noted that a slight decrease was observed in all four runs but only in the last two does this become greater than the error of measurement. That this decrease is due to the thermal reaction taking place at the temperature of the liquid is shown by the figures of Col. 9, which are calculated values of the decrease for the thermal reaction at the average temperatures given. The constants at these temperatures, which are shown in Col. 8, were obtained by determining the rate at the boiling point, 156°, and then extrapolating down over the small temperature interval involved using Smith's value of the heat of activation, 43,710 cal./mole. The rate at the boiling point was determined experimentally by keeping pinene at 156° in an atmosphere of nitrogen for periods of twenty-four hours. The rate thus found, $k_1 = 1.90$ X 10^{-6} min.$^{-1}$, was about

---

[8] Gildermeister and Hoffmann, "Die atherischen Öle," Schimmel and Co., Leipzig, 1910, Vol. I, p 305

50% higher than that obtained by a direct extrapolation of Smith's data using his rate for the liquid at 184.6°.

TABLE I

RESULTS OF EXPERIMENTS

Run	Furnace temp., °C.	Liquid temp., °C.	Time, min.	α_1	α_2	A	$k_1 \times 10^6$ (min.$^{-1}$)	$\Delta\alpha$ (calcd.)

Determination of the Intensity of the Radiation

The Effective Temperature of Furnace.—In order to determine the intensity of the radiation available for activation, it was first necessary to obtain a check on the effective black-body temperature of the furnace. This was done in the following way.

The flux of radiant energy coming from the furnace was determined after the method of Daniels[3] by absorbing the energy in a solution of copper chloride and measuring the rise in temperature produced. Coblentz[9] has shown that a 2-cm. layer of 2.5% cupric chloride solution will absorb practically all of the energy in the spectral region lying at longer wave lengths than 0.6 μ. Accordingly the furnace was set in position as for a run and a stream of cupric chloride solution was passed through the reaction vessel at a known rate, the temperature of the stream being taken at points on either side of the reaction vessel. Heating by conduction was reduced by passing a strong blast of air between the furnace and the window to such an extent that the average temperature of the air blast was maintained nearly the same as the temperature of the solution. Thus in one experiment the solution rose from 27.6 to 36.7° while the average temperature of the air blast was 38.2° and the time of flow for 500 cc. was 518 sec., giving a flux of 527 cal. per minute. The average of eight such experiments was 535 cal. per minute with a maximum deviation of 28 cal.

The effective black-body temperature of the furnace was then estimated by assuming some temperature and calculating from the geometry of the set-up and the transmission losses the corresponding flux in the reaction vessel. This was to be compared with the experimentally determined value and the assumed temperature corrected to give the correct flux. Thus the flux of radiation through a circular surface of diameter D from a circular black-body surface of the same diameter and parallel to the first at a distance d is given by[10]

$$F_\nu = \frac{1}{2D^2}\, c\, u_\nu T_\nu \left(\frac{D^2}{2} + d^2 - d\sqrt{D^2 + d^2}\right) \qquad (1)$$

---

[9] Coblentz, *Bulletin of the Bureau of Standards*, **9**, 110 (1913).

[10] J. W. T. Walsh, "Photometry," Constable and Co., London, 1926, p. 104.

where $F_\nu d\nu$ is the energy per unit area per second in the frequency range ν to $\nu + d\nu$, $u_\nu d\nu$ the density of radiant energy in the same frequency range, corresponding to the black-body temperature of the source, and c the velocity of light. T_ν is the fractional transmission of the intervening windows at the frequency ν.

The total flux was then obtained by graphical integration of Equation 1 over all values of ν using for u_ν the values given by the Planck radiation law, assuming a temperature of 800°, and for T_ν values obtained from Coblentz's[11] data on the transmission of mica.

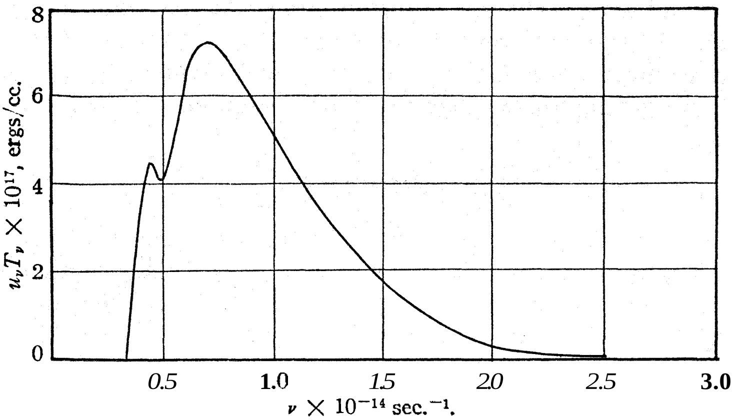

Fig. 2.—Transmitted energy distribution curve.

A plot of $u_\nu T_\nu$ against ν is shown in Fig. 2. The area under the curve was found to be 1.408×10^{-10} cal. per cc.

Substituting in Equation 1, $D = 5$ cm., $c = 3 \times 10^{10}$ cm./sec., $d = 2.2$ cm., one obtains

$$F_\nu d\nu = 3.19 \times 10^9 u_\nu T_\nu d\nu \text{ per sq. cm. per second} \tag{2}$$

$$F_{\text{total}} = \pi D^2/4 \times 3.19 \times 10^9 \times 60 \int_0^\infty u_\nu T_\nu d\nu = 529 \text{ cal. per min.} \tag{3}$$

Since the observed value was 535 cal. per min., it seems fair to treat the furnace as a black-body emitting at 800°, especially as the actual temperature over the greater part of the furnace was 40–50° above this, the temperature near the open end dropping to about 750°.

Intensity of Radiation.—In order to determine whether or not the radiation was of such an intensity that an observable change of rotation would have been noticed had the radiation been effective, we must compare the density of radiant energy which has been produced in the reacting substance with that in a hohlraum at the temperature of the liquid during the irradiation.

---

[11] Coblentz, "Investigations of Infra-red Spectra," *Carnegie Institution Publication Number* 65, 1907, Vol. III, p. 49.

The average intensity of radiation in the liquid layer as a fraction of the incident intensity can be obtained from the formula

$$\bar{I}/I_0 = \frac{1}{\alpha x_1}(1 - e^{-\alpha x_1})$$

where α is the absorption coefficient and x_1 the thickness of absorbing material.

Taking Coblentz's[11] data on pinene, the absorption coefficients α have been calculated at intervals over the range from 1 to 9μ, and, using these, values of $\bar{I}/I_0$ obtained from the above equation.

The flux of energy through the lower surface of the liquid is given by Equation 2. Making a correction for the slight divergence of the beam, multiplying by the average intensity ratio and dividing by the velocity of light, we get for the average radiation density of the frequency v the expression

$$\bar{u}_\nu = 2.57 \times 10^9 \frac{u_\nu T_\nu}{c} \frac{\bar{I}}{I_0}$$

Table II shows the values of 4, over the frequency range corresponding to wave lengths from 1 to 5.5μ, and also the values of the radiation density u_ν at 152" corresponding to the temperature of the liquid, the latter values being calculated from the Planck radiation law.

TABLE II

VALUES

$\lambda(\mu)$	$\nu \times 10^{-14}$	$\bar{u}_\nu \times 10^{19}$	$u_\nu \times 10^{19}$ (152°)
1	3	7.4×10^{-4}	3.69×10^{-9}
1.2	2.5	8.98×10^{-3}	3.84×10^{-7}
1.5	2	0.148	8.09×10^{-5}
2.0	1.5	0.805	9.85×10^{-3}
2.5	1.2	1.027	0.142
3	1	0.456	0.803
3.5	0.858	0.217	2.49
4	0.75	0.833	5.48
5	0.6	1.19	15.5
5.5	0.546	0.733	21.6

Figure 3 shows a plot of $\bar{u}_\nu$ and $u_\nu(t = 152°)$ against frequency v. It is to be noticed that out to a wave length of nearly 3μ the density of radiation produced is very much greater than that at 152°, so that if these shorter wave lengths were active the reaction rate should have been increased many times. The range of greatly increased intensity includes the red end of the visible and it is here we would expect an effect on the basis of the simple radiation hypothesis, since for pinene the total energy of activation corresponds to a wave length of 0.65μ. Past 3μ the induced density falls considerably below the other, so that these experiments do not furnish any information as to the effect of these longer wave lengths.

Discussion

The results obtained here show that radiation in the infra-red out to a wave length of 3μ does not accelerate the rate of racemization of pinene, and, therefore, that in this thermal reaction radiation over this range is not the agency which keeps up the quota of activated molecules. One must' still admit the possibility, however, of longer wave lengths being active, since at a temperature of 152° the maximum intensity of black-body radiation lies out as far as 12.5μ. Further, both N_2O_5 and pinene have strong absorption bands in the region beyond 3μ.[11,12]

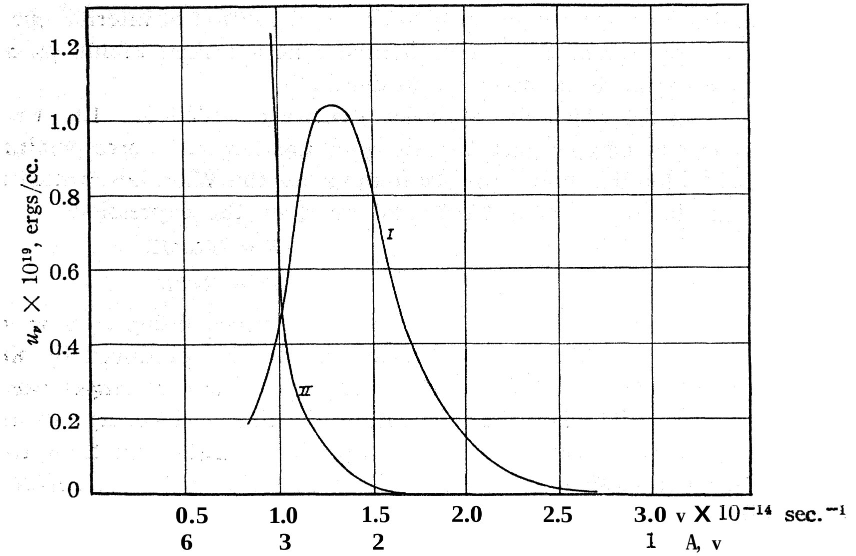

Fig. 3.—Energy distribution in liquid layer. I, Energy from furnace ($\bar{u}_\nu$). II, Black-body energy at 152".

Turning to the work of Lewis and Mayer, it appears at first sight as though they had extended the range of wave lengths over which radiation is shown to be inactive in this reaction out of 13μ. The method of treatment used by them, however, seems to require some further analysis. Under the conditions of their experiment, pinene coming from a nozzle at a temperature of 93° was shot through a radiation field corresponding to a black-body temperature of about 1000°K. and was condensed out on the farther side by liquid air. The length of time during which the molecules were exposed to the radiation was calculated to be 1.2×10^{-4} sec. To treat these data by the method which has been applied to the experiment just described, one may first ask the following question. By what factor is it necessary to increase the thermal reaction rate at 93° in order that it

---

[12] Daniels, THIS JOURNAL, 47, 2856 (1925).

may be observable during the time of exposure? Mayer has calculated that the minimum rate which he could have observed is $k_1 = 431$ sec.$^{-1}$, which would be the thermal rate at 800°K. By using the value here given of the reaction rate at 156° and extrapolating in the usual manner, one finds the thermal rate at 93° to be 4.68×10^{-12} sec.$^{-1}$. Hence the rate at 93° must be increased by a factor of 10^{14} if it is to be observable. This can take place in two ways, assuming that radiation is to be the activating agency. First, the density of radiation over the frequencies to be tested may be increased by a factor of 10^{14} over the corresponding densities in a hohlraum at 93°. Second, the molecules by successive absorption of quanta may be brought up to such a distribution of internal energies as would prevail at 800°, the thermal reaction then taking place. Let us now examine these processes in detail.

The frequency at which the radiation density at 1053°K., the temperature of the furnace, is just 10^{14} times as great as the corresponding density at 93° (366°K.) may easily be found from the Wien law, which is applicable in the region considered, and gives us the expression

$$\frac{u_\nu}{u_\nu'} = \frac{e^{h\nu/kT'}}{e^{h\nu/kT}} \quad \text{where} \quad \frac{u_\nu}{u_\nu'} = 10^{14} \quad \text{and} \quad \begin{array}{l} T = 1053\text{°K.} \\ T' = 366\text{°K.} \end{array}$$

This gives for ν the value 3.79×10^{14} sec.$^{-1}$, corresponding to a wave length of 0.79μ. At shorter wave lengths the density produced by the furnace is greater than 10^{14} times the density at 93° and at longer wave lengths it is less. (The fact that the actual distribution of energy in the furnace as used by Mayer was such as to produce densities at these frequencies two or three times that of black-body radiation at 1053°K. makes only a very slight change in this result.) Therefore, if we regard the molecules as remaining throughout the length of furnace substantially in the states which they have at 93°, then radiation has been proved to be inactive in this experiment only for wave lengths shorter than 0.79μ.

Now let us consider the second possibility that by successive absorption of quanta the molecules are distributed in states corresponding to a considerably higher temperature than 93° throughout a considerable portion of the length of the furnace. For the number of quantum jumps per second from a lower state i to a higher state j, we have the quantity $B_{ij}u_{\nu ij}$ where B_{ij} is Einstein's coefficient of absorption and $u_{\nu ij}$ is the radiation density at the frequency necessary to transfer the molecule from state i to state j. From correspondence principle considerations[13] a maximum value of B_{ij} can be given as of the order of 10^{20} c. g. s. units;[14] and taking

---

[13] See Tolman, "Statistical Mechanics with Applications to Physics and Chemistry," Chemical Catalog Co., New York, 1927, p. 179.

[14] Undoubtedly some arbitrariness is introduced by the use of the value 10^{20} for B_{ij}. This has been set as a probable upper limit and actually from absorption data values of 10^{14} to 10^{19} have been obtained. Tolman, *Phys. Rev.*, 23, 693 (1924).

the maximum intensity in the black-body spectrum at 1073°K.[15] we should have $u_{\nu ij} = 9.75 \times 10^{-17}$ ergs-sec. per cc., giving us about 10^4 jumps per second as the maximum possible number that could take place for any given absorption line. Thus in the 1.2×10^{-4} seconds taken to pass through the furnace a molecule could not make more than one jump on the average for each absorption line that it had in the neighborhood of the maximum intensity of radiation; while the number of jumps for lines of other frequencies would be even less. If this be so, the distribution of molecules among the energy states throughout the whole length of Mayer's tube may not have been appreciably different from that prevailing at 93°.

Hence Mayer's experiment has not proved the ineffectiveness of radiation out to 13μ in the *thermal* racemization of pinene, hut has shown that in the short length of time during which the molecules remained in his furnace, radiation corresponding approximately to 1053°K. was not able to raise his molecules from states corresponding to 93° to states high enough so that the reaction was appreciable.

The foregoing discussion makes evident the desirability, in testing the radiation hypothesis, of working in the presence of excess radiation *at temperatures* where the thermal rate is already appreciable,[16] as was done in the present experiments.

Summary

1. Experiments are described which show that the rate of racemization of pinene is not accelerated by a large increase in the density of radiation over the range of wave lengths out to 3μ.

2. The nature of the experiments does not warrant any conclusion as to the effectiveness of wave lengths longer than 3μ.

3. The work of Lewis and Mayer on pinene is criticized from the point of view of the justifiability of the conclusions which they drew as to the inactivity of the longer wave lengths, and it is shown that they have not proved that radiation of wave lengths out as far as 13μ is inactive in the thermal racemization of pinene.

PASADENA, CALIFORNIA

---

[15] The temperature used here is slightly higher than that given by Mayer. It is, however, more favorable to a high rate of activation and was used since data at this temperature were available.

ACTIVITY COEFFICIENT OF DIACETONE ALCOHOL IN AQUEOUS SALT SOLUTIONS

BY GÖSTA ÅKERLÖF

RECEIVED AUGUST 7, 1928 PUBLISHED APRIL 5, 1929

Introduction

Our present theories for the velocity of catalyzed reactions in concentrated solutions of strong electrolytes are handicapped because little is known concerning a number of the variables which may have to be considered. For an ever-increasing number of reactions we know quite definitely that the velocity is either a function of or parallel to the thermodynamic activities of the electrolytes present. Thus far our knowledge of the influence of changes of the activity coefficients of the reacting substance is very incomplete. This investigation has been carried out in order to get an idea of the magnitude of the changes of the relative activity coefficient of diacetone alcohol in concentrated hydroxide–salt solutions. Experimental methods suitable for this study were limited both in number and accuracy. The changes in partition coefficient between the salt solutions and an insoluble organic liquid have been utilized.

Experimental Method

According to Gibbs the activity of a certain component is the same in all phases of a polyphase system in equilibrium at constant temperature. The activity is defined as the product of the activity coefficient γ and the concentration c

$$\gamma_1 c_1 = \gamma_2 c_2 = \gamma_3 c_3 = \ldots$$

where the subscripts denote the different phases. Let us assume that the activity coefficient of diacetone alcohol in pure water has the value of unity. Dissolved in another solvent, as toluene, the activity coefficient may be considered as a constant and independent of the concentration, because the partition coefficient with pure water is a constant. We then obtain for the activity coefficient of diacetone alcohol in a salt solution

$$\gamma = k \times c_1/c_2$$

where k is the partition coefficient with pure water and c_1 and c_2 are the concentrations of the diacetone alcohol in the salt solution and toluene, respectively. These values are measured simultaneously.

To determine these concentration changes a Zeiss interferometer was employed. After some difficulties in obtaining clear spectra for solutions with solvents other than water had been overcome, the following procedure was adopted. First a series of salt solutions was made up in 500-cc. Erlenmeyer flasks. All salt concentrations were calculated as weight normality. The amount of water used was 400 g. at lower concentrations and 300 g. at higher ones. Usually a very carefully filtered, highly concentrated standard solution of the salt was used for making up the solutions. Most of the C. P. or analyzed chemicals used contained a large amount of dust.

After the salt solution had been given a careful mixing, about 50 cc. was poured over the edge of the flask, which was slowly rotated. Immediately after this, amounts of solution containing 100 g. of water were weighed off in two 250-cc. Erlenmeyer flasks with ground-glass stoppers. In order to avoid evaporation of water the weighing had to be done rapidly. The average accuracy of the weighing was about 0.1--0.2 g. Wetting of the ground surface inside the neck of the flasks by the solutions was avoided. To one of these weighed solutions was added 100 cc. of solvent containing about 1% of diacetone alcohol and to the other one also 100 cc. of solvent but with only 0.2% of the alcohol present. It was found that when the pure solvents used were shaken with an aqueous salt solution rather stable emulsions were formed. The addition of a small amount of diacetone alcohol seemed to prevent this and the solutions cleared rapidly. The difference in diacetone alcohol concentration of the two different samples of the solvent added to the salt solutions was measured very carefully.

After the solvent had been added the glass stoppers to the flasks were wetted with two or three drops of the solvent, rotated with a slight pressure until an optically clear joint had been obtained and finally pressed in hard. Then the flasks were shaken vigorously three or four times for three to five-minute periods at intervals of about one hour. Tests of the efficiency of the shaking seemed to show that after the second one the differences obtained probably were caused by other experimental errors. After the last shaking had been completed the solutions were left for twenty-four hours so that they became perfectly clear. If the measurements were started shortly after the last shaking the results seemed to be very erratic. The enormous sensitivity of the interferometer and the very small concentration differences that had to be used, required optically clear solutions.

For the measurement the two layers in each flask were first separated. The upper one was removed by pouring the greater part of the liquid slowly over the edge of the flask into a 150-cc. Erlenmeyer flask, which was immediately closed with a rubber stopper. A small separatory funnel was used to obtain the lower layer free from the upper one. The remaining solution was poured slowly into the funnel and then withdrawn ten to fifteen minutes later. It was found to be desirable to obtain the amount of diacetone alcohol in the salt solution indirectly. The solutions containing salt were therefore thrown away and only the solvent solutions were used for the measurement.

The difference between the apparent total amount of diacetone alcohol present and that retained by the organic solvent after shaking with the salt solution, gave the amount in the latter. This gives the following equation for the calculation of the activity coefficient of the diacetone alcohol

$$\gamma = \frac{R_0 - R_1}{R_1} \times \frac{R_2}{R_0 - R_2}\ .$$

where R_0 is the reading for the original solvent solutions, R_1 after shaking with water and R_2 after shaking with the salt solution (all values corrected).

The solutions were now ready to be used. The two compartments of the all-glass cells belonging to the interferometer were washed out carefully three or four times with their respective solutions, then filled to overflowing and the glass covers put on in such a way that no air bubbles were inclosed. Finally the cell was wiped dry, the end-plates polished and the cell placed in the little kerosene bath of the interferometer. Water could not be used for the bath, because it was impossible to remove all of the solvent from the outside of the cell by wiping, due to the afterflow from the casing around the upper part of the cell. When placed in water the thin oil film on the surface of the end-plates became uneven, which completely distorted or entirely blotted out the spectra. The correct reading of the interferometer was very difficult. The distance between two spectral bands was about 16 units on the scale. The greatest difficulty was to choose the right bands. At times four or five bands in the upper spectrum appeared to have nearly the same color and by pairs to coincide with the two middle bands of the lower spectrum. An error of three or four times 16 units, therefore, could easily be made. This necessitated high sensitivity to small variations in color and considerable experience in judging the appearance of the bands.

When the cells had been placed in the interferometer bath the liquid was stirred slowly at the rate of about twenty to forty turns a minute. The time required to get a reading varied between five and twenty minutes. Too rapid stirring caused splashing and usually gave very poor spectra. When the rate was too slow the time necessary to obtain a good reading lengthened considerably and sometimes also gave distorted spectra. Splashing of the bath liquid was rather difficult to avoid because the bath had to be kept nearly full and kerosene has a low viscosity. Exchange of kerosene for other liquids with higher viscosity (as ethyl phthalate) brought in other disadvantages which were considered as far from serious. Kerosene evaporating from the outside of the bath slowly attacked the Canada balsam with which the prisms of the interferometer were fastened. This caused continuous changes of the zero point of the instrument. In order to avoid these changes the commercial kerosene was fractionated and the fraction boiling around 350" was used. This decreased to a large extent the zero point changes. They amounted only to a few units a week.

A large number of solvents were tried out for these experiments. Solvents with low boiling point and high volatility, like toluene or benzene, could not be used. Bromobenzene and cymene were finally selected as most suitable. The former was first washed by inside spraying with water for four to five hours. The water velocity was about 2-3 liters a minute. At higher velocities emulsions were formed. Then the solvent was dried with fused calcium chloride and vacuum distilled in a large all-glass still. The commercial cymene was first distilled three times from concentrated potassium hydroxide solution. It was then washed in a continuous stream of water for four to five hours, dried and redistilled in high vacuum. When shaken with water this solvent separated rapidly and became perfectly clear. The diacetone alcohol was used as obtained from Eastman Kodak Co. It contained slight traces of water but attempts at further drying failed. Mesityl oxide and water were formed. The former is insoluble in the latter and therefore separated upon further addition of water. However, the amount of impurities present was too small to affect the results perceptibly.

Correction of the Interferometer Readings

The readings on the interferometer were not exactly proportional to the diacetone alcohol concentration. With increasing concentration the correction necessary to obtain proportionality with the true values increased. At the end of the scale the correction amounted to about 300 units. The correction curve seemed to be characteristic for the instrument and independent of the nature of the solvent employed. Table I gives a summary of the measurements for the determination of the correction curve.

For the calculation of the experimental results which will be presented below, the corrections were obtained graphically. The corrections necessary when the diacetone alcohol concentration in the salt solution phase also is measured directly might be indicated here. Diacetone alcohol has a higher refractive index than water. The addition of salt to pure water gives a higher refractive index to the solution. A given

[a] W. D. A. gives the amount of diacetone alcohol present in weight per cent. For cymene and bromobenzene, standard solutions containing 6.978 volume per cent. of diacetone alcohol were used. C. D. A. gives the number of cc. of these solutions diluted to a total of 100 cc.

[b] This value instead of 142 was used because it gave better agreement with the measurements for water and bromobenzene solutions.

amount of diacetone alcohol must then cause a smaller deviation in the interferometer when dissolved in the salt solution as compared with the one for pure water. With the proper scale correction applied, a linear decrease is obtained with increasing salt concentration. After correcting for scale deviation, the reading obtained for the salt solution used in the partition experiment and multiplying with the corrected decrease ratio for the salt solution used, all measurements are comparable and give the correct activity coefficient. However, this method is quite complicated to carry out and should ordinarily be avoided.

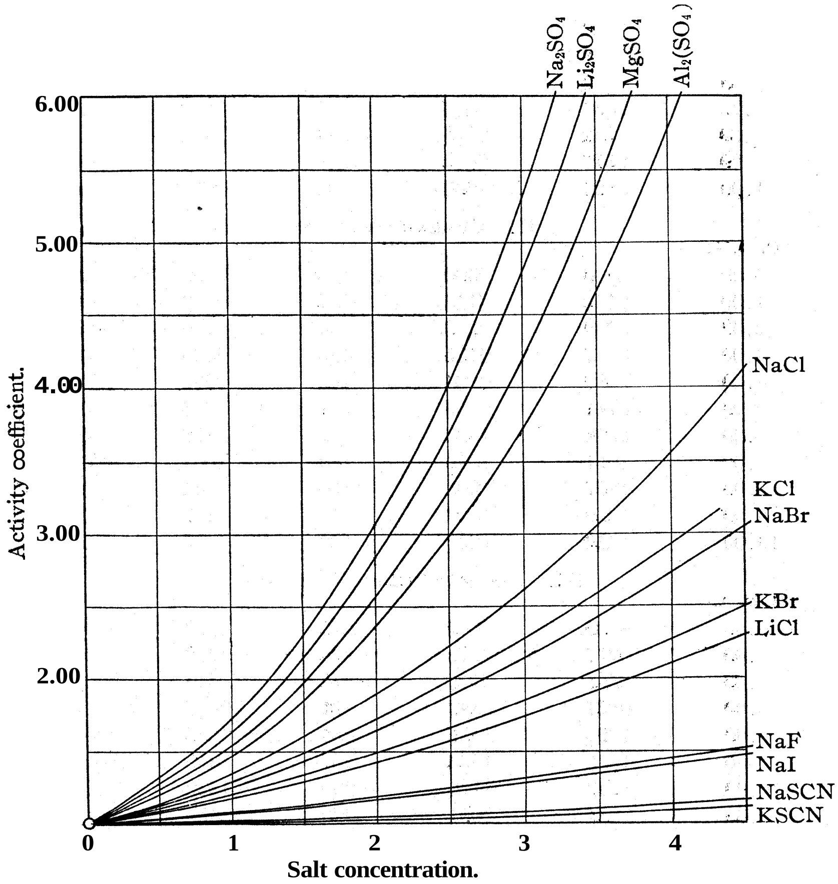

Fig. 1.—Curves for the relative activity coefficient of diacetone alcohol in various salt solutions.

Experimental Results

Table II gives a summary of the measurements. All interferometer readings are the uncorrected values. The temperature for the measurements was on the average 24° with a maximum variation of about one degree. A suitable thermostat was not available but the temperature coefficients seem to be quite small or negligible. The general accuracy of the results is a little difficult to judge but most probably the relative errors in the distribution of the curves seldom exceed 5%. The results are also independent of the nature of the solvents used, that is, the same values were obtained either for bromohenzene or cymene (a mixture of ethyl phthalate and bromobenzene also gave the same result). Up to the limit of the concentration that could be used for diacetone alcohol, the activity coefficients obtained seemed to be independent of the concentration either in the organic solvent phase or the salt solution used. All salt concentrations in Table II are expressed in weight normality per 1000 g. of water. Fig. 1 gives the curves for the measurements at increasing salt concentrations; Fig. 2 is the curve for the logarithm of the activity coefficients at constant total molarity in sodium–lithium chloride solutions. Fig. 3 shows the corresponding curves at varying constant total molarity. All curves in this last figure are drawn as straight, parallel lines because this seemed best to represent the results. It gives an analogy to the curves obtained by Åkerlöf[1] for the decomposition velocity of diacetone alcohol in alkali hydroxide–salt solutions at varying constant total molarity.

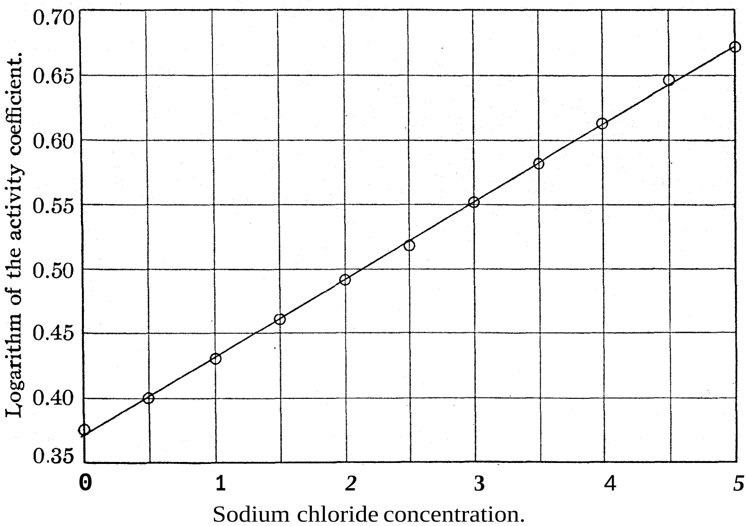

Fig. 2.—Curve for the logarithm of the relative activity coefficient of diacetone alcohol in sodium–lithium chloride solutions at constant total normality of 5 N.

Table II also contains the values for (log γ)/N. These values seem

---

[1] Åkerlöf, This Journal, 49, 2955 (1927).

to be fairly constant. Randall and Failey[2] have recently shown that this probably is true for non-electrolytes in salt solutions. In Table III is given a comparison between the values for the activity coefficients of a few gases in 2 N sodium and potassium chloride and sodium sulfate solutions and those obtained for diacetone alcohol in the same salt solutions,

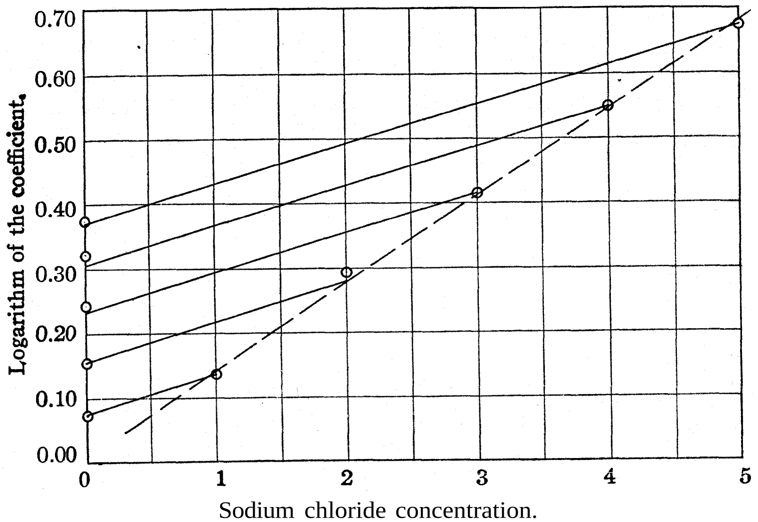

Fig. 3.—Curves for the logarithm of the relative activity coefficient of diacetone alcohol in sodium–lithium chloride solutions at varying constant total normality.

Considering the large probable errors of the solubility measurements used for the calculation of the activity coefficients of the gases, we might perhaps be justified in assuming them to be approximately independent of the nature of the gas employed or constant for a given salt solution.

[a] Values obtained from data in Abegg-Auerbach, "Handbuch der anorg. Chemie," **6**, 1 (1927). Other data from Randall and Failey.

If this is the case we apparently obtain the same or at least a very similar distribution of the curves for the activity coefficients of the gases in salt solutions as for those of diacetone alcohol.

Discussion of the Results

These measurements were undertaken in order to determine, if possible, whether or not the decomposition velocity of diacetone alcohol in alkali-hydroxide–salt solutions was influenced by changes in the activity coefficient of the reacting substance. In Fig. 4 are given some of the curves for the relative activity coefficients of ethyl acetate in various salt solutions as calculated from the solubility measurements of Glasstone and Pound.[3] A comparison of these curves with those in Fig. 1 shows a very striking similarity. Their distribution is nearly the same in both cases. In Fig. 5 are the curves for the velocity of hydrolysis of ethyl acetate by 0.1 N hydrochloric acid in various salt solutions.[4] Fig. 6 shows the corre-

sponding curves for the decomposition of diacetone alcohol in 0.1 *N* alkali hydroxide-salt solutions.[5] In the case of ethyl acetate there is a great similarity between the distribution of the curves for velocity and activity coefficients. For diacetone alcohol the two sets of curves are also distributed in a similar manner, although their direction is widely different. For sodium chloride solutions the velocity decreases and activity coefficient increases rapidly. The curves for sodium sulfate, chloride, bromide, iodide and sulfocyanide solutions follow each other in the same order and at about the same distance in relation to each other. The position of the activity curves for potassium salt solutions below those for sodium salts are exceptions to identical distribution of activity and velocity curves.

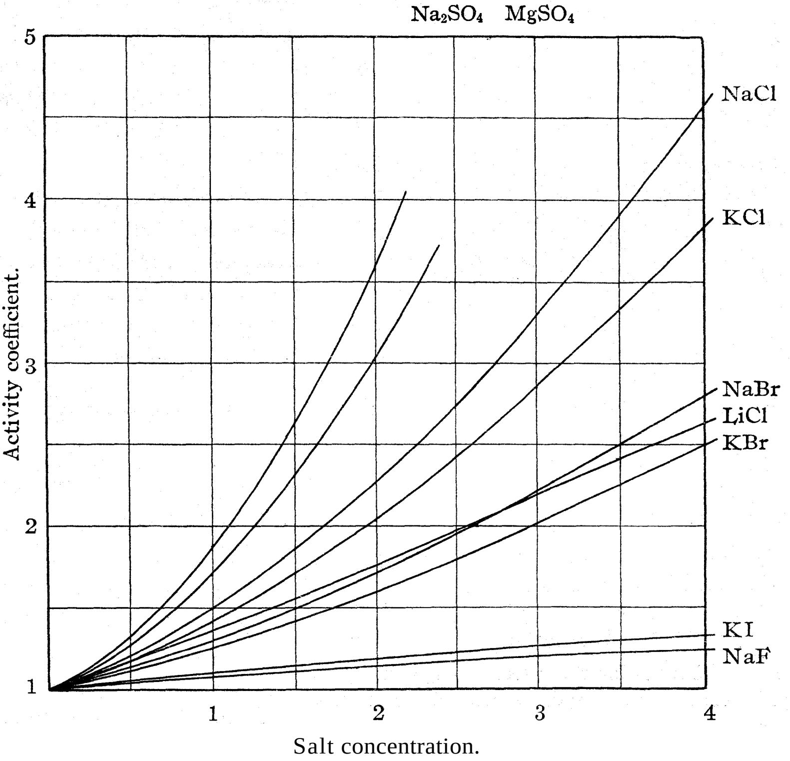

Fig. 4.—Curves for the relative activity coefficient of ethyl acetate in various salt solutions as calculated from solubility measurements of Glasstone and Pound, and Glasstone, Dimond and Jones.

In view of these facts we might feel inclined to believe that in the case of ethyl acetate velocity and activity of the reacting substance are

---

[5] Data for Fig. 6 are obtained from Åkerlöf, This Journal, 48,3046 (1926).

intimately connected. The data at present available are not very accurate but it seems as if this could be the case.[6] The use of a similar explanation for diacetone alcohol appears to offer great difficulties because direction and distribution of velocity and activity curves are not always the same. Decrease in velocity and increase of activity would give the velocity as an inverse function of the activity, while for sulfate solutions where both velocity and activity increase with increasing salt concentration, the former apparently would be proportional to a function of the latter.

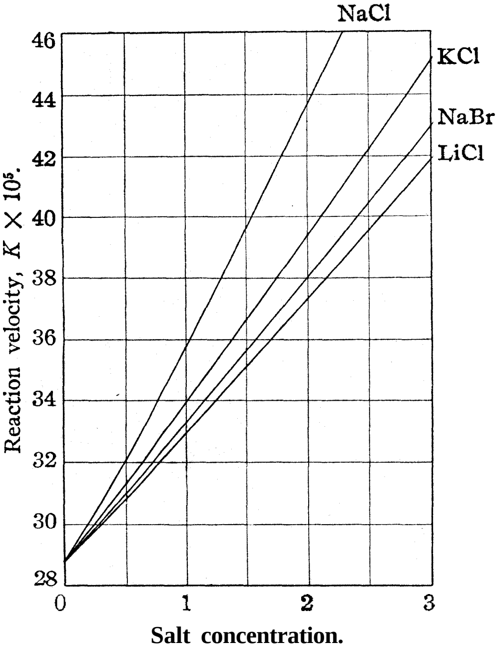

Fig. 5.—Curves for the velocity of hydrolysis of ethyl acetate by 0.1 N hydrochloric acid in various salt solutions.

According to the theory of Brönsted,[7] the velocity of a simple chemical reaction, which does not give definite intermediary products, is given by the equation

$$v = k(\mathrm{A})(\mathrm{B}) \frac{\gamma_{\mathrm{A}} \times \gamma_{\mathrm{B}}}{\gamma_{\mathrm{X}}}$$

where v is the velocity, k is a constant, (A) and (B) are the concentration of the two reacting substances A and B and γ_{A}, γ_{B} and γ_{X} are activity coefficients of A, B and X. The latter is a collision compound of momentary existence. If A is an ion, the intermediate is also an ion with the same valence. Then the velocity is proportional to the concentration of the reacting ion and the activity coefficient of the substance B.

Previously it has been shown by Åkerlöf[8] that the decomposition velocity of diacetone alcohol in pure aqueous solutions of the alkali hydroxides at higher concentrations is proportional to the activity coefficients of the hydroxides. Furthermore, the consideration of the velocity as a function of the activity of the reacting substance leads to different equations for different salts present. Adhering to the validity of the equation

[8] Åkerlöf, THIS JOURNAL, 49, 2966 (1927).

of Bronsted, this may indicate that the activity coefficient of diacetone alcohol is canceled by γ_X. Then we must also assume that X is formed by the addition of both cation and anion of the hydroxide and has the character of a neutral molecule. This would give the velocity as being proportional to the concentration of the hydroxide and as a function of the activity coefficient of the same in qualitative agreement with the measurements.

If this explanation approaches the true conditions, we could expect to find the same or at least a very similar distribution of the curves for velocity and activity coefficients of the hydroxides in hydroxide–salt solutions. When the salt present decreases the velocity this conclusion seems to be approximately valid, as shown in Fig. 7.[9] The sulfate solutions might seem to be an exception and therefore make our explanation questionable. On the other hand, the sulfates increase the activity coefficients of the reacting substance very rapidly and this increase is relatively many times larger than the increase in reaction velocity at corresponding salt

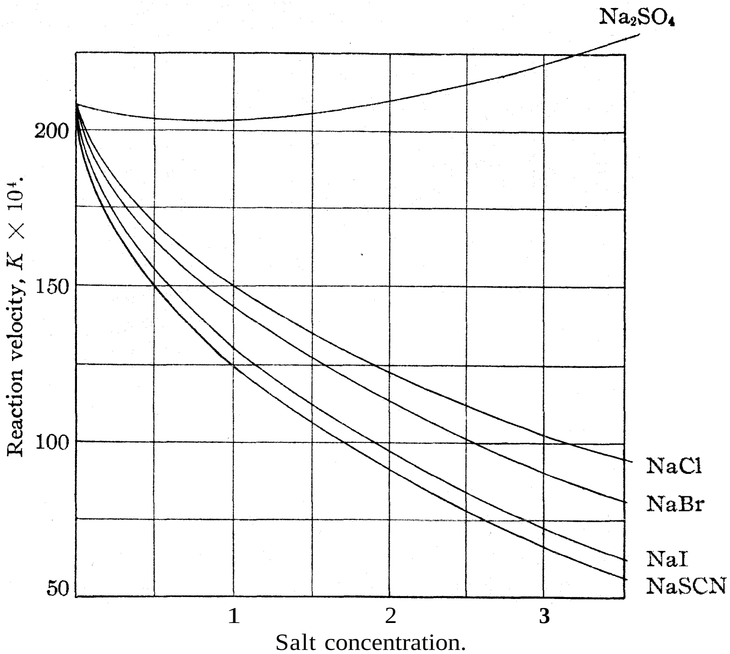

Fig. 6.—Curves for the decomposition velocity of diacetone alcohol in 0.1 N alkali hydroxide–salt solutions.

---

[9] Data for Fig. 7 are from measurements of Åkerlöf, THIS JOURNAL, 48, 3046 (1926); ibid., 48, 1160 (1926); Harned, *ibid.*, 47, 684, 689 (1925); Harned and James, *J. Phys.* Chem., 30, 1060 (1926); Douglas, "Tbesis," University of Pennsylvania, 1926.

concentrations. Most probably this must tend to cause larger deviations from a function of the activity of the electrolytes present.

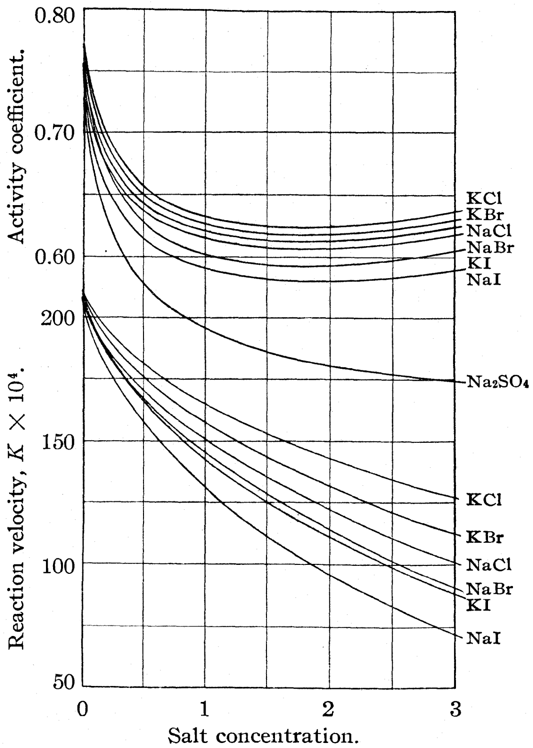

Fig. 7.—Curves for the decomposition velocity of diacetone alcohol in 0.1 *N* alkali hydroxide–salt solutions and the curves for the activity coefficient of the hydroxides in the same salt solutions.

Summary

The relative activity coefficient of diacetone alcohol in various salt solutions at 24 ± 1° has been measured, using an interferometric method to determine the partition coefficient of diacetone alcohol between the salt solutions and an insoluble organic liquid.

The results obtained agree closely in order of magnitude and distribution with the results of the calculation of the activity coefficient of ethyl acetate in the same salt solutions from solubility measurements of Glasstone and Pound. The relative activity coefficients for some permanent gases in these salt solutions are apparently also of the same order of magnitude and give most probably the same distribution as obtained for diacetone alcohol and ethyl acetate.

A short discussion has been given of the relation of these results to the theory of Bronsted of velocity of reactions catalyzed by strong electrolytes. It seems to be very difficult to find a thoroughly satisfactory explanation of the changes of the decomposition velocity of diacetone alcohol in various solutions of strong electrolytes.

THE SOLUBILITIES OF LEAD PHOSPHATES[1]

BY HORACE MILLET AND MAURICE JOWETT

RECEIVED AUGUST 20, 1928 PUBLISHED APRIL 5, 1929

Although some measurements have been made of the solubilities of the secondary and tertiary phosphates of lead in water, no measurements have been made under conditions sufficiently well defined to allow of calculation of the solubility products of these salts, and hence to allow of calculation of the solubilities under various conditions.

The solubilities of these salts are of biological interest in connection with lead poisoning and the lead treatment of cancer. Some evidence has been obtained by Aub and others,[2] and by Brooks[3] that inorganic lead compounds are transformed into lead phosphate in the body, lead phosphate being regarded as the least soluble salt of lead under body conditions.

The solubility of lead phosphates is thus probably the limiting factor with regard to lead-ion concentrations in the body, and the subject has been discussed from this point of view by W. C. M. Lewis.[4] The work of Fairhall[5] shows that the primary phosphate of lead, $PbH_4(PO_4)_2$, is much more soluble than the other phosphates except in very acid solutions and this salt is thus of no great biological importance.

We are not concerned here primarily with the biological aspects of the subject, the purpose of the present paper being to present measurements undertaken to determine the solubility products of the secondary and tertiary phosphates of lead. We shall, however, show reason to correct the statement[2] that whereas the tertiary phosphate is the stable salt under normal body conditions, a slight shift of equilibrium to the acid side converts this salt to the secondary phosphate.

---

Methods

Measurements of hydrogen-ion activity were carried out with the quinhydrone electrode, as described in an accompanying paper.[6]

Phosphates were estimated by the colorimetric method of Briggs,[7] which is accurate to 1–2% under the conditions maintained.

The lead-ion activity in the lead phosphate solutions has been determined by employing a lead electrode in a cell of the following type

Pb | Solution of lead salt ¦ Saturated KCl | Normal calomel electrode

Getman[8] has shown that lead can function as a reversible electrode, a finding which has been confirmed by us.

The value of E_0 for the lead electrode at 25° has been taken to be 0.122 volt;[9] hence the value of $p\mathrm{Pb}^{++}$, the negative logarithm of the lead-ion activity, is obtained from the relation

$$p\mathrm{Pb}^{++} = \frac{E - 0.4042}{0.02956}$$

where E is the observed e.m.f. of a cell of the type shown above.

The corresponding formula for 37.5' has been taken to be

$$p\mathrm{Pb}^{++} = \frac{E - 0.4106}{0.03080}$$

As no value of E_0 for the lead electrode was available **for** 37.5°, **this** was determined by measurements on several dilute solutions of lead nitrate at both 25 and 37.5°, the activity coefficient of lead-ion being assumed to be the same in both cases.

The lead electrodes were made by depositing lead electrolytically upon platinum, using very weak currents. (For use in acid solutions, the electrodes were amalgamated.) The technique of the lead electrode will be described more fully elsewhere by one of the authors.

Tertiary lead phosphate was made, following Alders and Stähler,[10] by adding slowly in dilute solution an equivalent amount of Na_2HPO_4 to a dilute boiling solution of lead acetate, the precipitate being washed repeatedly.

Secondary lead phosphate was prepared by adding in the hot 16.5 *g.* of lead nitrate dissolved in 500 cc. of water to 8 g. of potassium dihydrogen phosphate dissolved in 500 cc. of *N*/6 nitric acid. The precipitate was kept in the mother liquor at 25° for two days and then washed and dried.

The solutions for solubility determinations, to which a considerable excess of the appropriate solid salt was added, were kept in a thermostat

at the required temperature for several weeks before measurements were made, and evidence was obtained with each series that the lead-ion activities had reached practically constant values. Measurements of P_H were made on each solution on the same day that the lead-ion activity was measured and samples were simultaneously filtered for determination of phosphate.

General Considerations

In earlier measurements on the solubilities of the phosphates of lead[2] the importance of hydrogen-ion activity in determining the state of ionization of the phosphate was little considered. Since the solubility products of the phosphates are defined by the relations

$$S_2 = a_{\text{Pb}^{++}} \times a_{\text{HPO}_4^{--}} \qquad (1)$$
$$S_3 = a^3_{\text{Pb}^{++}} \times a^2_{\text{PO}_4^{---}} \qquad (2)$$

it is necessary to determine accurately the distribution of the total phosphate in solution between the various phosphate ions.

With this purpose in view the authors have determined values for the ionization constants of phosphoric acid.[3] The values required for our purposes are given in Table I. They are defined as follows

$$pK_1' = p\text{H}^+ + pC_{\text{H}_2\text{PO}_4^-} - pC_{\text{H}_3\text{PO}_4} \qquad (3)$$
$$pK_2' = p\text{H}^+ + pC_{\text{HPO}_4^{--}} - pC_{\text{H}_2\text{PO}_4^-} \qquad (4)$$
$$pK_2 = p\text{H}^+ + p\text{HPO}_4^{--} - p\text{H}_2\text{PO}_4^- \qquad (4a)$$
$$pK_3 = p\text{H}^+ + p\text{PO}_4^{---} - p\text{HPO}_4^{--} \qquad (5)$$

pK_2' and $\gamma_{\text{HPO}_4^{--}}$ in dilute solutions are taken as given by the relations

$$pK_2' = pK_2 - \frac{1.5\sqrt{\mu}}{1 + 1.5\sqrt{\mu}} \qquad (6)$$
$$-\log \gamma_{\text{HPO}_4^{--}} = \frac{2.0\sqrt{\mu}}{1 + 1.5\sqrt{\mu}} \qquad (7)$$

TABLE I

IONIZATION CONSTANTS OF PHOSPHORIC ACID

	25°	37.5°		25°	37.5°
pK_1	...	....	pK_1' (μ = 0.16)	1.94	2.04
pK_2	7.127	7.058	pK_2' (μ = 0.16)	6.680	6.589
pK_3	12.30	12.66[11]			

The third ionization constant is not known accurately but pK_3 enters into our calculations only in the form of an additive constant, since no measurements have been made in the region of P_H in which the tertiary phosphate ion is an appreciable fraction of the total phosphate concentration. Any alteration in the value of pK_3 chosen would simply necessitate a change in the value of pS_3 according to the equation

$$pS_3 = 3p\text{Pb}^{++} + 2p\text{HPO}_4^{--} - 2p\text{H}^+ + 2pK_3 \qquad (8)$$

which is derived by combining Equations 2 and 5.

---

[11] Sendroy and Hastings, *J. Biol. Chem.*, **71**, **783** (1926–27).

Equation 1 similarly can be stated in a logarithmic form

$$pS_2 = p\text{Pb}^{++} + p\text{HPO}_4^{--} \tag{9}$$

Solubilities of the Tertiary Phosphate.—Measurements of the solubility of $Pb_3(PO_4)_2$ have been carried out at 25 and 37.5° in dilute solutions and at an ionic strength of 0.16.

The solutions which the lead phosphate was allowed to saturate contained in all these experiments 0.005 M phosphate, a value which remained constant throughout the time of saturation.

This phosphate concentration was attained by mixing solutions of KH_2PO_4 and Na_2HPO_4 in various proportions, so that the PH might be varied. It was found that during saturation the PH values of the solutions changed, and always in an acid direction. We have no explanation to offer for this change, which sometimes amounted to 0.2; it was, however, a slow effect and the PH was sensibly constant for a long enough time for saturation to take place under definite conditions. The constancy of the phosphate concentration shows that no transformation of the solid phase to or from secondary phosphate could be taking place, since in this process, $Pb_3(PO_4)_2 + H_3PO_4 \rightleftharpoons 3PbHPO_4$, the phosphate concentration would decrease or increase, respectively.

The solubilities observed are hence really those of the tertiary phosphate, a conclusion supported by the sensible constancy of the calculated values of pS_3 over a range of PO_4^{---} concentration of more than twenty times.

TABLE II

SOLUBILITY DATA IN DILUTE SOLUTIONS

4	.71	3.203	9 157	42.10	8	.71	3.216	9.635	42.01

ratio $C_{\mathrm{HPO_4^{--}}}/C_{\mathrm{H_2PO_4^-}}$. The total phosphate concentration being known, $C_{\mathrm{HPO_4^{--}}}$ is obtained.

$\gamma_{\mathrm{HPO_4^{--}}}$ is calculated by the use of Equation 7 and hence $p\mathrm{HPO_4^{--}}$ obtained. $p\mathrm{PO_4^{---}}$ is then derived from Equation 5, or alternatively pS is derived directly from Equation 8.

The mean values for pS_3 derived (omitting the bracketed value) are 42.10 at 25" and 42.00 at 37.5°.

A set of measurements similar to those in dilute solutions have been made at an ionic strength of 0.16. Solutions of alkali phosphates were raised to this ionic strength by addition of sodium chloride. The data obtained are given in Table IV.

TABLE IV

SOLUBILITY DATA AT $\mu = 0.16$

Solid phase, $Pb_3(PO_4)_2$; C, phosphate, 0.005 M

No.	$p\mathrm{H}^+$	$p\mathrm{Pb}^{++}$	No.	$p\mathrm{H}^+$	$p\mathrm{Pb}^{++}$
	Temp., 25°			Temp., 37.5°	
9	7.015	8.460	13	6.887	8.081
10	6.774	8.243	14	6.719	7.905
11	6.429	7.917	15	6.317	7.518
12	6.202	7.584	16	6.173	7.265

Values of pK_2' for $\mu = 0.16$ are given in Table I. The ratio $C_{\mathrm{HPO_4^{--}}}/C_{\mathrm{H_2PO_4^-}}$ is calculated with the aid of Equation 4 and the observed PH. $C_{\mathrm{HPO_4^{--}}}$ is next obtained. We leave $\gamma_{\mathrm{HPO_4^{--}}}$ indeterminate for the present and hence derive values for $(pS_3 + 2 \log \gamma_{\mathrm{HPO_4^{--}}})$ given in Table V.

TABLE V

CALCULATION OF $(pS_3 + 2 \log \gamma_{\mathrm{HPO_4^{--}}})$, $\mu = 0.16$

No.	$(p\mathrm{HPO_4^{--}} + \log \gamma_{\mathrm{HPO_4^{--}}})$	$(p\mathrm{PO_4^{---}} + \log \gamma_{\mathrm{HPO_4^{--}}})$	$(pS_3 + 2 \log \gamma_{\mathrm{HPO_4^{--}}})$	No.	$(p\mathrm{HPO_4^{---}} + \log \gamma_{\mathrm{HPO_4^{--}}})$	$(p\mathrm{PO_4^{---}} + \log \gamma_{\mathrm{HPO_4^{--}}})$	$(pS_3 + 2 \log \gamma_{\mathrm{HPO_4^{--}}})$
	Temp., 25°				Temp., 37.5°		
9	2.466	7.743	40.87	13	2.478	7.531	40.74
10	2.558	8.076	40.88	14	2.542	7.767	40.69
11	2.745	8.608	40.97	15	2.759	8.382	40.76
12	2.904	8.994	40.74	16	2.858	8.625	(40.49)

The mean values for $(pS_3 + 2 \log \gamma_{\mathrm{HPO_4^{--}}})$ derived are 40.86 at 25° and 40.73 at 37.5°. Hence, from the values of pS_3 already obtained, $-\log \gamma_{\mathrm{HPO_4^{--}}}$ has a value of about 0.62 at 25° and 0.635 at 37.5'.

Thus in the solutions of $\mu = 0.16$, $\gamma_{\mathrm{HPO_4^{--}}}$ has the value 0.24 (25°) and 0.23 (37.5"). Making use of the values of pK_2 and pK_2' ($\mu = 0.16$) given in Table I, it can be calculated that $\gamma_{\mathrm{H_2PO_4^-}}$ has values of about 0.67 and 0.68 at 25 and 37.5". These values have already been shown[6] to agree with data obtained for pK_1 and pK_1' ($\mu = 0.16$). Thus it can be concluded that the two sets of data on the solubility of tertiary lead phosphate are in good agreement.

Solubilities **of** the Secondary Phosphate.—In an attempt to obtain the solubility product of $PbHPO_4$, a series of solutions similar to those above described ($\mu = 0.16$) and initially at similar *PH* values were saturated with solid $PbHPO_4$. It was observed, however, that the phosphate content of the solutions increased and the *PH* fell much more than was the case when the tertiary phosphate was the solid phase. There was thus reason to consider that the reaction $3\ PbHPO_4 \longrightarrow Pb_3(PO_4)_2 + H_3PO_4$ was taking place, and it appeared doubtful whether the solution would be truly saturated with $PbHPO_4$ or whether its lead-ion content would show a value intermediate between those corresponding to the solubilities of $PbHPO_4$ and $Pb_3(PO_4)_2$.

The observed phosphate concentrations were from 0.0057 to 0.0081 molar, the *PH* values ranged from 5.61 to 6.36, and the values of (pPb^{++} + pHPO$_4^{--}$) were 11.40–11.64 at 25° and 11.16–11.29 at 37.5'. The lead-ion activities were higher than those corresponding to the solubility of $Pb_3(PO_4)_2$. The ionic product for the secondary phosphate was not, however, a constant, and we concluded that experiments should be undertaken under conditions where the secondary phosphate was the more stable salt. Such conditions were attained by employing *PH* values in the region 2.0–2.5.

As before, four solutions were studied at each temperature, mixtures of KH_2PO_4 and HCl being made and their ionic strength raised to the value 0.16 by adding sodium chloride. The data and calculation of pS_2 are given in Table VI. From the observed *PH* and phosphate concentrations, pH$_2$PO$_4^-$ is calculated, using the values of pK_1' given in Table I, the values of $\gamma_{H_2PO_4^-}$ obtained in the last section and Equation 3. pHPO$_4^{--}$ is then obtained using the values of pK_2 given in Table I and Equation 4a.

TABLE VI

SOLUBILITIES OF $PbHPO_4$, $\mu = 0.16$

Temp.. °C.	pH$^+$	pPb^{++}	C, phosphate	pH$_2$PO$_4^-$	pHPO$_4^{--}$	pS_2
25	2.515	3.508	0.0320	1.770	6.382	9.89
	2.303	3.278	.0336	1.803	6.627	9.90
	2.494	3.345	.0173	2.042	6.675	10.02
	2.301	2.885	.0176	2.085	6.911	9.80
37.5	2.341	3.125	.0326	1.829	6.546	9.67
	2.156	2.763	.0344	1.876	6.778	9.54
	2.426	2.925	.0173	2.078	6.710	9.64
	2.067	2.438	.0181	2.196	7.187	9.62

The mean values derived for pS_2 are 9.90 at 25° and 9.62 at 37.5'. It can readily be calculated from the values of pS_3 previously obtained that the solubility of $Pb_3(PO_4)_2$ in the above solutions is greater than that observed for $PbHPO_4$. Thus the latter is the stable salt in these solutions.

From the values of pS_2 at the two temperatures it can be calculated that the heat of solution of $PbHPO_4$ at infinite dilution is about $-10{,}000$ cal. In view of the uncertainty in pK_3 it is not worth while to calculate a value for the heat of solution of $Pb_3(PO_4)_2$.

Equilibrium Conditions

The conditions under which both $PbHPO_4$ and $Pb_3(PO_4)_2$ will be in equilibrium with a solution can now be defined. The condition takes the form

$$\frac{S_2}{am\sim.--} = \frac{S_3^{1/3}}{a;<,---}$$

It may also be stated in the forms

$$a^2_{H^+} \times a_{HPO_4^{--}} = \frac{K_3^2\,S_2^3}{S_3}$$

$$a_{H^+} \times a_{H_2PO_4^-} = \frac{K_3^2\,S_2^3}{K_2\,S_3}$$

Numerical values are given in Table VII.

TABLE VII

EQUILIBRIUM CONDITIONS FOR $PbHPO_4$ AND $Pb_3(PO_4)_2$

	25°	37.5°
$a^2_{H^+} \times a_{HPO_4^{--}}$	$10^{-12.20}$	$10^{-12.18}$
$a_{H^+} \times a_{H_2PO_4^-}$	$10^{-5.07}$	$10^{-5.12}$

The conditions are very similar at both temperatures. The higher the phosphate concentration the lower the hydrogen-ion activity at equilibrium. Thus with M phosphate the $p\mathrm{H}^+$ is about 5, with $M/1000$ phosphate the pH+ is about 2.

This latter phosphate concentration is of the same order as is found in blood and in animal tissues, of which the $p\mathrm{H}^+$ is about 7.0–7.3. Thus under these conditions $Pb_3(PO_4)_2$ is definitely the stable phosphate of lead and the statement[2] that a slight shift to the acid side converts it to $PbHPO_4$ is quite erroneous. This statement was based on arguments physicochemically unsound.

Making use of the data obtained, the solubilities in (human) blood serum will now be calculated. The activity coefficients are assumed to be the same in serum as in 0.16 M sodium chloride. For low concentrations of lead salts in the latter solution $\gamma_{Pb^{++}}$ was found to be 0.17. The pH+ of serum is about 7.33, and its phosphate concentration about 1.2×10^{-3} molar. Hence it is calculated that the lead-ion concentration in serum saturated at 37.5° with $Pb_3(PO_4)_2$ is 5.5×10^{-8}, while the solubility of $PbHPO_4$ is much greater, namely, 6.3×10^{-6} molar.

In order to be able to calculate solubilities of $PbHPO_4$ and $Pb_3(PO_4)_2$ under various conditions in terms of lead-ion *concentrations* from the values obtained for pS_2 and pS_3, it is necessary to be able to evaluate $\gamma_{Pb^{++}}$. Data obtained by one of the authors, which will be published elsewhere,[12]

---

[12] **Millet,** *Trans. Faraday Soc.*, 25, (1929).

show that $\gamma_{Pb^{++}}$ is given fairly accurately by the Debye-Hückel expression in solutions of alkali chlorides up to 0.16 M.

Summary

Solubilities of $Pb_3(PO_4)_2$ and $PbHPO_4$ in aqueous solutions have been measured, lead-ion activities being determined with the lead electrode. The values of the solubility products deduced are as follows: $S_2 = a_{Pb^{++}} \times a_{HPO_4^{--}} = 10^{-9.90}$ at 25°; $10^{-9.62}$ at 37.5°. $S_3 = a^3_{Pb^{++}}$ X $a^2_{PO_4^{---}} = 10^{-42.10}$ at 25°, $10^{-42.00}$ at 37.5°, when K_3 (the third ionization constant of phosphoric acid) is taken to have the values $10^{-12.30}$ at 25° and $10^{-12.66}$ at 37.5".

The conditions for equilibrium between the two salts are discussed and the biological bearing of the work is mentioned. $Pb_3(PO_4)_2$ is the more stable salt under body conditions.

THE IONIZATION CONSTANTS OF PHOSPHORIC ACID[1]

BY MAURICE JOWETT AND HORACE MILLET

RECEIVED AUGUST 20, 1928 PUBLISHED APRIL 5, 1929

In the course of an investigation[2] on the solubilities of the secondary and tertiary phosphates of lead, it became evident that the values available in the literature for the ionization constants of phosphoric acid were insufficient for the purpose of that work.

We therefore have made measurements to determine the first ionization constant at 25 and 37.5". A few measurements bearing on the second ionization constant are also reported. Relevant data of other observers are also considered and a value is derived for the third ionization constant. The activity concept is made use of throughout.

Methods

Measurements of hydrogen-ion activity were made by means of cells in which a quinhydrone electrode was connected with a normal calomel electrode by a bridge of saturated potassium chloride solution. This bridge is assumed to eliminate liquid–liquid P. D's.

At 25° the P_H is obtained by means of the relation[3]

$$pH^+ = \frac{0.4136 - E}{0.05911}$$

---

[1] This investigation was undertaken on behalf of the Liverpool Medical Research Organization, Professor W. Blair Bell, Director, University of Liverpool.

[2] Millet and Jowett, THIS JOURNAL, 51, 997 (1929).

[3] Millet, *Trans. Faraday Soc.*, 23, 521 (1927).

where E, the e.m.f. of the cell, is positive when the quinhydrone electrode is the positive element.

The corresponding formula for 37.5° is[4]

$$pH^+ = \frac{0.4068 - E}{0.06160}$$

When the solutions have a high electrolyte concentration, a correction must be made for the so-called neutral salt error of the quinhydrone electrode. The corrections for an ionic strength of 0.16 have been taken by us as $\Delta pH^+ = -0.008$ at 25°[5] and $\Delta pH^+ = -0.006$ at 37.5°.[6] The hydrogen electrode standard is that of G. N. Lewis, Brighton and Sebastian.[7]

The e.m.f. measurements were carried out in duplicate. Solutions were made up at room temperature from recrystallized salts. No correction has been made for the expansion of the solutions with rising temperature.

The First Ionization Constant.—The first ionization constant of phosphoric acid, K_1, is defined by the relation

$$pK_1 = pH^+ + pH_2PO_4^- - pH_3PO_4 \qquad (1)$$

where pX denotes the negative logarithm of the activity of the chemical species X. It is also useful to define a quantity K_1' by the relation

$$pK_1' = pH^+ + pC_{H_2PO_4^-} - pC_{H_3PO_4} \qquad (2)$$

where pC_X denotes the negative logarithm of the concentration of the chemical species X.

Older work has not been calculated in terms of the activity concept, with the exception of the conductivity measurements of Noyes and Eastman at 18° given by Abbott and Bray,[8] which Sendroy and Hastings[9] state to fit the relation

$$pK_1' = 2.11 - 0.5\sqrt{\mu}$$

μ being the ionic strength.

The e.m.f. data of Ringer[10] do not lead to a definite value for pK_1, when calculated according to activity theory.

Measurements in Dilute Solutions.—Solutions were made up by diluting mixtures of decimolar KH_2PO_4 and decinormal HCl. The stoichiometric composition of the solutions and the PH values obtained are given in Table I.

TABLE I

COMPOSITION AND PH VALUES OF DILUTE SOLUTIONS

No.	Composition KH_2PO_4, *M*	HCl, *M*	PH values from quinhydrone elec.	No.	Composition KH_2PO_4, *M*	HCl, *M*	PH values from quinhydrone elec.
	Temp., 25°				Temp., 37.5"		
1	0.015	0.005	2.703	6	0.01667	0.010	2.406
2	.0225	.0065	2.675	7	.0225	.0065	2.718
3	.030	.008	2.667	8	.025	.009	2.578
4	.045	.011	2.652	9	.0375	.0195	2.307
5	.061	.014	2.651				

In order to calculate values of pK_1 from the above data, we must evaluate γ_{H^+} and $\gamma_{H_2PO_4^-}$, the activity coefficients of hydrogen ion and the primary phosphate ion. Since the solutions are not very concentrated, approximate relationships will be reasonably accurate.

According to Brönsted,[11] in solutions of hydrochloric acid and potassium chloride up to 0.1 molar the following relations hold good

$$-\log \gamma_{H^+}\gamma_{Cl^-} = 0.90\sqrt{\mu} - \mu$$
$$-\log \gamma_{K^+}\gamma_{Cl^-} = \sqrt{\mu} - 0.8\mu$$

Hence, assuming that $\gamma_{K^+} = \gamma_{Cl^-}$ and that γ_{Cl^-} is the same in corresponding solutions of potassium chloride and hydrochloric acid, we derive the equation

$$-\log \gamma_{H^+} = 0.4\sqrt{\mu} - 0.6\mu \qquad (3)$$

which is assumed to hold for the present cases.

Cohn,[12] working with mixtures of KH_2PO_4 and K_2HPO_4, was able to represent the activity coefficient of the primary phosphate ion by the relation

$$-\log \gamma_{H_2PO_4^-} = \frac{0.5\sqrt{\mu}}{1 + 1.5\sqrt{\mu}} \qquad (4)$$

which we likewise take as valid for the systems we are considering.

From the PH value, Equation 3 allows us to calculate C_{H^+}, a value for μ being assumed and subsequently replaced by a more accurate one. $C_{H_2PO_4^-}$ is then obtained from the principle of electrical equivalence ($C_{H_2PO_4^-} = C_{H^+} + C_{K^+} - C_{Cl^-}$), and $pH_2PO_4^-$ calculated with the use of Equation 4. $C_{H_3PO_4}$ is obtained by subtracting $C_{H_2PO_4^-}$ from the total phosphate concentration. Up to the present point we have no basis for any value for γH_3PO_4, which is left indeterminate.

Values of $pK_1 - \log \gamma_{H_3PO_4}$ are calculated in Table II. To save space, values of γ_{H^+} and $\gamma_{H_2PO_4^+}$ are omitted; they range from 0.908 to 0.868, and 0.882 to 0.810, respectively. The numbers refer to the solutions given in Table I.

The above values of $pK_1 - \log \gamma_{H_3PO_4}$ show no trend with concentration and hence we take $\gamma_{H_3PO_4} = 1$, and derive values for pK_1 at 25° of 2.10, and at 37.5° of 2.16.

---

TABLE II

CALCULATION OF pK_1 IN DILUTE SOLUTIONS

Temp., °C.	No.	μ	C_{H^+}	$C_{H_2PO_4^-}$	$C_{H_3PO_4}$	$pK_1 - \log \gamma_{H_3PO_4}$
25	1	0.017	0.00218	0.01218	0.00282	2.122
	2	.025	.00236	.01836	.00414	2.092
	3	.0325	.00243	.02443	.00557	2.096
	4	.0475	.00255	.03655	.00845	2.098
	5	.0635	.00258	.04958	.01142	2.105
37.5	6	.021	.00435	.01102	.00565	2.176
	7	.025	.00214	.01814	.00436	2.163
	8	.028	.00297	.01897	.00603	2.147
	9	.043	.00562	.02362	.01388	2.156

Britton's data[13] obtained by electrometric titration of phosphoric acid with caustic soda at 20°, using the hydrogen electrode, have been recalculated by us on the same basis as our own data, the mean value of pK_1 deduced being 2.01. This is lower than the value 2.08, which would be derived at 20° from our values at 25 and 37.5° if a constant temperature coefficient were assumed, and lower than the value calculated by Sendroy and Hastings for 18°, namely, 2.11.

Measurements at Total Ionic Strength 0.16.—For the purpose of the investigation already referred to,[2] values of pK_1' at an ionic strength of 0.16 were required. Solutions of similar composition to those already used were made up, sodium chloride being added to raise the ionic strength to approximately 0.16.

Since no suitable value for γ_{H^+} was available in the literature, γ_{H^+} was measured for a solution containing 0.01 *M* HCl and 0.15 M NaCl.

TABLE III

COMPOSITION AND PH VALUES OF SOLUTIONS (μ = 0.16)

No.	KH_2PO_4, M	HCl, M	NaCl, *M*	*Pa* (25°)	*PH* (37.5°)
1	0.03	0.0053	0.1281	2.825	2.885

---

[13] Britton, *J. Chem. Soc.*, 1927, 614.

The value found was 0.90 at 25° and 0.91 at 37.5°, and this was taken as valid for the solutions of which the PH was measured, the composition of which is given in Table III.

The value of pK_1' obtained is 1.94 at 25° and 2.04 at 37.5°. The values of pK_1, 2.11 and 2.21, have been calculated from values of $\gamma_{H_2PO_4^-}$ deduced elsewhere,[2] namely 0.67 and 0.68.

The agreement of these values of pK_1 with those obtained in more dilute solutions is sufficiently good to confirm the conclusion that $\gamma_{H_3PO_4}$ does not depart appreciably from a value of unity.

The Second Ionization Constant.—Many measurements have been made of the PH values of mixtures of the primary and secondary alkali phosphates but the majority are unsuitable for the accurate evaluation of the second ionization constant of phosphoric acid, K_2, since the ionic strengths of the systems investigated are too high.

K_2 may be defined by the relation $pK_2 = pH^+ + pH_2PO_4^- - pHPO_4^{--}$ and the quantity pK_2' is defined similarly to pK_1'.

Cohn[12] has, however, recently made an extensive investigation of mixtures of primary and secondary phosphates at 18°, and this author's measurements, which are in concordance with those of Sorensen and Michaelis, lead to a value of pK_2 which is probably very accurate. Reduced to the G. N. Lewis standard for the hydrogen electrode, this value is 7.130.

For other temperatures no values of any great accuracy appear to be available. Sendroy and Hastings[g] state that unpublished measurements at 20° give a value of about 7.18, and suggest that the value at 38° may be 7.15.

We have made a number of measurements of the PH of mixtures containing 0.0025 M KH_2PO_4 and 0.0025 M Na_2HPO_4 ($\mu = 0.01$). The mean values obtained are 6.997 at 25° and 6.928 at 37.5°, probably accurate to about 0.003 pH^+. From these values, using Cohn's relation

$$pK_2 = pK_2' + \frac{1.5\sqrt{\mu}}{1 + 1.5\sqrt{\mu}}$$

pK_2 is calculated to be 7.127 at 25° and 7.058 at 37.5'. The value at 25° is close to the value 7.130 obtained by Cohn at 18°.

The data of Michaelis and Garmendia[14] for the three most dilute solutions measured, when similarly calculated and reduced to the G. N. Lewis standard, give a value for pK_2 at 25° of about 7.11. Britton's data[13] on the same basis give a value of about 7.04 at 20°.

Measurements made by us on mixtures containing 0.0025 M KH_2PO_4 and 0.0025 M Na_2HPO_4, of which the ionic strength was raised to 0.16 with NaCl, gave pH^+ (and also pK'_2) values of 6.680 at 25° and 6.589 at 37.5°.

---

[14] Michaelis and Garmendia, *Biochem. Z.*, **67**, 431 (1914).

The Third Ionization Constant.—Sendroy and Hastings[9] have made PH measurements at 38° on mixtures of secondary and tertiary phosphates and found that pK'_3 could be represented approximately by the relation

$$pK'_3 = 12.66 - 2.25\sqrt{\mu}$$

pK_3 and pK'_3 are defined in a manner similar to pK_1 and pK'_1. As the data used lie between the limits $\sqrt{\mu} = 0.25$ and $\sqrt{\mu} = 0.50$, the extrapolation to infinite dilution is somewhat uncertain.

Suitable data for the calculation of pK_3 at other temperatures are scanty. Prideaux and Ward's measurements[15] were made at ionic strengths of 0.085 upward. Kolthoff's measurements[16] were also made at high ionic strengths; by a method not clearly explained this author calculates pK_3 at 18" to be about 12.30.

The electrometric titrations of Britton[13] at 20°, however, were carried out in the range $\mu = 0.033$ to $\mu = 0.047$, and the values obtained may be used in attempting to evaluate pK_3.

No very satisfactory basis is available for calculating the required activity coefficients—γ_{OH^-}, $\gamma_{H_2PO_4^{--}}$ and $\gamma_{PO_4^{---}}$.

As an approximate relation we have made use of an equation analogous to that used by Sendroy and Hastings

$$-\log y = 0.45\, n^2 \sqrt{\mu}$$

K_w has been taken as 0.68×10^{-14}. To Britton's PH values 0.04 has been added to correct them to the G. N. Lewis standard.

Then pK_3 is defined by the relation

$$pK_3 = pH^+ + pC_{PO_4^{---}} - pC_{H_2PO_4^{--}} + 2.25\sqrt{\mu}$$

From PH and γ_{OH^-}, C_{OH^-} is evaluated, and $C_{PO_4^{---}}$ and $C_{H_2PO_4^{--}}$ obtained from the principle of electrical equivalence.

Values at either end of the series have been omitted as being less accurate. The mean value of pK_3 obtained is 12.11. It should be noted that Britton's data give values for pK_1 and pK_2 about 0.1 lower than do other data. An additional error of the same order may be introduced into pK_3 owing to our having used a tentative formula for the activity coefficients. Thus the value 12.11 may be in error by 0.1–0.2. Sendroy and Hastings' value of 12.66 at 38" may be in error to a similar extent. Thus the temperature coefficient is a doubtful quantity, but a value of 12.3 might be interpolated for 25".

Heats of Ionization of Phosphoric Acid.—The heats of ionization of phosphoric acid, as far as the first two stages are concerned, may be calculated as follows from the values of pK_1 and pK_2 obtained in this paper.

---

[15] Prideaux and Ward, *J. Chem. Soc.*, **125**, 429 (1924).

[16] I. M. Kolthoff, *Rec. trav. chim.*, 46, 350 (1927).

Reaction	pK (25°)	pK (37.5°)	Heat evolved
$H_3PO_4 \longrightarrow H^+ + H_2PO_4^-$	2.10	2.16	+2000
$H_2PO_4^- \longrightarrow H^+ + HPO_4^{--}$	7.127	7.058	−2300

The calculated heats of ionization, which are in calories per mole, refer, of course, to the ionization at infinite dilution.

The values of pK_3 calculated are insufficiently accurate for the heat effect of the third ionization step to be calculated. Heat, however, is evolved in this ionization.

Summary

With the quinhydrone electrode measurements of the *P*H values of phosphate mixtures have been made which lead to the following values for the ionization constants of phosphoric acid

$$pK_1\ (25^\circ) = 2.10,\quad pK_1\ (37.5^\circ) = 2.16$$
$$pK_2\ (25^\circ) = 7.13,\quad pK_2\ (37.5^\circ) = 7.06$$

These figures are compared with those derived from other data.

From the data of Britton pK_3 at 20° is calculated to be about 12.1.

THE PRINCIPLES DETERMINING THE STRUCTURE OF COMPLEX IONIC CRYSTALS

By Linus Pauling

Received September 5, 1928 Published April 5, 1929

1. The Relative Stability of Alternative Structures of Ionic Crystals.—The elucidation of the factors determining the relative stability of alternative crystalline structures of a substance would be of the greatest significance in the development of the theory of the solid state. Why, for example, do some of the alkali halides crystallize with the sodium chloride structure and some with the cesium chloride structure? Why does titanium dioxide under different conditions assume the different structures of rutile, brookite and anatase? Why does aluminum fluosilicate, $Al_2SiO_4F_2$, crystallize with the structure of topaz and not with some other structure? These questions are answered formally by the statement that in each case the structure with the minimum free energy is stable. This answer, however, is not satisfying; what is desired in our atomistic and quantum theoretical era is the explanation of this minimum free energy in terms of atoms or ions and their properties.

Efforts to provide such a treatment for simple alternative structures, such as the sodium chloride and cesium chloride structures and the fluoride and rutile structures, have been made with the aid of the Born potential expression and modifications of it, Assuming that all ions repel each other according to a high inverse power of the distance between them (the repulsive potential being proportional to r^{-n}), the equilibrium energy of a crystal is given by

$$\Phi = -\frac{z^2e^2A}{R}\left(1 - \frac{1}{n}\right) \tag{1}$$

in which R is the equilibrium distance between two adjacent ions in the crystal, and A is the Madelung constant characteristic of the structure. A knowledge of how R changes from structure to structure for a given substance would then allow the prediction of which structure is stable, if Equation 1 were accurate. Methods of calculating R have been suggested.[1] It is found, however, that Equation 1 is in error by at least 2% in some cases,[1b] and this error of around 5000 cal./mole suffices to invalidate the theory in applications of this kind. An explanation of the sodium chloride–cesium chloride transition which accounts for the observed properties of the alkali halides has been reported,[2] but the considerations involved (including deformation phenomena) have not yet been given quantitative formulation.

The application of these methods to more complex crystals would involve the highly laborious calculation of the Madelung constant for a number of complicated ionic arrangements. Furthermore, the methods provide no way of determining the possible structures for which calculations should be made. An infinite number of possible atomic arrangements for a complicated substance such as a silicate are provided by the theory of space groups. There is desired a set of simple rules, which need not be rigorous in their derivation nor universal in their application, with the aid of which the few relatively stable structures can be identified among the multitude possible for a given substance. These rules could be used in the prediction of atomic arrangements for comparison with x-ray data. They would also provide a criterion for the probable correctness of structures suggested by but not rigorously deduced from experimental measurements. Finally, they would permit the intuitive understanding of the stability of crystals in terms of visualizable interionic interactions.

2. The Application of the Coordination Theory in the Determination of the Structures of Complex Crystals.—As a result of the recent increase in knowledge of the effective radii of various ions in crystals,[3] Professor W. L. Bragg has suggested and applied a simple and useful theory leading to the selection of possible structures for certain complex crystals. His fundamental hypothesis is this: if a crystal is composed of large ions and small ions, its structure will be determined essentially by the large ions, and may approximate a close-packed arrangement of the large ions alone,

---

with the small ions tucked away in the interstices in such a way that each one is equidistant from four or six large ions. In some cases not all of the close-packed positions are occupied by ions, and an open structure results. To apply this theory one determines the unit of structure in the usual way, and finds by trial some close-packed arrangement of the large ions of known crystal radius (usually oxygen ions with a radius of 1.35–1.40 Å.) compatible with this unit. The other ions are then introduced into the possible positions in such a way as to give agreement with the observed intensities of reflection of x-rays, the large ions being also shifted somewhat from the close-packed positions if necessary. With the aid of this method Bragg and his co-workers have made a very significant attack on the important problem of the structure of silicates, involving the determination of structures for beryl, $Be_3Al_2Si_6O_{18}$,[4] chrysoberyl, $BeAl_2O_4$,[5] olivine, $(Mg, Fe)_2SiO_4$,[6] chondrodite, $H_2Mg_5Si_2O_{10}$, humite, $H_2Mg_7Si_3O_{14}$, clinohumite, $H_2Mg_9Si_4O_{18}$,[7] phenacite, Be_2SiO_4,[8] etc.

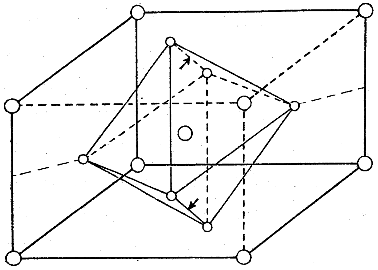

Fig. 1.—The unit of structure for rutile. Large circles represent titanium ions; small circles oxygen ions. An octahedron with a titanium ion at its center and oxygen ions at its corners is shown. The two edges marked with arrows are shared with adjoining octahedra.

During the investigation of the structure of brookite,[9] the orthorhombic form of titanium dioxide, a somewhat different method for predicting possible structures for ionic crystals was developed, based upon the assumption of the coördination of the anions in the crystal about the cations in such a way that each cation designates the center of a polyhedron, the corners of which are occupied by anions. This method leads for a given substance to a small number of possible simple structures, for each of which the size of the unit of structure, the space-group symmetry and the positions of all ions are fixed. In some cases, but not all, these structures correspond to close-packing of the large ions; when they do, the theory further indicates the amount and nature of the distortion from the close-packed arrangement.

The structures of rutile and anatase, the two tetragonal forms of titanium dioxide, have been determined by rigorous methods (Figs. 1 and 2). They seem at first sight to have little in common beyond the fact

that each is a coördination structure, with six oxygen atoms about each titanium atom at octahedron corners. From a certain point of view, however, they are closely similar. They are both made up of octahedra sharing edges and corners with each other; in rutile two edges of each octahedron are shared and in anatase four. In both crystals the titanium-oxygen distance is a constant, with the value 1.95–1.96 Å. The basic octahedra are only approximately regular; in each crystal they are deformed in such a way as to cause each shared edge to be shortened from 2.76 Å. (the value for regular octahedra) to 2.50 **if.,** the other edges being correspondingly lengthened.

As a result of these considerations the following assumptions were made: (1) Brookite is composed of octahedra, each with a titanium ion at its center and oxygen ions at its corners. (2) The octahedra share edges and corners with each other to such an extent as to give the crystals the correct stoichiometric composition. **(3)** The titanium-oxygen distances throughout are 1.95–1.96 Å. Shared edges of octahedra are shortened to 2.50 Å.

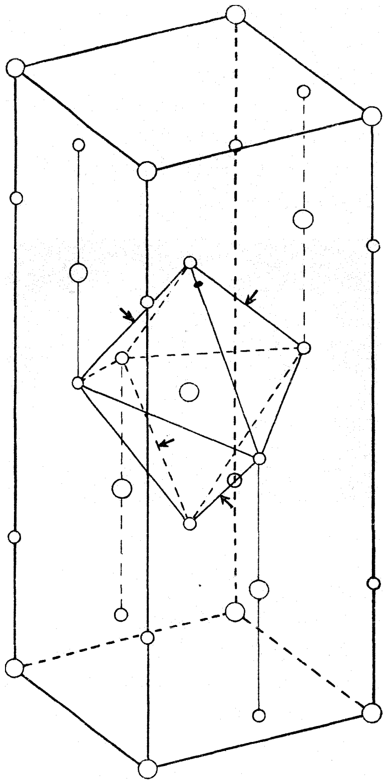

Fig. 2—The unit of structure of anatase. The titanium octahedron shares the four edges marked with arrows with adjoining octahedra.

Two structures satisfying these requirements were built out of octahedra. The first was not the structure of brookite. The second, however, had the same space-group symmetry as brookite (V_h^{15}), and the predicted dimensions of the unit of structure agreed within 0.5% with those observed. Structure factors calculated for over fifty forms with the use of the predicted values of the nine parameters determining the atomic arrangement accounted satisfactorily for the observed intensities of reflections on rotation photographs. This extensive agreement is so striking as to permit the structure proposed for brookite (shown in Fig. 3) to be accepted with confidence.

The method was then applied in predicting the structure of the orthorhombic crystal topaz, $Al_2SiO_4F_2$.[10] It was assumed that each aluminum ion is surrounded by four oxygen ions and two fluorine ions at the corners

[10] Linus Pauling, *Proc. Nat. Acad. Sci.*, **14**, 603 (1928).

of a regular octahedron, and each silicon ion by four oxygen ions at the corners of a regular tetrahedron. The length of edge of octahedron and tetrahedron was taken as 2.72 Å., corresponding to crystal radii of 1.36 Å. for both oxygen and fluorine ions. One structure was built up of these polyhedra. On studying its distribution of microscopic symmetry elements, it was found to have the space-group symmetry of V_h^{16}, which is that of topaz. Its unit of structure approximates that found experimentally, and the predicted values of the fifteen parameters determining the atomic arrangement account for the observed intensities of reflection from the pinacoids. This concordance is sufficient to make it highly probable that the correct structure of topaz has been found (Fig. 4).[11]

3. The Principles Determining the Structure of Complex Ionic Crystals.—The success of the coordination method in predicting structures for brookite and topaz has led to the proposal of a set of principles governing the structure of a rather extensive class of complex ionic crystals.

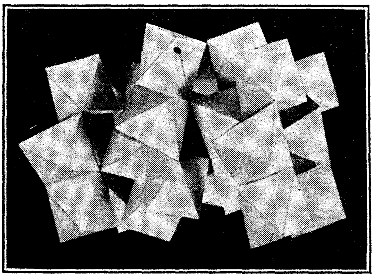

Fig. 3.—The structure of brookite.

The crystals considered are to contain only small cations, with relatively large electric charges, that is, usually trivalent and tetravalent cations, with crystal radii not over about 0.8 Å. All anions are large (over **1.35** Å.) and univalent or divalent. Furthermore, they should not be too highly deformable. The most important anions satisfying this restriction are the oxygen ion and the fluorine ion, with crystal radii 1.35–1.40 Å.[12]

This physical differentiation of the anions and cations under discussion in regard to size and charge finds expression throughout this paper. Markedly different roles are attributed anions and cations in the construction of a crystal; as a result a pronounced distinction between them has been made in the formulation of the structural principles.

Throughout our discussion the crystals will be referred to as composed of ions. This does not signify that the chemical bonds in the crystal arc necessarily ionic in the sense of the quantum mechanics; they should not, however, be of the extreme non-polar or shared electron pair type.[13] Thus compounds of copper[14] and many other eighteen-shell atoms cannot be

---

[11] Professor W. L. Bragg has written the author that the same ideal structure has been found by J. West (paper to be published in the *Proceedings of the Royal Society).*

[12] The crystal radii used in this paper are those of Pauling, THIS JOURNAL, *49,765 (1927).*

[13] (a) P. London, Z. *Physik,* 46,455 *(1928);* (b) L. Pauling, *Proc. Nat. Acad. Sci., 14, 359 (1928).*

[14] **Such** as $K_2CuCl_4{\cdot}2H_2O$, whose structure has been determined by S. B Hendricks and R. G Dickinson, THIS JOURNAL, *49,2149 (1927).*

treated in this way. Shared electron pair bonds are also present in complexes containing large atoms with a coordination number of four, such as the molybdate ion, $[MoO_4]^{--}$, the arsenate ion, $[AsO_4]^{--}$, etc.

The principles described in the following six sections have been deduced in part from the empirical study of known crystal structures and in part from considerations of stability involving the crystal energy.

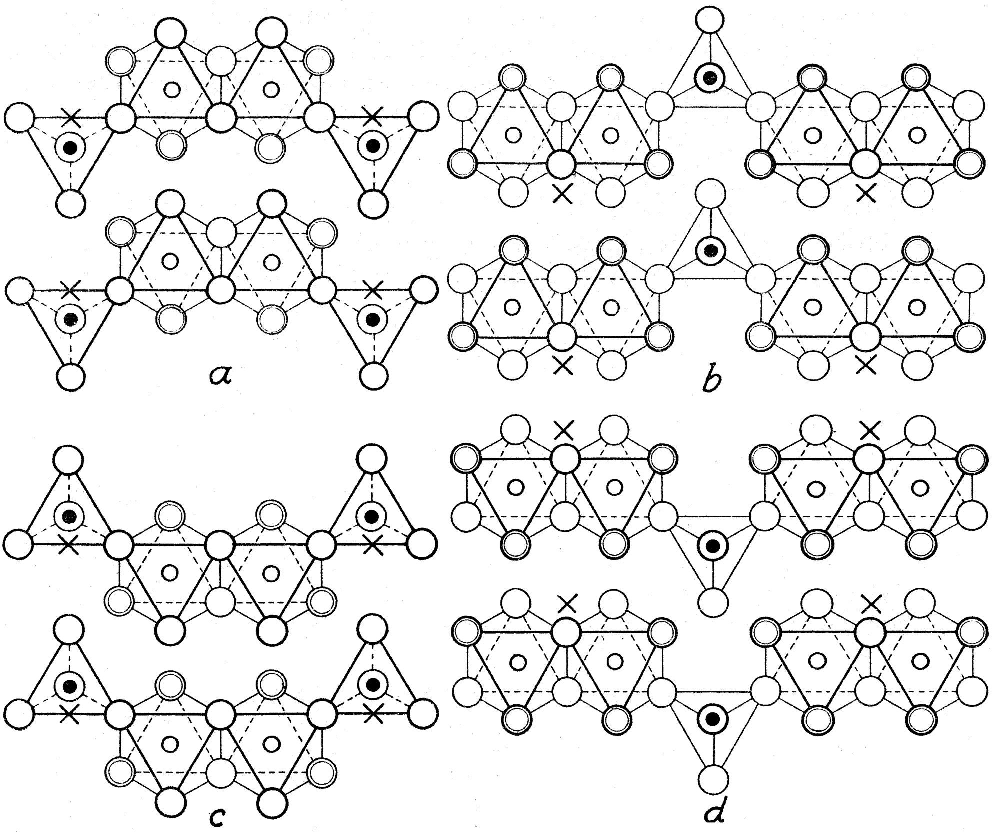

Fig. 4.—The structure of topaz. The layers are to be superposed in the order *abcd*, with *d* uppermost. The crosses are the traces of the corners of the unit of structure in the plane of the paper. Large circles represent oxygen, large double circles fluorine, small open circles aluminum, and small solid circles silicon ions.

4. The Nature of the Coordinated Polyhedra.—I. A *coordinated polyhedron of anions is formed about each cation, the cation–anion distance being determined by the radius sum and the coördination number of the cation by the radius ratio.*

In the case of crystals containing highly charged cations the most important terms in the expression for the crystal energy are those representing the interaction of each cation and the adjacent anions. The next terms in importance are those representing the mutual interaction of the anions. The negative Coulomb energy causes each cation to attract to itself a number of anions, which approach to the distance at which the Coulomb attraction is balanced by the characteristic cation–anion repulsive forces. This distance is given with some accuracy by the sum of the crystal radii of cation and anion.[12]

If too many anions are grouped about one cation, the anion–anion repulsion becomes strong enough to prevent the anions from approaching this closely to the cation. The resultant increase in Coulomb energy causes such a structure to be unstable when the anion–cation distance is increased to a value only slightly greater than the radius sum. Approximate lower limits of the radius ratio (the ratio of cation radius to anion radius) leading to a stable structure with given coordination number can accordingly be calculated purely geometrically.[15,12] The minimum radius ratios for tetrahedra, octahedra and cubes are given in Table I.

TABLE I

RADIUS RATIOS AND COORDINATION NUMBERS

Polyhedron	Conrdination number	Minimum radius ratio
Tetrahedron	4	$\sqrt{3}/\sqrt{2} - 1 = 0.225$
Octahedron	6	$\sqrt{2} - 1 = 0.414$
Cube	8	$\sqrt{3} - 1 = 0.732$

Since the repulsive forces are determined by the true sizes of ions, and not their crystal radii, the radius ratios to be used in this connection are the ratios of the univalent cation radii to univalent anion radii.[12] Values of this ratio for small ions are given in Table II, together with predicted and observed coordination numbers, the agreement between which is excellent.

TABLE II

COÖRDINATION NUMBERS FOR IONS IN OXIDES

Ion	Radius ratio	Predicted coordination number	Observed coordination number	Strength of electrostatic bonds
B^{+++}	0.20	3 or 4	3 or 4	1 or $^3/_4$
Be^{++}	.25	4	4	$^1/_2$
Li^{+}	.34	4	4	$^1/_4$
Si^{++++}	.37	4	4	1
Al^{+++}	.41	4 or 6	6	$^3/_4$ or $^1/_2$
Mg^{++}	.47	6	6	$^1/_3$
Ti^{++++}	.55	6	6	$^2/_3$
Sc^{+++}	.60	6	6	$^1/_2$
Mo^{++++++}	.53	6	6	1
Nb^{+++++}	.57	6	6	6
Zr^{++++}	.62	6	6 or 8	$^2/_3$ or $^1/_2$

---

[15] Such calculations were first made and substantiated by comparison with observed structures in some cases by V. M. Goldschmidt, "Geochemische Verteilungsgesetze der Elemente," Oslo, 1927.

The radius ratio for B^{+3} is only a little less than the lower limit for tetrahedra. The usual coordination number for boron with oxygen is **3** (in the borate ion, $[BO_3]^{-3}$). **It** is **four,** however, in the 12-tungstoborate ion,[16] in which a stabilizing influence is exerted by the tungsten octahedra.

So far as I know, Al^{+3} has the coordination number 6 in all of its compounds with oxygen the structures of which have been determined. The coordination number 4 would also be expected for it, however; it is probable that it forms tetrahedra in some of its compounds, as, for example, γ-alumina, the cubic form of Al_2O_3, and the feldspars, in which there occurs replacement of Na^+ and Si^{+4} by Ca^{++} and Al^{+3}. This possibility is further discussed in Section 11.

Zr^{+4} has the coordination number 8 in zircon. The polyhedron of oxygen ions about it is, however, not a cube. It is on account of the ease with which these polyhedra are distorted that large cations, with coordination numbers greater than six, are not included in the field of application of the suggested principles. Octahedra and tetrahedra retain their approximate shapes even under the action of strong distorting forces, and, moreover, rules have been formulated governing the distortion that they do undergo (Section 9).

5. The Number of Polyhedra with a Common Corner. The Electrostatic Valence Principle.—The number of polyhedra with a common corner can be determined by the use of an extended conception of electrostatic valence. Let ze be the electric charge of a cation and ν its coordination number. Then the *strength of the electrostatic valence bond* going to each corner of the polyhedron of anions about it is defined as

$$s = \frac{z}{\nu} \tag{2}$$

Let $-\zeta e$ be the charge of the anion located at a corner shared among several polyhedra. We now postulate the following *electrostatic valence principle: I. In a stable coördination structure the electric charge of each anion tends to compensate the strength of the electrostatic valence bonds reaching to it from the cations at the centers of the polyhedra of which it forms a corner; that is, for each anion*

$$\zeta = \Sigma_i \frac{z_i}{\nu_i} = \Sigma_i s_i \tag{3}$$

In justification of this principle it may be pointed out that it places the anions with large negative charges in positions of large positive potentials; for the bond strength of a cation gives approximately its contribution to the total positive potential at the polyhedron corner (the factor $1/\nu$ accounting for the larger cation–anion distance and the greater number of adjacent anions in the case of cations with larger coordination number),

---

[16] Pauling, unpublished material.

and the application of the principle requires that the sum of these potentials be large in case the valence of the anion is large.

It is not to be anticipated that Equation 3 will be rigorously satisfied by all crystals. It should, however, be always satisfied approximately. As a matter of fact, almost all crystals which have been investigated conform to the principle. Equation 3 is necessarily true for all crystals the anions of which are crystallographically equivalent, such as corundum, Al_2O_3,[17] rutile, anatase, spinel, $MgAl_2O_4$, garnet, $Ca_3Al_2Si_3O_{12}$,[18] cryolithionite, $Na_3Li_3Al_2F_{12}$,[19] etc. It is also satisfied by topaz; each oxygen ion, common to one silicon and two aluminum ions, has $\Sigma s_i = 2$ (see Table II for a list of values of s), while each fluorine ion, attached to two aluminum ions only, has $\Sigma s_i = 1$. Similarly in beryl some oxygen ions are shared between two silicon ions, and some between one silicon, one beryllium and one aluminum ion; in each case $\Sigma s_i = 2$. In chondrodite, $H_2Mg_5Si_2O_{10}$, humite, $H_2Mg_7Si_3O_{14}$, and clinohumite, $H_2Mg_9Si_4O_{18}$, there are oxygen ions common to one silicon tetrahedron and three magnesium octahedra ($\Sigma s_i = 2$), and OH– groups common to three magnesium octahedra ($\Sigma s_i = 1$). This list of examples could be largely extended.

6. The Sharing of Edges and Faces.—The electrostatic valence principle indicates the number of polyhedra with a common corner but makes no prediction as to the number of corners common to two polyhedra; that is, whether they share one corner only, two corners defining an edge, or three or more corners defining a face. In rutile, brookite and anatase, for example, each oxygen ion is common to three titanium octahedra (and hence has $\Sigma s_i = 2$, satisfying Equation 3); but the number of edges shared by one octahedron with adjoining octahedra is two in rutile, three in brookite and four in anatase. In corundum on the other hand, each aluminum octahedron shares one face and three edges with other octahedra. The reason for this difference is contained in the following rule. **III.** *The presence of shared edges, and particularly of shared faces, in a coördinated structure decreases its stability; this effect is large for cations with large valence and small coördination number, and is especially large in case the radius ratio approaches the lower limit of stability of the polyhedron.*

This decrease in stability arises from the cation–cation Coulomb terms. The sharing of an edge between two regular tetrahedra brings the cations at their centers to a distance from each other only 0.58 times that obtaining in case the tetrahedra share a corner only; and the sharing of a face decreases this distance to 0.33 times its original value (Fig. 5). The corresponding positive Coulomb terms cause a large increase in the crystal energy and decrease in the stability of the structure, especially for highly

[18] G. Menzer, *Z. Krist.*, *63*, 157 (1926).

[19] G. Menzer, *ibid.*, 66, 457 (1927).

charged cations. The effect is not so large for regular octahedra, amounting to a decrease in the cation–cation distance to the fractional value 0.71 for a shared edge and 0.58 for a shared face.

These calculated decreases are valid only in case the change in structure is not compensated by deformation of the polyhedra. Some compensating deformation will always occur; the rules governing deformation (Section 9) show that it will be small in case the radius ratio approaches the lower limit of stability for the polyhedron, and will increase with the radius ratio.

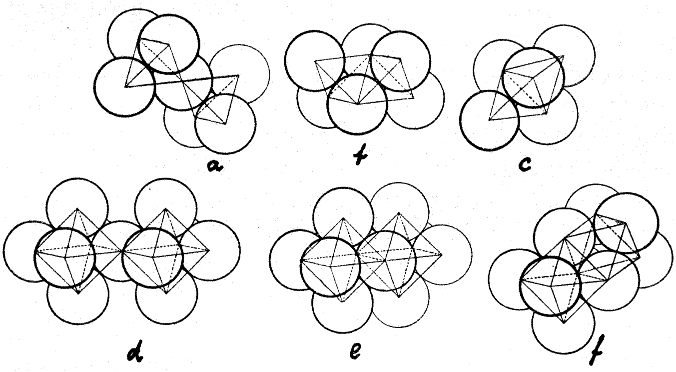

Fig. 5.—a, *b* and *c* show two tetrahedra of oxygen ions with a corner, an edge and a face in common; *d*, e and *f* show two octahedra of oxygen ions with a corner, an edge and a face in common.

In agreement with expectation, silicon tetrahedra tend to share only corners with other polyhedra when this is possible (as in topaz, $Al_2SiO_4F_2$, etc.), titanium octahedra share only corners and edges, while aluminum octahedra, when constrained by the stoichiometrical formula of the substance, will share faces in some cases, as in corundum, Al_2O_3. The effect of large radius ratio in diminishing the instability due to an increase in the number of shared edges is shown by the approximate equality in free energy of rutile, brookite and anatase, with two, three and four shared edges, respectively. As a matter of fact, the order of stability is just that of the number of shared edges, rutile being the most stable,[20] in agreement with expectation. Many other dioxides also crystallize with the rutile structure but no other is known with the brookite or anatase structure.

The effect of small valence and large coordination number is further shown by the observation that silicon tetrahedra, which share comers only with aluminum octahedra, share edges with magnesium octahedra (in olivine, chondrodite, humite, clinohumite) and with zirconium polyhedra with coordination number eight (in zircon).

7. **The Nature of Contiguous Polyhedra.**—*IV. In a crystal con-*

---

[20] C. Doelter, "Handbuch der Mineralchemie," Theodor Steinkopff, Dresden, 1918, Vol. III, Part 1, p. 15.

taining different cations those with large valence and small coordination number tend not to share polyhedron elements with each other. This rule follows directly from the fact that cations with high electric charges tend to be as far apart from each other as possible, in order to reduce their contribution to the Coulomb energy of the crystal.

The rule requires that in silicates the silicon tetrahedra share no elements with each other if the oxygen–silicon ratio is equal to or greater than four (topaz, zircon, olivine, orthosilicates in general). If stoichiometrically necessary, corners will be shared between silicon tetrahedra, but not edges or faces. In the various forms of silicon dioxide all four corners of each tetrahedron are shared with adjoining tetrahedra. In diorthosilicates the Si_2O_7 group is formed of two tetrahedra sharing a corner. The metasilicates should not contain groups of two tetrahedra with a common edge, but rather chains or rings, each tetrahedron sharing two corners (as in beryl, with a ring of six tetrahedra, stable because of the approximation of the tetrahedral angle to 120°). Other silicates are no doubt similar. It is of interest that the electrostatic valence principle requires that corners shared between two silicon tetrahedra be not shared also with other polyhedra; this is true for beryl.

8. The Rule of Parsimony.—V. *The number of essentially different kinds of constituents in a crystal tends to be small.* First, the electrostatic bonds satisfied by all chemically similar anions should be the same if possible (topaz, all oxygen ions common to two aluminum octahedra and one silicon tetrahedron, all fluorine ions common to two aluminum octahedra). This does not require the anions to be crystallographically equivalent (in topaz the oxygen ions are crystallographically of three kinds, in brookite of two kinds); crystallographic non-equivalence does not imply essential difference from the standpoint of the coordination theory. Often the preceding rules do not permit all anions to be alike, as, for example, in the case of silicates with an oxygen–silicon ratio greater than four, in which the four orthosilicate oxygens are necessarily different from the others. In these cases the number of different kinds of anions will, however, be small.

Second, the polyhedra circumscribed about all chemically identical cations should, if possible, be chemically similar, and similar in their contiguous environment, that is, in the nature of the sharing of corners, edges and faces with other polyhedra. For example, each aluminum octahedron in topaz has as corners four oxygen and two fluorine ions, and each shares two edges with other octahedra and four corners with silicon tetrahedra. The titanium octahedron in rutile shares two edges, in brookite three and in anatase four, but no structure is known in which these different octahedra occur together. The polyhedra which are similar in these respects may or may not be crystallographically equivalent, for they may differ in their remote environment. Thus the contiguously similar tetrahedra of silicon atoms about carbon atoms in carborundum are crystallographically of several kinds (five in carborundum I).

9. Distortion of the Polyhedra.—The above rules suffice to indicate the nature of the structure of a given crystal, so that a structure can be composed of regular polyhedra in accordance with them, and its space-group symmetry and approximate dimensions compared with those found by x-ray analysis. In this way a structure can be identified as giving approximately the correct atomic arrangement (as was done for brookite and for topaz); but the actual atomic arrangement may differ considerably from this "ideal" arrangement corresponding to regular polyhedra, as a resultant of distortion of the polyhedra. The investigation of the agreement between observed intensities of x-ray reflections and structure factors calculated for all atomic arrangements involving small displacements from the ideal arrangement would be extremely laborious. It is accordingly desirable to be able to predict with some accuracy the nature and the amount of the distortion to be expected for a given structure.

In not too complicated cases this can be done theoretically by finding the minimum in the crystal energy with respect to variations in the parameters determining the structure, with the use of a theoretical expression for the interionic repulsion potential. Such calculations have been carried out for rutile and anatase,[21] leading to the result that in each case the shared edges of the titanium octahedra are shortened to the length 2.50 Å., other edges being compensatorily lengthened. This distortion is actually found experimentally for these crystals. It was accordingly assumed to hold for brookite also, and the atomic arrangement derived in this way was shown to be in complete agreement with the observed intensities of x-ray reflection.

In general it is not possible to make such calculations on account of the excessive labor involved. It can be seen, however, that the cation–cation repulsion will shorten shared edges and the edges of shared faces, and reasonably confident application may be made of the following rule. Polyhedra of oxygen ions about trivalent and tetravalent cations are distorted in such a way as to shorten shared edges and the edges bounding shared faces to a length of about 2.50 Å. Edges bounding shared faces have been observed to be shortened to 2.50 Å. in corundum, Al_2O_3, and to 2.55 Å. in hematite, Fe_2O_3, in agreement with the foregoing rule.

It is furthermore to be anticipated that the cation–cation repulsion will operate in some cases to displace the cations from the centers of their coordinated polyhedra. This action will be large only in case the radius ratio approaches the lower limit for stability, so that the size of the polyhedron is partially determined by the characteristic anion–anion repulsive

---

[21] Linus Pauling, *Z. Krist.*, **67**, *377* **(1928).**

forces (the distribution of closely neighboring cations must, of course, be one-sided in addition). Hematite and corundum provide an example of this effect. In these crystals each octahedron shares a face with another octahedron. Now in an iron octahedron, with radius ratio about 0.48, the repulsive forces principally effective in determining the interionic distances are those between iron and oxygen ions. The Coulomb repulsion of the two iron ions accordingly can produce only a small displacement of these ions from the octahedron centers; the iron ions in hematite are observed to be 2.06 Å. from the oxygen ions defining the shared face and 1.99 Å. from the other oxygen ions. In an aluminum octahedron, on the other hand, with radius ratio 0.41, the characteristic repulsive forces between oxygen ions as well as those between oxygen and aluminum ions are operative; as a result of this "double repulsion"[12] the distance from the center of the octahedron to a corner is somewhat greater than the sum of the crystal radii of aluminum and oxygen. The aluminum ions are correspondingly mobile and the aluminum–aluminum Coulomb repulsion is to be expected to cause a large displacement in their positions. This is observed; the two aluminum-oxygen distances in corundum are 1.99 Å. and 1.85 Å.

The nature and approximate amount of the distortion to be expected in other cases can be similarly estimated; an example will be given in a later paper.[16]

10. The Close-Packing of Large Ions.—In piling together polyhedra in the attempt to predict a possible structure for a crystal with the aid of the principles described above, the recognition from the observed dimensions of the unit of structure that the atomic arrangement is probably based on a close-packed arrangement of the anions is often of very considerable assistance, for it indicates the probable orientation of the polyhedra, which can then be grouped together to form the completed structure. This was done in the determination of the structure of topaz and contributed considerably to the ease of solution of the problem. The approximation of the dimensions of the unit of structure of topaz to those of a close-packed structure does not, however, suffice to determine the positions of the anions, for there are two types of close-packing, simple hexagonal and double hexagonal,[22] which have these dimensions. This ambiguity

[22] An infinity of equally close-packed arrangements of spheres can be made from the close-packed layers A, with a sphere at $X = 0$, $Y = 0$ (X, Y and Z being hexagonal coördinates), B, with a sphere at $X = 1/3$, $Y = 2/3$, and C, with a sphere at $X = 2/3$, $Y = 1/3$. For simple hexagonal close-packing these layers are superposed in the order ABABAB..., for cubic close-packing in the order ABCABC... for double hexagonal close-packing in the order ABACABAC..., and so on, with ever-increasing complexity. In only the first two are the spheres crystallographically equivalent, and only these two have been generally recognized in the past; this restriction is, however, undesirable from the standpoint of the coordination theory.

was no serious obstacle in the prediction of the structure by the coordination method; the octahedra and tetrahedra were suitably piled together and the resultant arrangement of oxygen and fluorine ions was found to be double hexagonal close-packing.

Hrookite is also based upon a double hexagonal close-packed arrangement of the oxygen ions. The dimensions of the unit of structure differ so much on account of distortion from those for the ideal arrangement, however, that the existence of close-packing was recognized only after the structure had been determined.

It may be pointed out that in some structures easily derivable with the coördination theory, such as the rutile structure, the anion arrangement approximates no type of close-packing whatever.

11. Applications of the Theory.—As an illustration of the application of the foregoing principles some predictions may be made regarding the structure of cyanite, andalusite and sillimanite, the three forms of Al_2SiO_5. From the rule of parsimony we expect all aluminum octahedra to be similar and all silicon tetrahedra to be similar. Let the number of octahedra one corner of which is formed by the i^{th} oxygen ion be α_i; then the stoichiometrical oxygen–aluminum ratio, 5:2, requires that

$$\sum_i \frac{1}{\alpha_i} = \frac{5}{2} \tag{4}$$

in which the sum is taken over the six oxygen ions forming one octahedron. Four out of five oxygen ions, in accordance with Rule IV, will be distinguished through being attached to silicon ions; this fact is expressed by the equation

$$\sum_i{}' \frac{1}{\alpha_i} = 2 \tag{5}$$

in which the prime signifies that the sum is to be taken over these oxygen ions only. Let us now assume that the oxygen ions are of only two kinds with respect to their values of a, those attached to silicon ions, n_1 in number, forming one class, and those not attached to silicon ions, n_2 in number, forming the other class. Equations 4 and 5 then become

$$\left.\begin{aligned} \frac{n_1}{\alpha_1} + \frac{n_2}{\alpha_2} &= 5/2 \\ \frac{n_1}{\alpha_1} &= 2 \end{aligned}\right\} \text{ with } n_1 + n_2 = 6 \tag{6}$$

The only solution of these equations involving integers is $n_1 = 4$, $\alpha_1 = 2$, $n_2 = 2$, $\alpha_2 = 4$. Thus about each aluminum ion there will be four oxygen ions common to two aluminum octahedra and one silicon tetrahedron, and two oxygen ions common to four octahedra.[23] For both kinds of oxy-

---

[23] It is possible that the aluminum octahedra may be of more than one kind. In this case average values of the sums would have to be used in Equations 4 and 5, and the equations would no longer possess a single solution.

gen ions $\Sigma s_i = 2$, so that the principle of electrostatic valence, which was not used in the derivation of Equation 6, is satisfied.

This result, while limiting considerably the number of possible structures for these crystals, by no means determines their structures. Further information is provided by Rule III, from which it is to be expected that the silicon tetrahedra share only corners with aluminum octahedra, and the octahedra share only corners and edges (and possibly one face) with each other.

These predictions are not incompatible with Professor Bragg's assignment of a cubic close-packed arrangement of oxygen ions to cyanite.[7a] They are, however, in pronounced disagreement with the complete atomic arrangement proposed by Taylor and Jackson,[24] whose suggested structure conflicts with most of our principles. Their structure is far from parsimonious, with four essentially different kinds of octahedra and two of tetrahedra. Each silicon tetrahedron shares a face with an octahedron, contrary to Rule III. The electrostatic valence principle is not even approximately satisfied; one oxygen ion, common to four aluminum octahedra and one silicon tetrahedron, has $\Sigma s_i = 3$, while another, common to two octahedra only, has $\Sigma s_i = 1$. For these reasons the atomic arrangement seems highly improbable.

The coordination theory and the principles governing coördinated structures provide the foundation for an interpretation of the structure of the complex silicates and other complex ionic crystals which may ultimately lead to the understanding of the nature and the explanation of the properties of these interesting substances. This will be achieved completely only after the investigation of the structures of many crystals with x-rays. To illustrate the clarification introduced by the new conception the following by no means exhaustive examples are discussed.

Let us consider first the silicates of divalent cations with coordination Number 6, and hence with electrostatic bond strength $s = {}^1/_3$. An oxygen ion forming one comer of a silicon tetrahedron would have $\Sigma s_i = 2$ if it also formed a corner of three R^{++} octahedra; if it were not attached to a silicon ion, it would have to form a corner of six R^{++}octahedra to satisfy the electrostatic valence principle. But six octahedra can share a corner only by combining in the way given by the sodium chloride structure, and this arrangement, involving the sharing of many edges, is expected not to be stable as a part of the structure of a complex silicate.[25] Accordingly, we conclude that no oxygen ions not attached to silicon occur in these silicates; that is, the oxygen–silicon ratio cannot be greater than

---

[24] W. H. Taylor and W. W. Jackson, *Proc.* Roy. *Soc. London,* **119A, 132** (1928).

[25] The instability of the sodium chloride structure for oxides is shown by the heat of the reactions $CaO + H_2O = Ca(OH)_2 +$ 15,500 cal. and $MgO + H_2O = Mg(OH)_2 +$ 9000 cal.

4:1. The silicates which will occur are orthosilicates, $R^{++}{}_2SiO_4$, metasilicates, $R^{++}SiO_3$, etc. This is verified by observation; no basic silicates of such cations are known, although many normal silicates such as forsterite Mg_2SiO_4, etc., exist.

A univalent anion (F^-, $OH-$) may be shared among three R^{++}octahedra alone, so that compounds may occur in which these anions are present in addition to the SiO_4 groups. Such compounds are known: $Mg_3SiO_4(F, OH)_2$, prolectite, $Mg_5(SiO_4)_2(F, OH)_2$, chondrodite, etc.

Compounds of simple structure according to the coordination theory are those in which the number of essentially different kinds of anions is small. In a simple orthosilicate containing aluminum and a divalent cation each oxygen ion would form the corner of a silicon tetrahedron ($s = 1$), an aluminum octahedron ($s = {}^1/_2$), and one or two R^{++} polyhedra (one tetrahedron or two polyhedra with $v = 8$). The composition of the substance would then be given by the formula $R^{++}{}_3Al_2Si_3O_{12}$. Similarly, in simple metasilicates there would occur such oxygen ions in addition to those common to two silicon tetrahedra; the corresponding formula is $R^{++}{}_3Al_2Si_6O_{18}$. This result is in striking agreement with observation. The most important double orthosilicates of divalent and trivalent metals are the garnets: $Ca_3Al_2Si_3O_{12}$, grossular, $Ca_3Cr_2Si_3O_{12}$, uvarovite, $Ca_3Fe_2Si_3O_{12}$, topazolite, etc., and the only double metasilicate is beryl, $Be_3Al_2Si_6O_{18}$.

The radius ratio of potassium ion and oxygen ion is 0.76, so that the coördination number to be expected for potassium ion in silicates is 8, the corresponding electrostatic bond strength being ${}^1/_8$. In potassium aluminum silicates containing aluminum octahedra the electrostatic valence principle would require at least four potassium polyhedra to have a common corner together with a silicon tetrahedron and an aluminum octahedron; this is not spatially possible. It is accordingly highly probable that in these compounds, the structure of none of which has yet been satisfactorily investigated with x-rays, the aluminum ions have a coordination number of 4. There could then occur oxygen ions with $\Sigma s_i = 2$ common to a silicon tetrahedron, an aluminum tetrahedron and two potassium polyhedra. The potassium–aluminum ratio would then be 1:1. In a large number of silicates, in particular the important feldspars, this ratio is observed: $KAlSiO_4$, phakelite, $KAlSi_2O_6$, leucite, $KAlSi_3O_8$, potassium feldspar (microcline, orthoclase), $(K, Na)_8Al_8Si_9O_{34}$, nepheline, etc. In other silicates containing more than this amount of aluminum, such as muscovite, $H_2KAl_3Si_3O_{12}$, etc., it is probable that the excess aluminum ions usually have the coordination Number 6.

Other alkali ions (except lithium) also probably have the coordination Number 8 as a rule, and should similarly have a tendency to a 1:1 ratio with aluminum; this is shown in $NaAlSi_3O_8$, albite, $H_2Na_2Al_2Si_3O_{12}$, natrolite, $H_2Cs_4Al_4Si_9O_{27}$, pollucite, etc.

In spodumene, $LiAlSi_2O_6$ and petalite, $LiAlSi_4O_{10}$, it is possible that oxygen ions (with $\Sigma s_i = 2$) are common to a silicon tetrahedron, an aluminum tetrahedron and a lithium tetrahedron (the radius ratio for lithium ion is 0.33).

No aluminum silicates of alkali metals are known in which the Al^{+3}:R^{+1} ratio is less than 1:1.

Summary

A set of principles governing the structure of complex ionic crystals, based upon the assumption of a coordinated arrangement of anions about each cation at the corners of an approximately regular polyhedron, is formulated with the aid of considerations based upon the crystal energy. Included in the set is a new electrostatic principle which is of wide application and considerable power.

It is shown that the known structures of many complex crystals, in particular the complex silicates, satisfy the requirements of these principles.

As an illustration of the application of the principles in the prediction of structures with the coordination theory, some properties of the structures of the three forms of Al_2SiO_5, cyanite, andalusite and sillimanite, are predicted.

It is further shown that the theory requires that no stable basic silicates of divalent metals exist, and that in aluminum silicates of alkali metals there should be at least one aluminum ion for every alkali ion.

The structures of aluminum silicates of divalent metals which are simplest from the coordination standpoint are shown to correspond to the formulas $R_3^{++}Al_2Si_3O_{12}$ and $R_3^{++}Al_2Si_6O_{18}$, which include the most important minerals of this class, the garnets and beryl.

SOLUBILITY IN THE GASEOUS PHASE, ESPECIALLY IN THE SYSTEM: $NH_3(l)$-$NH_3(g)$, $H_2(g)$, $N_2(g)$

BY H. L. CUPPLES

RECEIVED SEPTEMBER 7, 1928 PUBLISHED APRIL 5, 1929

A number of investigators have found that a solubility effect may be shown within a gaseous phase, especially under circumstances in which the density of the gaseous phase is relatively high. Pollitzer and Strebel[1] were perhaps the first to mention this phenomenon.

The two-phase system $NH_3(l)$-$NH_3(g)$, $H_2(g)$, $N_2(g)$ in which the H_2 and N_2 were maintained at the constant mole ratio of $3H_2$:N_2 has been experimentally investigated by Larson and Black.[2] Concentrations

---

[1] Pollitzer and Strebel, *Z. physik. Chem.*, **110**, 785 (1924).

[2] Larson and Black, THIS JOURNAL, 47, 1015 (1925).

of ammonia in the gas phase were found to be as much as six times the concentrations calculated with the aid of the perfect gas laws, **and** an application of the Poynting equation[3] for increase of vapor pressure with total pressure did not yield satisfactory results. These authors suggest that the observed concentrations are possibly due to a positive solubility effect of the gaseous phase for ammonia vapor.

Lurie and Gillespie[4] have recently studied a similar system in which they measured the composition of mixtures of nitrogen and ammonia in equilibrium with a mixture of barium chloride and barium chloride octa-ammine, their experiments extending up to total pressures of approximately 60 atmospheres at 45°. At this temperature and within the pressure range studied it was found that the equilibrium concentrations of ammonia exhibited a considerable solubility effect when compared with values calculated with the assumption of Gibbs' rule of additive pressures. An applicaiion of the equation of state for mixtures of Keyes and Burks, however, yielded satisfactory agreement with the experimentally determined concentrations.

Considering the available data for a number of cases of gaseous solutions (including the NH_3–H_2–N_2 system), Randall and Sosnick[5] have presented *a* series of curves of "activity coefficients" which enable rough quantitative predictions of values in other mixtures and at other temperatures.

A Concept of "Zero Solubility."—In order that we may further examine the nature of phenomena similar to those mentioned above, it will be necessary first to define what we mean by "solubility" in systems of this kind. For this purpose let us consider a closed system containing only a gaseous component, A. Let us next imagine this system to be partially filled with a non-volatile liquid component, B, allowing none of Component A to escape from the system. It is apparent that, when equilibrium is attained, Component A will be uniformly distributed throughout the liquid phase and uniformly distributed throughout the gaseous phase, but in general its distribution will not be uniform throughout the system as a whole. With a certain choice of components, Component A might be found to be almost entirely in the liquid phase, its density in the gaseous phase being much less than its original density before the introduction of the liquid phase. This might be expressed by stating that the gas is very soluble in the liquid. With another choice of components, Component A might remain largely in the gaseous phase, its density accordingly being greater than before the introduction of the liquid. In this case the gas might be said to be comparatively insoluble in the liquid.

---

[3] Poynting, **Phil.** *Mag.*, **[4] 12, 32 (1881).**

[4] Lurie and Gillespie, THIS JOURNAL, 49, **1146 (1927).**

[5] Randall and Sosnick, *ibid.*, 50, **967** (1928).

The unique case is that in which Component A remains uniformly distributed throughout the entire system, its density in each phase being identical with its original density before introduction of the liquid. As the spatial distribution of Component A is in this case entirely unaffected by the presence of Component B, it follows that the activity of Component A at each point throughout the system is dependent only on its volume concentration and temperature. It seems quite logical to consider this as a case of "zero solubility," and from this point of view we may define a "solubility effect" as being a change in the activity of one component which is due to the presence of other components.

Application to the System **NH_3(l)-NH_3(g), H_2(g), N_2(g).**—Let us first consider a simple closed system containing liquid ammonia in equilibrium with ammonia gas at constant temperature. Under these conditions the pressure exerted by the ammonia vapor is the normal vapor pressure of ammonia at the temperature considered. Next let us imagine the liquid phase to be separated from the gaseous phase by a piston permeable to ammonia vapor but impermeable to ammonia liquid; by means of this piston let us exert a definite pressure upon the liquid phase, thus increasing the activity of ammonia in this phase. If equilibrium conditions are maintained, it is evident that the activity of ammonia in the gaseous phase will correspondingly increase; this increase in activity is developed by an increase in the density of ammonin in the gas phase. The net result is that increase of pressure on the liquid ammonia phase causes an increase in the density of ammonia in the gas phase; this phenomenon is often referred to as the Poynting effect. It is obvious that no solubility effects are involved in the Poynting effect, as the gas phase is assumed to contain no constituent other than ammonia.

We may, however, employ a different device for exerting pressure upon the liquid ammonia phase. In the absence of the semi-permeable membrane which has previously been assumed to exert this pressure, let us pump into the system an "inert" gas which is substantially insoluble in the liquid phase. By this means we may exert the same pressure on the liquid ammonia as was previously exerted through the assumed semi-permeable membrane. The significant difference between conditions in the two assumed cases is that in this second case the gas phase contains a high concentration of the "inert" gas. The question at once arises as to whether or not this "inert" gas has a solubility effect. It seems logical to consider that no solubility effect is exhibited if the volume concentration of ammonia in the gaseous phase is identical with what it would be were the same pressure applied to the liquid phase through the medium of a semi-permeable piston. This is in conformity with the definition of solubility effect which we have developed above, namely, that a solubility effect is a change in the activity of the solute due to the presence of the solvent; in this case the solvent is the "inert" gas by means of which we exert an increased pressure upon the liquid ammonia, while the solute is the ammonia in the gas phase.

We may now proceed to examine this system in greater detail, in accordance with our present conception of a solubility effect.

Activity of Ammonia in the Liquid Phase.—The activities of liquid ammonia at pressures greater than its normal vapor pressure, relative to its activity a' at the same temperature and under the pressure of its saturated vapor, have been calculated by applying the equation[6]

---

[6] See Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. *225.*

$$RT \ln a/a' = \int_{P'}^{P} V dP \qquad (1)$$

This calculation has been made in a manner entirely similar to that used by Randall and Sosnick,[5] except that approximate corrections have been made for the decrease in volume of the liquid ammonia at pressures greater than the vapor pressure, and for the solubility of the $3H_2:N_2$ mixture in the liquid ammonia phase. For this purpose a rough value of 5×10^{-5} was used for the compressibility factor for liquid ammonia, and the solubilities of hydrogen and nitrogen in the liquid phase have been estimated by graphical interpolation and extrapolation of the data of Larson and Black,[7] who worked in this instance at pressures up to 150 atmospheres. The activity values as given by Randall and Sosnick would probably have been used in these calculations had they been available at the time this material was in course of preparation.

Activity of Ammonia in the Gaseous Phase.—The calculation of the concentration of ammonia in the gas phase from its activity presents difficulty. In the absence of experimental information Lewis and Randall[8] considered all gaseous solutions to be nearly perfect solutions, and assumed the fugacity of each constitutent to be proportional to the mole fraction of that constituent, at every temperature and at every pressure. More recent experimental data have shown that gaseous mixtures at higher pressures may present the same kinds of deviations as liquid mixtures, although the deviations are not, in general, so large.[5,9]

Keyes[10] has employed his equation of state for similar calculations with gaseous mixtures, assuming a simple additive rule for combining the constants of the individual gases to obtain the constants for the mixture.

For our present purpose we shall make the very simple assumption that the activity of ammonia vapor is dependent only on its volume concentration and temperature, and is entirely independent of the other gases which may be present. This is equivalent, according to the definition which we have adopted above, to assuming that there is no solubility effect toward ammonia vapor in the gas phase, and agreement of calculated with observed results will be a strong indication of the relative unimportance of such an effect.

Because of its convenient form for the direct evaluation of certain desired integrals, the P-V-T relationships of ammonia vapor will be expressed by means of the Bureau of Standards equation.[11] While it is known that this equation well reproduces the experimental data, its

accuracy becomes increasingly uncertain as it is extrapolated to pressures which are increasingly greater than the normal vapor pressure of liquid ammonia at a particular temperature. Randall and Sosnick[5] have clearly shown how certain equations of state may lead to erroneous values of fugacity when they are too far extrapolated. It is easy to show that similar limitations apply to the Bureau of Standards equation of state, and for this reason the present calculations have not been extended beyond total pressures of 600 atmospheres.

Method of Calculation

The activities of liquid ammonia in the presence of compressed $3H_2:N_2$ mixture at various pressures and temperatures, calculated as previously described, are shown in Table I, Col. 3. These activities are relative to the activity of $NH_3(l)$ at the same temperature and under the saturation pressure of its own vapor. Under equilibrium conditions the activities in the liquid and gas phases are, of course, necessarily equal, when referred to the same standard state.

At a given temperature and total pressure it is next required to determine the pressure of ammonia vapor at which its activity will equal the activity of ammonia in the liquid phase. For this purpose Equation 1 has again been utilized, the integration being carried out by substituting for V its value in terms of P (at constant temperature), as given by the Bureau of Standards equation of state. At a given temperature this integral has been evaluated for a number of different values of P and a curve constructed in which a/a' has been plotted as ordinate against P as abscissa. From this plot it is then possible to read directly the value of P at which ammonia vapor has the same activity as its calculated value in the liquid phase. These values of P are given in Table I, Col. 4. Substitution of these values of P directly in the equation of state for ammonia vapor gives the corresponding values for the specific volumes of ammonia vapor. Multiplication by 17.03 gives the molal volumes as shown in Table I, Col. 5.

Let us now consider a volume of the compressed gaseous mixture in equilibrium with liquid ammonia, equal in cc. to RT, where RT is expressed in cc.-atm. At any given temperature and value of the molal volume of ammonia, RT/Molal Volume will represent the number of moles of ammonia contained in this volume. These values are given in Table I, Col. 6.

The number of moles of the "inert" gas ($3H_2:N_2$) which are present in this same volume will be estimated by an application of the principle of additive pressures. Consider a volume of $3H_2:N_2$ mixture in equilibrium with the mixture containing ammonia, through a membrane permeable to hydrogen and to nitrogen but impermeable to ammonia. We

shall assume the density of the $3H_2:N_2$ mixture to be the same on both sides of the membrane, and the $3H_2:N_2$ mixture in both cases to exert a pressure equal to $(P-p)$, where P is the total pressure exerted by the mixture containing ammonia vapor and p is the pressure exerted by the ammonia vapor itself, as given in Table I, Col. 4. The number of moles of $3H_2:N_2$ mixture in the volume RT will accordingly equal the pressure $(P-p)$, in atmospheres, divided by a compressibility factor, F, where F is equal to the P V product for one mole of $3H_2:N_2$ mixture, at the temperature and pressure under consideration, divided by the value of RT at that temperature. Values for F have been estimated by graphical interpolation and extrapolation of the data of Bartlett, Cupples and Tremearne,[12] and the values thus calculated for the number of moles of $3H_2{:}N_2$ present in the volume RT are given in Table I, Col. 7.

The mole fractions of ammonia in the gaseous mixtures may be obtained by dividing the values given in Col. 6 for the number of moles of ammonia in the volume RT, by the sum of the values in Cols. 6 and 7. These values, in mole per cent., are shown in Col. 8. In Col. 9 are shown the corresponding values which have been graphically interpolated from the experimental data of Larson and Black.

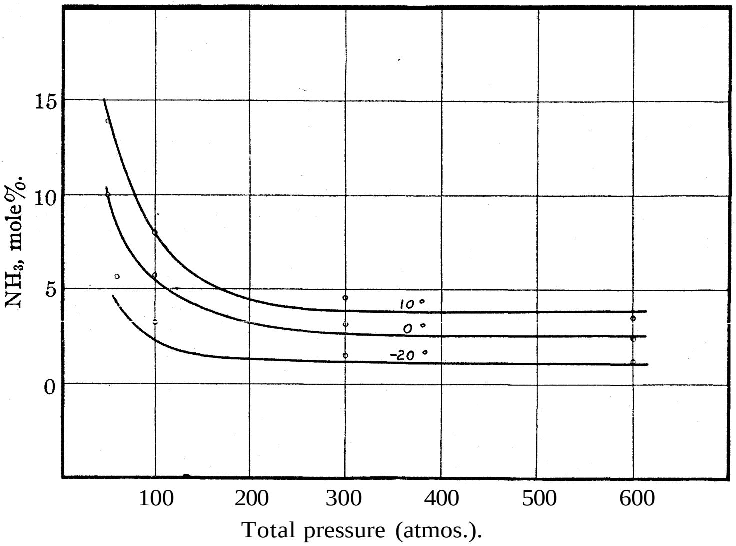

Fig. 1.—Mole percentage of ammonia in $3H_2{:}N_2$ mixture in equilibrium with liquid ammonia. Curves show calculated values; circles show experimental values.

Discussion

Considering the nature of the calculations and the assumptions which are necessarily involved, the calculated values may be said to be in good agreement with the experimental data. Within the pressure range covered by the calculations (600 atmospheres' total pressure), there seems to be no consistent deviation of substantial magnitude, such as would be shown if the gaseous phase had a significant solubility effect for ammonia vapor. Although there is a considerable deviation at the lower temperatures measured by Larson and Black, as illustrated in Fig. **1,** it should be noted that this deviation *does not increase with increasing*

---

[12] Bartlett, Cupples and Tremearne, THIS JOURNAL, 50, 1275 (1928)

pressure, as would be expected if it were due to a solubility effect of the compressed gaseous mixture.

A point of interest which appears from these calculations is the fact that comparatively little reduction in the mole per cent. of ammonia in the gas mixture is to be expected on increasing the total pressure beyond 600 atmospheres. At 0° an increase of pressure from 600 to 1000 atmospheres will decrease the volume of the gas mixture to about 75% of its initial value, simultaneously increasing the activity of $NH_3(l)$ to 152% of its initial value. It is quite possible that at some pressure a minimum value is attained, beyond which the mole per cent. of ammonia in the gas phase increases with increasing pressure. A few of the calculated values do, in fact, indicate a somewhat higher molal concentration of ammonia at 600 atmospheres' total pressure than at 400 atmospheres' total pressure, but at these high pressures this may possibly be due, at least in part, to errors incident to the extrapolation of the equation of state for ammonia vapor.

Summary and Conclusions

A concept of solubility is presented which seems to be especially applicable to systems involving one or more gaseous components. According to this concept, a solubility effect is defined as being a change in the activity of one component which is due to the presence of other components.

A method is outlined by which the two-phase system $NH_3(l)$–$NH_3(g)$, $H_2(g)$, $N_2(g)$ has been examined for the presence of such a solubility effect. It is concluded that, within the fairly large error of calculation, there is no indication of a solubility effect of the gas phase for ammonia vapor.

An analogous treatment can be applied to other similar systems for which the required data are available. It is to be expected that the conclusions which may be reached will vary in each individual case.

THE OXIDATION OF IODIDE ION BY PERSULFATE ION. I. THE EFFECT OF TRI-IODIDE ION FORMATION ON THE REACTION VELOCITY[1]

BY ERIC JETTE AND CECIL V. KING

RECEIVED SEPTEMBER 15, 1928 PUBLISHED APRIL 5, 1929

A. Introduction

Thermal and photochemical reactions in which iodine is liberated from iodides by oxidizing agents have been the subject of numerous investigations, in nearly all of which the effect of the equilibrium $I_2 + I^- \quad I_3^-$ has been considered, although not always in an adequate manner. As a general conclusion from such investigations it may be said that one cannot predict with assurance what effect the presence of tri-iodide ion will have on any particular reaction since it depends largely upon the specific properties of the system. In connection with another problem the present writers were forced to investigate in some detail one of these reactions, namely, that between persulfate and iodide ions, a reaction which has been used by Bronsted[2] as a confirmation of his theory of reaction velocity.

The first to work with this reaction was Price,[3] who observed in one of his many experiments that adding iodine to the initial mixture decreased the velocity of the reaction and noted that the probable cause was the formation of tri-iodide ion. The single experiment which Price performed with iodine present in the initial mixture does not supply sufficient information for detailed study of the tri-iodide ion effect. Recently Kiss and his co-workers[4] have investigated the reaction and found (*cf.* Table IV of ref. 4c) that the presence of iodine in the initial mixture decreased the reaction velocity, but when the concentration of iodide ion was corrected for the amount of tri-iodide present, the velocity constant was the same as when no iodine was present at the beginning of the experiment. On this basis they concluded that the tri-iodide ion does not react with the persulfate ion. The work of Kiss, Bruckner and Zombory is seriously marred (1) by errors or gross misprints in the equations for the reaction velocity and for the concentration of tri-iodide ion, (2) by so incomplete a statement as to the meaning of their quantitative values and symbols that after

considerable effort the present writers were unable to use the experimental results quoted in the correct equations or to calculate the constants given in the original communication and **(3)** by the presence of an unknown impurity in the persulfate used for nearly all their experiments, resulting in velocity constants approximately 15% too high; this fact was found and noted by the original experimenters. While all the calculations contained in each one of the papers quoted are presumably made on the same basis, the conclusions regarding the neutral salt effects, agreement with the Bronsted theory and the mechanism of the catalytic effects of iron and copper ions must remain in considerable doubt until the quantitative results are recalculated on a correct basis. More detailed criticisms will be given at various points in the present paper.

B. Materials and Methods

All the salts used in this investigation were "C. P." materials, which were recrystallized at least once from distilled water before using. The potassium persulfate (Baker's "Analyzed") was recrystallized between 50 and 0° and dried over sulfuric acid in a vacuum desiccator. The iodine was a "C. P." grade which was resublimed once with addition of potassium iodide and the product then sublimed once more. The particular purpose of purifying these salts and iodine was for the removal of traces of ferric salts which might have been present, especially in the persulfate, since ferric ion has a very pronounced catalytic effect on the reaction. No observable color was obtained on adding ammonium thiocyanate to any of these salts. Two different lots of each of the three principal substances, potassium iodide, potassium persulfate and iodine were prepared during the course of the investigation. Reaction velocity curves obtained with the first and second lots agreed within experimental error.

The water used in making the solutions was ordinary laboratory distilled water redistilled from potassium permanganate acidified with sulfuric acid and condensed in a block tin condenser, the first portions being rejected.

Most of the solutions, including the potassium persulfate and potassium iodide solutions, were made up by weighing the proper amount of dry salt, dissolving and making up to volume in standardized flasks. The iodine in solutions containing it at the start of the reaction was titrated before use by the method used later in determining the reaction velocity curve. The sodium thiosulfate solution used for the iodine titrations was standardized at frequent intervals against the iodine liberated from potassium iodide solutions by standard potassium permanganate solution, using freshly prepared starch solution as indicator. The concentration of the permanganate solution was determined by means of pure sodium oxalate.

Preliminary experiments carried out in glass-stoppered bottles gave continuously decreasing values for the bimolecular "constant," a result which might have been due to loss of iodine from the solution. In order to eliminate this possibility all the experiments reported in the present article were conducted in sealed pyrex bulbs each containing 50 cc. of the reaction mixture measured from standardized pipets. In most cases the bulbs were of 100-cc. capacity.

Equal volumes of the two solutions (usually measured from the same flask) were mixed as rapidly as possible, pipetted quickly into the prepared bulbs and sealed. They were then placed in a large thermostat at a temperature of 25.00 ±0.01°. After the reaction had proceeded for a given time, the tip of the bulb was removed and the titration of the iodine by means of a standardized sodium thiosulfate solution (approximately 0.01 molar) completed in the shortest possible time, the entire titration taking place without transferring the solution from the bulbs. Since the openings of the bulbs were quite small, and the titrating solution was made to flow over the inner surface of the bulb, and especially since the iodine in the solution was reduced to a very low concentration in less than one-half minute after opening, practically no loss of iodine occurred. Whenever the speed of the reaction was not too great, an excess of thiosulfate was added and the first titration checked by a back titration with a standard iodine (in potassium iodide) solution. In spite of these precautions, however, the velocity constants still decreased as the reaction proceeded, showing that the effect must be inherent in the reaction, as it has been considered by other investigators from results obtained by methods differing somewhat in details.

In some of the experiments the initial reaction mixture was saturated or nearly so with iodine. In these cases the individual solutions containing potassium persulfate and potassium iodide were saturated separately with iodine and 25-cc. samples of the solutions were titrated immediately to obtain the initial amount of iodine present. Into each reaction bulb 25 cc. of each of the two solutions were pipetted from standardized pipets. The solubility of iodine in the final mixture was unknown but this was not particularly important for the present purpose; if the final solution was not quite saturated just after mixing, it became so very soon due to the iodine formed by the reaction. The minimum time required for these titrations was two minutes, the maximum about five minutes, which accounts for the slight irregularities in the results with saturated iodine solutions. In these experiments also the entire titration was performed in the reaction bulb.

C. Theory and Results of Experiments with Initial Solutions Containing Only Potassium Persulfate and Potassium Iodide

The reaction between $S_2O_8^{-}$ and I^- ions has usually been considered a bimolecular reaction, although the stoichiometric equation for the potassium salts is

$$2KI + K_2S_2O_8 \longrightarrow 2K_2SO_4 + I_2 \tag{1}$$

The main reason for so considering it is the fact that the velocity constants as calculated from experimental results[5] by means of the ordinary bimolecular equation

$$-\frac{dC_{S_2O_8^{--}}}{dt} = kC_{S_2O_8^{--}}C_{I^-} \tag{2}$$

or one of its integrated forms, showed less variation than if the equations for unimolecular or trimolecular reactions were used. The values of k obtained always decreased as the reaction progressed, the decrease being accounted for by the formation of the tri-iodide ion.

Bronsted considers the reaction to take place in two steps, the first of which is the formation of a critical complex, namely:

$$S_2O_8^{--} + I^- \longrightarrow (S_2O_8I)^{---} \tag{3}$$

$$(S_2O_8I)^{---} + I^- \longrightarrow 2SO_4^{--} + I_2 \tag{4}$$

On the basis of these reactions and his theory of reaction velocity, Brönsted writes the velocity equation

$$-\frac{dC_{S_2O_8^{--}}}{dt} = kC_{S_2O_8^{--}}C_{I^-}\frac{f_{S_2O_8^{--}}f_{I^-}}{f_{(S_2O_8I)^{---}}} = kC_{S_2O_8^{--}}C_{I^-}F \tag{5}$$

---

[5] Cf. Price, ref. **3,** p. 477.

in which f represents the activity coefficients of the ions indicated and F is called the "kinetic activity factor." Since all the ions in Equation 3 have the same sign, the salt effect is positive and with increasing ionic strength the value of k should increase. If the initial concentration of $K_2S_2O_8$ is a moles per liter and that of KI is $2a$, then the initial ionic strength[5] of the solution is $5a$ while after the reaction has gone to completion it is $6a$ so that the value of k should increase in each experiment. A large amount of data is at hand to show that if the ionic strength of the solution is increased by the addition of ionogens which do not take part in the reaction, the reaction velocity increases. This confirmation of Brönsted's theory has already been pointed out by Kiss and Zombory and Kiss and Bruckner as well as by Bronsted.

Three possible assumptions which may be made in discussing the effect of the tri-iodide ion formation on the speed of reaction are as follows. (1) The tri-iodide ion does not react with the persulfate ion. (2) The tri-iodide ion reacts at the same rate as the iodide ion. (3) The tri-iodide ion reacts but at a rate different from that of the iodide ion. The first assumption was made by Kiss and Zombory and Kiss and Bossányi and will be shown to be incorrect. The second is improbable from the start since the reaction should then proceed just as if no tri-iodide ion was formed and it would be necessary to invoke the aid of unknown inhibitors to account for the actual behavior of the velocity curve. The third assumption will be shown to be correct in the present article. Before proceeding to this point, however, it will be pertinent to demonstrate that correcting the momentary iodide-ion concentration for the presence of tri-iodide ion is quite inadequate and, further, that the apparent constancy of the velocity constant when so corrected reported by Kiss and his co-workers is due to errors in the equations used and in the choice of the equilibrium constant.

The equilibrium

$$\mathrm{I}_2 + \mathrm{I}^- \rightleftarrows \mathrm{I}_3^- \tag{6}$$

has been the subject of considerable work by Bray and MacKay[6] and more recently by Jones and Kaplan.[7] The only true equilibrium constant which can be discussed in this case is the one in terms of the activities of the three substances. The equation is

$$K_a = \frac{a_{\mathrm{I}^-}a_{\mathrm{I}_2}}{a_{\mathrm{I}_3^-}} = \frac{C_{\mathrm{I}^-}C_{\mathrm{I}_2}}{C_{\mathrm{I}_3^-}} \times \frac{f_{\mathrm{I}^-}f_{\mathrm{I}_2}}{f_{\mathrm{I}_3^-}} \tag{7}$$

where a represents activities, C concentrations and f activity coefficients. If it may be assumed that $f_{\mathrm{I}_2} = 1$ and that $f_{\mathrm{I}^-}/f_{\mathrm{I}_3^-} = 1$ or *const.* the ordinary equilibrium equation

$$K = \frac{C_{\mathrm{I}^-}C_{\mathrm{I}_2}}{C_{\mathrm{I}_3^-}} \tag{8}$$

is obtained.

---

[6] Bray and MacKay, THIS JOURNAL, 32, 914 (1910).

[7] Jones and Kaplan, *ibid.*, 50, 1845, 2066 (1928).

Bray and MacKay fixed a_{I_2} in their experiments by keeping the solution saturated with iodine. By making the assumptions that $f_{I^-}/f_{I_3^-} = 1$ and that the concentration of free I_2 in a solution of potassium iodide is the same as in pure water, 0.000136 mole per liter, they found that the values of K in Equation 8 increased steadily from 0.00131 in 0.1 molar potassium iodide to 0.00150 in 0.001 molar potassium iodide and an extrapolated value of 0.00153 for pure water (at 25°). Jones and Kaplan fixed a_{I_2} in the potassium iodide solutions by equilibrating the latter with solutions of iodine in water of known concentration and vapor pressure. Their solutions were not saturated with iodine and they obtained for potassium iodide solutions of concentration from 0.01 to 0.333 molar values of the equilibrium constant in Equation 8 varying slightly around 0.00140 at 25°.

In order to obtain these values for the equilibrium constant K, however, it is necessary for all of these investigators to assume that

$$(C_{I_2})_{H_2O} = (C_{I_2})_{KI\ Soln} \text{ or } (f_{I_2})_{H_2O} = (f_{I_2})_{KI\ Soln}.$$

While it is thermodynamically true that $(a_{I_2})_{H_2O} = (a_{I_2})_{KI\ Soln.}$ under these conditions, some doubt must rest upon the other assumption, although there is no apparent way *at* present to avoid making it; no experimental evidence is available for its support.[8]

From the preceding discussion it will be seen that any correction introduced into the reaction velocity equation will in itself involve uncertainties except in those cases where the reaction mixture is saturated with respect to iodine over the entire course of the reaction. Even in the latter case it will still be uncertain that $f_{I^-}/f_{I_3^-} = 1$ or a constant. It is worth noting that Lewis and Randall[9] do not make either assumption, although it is evident that both are approximately true.

As a matter of practical expediency it will be necessary to set aside these theoretical objections, since more exact information on the various terms of Equation 7 is not available, and to assume that over the range of potassium iodide concentrations concerned in the present paper, the series of values for the equilibrium constant K are as determined by Bray and MacKay.[10]

---

[8] That the present situation is anything but clear may be seen from the fact that the equilibrium constant K in Equation 8 increases as the concentration of potassium iodide decreases from 0.01 to 0.001 molar, while in barium iodide solutions over the same range of concentrations K increases. Cf., footnote 10 and Pearce and Eversole, *J. Phys. Chem.*, 28, 245 (1924).

[9] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 527.

[10] Lewis and Randall, ref. 9, and Jones and Hartmann, THIS JOURNAL, 37, 241 (1915), have applied small corrections to these values or the data which determine them. The differences are immaterial over the range considered A part of the table given by Bray and MacKay is

$KI + KI_3$	=	0.010	0.005	0.002	0.001	0.000
$C_{I^-}/C_{I_3^-} = K'$	=	1.06	1.08	1.11	1.14	(1.16)
$K = K'C_{I_2}$	=	0.00140	0.00143	0.00147	0.00150	(0.00153)

Letting the initial concentration of potassium persulfate be *a* moles per liter and that of potassium iodide be $2a$, then according to the stoichiometric equation, for every x moles per liter of persulfate used in the reaction, $2x$ moles of potassium iodide will also disappear and x moles of iodine be produced. Since the equilibrium constant may then be expressed by the equation

$$K = \frac{C_{\mathrm{I}^-}}{C_{\mathrm{I}_3^-}} C_{\mathrm{I}_2} = \frac{(2a - 2x - C_{\mathrm{I}_3^-})\,(x - C_{\mathrm{I}_3^-})}{C_{\mathrm{I}_3^-}}$$

we find for the concentration of tri-iodide ion at any time during the reaction

$$C_{\mathrm{I}_3^-} = \frac{K + 2a - x}{2} - \sqrt{\left(\frac{K + 2a - x}{2}\right)^2 - 2x(a - x)} \tag{9}$$

If the effect of the tri-iodide ion is merely to reduce the concentration of iodide ion, then the bimolecular reaction velocity equation becomes

$$-\frac{\mathrm{d}C_{\mathrm{S_2O_8}^{--}}}{\mathrm{d}t} = k_1 C_{\mathrm{I}^-}\, C_{\mathrm{S_2O_8}^{--}} = k_1(2a - 2x - C_{\mathrm{I}_3^-})(a - x) \tag{10}$$

The corresponding equations given by Kiss and Zombory[4c] are

$$C_{\mathrm{I}_3^-} = \gamma = \frac{K + 2(b - x) + x}{2} \sqrt{\frac{K + 2(b - x) + x}{2} - 2(b - x)}$$

and

$$2k_1' = k_1 = \frac{dx}{dt}\,\frac{1}{(a - x)\,(b - x - \gamma)}$$

where *a* is the molar concentration of potassium persulfate, $2b$ is the molar concentration of potassium iodide and x is "the amount of I_2 formed." These equations are either grossly misprinted or derived upon some unknown basis. That they are incorrect may be seen in the case of the first by setting $x = 0$, for which it does not yield $C_{\mathrm{I}_3^-} = 0$ as demanded by experiment and theory. The second equation can be correct only if $\gamma = C_{\mathrm{I}_3^-}$ really means twice the tri-iodide concentration, in which case the first equation becomes still more puzzling.

The equation for the tri-iodide correction given by Kiss and Bruckner[4a] is

$$C_{\mathrm{I}_3^-} = y = \frac{b + K}{2} - \sqrt{\frac{(b + K)^2}{4} - x(b - x)}$$

where *b* is the equivalent concentration of potassium iodide and x is, presumably, equivalents of iodine formed. This equation results if in Equation 8 we put $C_{\mathrm{I}^-} = b - x - y$ and $C_{\mathrm{I}_2} = x - y$. The latter, however, means that the equivalent concentration of iodine is inserted into Equation 8, which is unjustified in this case since the equilibrium constant used by these writers is in terms of molar concentrations. The correct equation with b and x as equivalent concentrations is

$$y = \frac{K + b - x/2}{2} - \sqrt{\left(\frac{K + b - x/2}{2}\right)^2 - \frac{x}{2}(b - x)}$$

The experimental results on the reaction between potassium persulfate and potassium iodide in solutions containing initially only these salts are given in Table I and graphically in Fig. 1, Curve 1. Table I summarizes the results of three independent experiments performed at different times with two different samples of each of the salts. The agreement between the results of the three experiments can be seen on the curves. The decrease in the value of k' is evident. These values of k' were calculated by means of the integrated form of Equation 2, which for this case becomes

$$k' = \frac{1}{2at}\,\frac{x}{a - x} \tag{11}$$

Since k' is only the average value for the reaction between the beginning of the reaction and the time stated, and since several of the velocity equations which will be used cannot be integrated, it will be more convenient for purposes of comparison to use values taken from the single curve representative of all the experimental values. These values are given in Table II. The slope of the curve at each of the various times

[a] Using interpolated values for the equilibrium constant K.

was determined by finding the difference in the values of x at two times at equal time intervals above and below the desired time and dividing this difference by the total time interval. The velocity constant k in Col. 4 is calculated from the differential Equation 2. Since these values are obtained from the slopes of the curve at the individual points, they represent more nearly than the values of k' in Table I, the actual behavior of the velocity curve at the various times. The decrease in k is therefore very much more marked than that of k'.

The constant obtained in a comparable experiment by Price,[11] agrees very well with our value when the results are recalculated to a common basis and the effect of the slight difference in the ionic strengths of the solutions is taken into account.

Column 5 of Table II contains the concentrations of tri-iodide ion as calculated by Equation 9, using interpolated values for the equilibrium at the different concentrations of $KI + KI_3$. When this is taken into consideration by means of Equation 10, the resulting k increases approximately 40% during the first two-thirds of the reaction. Col. 8 contains values for the velocity constant calculated in the same way but setting[L2] $K = 0.0061$, the value used by Kiss and his co-workers. This particular value was determined for a special purpose in which a knowledge was desired of the tri-iodide equilibrium in a solution containing 1.65 molar potassium chloride and 0.1 molar hydrochloric acid besides iodine and potassium iodide. It has no significance in solutions such as used in the experiments under discussion[13] and by Kiss. Therefore, unless we are willing to assume that the values of the equilibrium constant as determined by Bray and MacKay are only about one-quarter of the true values,[14] we must conclude that (1) the constancy of k in Col. 8 is fortuitous,[15] and (2) the correction of the iodide-ion concentration by subtracting the concentration of the tri-iodide is not adequate to account for the experimentally determined velocities. The assumption made by Kiss and his co-workers on the basis of the constancy of k that the tri-iodide ion does not react with persulfate ion is unjustified.

---

[11] Cf. Price, Ref. **3,** p. **478,** Table 6.

[12] Brönsted and Pedersen, *Z. physik.* Chem., **103, 307 (1922).**

[13] In the present article no account has been taken of the possible effect of the $K_2S_2O_8$ and K_2SO_4 on the equilibrium constants because these substances, at the concentrations involved, have practically no influence on the solubility of iodine.

[14] This is entirely out of the question since their values are in good agreement with those of earlier workers such as Jakowkin and Maitland (for references and summary see Bray and MacKay, ref. 6, p. **915)** and those of the very recent work of Jones and Kaplan, ref. **7.**

[15] Kiss, Zombory and Bruckner found this constancy using $K = 0.0061$, presumably by applying the equations quoted above given in their articles. The fact that the present writers also obtain constant values for k by applying the correct equations makes the articles by Kiss and his co-workers only more difficult to understand.

The value of $-dC_{S_2O_8^{--}}/dt$ for t = 0 in Table II is, obviously, extrapolated. The value of k found from this is in good agreement with values obtained by several other less exact methods. Extrapolation of the values of k' from Table I gave a value somewhere between 0.124 and 0.126. Similar procedures using values of x from the curve and applying Equation 11 gave 0.1251 and again from the plot of k (Table II) 0.1260. From another method, to be described in the next section, also depending upon extrapolations, 0.1285 was obtained. Since the value of k at t = 0 represents the velocity constant of the reaction when complicating factors such as the tri-iodide equilibrium are negligibly small, it will be important in several parts of the article. For its value we shall choose k = 0.125.

D. Theory and Results of Experiments with Solutions Containing Iodine at the Beginning of the Reaction

All of the experiments by other investigators, as well as those reported above, indicate that the most troublesome factor in studying the reaction between $S_2O_8^{--}$ and I^- ion is the formation of I_3^- ion. The present writers believed that one way of clearing up the situation would be to make it worse. Accordingly, several experiments were performed in which various amounts of iodine had been added to the initial reaction mixture, in some cases the solutions being saturated with this substance throughout the reaction. The results for solutions saturated with iodine are given in Table III (experimental values) and Table IV (from a smoothed curve). The results for the unsaturated solutions are included in Table V, which will be discussed in detail later. Experiments 19 and 20 cited in Table III were performed several weeks apart, using different samples of all three substances. Several conclusions follow from these results: (1) the presence of the iodine has decreased the velocity of the reaction; (2) the reaction velocity constant shows a lower value than in Tables I and II but no drift in value regardless of the method of computation; (3) while in saturated solution of iodine in a given concentration of potassium iodide (over this range of concentrations) the actual concentration of iodide ion is only about one-half the amount if iodine were absent, the reaction proceeds at approximately 75% of the initial rate of the reaction without iodine present. The ratio of the two velocity constants and thus of the initial rates of reaction is 0.0958/0.1250 = 0.76; (4)

[a] Interpolated values of K' were used in obtaining these values.

if we are not to assume that tri-iodide ion or iodine "catalyzes" the reaction, then the tri-iodide ion must react with persulfate ion.

Before considering the last of these conclusions, it will be pertinent to discuss the reason for the constancy of the values in Cols. 5 and 7 of Table IV. The results of Bray and MacKay (see above) indicate that if the activity of the iodine in a potassium iodide solution is maintained at a constant value by saturating the solution with iodine, the ratio of iodide-ion concentration to tri-iodide-ion concentration remains practically constant over the range of potassium iodide concentrations involved.[16] In solutions in which the iodine activity is changing this is no longer true. Therefore whether iodide ion alone, tri-iodide ion alone, or both ions simultaneously react with persulfate ion, maintaining a constant iodine activity will immediately simplify the entire problem by making, practically, a single factor, that is, the total concentration of iodide plus tri-iodide ions in the solution, responsible for the actual concentration of each one.[17] If we may take the average ratio of the concentrations of these two ions in saturated iodine solutions, setting $C_{I^-}/C_{I_3^-} = K^r = 1.07$ for the range involved in Table IV, it can then be shown algebraically that, since

$$C_{I^-} + C_{I_3^-} = 2(a - x) \qquad (12)$$

Equation 10 may be transformed into

$$-\frac{dC_{S_2O_8^{--}}}{dt} = \frac{K'}{K' + 1} k_1 2(a - x)^2 \qquad (13)$$

By direct comparison of Equations 2 and **13** and inserting the values of K^r and k_1, we get

$$k = \frac{K'}{K' + 1} k_1 = \frac{1.07}{2.07} \times 0.1853 = 0.0958$$

These relationships thus explain the constancy observed among the values in Cols. 5 and 7 of Table IV, for it is evident that taking the tri-iodide concentration into consideration merely modifies Equation 2 by a constant factor when the solution is saturated with iodine throughout the reaction.

Table V summarizes the results of several experiments in which the initial concentrations of iodine were varied.[18] The values of x for each value of t were plotted against the total iodine concentrations ($I_2 + I_3^-$) at the same time and the curve extrapolated to zero iodine concentration

---

[16] See footnote 10.

[17] In investigations of the HIO_3–HI reaction Abel and Stadler, *Z. physik. Chem.*, **122**, 49 (1926), found that saturating the solution with iodine simplified the problem.

[18] Only interpolated values are included in Table V. The experimental values on which Col. **3** is based were somewhat erratic, hence the values in this column were given less weight than those in other columns in the subsequent calculations. The values of k^t (Equation 11) calculated from the results in Cols. **3** and 4 decrease as the time increases but not quite as much as those given in Table I.

(Col. 6). The iodine concentrations for Col. 2 were obtained from the total iodide concentration $(2a - 2x)$ and the solubility table given by Bray and MacKay. The extrapolated values, while not very accurate (see Curve 4, Fig. 1) and becoming more uncertain for the higher values of t, give a constant which is in reasonably good agreement with those found by other methods. The reaction velocity curve obtained in this way is, of course, the result of a purely empirical process which gives merely the curve which would have been obtained from all the experiments cited above, including those in Table I, if the presence of iodine did not interfere with the reaction. By itself this method gives no indication as to the mechanism of the interference. The results in Table V directly contradict the statements made by Kiss and Zombory.[19]

					Av.	.1285

Returning to the initial slope of the reaction between iodide and persulfate ions in solutions containing no iodine at the start, it can readily be seen that in a solution of the same ionic strength and concentration of persulfate ion, but with the molar iodide-ion concentration equal to instead of twice that of the persulfate ion, the initial slope of the curve would have been half the limiting value given in Table II, that is, 3.13×10^{-6}. An experiment with a mixture of 0.005 molar $K_2S_2O_8$, 0.005 molar KI and 0.005 molar KNO_3 gave 3.27×10^{-6} as an extrapolated value of $-dC_{S_2O_8^{--}}/dt$ at $t = 0$. This agreement is within the errors of experiment and extrapolation. The results of this experiment are plotted on Fig. 1 but not tabulated, since the work of Price is sufficient to establish the proportionality between the velocity and the concentrations of the reactants.

While the possibility that the tri-iodide ion may act as a catalyst for the iodide–persulfate ion reaction cannot be excluded entirely, the probability of such an effect seems to be very low, especially in view of the

---

[19] Ref. 4 *c*, pp. 227 and 229.

very satisfactory agreement to be shown below between experimental results and results of calculations based on the hypothesis that the tri-iodide ion itself reacts with the persulfate ion. The possibility that iodine may act as a catalyst must be rejected, however, on the grounds of the agreement just mentioned and because the behavior of the free iodine concentration could not possibly account for the observed results. In order to satisfy the latter, the free iodine concentration must vary in the same way as the tri-iodide ion concentration, that is, the ratio of tri-iodide-ion concentration to free iodine concentration should be constant. In saturated iodine solutions the concentration of free iodine is constant while that of the tri-iodide ion decreases continuously, but in the unsaturated solutions the tri-iodide concentration passes through a maximum during the course of the reaction.

On the other hand, if both iodide and tri-iodide ions react with persulfate ion and if the mechanism of the reaction between tri-iodide ion and persulfate ion is similar to that represented by Equations 3 and 4, the equation for the reaction velocity becomes

$$-\frac{dC_{S_2O_8^{--}}}{dt} = k_{I^-}C_{I^-}C_{S_2O_8^{--}} + k_{I_3^-}C_{I_3^-}C_{S_2O_8^{--}} \qquad (14)$$

For saturated iodine solutions the average velocity constant from Tables III and IV may be taken as 0.0958. The initial value for the unsaturated solutions from Table II is 0.125 which is the value of k_{I^-}. Again assuming that over the range of concentrations involved we may call the ratio $C_{I^-}/C_{I_3^-} = K'$ sensibly constant and equal to 1.07 in saturated iodine solutions, by combining this relation with Equation 8, we obtain from Equation 14

$$-\frac{dC_{S_2O_8^{--}}}{dt} = 2\left(\frac{K'k_{I^-} + k_{I_3^-}}{K' + 1}\right)(a - x)^2 \qquad (15)$$

By direct comparison with Equation 2, there results

$$k = 0.0958 = \frac{1.07 \times 0.125 + k_{I_3^-}}{1.07 + 1}$$

from which $k_{I_3^-} = 0.0645$.

For the reactions in which the solutions were not saturated with iodine, Equation 14 becomes

$$-\frac{dC_{S_2O_8^{--}}}{dt} = 2k_{I^-}(a - x)^2$$
$$-(k_{I^-} - k_{I_3^-})(a - x)\left[\frac{K + 2a - x}{2} - \sqrt{\left(\frac{K + 2a - x}{2}\right)^2 - 2x(a - x)}\right] \qquad (16)$$

The first term on the right is the simple expression for the case where no iodine is present at any point during the reaction; the second represents the effect of the tri-iodide ion. The term in square brackets is the concentration of tri-iodide ion, and for the experiments reported in Tables I and II it is identical with the values in Col. 5 of Table II.

TABLE VI

COMPARISON OR THE FINAL CALCULATED VELOCITY WITH THE OBSERVED VELOCITY

$C_{KI} = 2a = 0.01\ M$; $C_{K_2S_2O_8} = a = 0.005\ M$; $C_{I_2} = 0$ initially

Time, min.	$2k_{I^-}(a-x)^2$ × 10^6	2nd term in Eq 16 × 10^6	$-\frac{dC_{S_2O_8^{--}}}{dl}$ Calcd × 10^6	Obs. × 10^6
60	5.42	−0 OH4	5 34	5 35
100	4.96	− 127	4 83	4 82
200	4.06	− .199	3 86	3.77
400	2.92	− .261	2 66	2 57
800	1.75	− .270	1 48	1 46
1200	1.184	− .238	0 946	0 945
1400	1.006	− ,220	0 786	0 795

$k_{I^-} = 0.1250$; $k_{I_3^-} = 0.0645$. $K' = 1.07$

Values of the slopes of the velocity curve calculated by Equation 16 are given in Table VI, Col. 4 and for comparison the observed values are included in Col. 5. Col. 2 shows the slopes which would be observed if tri-iodide ions were not formed during the reaction. These calculations demonstrate conclusively that the observed reaction velocity is the sum of the velocities of two reactions, the first involving the iodide ions and the second the tri-iodide ions, and, furthermore, that the tri-iodide ion reacts at approximately one-half the rate of the iodide ion. The conclusion drawn by Kiss and Bossányi[4d] that the reaction between tri-iodide and persulfate ions is not appreciable at this temperature is unjustified.

Summary

The velocity of the reaction between iodide and persulfate ions is reinvestigated from the standpoint of the effect of tri-iodide ion formation. It is shown that earlier work on this reaction is insufficient and in some cases marred by too serious errors to be used for such a study.

Experiments have been made in solutions containing no iodine in the initial mixture and in solutions saturated with this substance. It is shown that by maintaining a constant iodine activity, it is possible to simplify the theoretical treatment and interpretation of the experimental data so that the observed reaction velocity may be analyzed into two parts, one being due to the iodide ion and the other to the tri-iodide ion.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY. WASHINGTON SQUARE COLLEGE, NEW YORK UNIVERSITY]

THE OXIDATION OF IODIDE ION BY PERSULFATE ION. II. THE EFFECT OF REMOVING THE PRODUCTS OF THE REACTION ON THE REACTION VELOCITY[1]

BY CECIL V. KING AND ERIC JETTE

RECEIVED SEPTEMBER 15, 1928 PUBLISHED APRIL 6, 1929

A. Introduction

The investigations reported in the first article of this series[2] showed that due to the formation and slower reaction of tri-iodide ion the reaction observed when solutions of potassium persulfate and potassium iodide are mixed is the sum of two concurrent slow reactions. It was also found that by means of an empirical procedure a velocity curve could be obtained in which the effects of the iodine and tri-iodide ion were eliminated. Further evidence of the correctness of these results was sought from experiments in which the iodine was more or less completely removed from the reaction by means of organic solvents and of a very rapid reaction. The earlier conclusions were also checked by repeating the experiments reported in the first article in solutions of considerably higher ionic strength. Experiments were likewise performed to show whether the removal of the other product of the reaction, the sulfate ion, had any effect on the reaction velocity. These experiments involved the determination of the salt effect due to the presence of several neutral salts.

B. Materials and Methods

The preparation of salts and solutions has already been described in the previous article. In some cases to be mentioned, however, it was necessary to use analyzed stock solutions for preparing solutions of the desired final concentration.

The organic solvents chloroform, carbon tetrachloride and carbon disulfide were redistilled, rejecting the first and last portions. The original materials were of "C. P." grade. The paraffin hydrocarbon was carefully treated to remove unsaturated compounds by shaking with concentrated sulfuric acid, boiling several times with alkaline permanganate solution and finally distilling; the portion boiling between 96 and 102" was collected for use

The sealed bulb method already described was used in all experiments excepting those where sodium hydroxide was present. Bulbs of 200-cc. capacity were used in the experiments with the solvent, each bulb containing 50 cc. of the reacting mixture (measured from a standard pipet) and 50 cc. of the solvent. Before sealing off, the bulbs were filled with nitrogen. The bulbs were placed in a device which turned them end over end in the thermostat at the rate of 10–15 turns per minute. Equilibrium between the iodine in the aqueous and solvent layers was thus established very quickly.

For the experiments involving sodium hydroxide, the reaction mixture was placed in a glass-stoppered bottle and a 50-cc. sample withdrawn from time to time. Five cc.

---

[1] Presented at the Swampscott Meeting of the American Chemical Society, September 12, 1928.

[2] Jette and King, THIS JOURNAL, 51, 1034 (1920).

of 1 molar sulfuric acid and 2 cc. of 1 molar potassium iodide was added and the iodine liberated by the iodate present titrated immediately with 0.01 molar sodium thiosulfate, using freshly prepared starch solution as indicator. Blanks were run on the reagents used. The temperature of the thermostat in which the reaction vessels were placed was 25.00 ± 0.01°.

C. Experiments with Organic Solvents Present

The results of attempts to find the influence of removing practically all of the iodine as fast as it was formed by means of organic solvents are summarized in Table 1. The symbols and concentration units are identical with those in the previous article. The value of k' is calculated from the integrated bimolecular equation

$$k' = \frac{1}{2at}\,\frac{x}{(a - x)} \tag{1}$$

The initial concentration of potassium persulfate is a moles per liter, of potassium iodide $2a$ moles per liter and x is the moles of persulfate ion consumed or iodine produced during the reaction. Several observations may be noted. (1) In all four cases the velocity curves (not plotted in Fig. 1) are above that in which no solvent was present. (2) For the first three solvents in the table the values of k' within each column are practically constant.[3] The average values of k' for the chloroform case is slightly above and for the paraffin hydrocarbon case slightly below the value 0.125 which was chosen in the previous article as the velocity constant for the iodide-ion reaction.

No satisfactory explanation has been obtained for the higher values of k' in the carbon disulfide and carbon tetrachloride experiments nor for the continuously decreasing values of Col. 8. The high values may be due to the specific effects of these substances in spite of their minute concentration in the aqueous layer. It is to be emphasized, however, that no far-reaching conclusions are to be drawn from the individual

---

[3] In their study of the HIO_3–HI reaction, Abel and Stadler, *Z. physik* Chem., 122, 49 (1926), found good pentamolecular velocity constants when the iodine was removed continuously by shaking with benzene.

numerical values in Table I due to an experimental difficulty involved to a greater or less, but unfortunately unknown, degree in each of the individual measurements. While the reaction bulbs were filled with nitrogen before sealing, so that no actual combustion of the vapors was observed, the local high temperatures to which the vapors of these organic substances were momentarily exposed always caused some decomposition and possibly some interaction with water vapor. Although the amount of these decomposition and interaction products was probably quite small, their nature is unknown. In some cases they may remove iodine from the solution, while in others they may liberate it from the iodide ions present or accelerate the reaction by the production of acids. In view of these conditions, the authors have limited the conclusions to be drawn from these experiments to the following statement. When the iodine formed by the reaction between persulfate and iodide ions is removed practically completely from the aqueous layer by means of an organic solvent for iodine, the values of k' obtained are generally more constant than when iodine is allowed to accumulate in the aqueous solution and in some cases the value of k' approaches closely the value of the true constant for the iodide–persulfate ion reaction.

D. The Reaction Velocity in the Presence of Sodium Hydroxide

In another series of experiments the iodine was removed from the system by means of sodium hydroxide. This method depends upon the fact that in the presence of a sufficiently high concentration of hydroxyl ions, iodine undergoes an internal oxidation-reduction according to the following equation

$$3I_2 + 6OH^- \rightleftharpoons 5I^- + IO_3^- + 3H_2O \qquad (a)$$

In combination with the iodide–persulfate ion reaction

$$S_2O_8^{--} + 2I^- \longrightarrow 2SO_4^{--} + I_2 \qquad (b)$$

the final result is the oxidation of iodide ion to iodate ion, the gross equation for which is

$$3S_2O_8^{--} + I^- + 6OH^- \longrightarrow 6SO_4^{--} + IO_3^- + 3H_2O \qquad (c)$$

In using these reactions the main assumption introduced was that the velocity determining reaction which, according to Bronsted, is

$$S_2O_8^{--} + I^- \longrightarrow (S_2O_8I)^{---} \qquad (d)$$

remains the same as in the absence of sodium hydroxide. As a corollary, it follows that regardless of its own mechanism, Reaction (a) must be assumed to proceed at a much faster rate than (d). It is also necessary definitely to assume that the final oxidation product of the iodide ion is the iodate ion. This last assumption has a very important effect on the equations for the reaction velocity, and the constancy of the velocity constant is a check on its validity. An unequivocal proof that (d) represents the velocity determining reaction is not possible, at any rate not from the present experiments. However, a close agreement in the values of the velocity constants obtained from two comparable experiments, in one of which sodium hydroxide was present while in the other it was not, would argue in favor of this view.

Two different velocity equations were used depending on the ratio of persulfate to iodide ions. If we let the initial molar concentration of potassium persulfate be a and that of potassium iodide be 2b then according to Reaction (c) above, when x moles per liter of persulfate ion has been reduced, $x/3$ moles per liter of iodide ion also has disappeared. We then get for the momentary concentrations of persulfate and iodide ions

$$C_{S_2O_8^{--}} = a - x \text{ and } C_{I^-} = 2b - \frac{x}{3}$$

From these and the velocity equation there is obtained

$$-\frac{dC_{S_2O_8^{--}}}{dt} = kC_{S_2O_8^{--}}\, C_{I^-} = \frac{1}{3}\, k(a - x)\,(6b - x)$$

which upon integration and transformation to ordinary logarithms gives

$$k = \frac{6.909}{(6b - a)t} \log_{10} \frac{a(6b - x)}{6b(a - x)} \qquad (2)$$

Results of two experiments using this equation[4] are given in Tables II and III. The results in the latter are comparable with those in Table VII, since the ionic strength is the same in both The difference in the specific effects of nitrate and hydroxyl ions and to a lesser extent of potassium and sodium ions is evident from these two tables as well as the corresponding curves.

[4] In these experiments the ratio of persulfate-ion concentration to iodide-ion concentration was not as simple as in the other experiments due to a slight error in making up one of the solutions. The simplification of Equation 2 for the case where the iodide concentration is $2a$ will be obvious.

Tables IV and V contain the results of experiments in which the initial molar concentration of potassium iodide was one-third of that of the potassium persulfate. The velocity equation for this case is somewhat simpler, namely

$$k = \frac{3}{at} \times \frac{x}{(a - x)} \tag{3}$$

The ionic strength of the solution used for the experiments in Table V is the same as for the experiments reported in Table I of the present article and Tables I and II of the previous article. The difference between the average value of k in Table V and the limiting value for the iodide–persulfate ion reaction obtained in the first article may be ascribed to specific effects of the sodium and hydroxyl ions, chiefly the latter, on the reaction velocity. The constancy of k in all four experiments given in Tables II, III, IV and V, and the agreement between the values of the constants in Table V with that of the limiting value (0.125) recorded in the previous article, are sufficient to justify the assumptions made regarding the velocity-determining reaction and the final oxidation product of the iodide ion.

E. The Effect of Removing the Sulfate Ion

Reaction (b) is, for all practical purposes, an irreversible reaction and therefore the presence of the final products of the reaction in actually attainable concentrations should have no measurable effect on completeness of the reaction. It was considered as a possibility, however, that the removal of the reaction products might increase the velocity. The removal of the iodine already discussed would obviously not serve as a test of this possibility.

The removal of sulfate ion is most easily accomplished by precipitation as barium sulfate. The addition of soluble barium salts increases the initial ionic strength, while the precipitation of the insoluble barium sulfate involves the continuous decrease of this factor. In order to reduce the complications involved in a large percentage change in ionic strength, the new series of experiments was performed keeping the iodide and persulfate concentrations the same as before but making the solutions also 0.10 molar with respect to potassium nitrate. The results of experiments containing potassium iodide, potassium persulfate and potassium nitrate are given in Table VII and will be discussed later. An additional complicating factor is present in that barium ions may have a specific effect on the reaction velocity quite apart from the influence due to the precipitation of barium sulfate. Therefore, the reaction velocities were also measured in the presence of magnesium and calcium salts. Since calcium sulfate is relatively insoluble, two series of experiments were made with solutions initially saturated with this salt, in one of them calcium nitrate also being present.

TABLE VI

EFFECT OF NEUTRAL SALTS ON THE REACTION VELOCITY

$K_2S_2O_8$ = 0.005, KI = 0.01 and KNO_3 = 0.10 molar in all experiments

Results of all of these experiments are summarized in Table VI. It will be seen that barium nitrate has a definitely greater effect on the reaction velocity than the corresponding magnesium and calcium salts at the same concentration.[5] Whether the higher velocities thus ob-

---

[5] The titration values at various times for the 0.01 molar solutions of calcium nitrate and magnesium nitrate fell within experimental error on the *same* curve and

served are to be interpreted as due to the removal of the sulfate ion or to the specific effect of barium ions cannot be decided by means of such experiments but the velocities observed seem to be somewhat too great for the latter explanation alone to suffice. It may be observed that when the values of k' are plotted against *t* the resulting curves for the solutions containing barium ions drop more rapidly than those of the solutions containing magnesium and calcium. The curve for the solution saturated with calcium sulfate and containing 0.01 molar calcium nitrate shows the same behavior, being very nearly parallel to the 0.01 molar barium nitrate curve, although the curve for the saturated calcium sulfate alone decreases less rapidly and cuts across the latter. A very probable explanation of these differences may be found in the fact that in these solutions the ionic strength is decreasing appreciably while in the solutions in which no precipitation takes place there is a slight increase.

F. The Influence of Tri-iodide Ion Formation in Solutions of Higher Ionic Strength

Finally, the conclusions drawn in the first article of the series were checked by experiments in which the reaction velocities were made considerably higher than previously by using solutions containing 0.10 molar potassium nitrate. The experimental methods were the same as those of the earlier article. The results are given in Tables VII and VIII and Curves 1 and 6 on Fig. 1.

1480	.003727	.198
	Av.	.199

In order to apply the equations already derived to the experiments, it was necessary to know the equilibrium constant for the reaction $I_2 + I^- \rightleftarrows I_3^-$ in solutions containing 0.10 molar potassium nitrate. The constant was obtained from measurements of the solubilities of iodine in

those for 0.01 molar potassium sulfate very slightly below this curve. Plots of k' against x gave the same results but the potassium sulfate results were somewhat more definitely lower than the others.

solutions containing 0.10 molar potassium nitrate besides potassium iodide at several different concentrations. The concentrations of the individual substances were calculated by the aid of the assumption that the solubility of free iodine in solutions containing potassium iodide is the same as in the pure "solvent," which in this case is 0.10 molar potassium nitrate. The solutions were saturated in sealed pyrex bulbs, the mixtures being rotated in the thermostat at 25.00 ± 0.01" for three days. The materials and technique were in other respects the same as in determining the initial concentrations of iodine in the velocity experiments already described. The results are given in Table IX, which is self-explanatory. It is noteworthy that potassium nitrate at this concentration has but little effect on the solubility of iodine and the equilibrium constant.

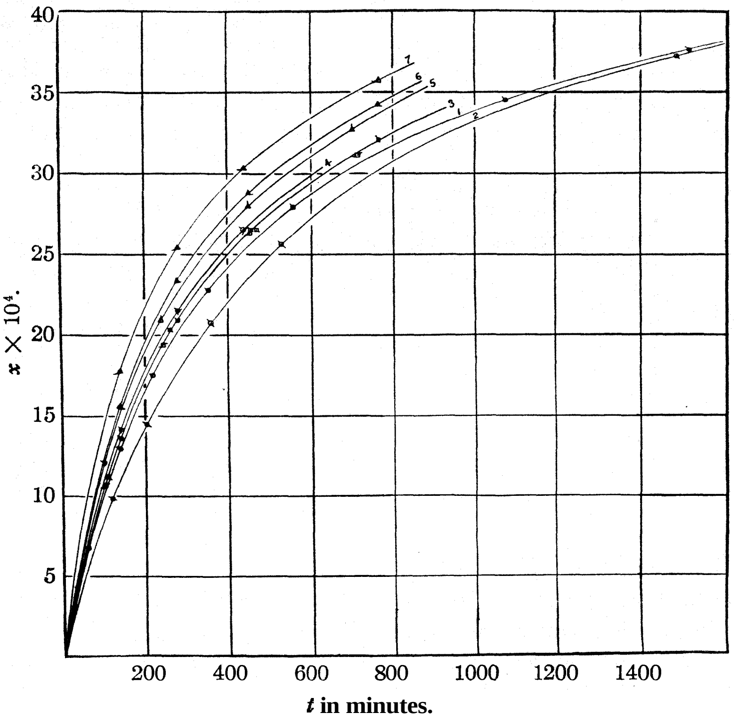

Fig. 1.—$K_2S_2O_8$, 0.005; KI, 0.01; KNO_3, 0.10. Curves: 1, salts alone; 2, with saturated iodine; 3, with 0.01 M magnesium nitrate, with 0.01 M calcium nitrate and with 0.01 M potassium sulfate; 4, with 0.01 M barium nitrate; 5, with 0.05 M magnesium nitrate; 6, with 0.05 M calcium nitrate; 7, with 0.05 M barium nitrate.

The value of k_{I^-} at $t = 0$ was determined by extrapolating the curves obtained by plotting k against t. The values of k **were** obtained from

TABLE IX

EQUILIBRIUM CONSTANT FOR $I_2 + I^- \rightleftharpoons I_3^-$

Moles KI per liter	Total I_2 = Ia + I_3^-	C_{I_2}	$C_{I_3^-}$	C_{I^-}	$K' = \frac{C_{I^-}}{C_{I_3^-}}$	$K = K'C_{I_2}$

				Av.	1.059	.001350

Table VII and also from the values observed (see Table X) from the smoothed curve. The extrapolation in the first case gave $k_{I^-} = 0.262$; in the second case, 0.269. The value $k_{I^-} = 0.265$ was chosen for subsequent use. The accuracy of the extrapolated values is somewhat less than in the case when no potassium nitrate was present due to the more rapid change in k with time. Accurate extrapolation of $dC_{S_2O_8^{--}}/dt$ was impossible. The value for $k_{I_3^-}$ is 0.169. The calculated results given in Table X were made with the same equations and with the same assumptions as those in Table VI of the first paper. The calculated slopes are all slightly higher than the observed values but the difference is easily within the error of determining k_{I^-}. The conclusion that the iodide and tri-iodide ions each react with the persulfate ions at characteristic rates is therefore confirmed.

Summary

Further investigations were made on the reaction between iodide and persulfate ions. In the first article of the series it was found possible, by means of an empirical procedure, to obtain the velocity curve for the reaction if iodine or tri-iodide ion did not interfere with the reaction. These results have been confirmed by experiments in which the iodine was removed continuously from the reaction mixture by shaking with organic solvents and by reaction with sodium hydroxide. The effect of certain neutral salts on the reaction velocity was also determined.

It was found that removal of the sulfate ion as barium sulfate or calcium sulfate probably does not increase the velocity, although the effect of adding barium ion to the reacting mixture seems to be somewhat greater than it should if it is to be explained merely as a specific salt effect. Finally, the main conclusion of the first article, that is, that the observed reaction velocity is the sum of the velocities of the iodide and of the triiodide ions reacting with persulfate ion, was confirmed by measurements at considerably greater velocities.

STUDIES ON SILICODUODECITUNGSTIC ACID.

I. THE PREPARATION OF SILICOTUNGSTIC ACID[1]

BY ARTHUR G. SCROGGIE[2]

RECEIVED SEPTEMBER 29, 1928 PUBLISHED APRIL 5, 1929

Silicotungstic acid originally prepared and described by Marignac[3] in 1863, has lately become an important analytical reagent on account of its ability to precipitate alkaloids. The present official method for the determination of nicotine is based on this property.

Drechsel[4] improved the original method of separating the acid by isolating it in the form of a complex which it formed with ether in the presence of a mineral acid. This procedure was only slightly modified by North and Beal,[5] who in 1925 extended the usefulness of this reagent by producing it in the form of a dry powder, stable in air and readily handled without decomposition. They also introduced a volumetric method, in which silicotungstic acid was used for the quantitative determination of alkaloids without previous isolation and purification. More recently Salzberg[6] has questioned the purity of the acid when prepared according to North's directions, and also North's assumptions with regard to the end-products obtained following decomposition of the acid by means of excess of alkali.

Because of the lack of agreement in the literature and the unsatisfactory status of the knowledge concerning silicotungstic acid, the researches of the present writer were undertaken with the following objectives: (a)

---

[1] Throughout this paper the term silicotungstic acid will be understood to refer to silicoduodecitungstic acid.

[2] This communication is an abstract of a portion of a thesis submitted by Arthur G. Scroggie in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[6] Salzberg, Master's "Thesis," University of Illinois, 1925; unpublished report, University of Illinois, 1925.

to investigate the possibility of forming the complex with new reagents and to determine the optimum concentrations for a maximum yield of acid, (b) to follow up the work of Salzberg and investigate quantitatively the methods of purification and dehydration of the acid, (c) to examine the methods of analysis of the acid and (d) to identify the end-products obtained by decomposing the acid with an excess of alkali.

1. Complex Formation.—Originally Drechsel had used ether and sulfuric acid to isolate the silicotungstic acid, but North had substituted hydrochloric acid for sulfuric, since an excess could be removed by heating. Rosenheim[7] has suggested that the compound concerned is of the oxonium salt type, but no records were found in the literature of investigations to establish this point or to find substitutes for the ether and acids previously used.

The method of extraction by a complex consists in adding ether to an aqueous solution of silicotungstic acid which contains a large excess of free mineral acid and then agitating the mixture. The complex sinks to the bottom as a heavy oily liquid and the excess of solvent floats on the surface of the aqueous layer.

To be suitable for the formation of a complex then, a solvent must be immiscible with and lighter than water, as well as a solvent for silicotungstic acid. If the oxonium salt theory is correct the solvent must also contain an oxygen atom.

A large number of solvents were tried in a qualitative way and the following facts established. Of the solvents containing oxygen, a number of esters, ketones and aldehydes could be substituted for ether, but ethyl acetate was the only one that seemed to merit quantitative investigation; a number of other solvents, including the lower alcohols, ketones, etc., were miscible with water and could not be used; acetic acid in addition to miscibility with water did not dissolve silicotungstic acid. Of the solvents which do not contain oxygen none was found to be satisfactory since they did not dissolve silicotungstic acid. These included petroleum ether, benzene, toluene, chloroform, carbon tetrachloride and carbon disulfide.

These results are in agreement with the work of Baeyer and Villiger[8] on oxonium compounds and are a general confirmation of this theory of the nature of the complex, but it was not found possible to isolate the pure compound for analysis.

Experiments demonstrated that nitric acid could be substituted for the usual precipitating agents, hydrochloric acid or sulfuric acid, but owing to its effect on the specific gravity of the solution it was not as efficient an agent as the ones previously used. Acetic acid would not

---

[7] Rosenheim and Jaenicke, Z. anorg. *Chem.*, 100,319 (1917)

[8] Baeyer and Villiger, *Ber.*, ***34*,** **2679** (1901)

cause the separation of the complex and was distinguished by its ability to prevent this action by the stronger acids. Sodium chloride in a concentration of 20% was found to be quite effective, particularly with ethyl acetate. Lithium chloride, nitrate and sulfate were all effective, but sodium sulfate, perchlorate and the salts of other metals could not be used. Just why the Li^+ is so much better than the Na^+ is not understood.

The presence of salt in a solution lowered the amount of mineral acid necessary to cause the separation of the complex, and a yield of 85–90% based on the weight of tungstate taken could be obtained using salt and ethyl acetate without any mineral acid. This method in fact is the most efficient for the extraction of the original process mixture which already contains 10 to 15% of salt. The combination ether and sodium chloride is not satisfactory, however, since the yield is only 50–60% of the theoretical. For purification of the acid by re-extraction from a solution which does not contain salt, ether and hydrochloric acid is the most efficient combination, and a yield of 98% can be obtained by adding an amount of hydrochloric acid equal to one-third of the original volume of the solution.

2. Methods of Analysis of the Acid.—As a preliminary step toward establishing the purity of the acid when prepared according to North's directions, methods of analysis were carefully examined. North dried the acid in an oven at 70° and then analyzed it in two ways: (I) by igniting the acid in a muffle furnace at a dull red heat, considering the loss in weight as water and the residue as anhydride; (8) by titrating the acid with standard alkali, using methyl orange as an indicator, which gave an end-point after the addition of four equivalents of base.

In the present investigation, the best temperature for ignition of the acid was found to be between 400 and 500°, since a sample of anhydride heated above this temperature underwent a progressive loss in weight depending, for any one sample, on the time arid temperature of ignition. Method II was improved by using very dilute alkali solutions, which gave sharper end-points, and the use of chlorophenol red as an indicator (PH range 5.0 to 6.0) because silicotungstic acid had been shown to give precipitates with methyl orange and most compounds containing basic nitrogen.

Salzberg used a third method of analysis which consisted in precipitating the silicotungstic acid with an excess of cinchonine solution, filtering the precipitate and igniting it to obtain the anhydride as a residue. In the hands of the writer this method gave results which varied slightly with different conditions and were uniformly higher than the value for the anhydride given by the first method mentioned. This method was not considered as reliable as the previous ones.

3. Purification of the Acid.—North dried the acid at 70° and obtained the following values for the percentage of anhydride: 94.58% (Method I), and 94.94% (Method II). He concluded that the acid had retained 5 molecules of water of hydration and had the formula $4H_2O·SiO_2·12WO_3·5H_2O$ (anhydride, 94.64%).

In the present investigation three samples of acid were prepared: (A) according to North's directions, (B) by re-extracting the above acid with ether (Salzberg's directions) and (C) by reforming the complex with ether twice. All samples were dried at 70° and analyzed, with the following results.

PERCENTAGE OF ANHYDRIDE

Sample	Method I, %	Method II, %	Mean, %
A	95.62	83.50	89.56
B	95.30	95.34	95.32
C	95.21	95.41	95.31

These results indicated an impurity in Sample A, the crude product, which was confirmed by precipitation of samples of the acid with cinchonine, filtering the precipitate and taking the filtrate to dryness in the presence of perchloric acid. The residue from Sample A, after adjusting for a blank on the reagents, was 1.2% of the sample weight, while the analyses of Samples B and C showed that within the limits of experimental error the impurity had been completely removed. These results confirmed the work of Salzberg and showed that a pure acid could be obtained only by following purification by reformation of the complex by means of ether and mineral acid, and also showed that a second reformation was not necessary.

4. Dehydration of the Acid.—In drying in an oven at 70° the acid, after a large initial loss, underwent a very gradual loss in weight which extended over several days and varied with the humidity of the atmosphere. Salzberg reported finding more moisture in a series of samples dried at 100° than he obtained from a series of samples dried at 70°. To solve these difficulties drying agents were tried as substitutes for the oven method and found to be far superior. Anhydrone or dehydrite under reduced pressure would dry small samples of the acid to constant weight in less than twenty-four hours. Hempel type desiccators were used and were evacuated by means of a Hyvac pump to a pressure of approximately 7 mm. Analysis of the acid as dried with different reagents gave the following percentages of anhydride as determined by ignition.

Drying agent	Dehydrite	H_2SO_4	$CaCl_2$	KOH *or* NaOH
Anhydride, %	95.40	95.50	95.31	95.25

All of these results correspond to an acid with somewhat less than the four molecules of water of crystallization expressed in the formula $4H_2O·SiO_2·12WO_3·4H_2O$, and would indicate that the last four molecules of water of hydration are retained quite persistently.

5. Decomposition of the Acid by Means of Excess of Alkali.—North assumed that the acid would be decomposed by a reversal of the process of preparation, which would require 26 equivalents of base per molecule of acid, according to the following

$$4H_2O{\cdot}SiO_2{\cdot}12WO_3 + 26NaOH \longrightarrow Na_2SiO_3 + 12Na_2WO_4 + 17H_2O$$

He carried out the determination by adding an excess of alkali, boiling the solution and back-titrating the excess with a standard acid, using phenolphthalein as indicator. His experimental values were 26 and 25.5 equivalents.

Salzberg, repeating the work with a purer acid, got values ranging from 23.5 to 24.5 equivalents and concluded that the theoretical value was 24 equivalents, which he explained by assuming that the silicic acid formed in the decomposition was not neutralized under the conditions of the experiment.

The writer by carrying out the decomposition in a system free from atmospheric carbon dioxide was able to get results that verified the latter theory. The experimental values obtained were 24.06 and 24.09 equivalents (assuming the acid to retain 4 molecules of water of hydration). The decomposition may therefore be represented by the following

$$4H_2O{\cdot}SiO_2{\cdot}12WO_3{\cdot}4H_2O + 24NaOH \longrightarrow H_2SiO_3 + 12Na_2WO_4 + 19H_2O$$

This decomposition is analogous to the decomposition of the yellow ammonium phosphate precipitate by alkali when the third hydrogen of phosphoric acid is not replaced by the alkaline metal. Assuming the theoretical ratio of 24 equivalents of base per molecule of acid, the reaction was used to analyze the acid, and it might be possible to work out *a* volumetric method for the analysis of the alkaloidal salts of silicotungstic acid as well, but this work was not undertaken.

6. **A** Modification of the Method of **Isolation** and Dehydration of **Silicotungstic** Acid.—As a result of these investigations, the writer would amend North's directions for the preparation of the acid as follows. Extract the original process mixture by adding an excess of ethyl acetate and 10–15% of common salt; dissolve the complex obtained in this operation in a liter of dilute hydrochloric acid (1 vol. of HCl to **3** vols. H_2O) and extract with an excess of ether which has been washed with 10% sodium hydroxide solution; take the complex to dryness on the water-bath, add water and take to dryness again; repeat this procedure till the residue no longer smells of volatile acid.

A very pure product can be obtained by recrystallizing this first yield from water; if the crystals are washed with an alcohol–chloroform mixture the loss by solution is not great. A current of air passed over the crystals for a few hours will dehydrate them sufficiently to permit of coarse powdering, after which they may be dried to constant weight by exposure to a good drying agent.

The acid produced in this way will absorb a small amount of moisture if exposed to the air.

The mother liquors, which are occasionally dark colored, may be readily clarified by heating with norite for a few minutes and filtering off the suspended matter.

The writer wishes to take this opportunity of thanking Dr. George D. Beal for suggesting this problem, and of expressing his regret that circumstances forced the latter's withdrawal from active participation in the work at such an early date.

Summary

1. The comparative value of different reagents for the formation of a complex with silicotungstic acid has been established and the probability that the compound formed is an oxonium salt has been indirectly confirmed.
2. Salzberg's conclusion with regard to the purity of the acid when prepared according to North's directions has been verified.
8. The truth of the assumption that the acid is decomposed by twenty-four molecules of base has been established experimentally.
4. The methods of analysis have been improved.
5. A new method of isolating the acid, depending on the formation of a complex with ethyl acetate, and a new method of dehydrating it have been proposed.

ZIRCONIUM. III. INFLUENCE OF LITHIUM, RUBIDIUM, CESIUM AND MAGNESIUM UPON THE DETECTION OF POTASSIUM BY ZIRCONIUM SULFATE[1]

BY RUFUS D. REED AND JAMES R. WITHROW

RECEIVED OCTOBER 20, 1928 PUBLISHED APRIL 5, 1929

We have shown the availability of zirconium sulfate as a reagent for potassium in the presence of sodium[2] and ammonium.[3] The less frequently occurring members of the fifth group, rubidium and cesium, both interfere with the detection of potassium by sodium cobaltic nitrite, perchloric acid or chloroplatinic acid. Lithium can be separated from ions of these elements by perchloric acid or chloroplatinic acid. Tread-

The authors are indebted to the Chemical Department of this University in that Professor Marion Hollingsworth of the Analytical Chemical Division of that Department furnished the rubidium and cesium chlorides used as the basis of part of this work.

[2] Reed and Withrow, THIS JOURNAL, 50, 1519 (1928).

[3] Reed and Withrow, *ibid.*, 50, 2985 (1928).

well-Hall states concerning sodium cobaltic nitrite and lithium,[4] "moderate amounts of alkaline earth elements or of lithium and sodium do not interfere." Concerning magnesium Prescott and Johnson[5] stated, "potassium and large amounts of sodium may be readily detected in the presence of magnesium." Yet because of interference with the detection of small amounts of sodium, magnesium is removed prior to testing for the fifth group, to determine whether these fifth group elements would interfere with the detection of potassium by zirconium sulfate. The sensitiveness of this reagent for potassium in the presence of lithium, rubidium, cesium and magnesium was therefore investigated.

The results indicated that in a 2-cc mixture, zirconium sulfate detected 1.0 mg. or more potassium in the presence of 50 mg. of lithium sulfate, 16.6 mg. of rubidium sulfate or 11.6 mg. of cesium sulfate. It also detected 0.5 mg. or more of potassiuin in the presence of 50 mg. of magnesium sulfate. With no possibly interfering ions present, the zirconium sulfate reagent detected 0.5 mg. or more potassium.

The literature indicated that while Rosenheim and Frank[6] had prepared, "by the use of rubidium and cesium sulfates, compounds analogous in external appearance and in composition" to potassium zirconyl sulfate, no one had ascertained whether the presence of lithium, rubidium, cesium or magnesium would interfere with the reaction between potassium sulfate and zirconium sulfate, though the reference indicated the probability that they would interfere.

Experimental

In order to determine the effect of lithium, rubidium, cesium and magnesium upon the detection of potassium by zirconium sulfate, the following solutions were prepared.

Potassium Sulfate Solution and Zirconium Sulfate Solution.—These solutions were prepared in exactly the same way as described in the work on effect of ammonium ion on detection of potassium by zirconium sulfate.[2] The zirconium sulfate solution analyzed for **0.0871** g. of zirconium sulfate and an excess of 0.0395 g. of sulfate ion, due to excess sulfuric acid, per cubic centimeter.

Lithium Sulfate, Rubidium Sulfate, Cesium Sulfate and Magnesium Sulfate Solutions.—These solutions were prepared by dissolving potassium-free anhydrous salts in water and diluting to known volume.

Procedure.—Solutions containing known amounts of potassiuin and of either lithium, rubidium, cesium or magnesium sulfate were prepared by mixing known volumes of the proper solutions. The procedure of the test was the same as given in the preceding work.[2] The results appear in the table.

Discussion

The results indicate that zirconium sulfate will detect 1.0 mg. or more potassium in the presence of 50 mg. of lithium sulfate (Expts. 1–4), 16.6 mg. of rubidium sulfate (Expts. 6–10) or of 11.6 mg. of cesium sulfate (Expts. 11–15). It did not detect 0.5 mg. of potassium in the presence of 11.6 mg. of cesium sulfate (Expt. 12). It detected 0.5 mg. or more potassium in the presence of 50 mg. of magnesium sulfate (Expts. 16–20). To detect 1 mg. of potassium in the presence of any members of the fifth group, a comparison with a blank run should be made concurrently. With lithium or magnesium present, comparison with a blank should be made in testing for 4.5 mg. or less potassium (Expts. 3 and 19).

Comparison of Reagents for Potassium.—In order to compare zirconium sulfate, sodium cobaltic nitrite, chloroplatinic acid and perchloric acid as reagents for the fifth group elements, a series of tests was made as tests are usually made in qualitative analysis—adding the reagent to the solutions to be tested. None of the four reagents gave a precipitate with 11% sodium acetate, 5.5% magnesium sulfate or 5.5% lithium sulfate. Sodium cobaltic nitrite solution gave a slight precipitate with a saturated lithium sulfate solution. Sodium cobaltic nitrite and chloroplatinic acid gave precipitates with 11% ammonium chloride, 1.92% rubidium sulfate and 1.16% cesium sulfate solutions as well as with 8.8% potassium sulfate solution. Perchloric acid gave a precipitate with the same solutions except the 1.16% cesium sulfate solution, but when a more concentrated cesium sulfate solution was prepared, it gave an immediate precipitate. *Zirconium sulfate gave a precipitate with the 8.8% potassium sulfate solution only.*

Reagents for the detection of potassium, other than zirconium sulfate, cannot be used in the presence of all members of the fifth group of metals. Sodium cobaltic nitrite, perchloric acid and chloroplatinic acid give a precipitate with rubidium and cesium as well as with potassium and ammonium. The perchloric acid method requires the use of absolute alcohol and the chloroplatinic acid requires the use of 80% alcohol to separate potassium from sodium and lithium.

Summary

Zirconium sulfate will detect 1.0 mg. or more of potassium in 2 *cc.* of reaction mixture in the presence of lithium, rubidium, cesium or magnesium ions, as well as those of sodium and ammonium. The detection of potassium by zirconium sulfate is accomplished without the use of alcohol or complicated procedure. It should always be used as the preliminary reagent, therefore, in looking for potassium, before going through the ordinary more complicated procedure.

A STUDY OF THE DETERMINATION OF CHLORIDE IN BROMIDES

BY R. K. MCALPINE

RECEIVED OCTOBER 24, 1928 PUBLISHED APRIL 5, 1929

In 1926 Berg[1] introduced an interesting modification of the usual procedure for determining chloride in the presence of bromide by using acetone in aqueous solution to absorb the bromine set free in a differential oxidation process that employed potassium bromate in dilute sulfuric acid solution. The following equation shows the reaction involved:

$$6CH_3COCH_3 + 2KBrO_3 + 4KBr + 3H_2SO_4 = 6CH_3COCH_2Br + 3K_2SO_4 + 6H_2O$$

The chloride was then titrated by a modification of the Volhard method. The experimental data in Berg's article showed that the procedure recommended worked within moderate limits and it was suggested that the nephelometer could be used to determine very small amounts of chloride.

---

[1] Berg, *Z. anal. Chem.*, **64**, 342 (1926).

The present work was undertaken to replace potassium bromate with potassium permanganate and to extend the usefulness of the procedure in determining small amounts of chloride in bromides. Potassium permanganate has several advantages as an oxidizing agent. It is inexpensive, readily obtained free from halide, highly colored so that excess is easy to recognize, and easily reduced by hydrogen peroxide so the excess is simple to destroy.

Two general errors are possible in such work; one, incomplete removal of the bromide, leading to high results; the other, loss of chloride, leading to low results. Correct figures might be obtained by reducing both errors to negligible magnitude or from compensation of the two.

In the present work the chloride was determined gravimetrically, since such a precipitate could then be examined for bromide. The silver chloride was collected on a Jena filtering crucible, the weight of which is not affected by more than one or two-tenths of a milligram by the ordinary processes of filtering and washing. At the balance the more accurate procedure was adopted of using a counterpoise and weighing by substitution. This method of weighing easily reduces the ordinary error of four or five-tenths of a milligram to one-tenth of a milligram.

There were available as materials for study several commercial bromides of sodium and potassium and two specimens of potassium bromide of a high degree of purity. One of the latter had been prepared in connection with earlier work in the Laboratory[2] from recrystallized potassium oxalate and purified bromine; the other was made from Kahlbaum's potassium bromate that had been further purified by several recrystallizations using centrifugal drainage of the crystals. The potassium bromate was converted to bromide by careful heating in an electric furnace. A standard chloride solution was prepared from very pure sodium chloride, the concentration being determined by precipitation as silver chloride.

The accessory reagents used included potassium permanganate, sulfuric acid, nitric acid, silver nitrate, manganous sulfate, acetone, ether and hydrogen peroxide. Commercially available preparations were selected that were found on test to be either free from halide or to contain so small an amount that the total error for all combined would not exceed a tenth of a milligram. In the case of hydrogen peroxide, Merck's "Perhydrol" was used, being diluted to one-tenth its concentration and stabilized with diluted sulfuric acid.

Analytical Procedures

The analytical studies carried out may be divided into three general groups: (I) the use of permanganate in moderate excess in slightly acid solution, (II) the use of permanganate in slight excess in strongly acid

---

[2] Willard and McAlpine, This Journal, 43, 797 (1921).

solution and (III) the development of a concentration method for working with larger samples.

(I) The use of permanganate in slightly acid solution. The procedure first tried was patterned after that developed by Berg, using a moderate excess of potassium permanganate in relatively low acidities and with a large excess of acetone to react with the bromine. The reactions were carried out in a half-liter, glass-stoppered Erlenmeyer flask so that the final solution after addition of the silver nitrate could be shaken vigorously to coagulate the precipitate. Five ml. each of nitric acid (1:1) and of ether were added to assist this process.

By separate experiments with potassium bromide and sodium chloride solutions (see Table I) conditions were worked out such that the bromine from 50 mg. of potassium bromide could be converted completely to bromo-acetone and that 100 mg. of chlorine as chloride would suffer only the negligible loss of three- or four-tenths of a milligram. A quantitative determination of chloride in such a synthetic mixture gave a result containing no measurable error.

TABLE I

DETERMINATIONS OF CHLORIDE USING A MODERATE EXCESS OF POTASSIUM PERMANGANATE IN SLIGHTLY ACID SOLUTION

H_2SO_4 added Vol., ml.	Concn., *N*	Acetone ml.	KBr, g.	Cl–, g.	Time before reduction, min.	Error calcd. as Cl–, g.

50	1.5	25	.050	.00	5	.0000
50	2.0	25	.050	.00	2	.0000
50	2.5	25	.050	.00	2	.0000
50	1.5	25	.00	.1001	2	– .0003
50	1.5	25	.00	.1001	5	– .0004
50	1.5	25	.00	.0100	2	– .0001
50	1.5	25	.00	.0501	2	– .0002
50	1.5	25	.00	.2503	2	– .0006
50	2.5	25	.00	.0100	5	– .0004
50	2.5	25	.00	.0501	5	– .0005
50	2.5	25	.00	.2503	5	– .0011
50	1.5	25	.050	.1001	5	.0000

The directions worked out for the last determination in Table I were as follows. Use 25 ml. of acetone and 50 ml. of 1.5 *N* sulfuric acid in a total volume of approximately 85 ml. Add dropwise a 5% solution of potassium permanganate until the characteristic color persists, then 15 to 20 drops in excess. Let the solution stand for five minutes, reduce with 2 ml. of the hydrogen peroxide solution, add 5 ml. of nitric acid (1:1) and 5 ml. of ether, precipitate with silver nitrate, filter, wash with 1% nitric acid, dry and weigh.

On increasing the sample of potassium bromide to one gram the results of this method were not satisfactory. Qualitatively the reaction started smoothly with immediate decolorization of the permanganate and production of a yellow color of bromine that disappeared as the reaction with acetone took place; hydrated manganese dioxide soon started to precipitate and from then on the decolorization proceeded more and more slowly. The time required for disappearance of color when five drops of the reagent were added lengthened to one, two and even five minutes. At the latter stage the oxidation of the bromide was still far from complete. By continued addition of permanganate the test for bromide became faint, but by that time half an hour or more had been consumed with this operation. Even then quantitative tests showed that with 1 g. of potassium bromide and 100 mg. of chloride, the final precipitate gave a distinct test for bromide and yet its weight corresponded to a loss of over one milligram of chloride.

Further studies in dilute acid solution were therefore abandoned and the work entered its second phase.

(II) The use of permanganate in strongly acid solution. Since the oxidation potential of permanganate ion increases distinctly with the acidity of the solution, it seemed probable that conditions could be found such that with only a slight excess of permanganate the bromide would be completely changed to bromo-acetone without appreciable loss of chloride.

Test experiments showed that with increasing acidity, ranging from 3 to 10 N sulfuric acid, the volume of permanganate solution that was decolorized promptly by half a gram of potassium bromide increased very appreciably. At the same time precipitation of hydrated manganese dioxide decreased, finally ceasing entirely, and the color at the end-point became more definitely that of a dilute permanganate solution. These differences were distinct arguments in favor of using these newer conditions providing (a) the bromide was thus completely converted to bromo-acetone, (b) the chloride was not attacked, (c) the end-point

TABLE II

PERMANENCE OF THE PERMANGANATE END-POINT

Solution tested						
H_2SO_4 (1:1), ml.	$MnSO_4$ 0.3 N ml.	Acetone. ml.	Bromide added, g.	Chloride added, g.	$KMnO_4$ added, 5% soln.	Duration of color
50	0.0	25	0.0	0.0	1 drop	Permanent[a]
50	10.0	25	.0	.0	1 drop	Permanent[a]
50	0.0	25	.0	.10	1 drop	20 sec.
50	10.0	25	.0	.10	1 drop	5 min.
50	10.0	25	.0	.01	1 drop	18 min.
50	10.0	25	.05	.00	1.28 ml.	15 min.
50	10.0	25	.05	.01	1.30 ml.	10 min.

[a] In using the word permanent in this connection it should be noted that while one drop of the permanganate solution in 85 ml. produced a deep color in water alone, the color in these cases shifted rapidly to a light pink—deeper with manganous sulfate present than without—but when this light stage was once reached it did not undergo further change over a period of several minutes.

was reasonably permanent and, finally, (d) that the chloride could be quantitatively precipitated from such a solution. Quantitative experiments showed that these conditions were all fulfilled when one important modification was introduced, namely, the addition of 10 ml. of **0.3** N manganous sulfate solution to inhibit the oxidation of the chloride. In Table II are given data showing the satisfactory character of the end-point with manganous sulfate present.

The following quantitative procedure was finally adopted: measure out the volume of concentrated bromide solution to be analyzed, add 25 ml. of acetone, 10 ml. of 0.3 N manganous sulfate solution and 50 ml. of (1:1) sulfuric acid, cool in running water to 15–20°, add 5% potassium permanganate solution slowly with swirling until an end-point is reached, then add sufficient sulfuric acid to make the solution 11–11.5 N with respect to the acid, cool again and titrate to an end-point. Add one drop extra of the permanganate solution, let stand for one and a half to two minutes, reduce with **a** few drops of hydrogen peroxide, add ether and nitric acid as usual, precipitate with 0.25 N silver nitrate, adding 4 ml. excess, shake for one minute, filter, wash, dry and weigh.

Typical determinations using this procedure are given in Table III.

TABLE III

DETERMINATIONS OF CHLORIDE USING A SLIGHT EXCESS OF PERMANGANATE IN STRONGLY ACID SOLUTION

(b) Commercial Salts

Salt	**Sample no.**	**Wt. of sample, g.**	**Chloride found, %**	**Bromide test on ppt.**
NaBr	1	0.500	1.00	Neg.
NaBr	1	1.000	1.10	Pos.
NaBr	1	1.000	1.05	Neg.
NaBr	2	0.500	0.69	Pos.
NaBr	3	.500	.29	Pos.
KBr	4	.500	.38	Pos.
KBr	5	.500	.40	Pos.

Preliminary quantitative experiments during the development of the above procedure using amounts of potassium bromide ranging from 50 mg. to 1 g. and with chloride added in quantities ranging from 1–200 mg. gave a maximum negative error of 2.4 mg. and a maximum positive error of **3** mg., calculated as chloride. The negative error was cut down by cooling the solution more carefully and the positive error was decreased by adding the extra drop of permanganate solution and letting stand a minute longer before reducing. With the procedure thus modified the errors on a 1-g. sample were found to lie within ±1 mg., an accuracy of 0.1%.

The work with half-gram and gram samples indicated that the rate of hydrolysis of the bromo-acetone might increase sufficiently with higher concentrations to offset any gain in accuracy that a larger sample might be expected to give. To show this more definitely two solutions of bromo-acetone of differing concentrations were prepared. Treatment with silver nitrate showed that silver bromide did precipitate more readily from the solution of higher concentration. Further, the rate of precipitation was not affected by an increase in the excess of acetone from ten-fold to two hundred and fifty-fold. In both solutions, however, the rate was decreased by an increase in acidity, falling off in one case to one-fifth by a change from 0.16 to 10 N, and in the other case to one-third by a change from approximately 2.6 to 11 N. The readiness with which opalescence developed even in the latter solution made it evident that the use of the nephelometer to determine small amounts of chloride could be of only limited value. Accordingly it was clear that an increase in accuracy would require a concentration method whereby most of the bromine could be removed before the acetone was added.

(III) Development of a concentration method. In removing most of the bromine by permanganate oxidation and direct volatilization it must be remembered that only half as much permanganate is required to convert bromide to free bromine as to change it to bromo-acetone. This is shown in the following equations

$$2KMnO_4 + 10KBr + 8H_2SO_4 = 5Br_2 + 6K_2SO_4 + 2MnSO_4 + 8H_2O \qquad (1)$$

$$4KMnO_4 + 10KBr + 10CH_3COCH_3 + 11H_2SO_4 = 10CH_3COCH_2Br + 4MnSO_4 + 7K_2SO_4 + 16H_2O \qquad (2)$$

In preliminary experiments there was added an amount of the 5% potassium permanganate solution that left about 0.2 g. of bromide unoxidized. The flask was then left on the edge of the hot-plate until the color became light yellow, cooled, treated with acetone and the rest of the operation carried out as before.

With 10-g. samples the final process of filtering out the silver chloride became slow. This was aggravated by the fact that the acetone interfered with the usual coagulation of a small precipitate so that the latter would occasionally mat in the filtering crucible and clog it seriously. This difficulty had been encountered in earlier work and largely overcome by using regulated suction such that the first filtering was complete in three to eight minutes. To reduce the volume sufficiently so that the same time range could be used here it was only necessary to substitute solid potassium permanganate for the solution and to use limited amounts of water, thus keeping the final volume within 100 ml. Since the mechanical difficulty referred to became evident only in the case of very small precipitates, one could eliminate it by adding a definite amount of chloride immediately before precipitating with silver nitrate. The final weight of precipitate could then be corrected for the amount of chloride added. This modification was regularly introduced when determining the small amounts of chloride that might be present in high grade analytical reagents.

Larger samples than 10 g. were not used because even with this amount salts frequently crystallized out when the acetone was added and the solution cooled. In such cases the salt redissolved when the precipitate was washed but the filtrate was usually cloudy and required refiltration.

A further source of error lay in the possible loss by volatilization of hydrogen chloride in the heating used to remove the bromine. Quantitative studies showed that with 100 mg. of chloride present and 50 ml. of (1:1) sulfuric acid, standing on the edge of the hot plate for one hour caused considerable loss of chloride. With smaller amounts of chloride the loss decreased and with the acidity lowered to 50 ml. of (1:3) sulfuric acid the loss became negligible.

The following is the procedure recommended for the concentration method: weigh out 10 g. of the bromide and 0.1 g. less than an equivalent amount of potassium permanganate (as calculated from Equation 1), transfer to a half-liter, glass-stoppered Erlenmeyer flask, add 40 ml. of water and 10 ml. of 0.3 *N* manganous sulfate solution and swirl for one or two minutes to dissolve the salts. Add 25 ml. of (1:1) sulfuric acid and place on the edge of the hot plate until the solution becomes light yellow (thirty to fifty minutes). Cool, add 10 ml. of acetone and sufficient sulfuric acid to make the solution 11 to 11:5 N with respect to the acid, cool again to 15–20' and treat dropwise with a 5% solution of potassium permanganate until one drop gives a permanent pink color. Add one drop more, let stand for one to two minutes, insert a tube into the flask above the solution and blow out any slight bromine vapors present; then reduce with a few drops of diluted Perhydrol solution. Add a measured volume of standard sodium chloride solution (20 mg. of chlorine), 5 ml. each of ether and of (1:1) nitric acid and precipitate with 0.25 *N* silver nitrate solution. Swirl the solution while the latter reagent is run in slowly until the solution shows a distinct decrease in opalescence, then add 4 ml. more of the reagent. Insert the stopper, shake for one minute, cool (to avoid loss when removing stopper), transfer the precipitate to a weighed filtering crucible, wash with 1% nitric acid, dry for three hours at 130°, cool and weigh. From the weight found subtract the weight corresponding to the amount of chloride added and calculate the percentage of chloride.

Typical determinations using this procedure are given in Table IV.

TABLE IV

ANALYSES OF BROMIDES BY THE PRELIMINARY CONCENTRATION METHOD

Salt analyzed	Wt. of sample, g.	Chloride found, %	Bromide test on ppt.
Best comml. NaBr	10.0	0.190	Slight[a]
Best comml. NaBr	10.0	.190	Faint
Best comml. NaBr	10.0	.189	Faint
Special KBr[b]	4.0	.014	Faint
Special KBr	8.0	.010	Faint

[a] Studies of known bromide–chloride mixtures showed that the precipitatt with silver nitrate gave a recognizable test for bromide with as low as 0.2 mg. of bromine. In testing for bromide the precipitate in the crucible was treated with a little water, plus a few drops of sulfuric acid and several tenths of a gram of granular zinc. After standing for four or five minutes the solution was filtered and the filtrate tested by adding a little more sulfuric acid, one or two drops of permanganate solution and then shaking out with carbon tetrachloride.

[b] This salt was the material prepared from potassium oxalate and bromine as earlier described.

Magnitude of Errors in the Final Procedure.—The positive error due to inclusion of silver bromide in the final precipitate might be caused by incomplete oxidation of the bromide or by partial hydrolysis of the bromo-acetone. The material presented in Table II (last two lines) showing the permanence of the permanganate end-point indicates that the bromide must be completely oxidized. It has already been shown that a bromo-acetone solution reacts slowly with silver nitrate but from the work done it would appear that this reaction was not sufficient to account for the slight tests for bromide obtained in the latter part of this study. In the precipitation of silver chloride, however, it would be possible for more silver bromide to be carried down than might separate from the solution by itself.

This point was tested experimentally by preparing a solution containing a little over 0.3 g. of bromine as bromo-acetone, adding 100 mg. of chloride and then, with other conditions the same as in the above determinations, the chloride was precipitated with silver nitrate. An excess weight was obtained corresponding to 0.6 mg. of bromine carried down. This amount would be sufficient to account for the bromide tests since examination of the method used in testing the precipitates showed it to be capable of recognizing as little as 0.2 mg. of bromine. The excess weight of the precipitate calculated as chloride would introduce an error of only 0.4 mg., and since the amount of bromo-acetone used was greater than would commonly be present at the end of the concentration method, this figure would appear to be a maximum for this error.

Loss of chlorine by volatilization of hydrogen chloride had already been reduced to negligible magnitude by control of the acidity during removal of the bromine. To determine directly the extent of oxidation by permanganate under the final conditions two test experiments were run. One hundred milligrams of chloride in a solution prepared as for a regular determination lost 0.4 mg. of chlorine on treatment at room temperature (22°) with one drop of 5% permanganate solution and letting stand for one and a half minutes before reduction. The second solution, cooled to 15°, was treated with two drops of the permanganate solution and let stand for two minutes before reduction. The loss this time was only 0.5 mg. This loss may be taken as a maximum when small quantities of chloride are to be determined, for in such cases one would never be dealing with as much chloride as was present in these experiments.

The errors of the method as finally developed may, therefore, be considered to lie within the limits of ±0.5 mg. and to be compensating in character.

Summary

1. A method has been worked out for the determination of chloride in bromides using potassium permanganate and acetone to convert the

bromide to bromo-acetone. The chloride is then determined gravimetrically as silver chloride,

2. The various errors of the process have been carefully studied.
3. On a 1-g. sample the accuracy of the procedure lies within 0.1%.
4. The rate at which a solution of bromo-acetone reacts with silver nitrate makes the nephelometric method inaccurate for small amounts of chloride.
5. By using a preliminary concentration method samples up to 10 g. can be employed for the accurate analytical testing of high grade reagents.

THE TRANSFERENCE NUMBER OF BARIUM CHLORIDE AS A FUNCTION OF THE CONCENTRATION

BY GRINNELL JONES AND MALCOLM DOLE

RECEIVED OCTOBER 31, 1928 PUBLISHED APRIL 5, 1929

Introduction

According to the classical electrolytic dissociation theory of Arrhenius the transference number of the ions should be independent of the concentration, but there are numerous well-established exceptions to the old rule. It has been the common practice to explain away the known variation of the transference number with the concentration as due to the presence of complex ions or as due to hydration in amounts which vary with the concentration, but these speculations have as a rule been qualitative only, with little serious attempt to develop a consistent quantitative theory or to express the variation of the transference number quantitatively as a function of the concentration.

The newer theory of complete electrolytic dissociation of Debye and Hückel gives a new point of view for the study of transference numbers. The new theory, unlike the old, does not neglect the electrostatic forces between the ions. According to this theory, at finite concentrations, the interionic forces tend to maintain a space lattice distribution of the ions and to oppose any disturbance of this arrangement by an outside electric field from an electrode and thus decrease the mobility of the ions. Therefore, the velocity of motion of an ion is not proportional to the potential gradient due to the outside electrode alone regardless of the concentration but is a decreasing function of the concentration. Debye and Hückel[1] have derived from this standpoint an equation for the variation of the equivalent conductance of strong electrolytes as a function of the concentration. This equation fits the facts fairly well at extreme dilutions

---

[1] P. Debye and E. Hückel, *Physik. Z.*, 24,185 (1923); 24,305 (1923); E. Hückel, *Ergebnisse der Exakten Naturwissenschaften*, 3,199 (1924).

(under 0.01 N) but fails quantitatively at higher concentrations. Owing to the abundance of relatively reliable conductance data and the scarcity of reliable data on transference numbers, especially at high dilutions, the proponents of this new theory have apparently confined their attention to conductance data in testing the predictions of the theory in regard to ionic migration velocities. The newer theory, however, predicts that the influence of interionic attraction on the mobility is not proportionally the same for all ions but is a function of the size of the ion, of the temperature and of the dielectric constant of the solvent, and especially of the valence. Therefore the new theory, unlike the old, would predict that the transference numbers of ions should be a function of the concentration. So far as we know no one has yet published the derivation from these new premises of an expression for the variation of the transference number as a function of the concentration, valence and nature of the ions.[2]

The present paper records the first results of an attempt to study experimentally the variation of transference numbers with concentration and to determine the factors which influence this variation.

Experimental Part

Analytical Method.—The best available barium chloride was dissolved in hot water, filtered, precipitated by adding pure, freshly distilled alcohol, dried in a centrifuge, recrystallized from water, dried in a centrifuge and finally dried in an electric oven at 120". Spectroscopic tests gave no evidence of the presence of strontium or calcium, although the original material when tested in a similar fashion showed the presence of strontium. Solutions were made up of approximately the concentration desired and the exact concentrations determined by analysis as described below.

The most exact determinations of the transference numbers of chlorides by the analytical method have been made by Washburn,[3] whose technique is a distinct advance over that of all earlier experimenters, but in spite of his fundamental improvements Washburn's method is involved, difficult, laborious and time consuming, and considerable skill and practice are needed to obtain reliable results. It should be especially noted that evaporation of the solutions during the operations of separating the electrolyte into five portions and filtering out the silver–silver chloride mixtures composing the electrodes, changes the concentration of the solution and thus introduces an error Every detail of manipulation must be planned to reduce this source of error as much as possible. The error due to unavoidable evaporation during manipulation can be minimized by using an apparatus of large volume of the anode and cathode chambers. For the anode Washburn recommends a Soxhlet extraction tube of filter paper filled with electrolytic silver crystals in which a coil of silver wire is buried. During the experiment silver chloride is formed on the silver wire and crystals, but contrary to Washburn's experience, we found that the silver chloride formed during electrolysis

---

[2] This has been done by the junior author, but since the conductivity data are also needed to evaluate the constants of the equation, the theoretical discussion is postponed until a subsequent paper when data on the conductivity and viscosity of barium chloride solutions will be presented and correlated with the transference data. See Malcolm Dole, Harvard Ph.D. "Dissertation," 1928.

[3] E. W. Washburn, THIS JOURNAL, **31**,322 (1909)

cemented the crystals together. During the mechanical disintegration of the anode loss by evaporation was unavoidable and thus made the solution stronger than it should have been.

This difficulty was overcome by the invention of a more satisfactory form of anode. A silver wire gauze was attached to a silver wire and rolled into a cylindrical coil of three layers about 1 cm. long and slightly less than the glass tube in diameter. The gauze was covered with an adherent but spongy coating of metallic silver by the pyrogenetic decomposition of silver oxide, thus producing a much larger surface than is available in the Washburn form of electrode. These anodes would carry a current of 0.1 ampere for eight hours without the slightest formation of acid in the electrolyte due to the evolution of oxygen instead of the formation of silver chloride, provided the potential gradient in the electrolyte did not exceed one volt per centimeter. At the beginning of the experiment the lower end of the anode is attacked and as it becomes covered with silver chloride the zone of the reaction gradually moves upward and at the end of the experiment the upper portion is being used. The potential necessary to cause oxygen evolution is approximately one volt greater than that required to change silver to the chloride. Therefore if the potential gradient in the solution exceeds one volt per centimeter, oxygen may be formed at the lower edge of the anode instead of chloride being formed one centimeter higher up on the electrode. In our apparatus the distance between the electrodes was about 100 centimeters. We found that if 100 volts were used, gassing would occur on the lower edge of the electrode before the silver on the upper part of the electrodes had been covered with chloride. By restricting the voltage used to 70 volts there was an adequate margin of safety to avoid gassing at the anode until its capacity had been fully used. With the more concentrated solutions this limitation was of no consequence because we found it best to limit the current to 0.1 ampere to avoid excessive heating and to avoid gassing at the cathode and 70 volts was not necessary to give 0.1 ampere. With 0.1 molal and weaker solutions this limitation to 70 volts limited the current that could be used.

With our new form of anode no filter paper is required. The silver chloride formed during electrolysis adheres firmly to the anode and yet the anode remains porous so that the weak electrolyte within the anode can readily be mixed with the anode liquid without disintegrating the anode by shaking and diffusion and without opening the anode chamber. At the end of the experiment the anode chamber filled with anode and anode electrolyte was weighed, then the anode removed intact, washed with water and dried in an oven without the loss of silver chloride. The rest of the manipulation is similar to that of Washburn except that no filtration of the anode liquid is required and therefore the amount of evaporation is much less than in his procedure.

After the new form of anode had been developed and the experimental technique seemed to be satisfactory in other respects and we were getting results from the anode side which seemed to be reliable, the results from the cathode side continued to be erratic. For the cathode we were using a silver plate covered with a layer of precipitated silver chloride in accordance with Washburn's recommendation.[4] We found that such an electrode would carry a current of 0.1 ampere without evolution of hydrogen or formation of alkali. Since we could find no evidence of any other abnormal reaction at this electrode we were at length forced to conclude that the difficulty was in the washing of the silver chloride for the cathode with the original solution and in the filling of the electrode chamber.

Repeated washing of the precipitate with the solution to be used improved the

[4] S. A. Braley and J. L. Hall, THIS JOURNAL, 42, 1770 (1920); S. A. Braley and R. F. Schueider, *ibid.*, 45, 1121 (1923), who used Washburn's method without modification, were unable to get reliable results with the cathode portions.

results somewhat but did not solve the problem. After much experimentation two different procedures were adopted, one suitable for the more concentrated solutions and the other suitable for the more dilute solutions. We tried a form of cathode somewhat similar to those used by Dewey[5] but modified so as to give a larger surface of silver. This larger surface of silver was obtained by decomposing silver oxide by heat. The first steps in making these cathodes were identical with the procedure used in making the anodes already described. Then the electrode was coated heavily with silver chloride by electrolysis in a chloride solution, washed and dried. These cathodes proved to be satisfactory for use with the dilute solutions (0.03 molal and under). With these solutions the current density was necessarily low on account of the high internal resistance and the necessity of limiting the potential gradient to one volt per centimeter as explained above. With the more concentrated solutions, however, these new cathodes failed because they would not carry the heavier currents needed without evolution of hydrogen. We were therefore forced to return to the Washburn type of cathode for use with the more concentrated solutions but were able to find a modification of the procedure which solved the difficulties described above.

The procedure finally adopted was as follows. A suitable quantity of silver nitrate was weighed out, dissolved in hot water, precipitated from hot solution by an excess of sodium chloride, thoroughly washed with hot water and then the supernatant water decanted. The damp precipitate was added to a glass-stoppered bottle containing all of the barium chloride solution to be used in the experiment and the whole thoroughly shaken. Of course, this changed the composition of the solution but no harm resulted, because it was later analyzed in the middle portions after the experiments. The bottle was allowed to stand until the precipitate had settled and most of the clear solution was decanted into a dry bottle. The precipitate was brought into suspension by shaking and the suspension poured into the cathode chamber through a funnel. The funnel was then withdrawn and the entire apparatus filled with clear solution and tightly closed. This procedure ensured that the barium chloride solution was uniform in composition throughout the entire apparatus. Certainly the agreement between the results obtained from the anode and cathode sides of the apparatus was greatly improved after this procedure was adopted. The five portions of the electrolyte were analyzed gravimetrically by precipitation of the chloride as silver chloride. This work must be done with great care because the errors in the analysis were magnified in the subsequent calculations, but this unusually accurate analytical method is so well known that it need not be described here.

The rest of the manipulation need not be described in detail since there were no significant variations from Washburn's procedure. In some cases the analyses of the anode middle and the cathode middle portions were omitted after it had been shown by measurements of the conductivity that these solutions were the same as the middle portion. During the electrolysis the apparatus was mounted in a thermostat at 25 ± 0.02°.

The results are computed on the assumption that the water does not move under the influence of the current and are, therefore, "Hittorf" numbers rather than "true" transference numbers in the sense that these terms are used by Washburn.

In the following table are given all the results that we believe to be reliable. It was not until Expt. 16 that our improved technique in handling the cathode was adopted. All earlier results obtained from the cathode side are rejected. Some of the later experiments had to be rejected because variations in the procedure were tried which proved to be unsuccessful. A few were lost by accident in the analysis. Some of the

missing numbers represent attempts to use 0.003 molal solutions but we were unable to obtain a reliable result with such dilute solutions. None of the results were rejected because they were not consistent with the new formula given below.

The Transference Number as a Function of Concentration.—The transference number, t, was plotted against the square root of the concentration, giving a smooth curve which was nearly straight but showed a definite curvature. It was then found that by plotting $1/(t+1)$ against $\sqrt{c}$ (Fig. 1, Curve I) a perfect straight line was obtained with all the experimental points falling on a straight line within the limit of error of the experiment. Then by the method of least squares the constants of the equation of this straight line were computed, giving

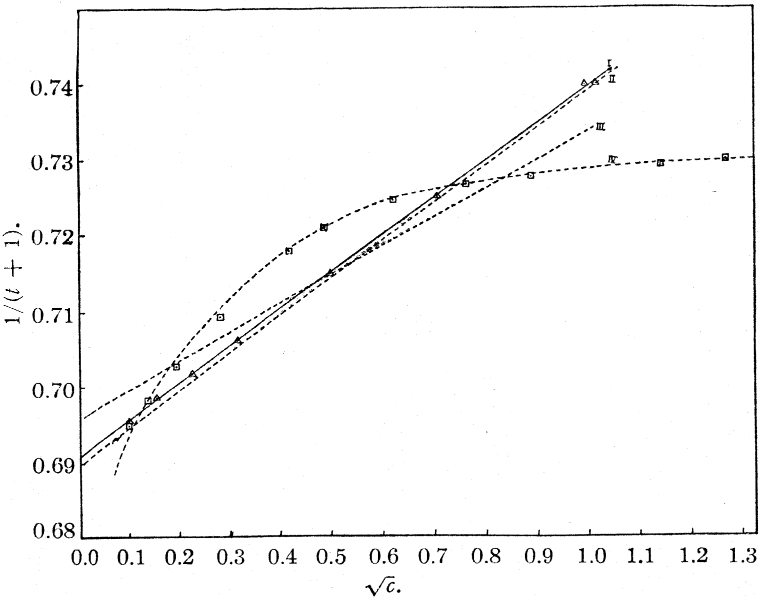

Fig. 1.—Reciprocal of transference number plus one, $1/(t+1)$, against square of the concentration, $\sqrt{c}$. The straight line I with points in triangles represents our data by the analytical method and is plot of Equation 1. The results obtained by the electromotive force method are represented by broken lines. The straight line II represents our data based on Equation 20. The straight line III represents our interpretation of Lucasse's data based on Equation 21. Curve IV with points in squares represents Lucasse's interpretation of his own data.

$$\sqrt{c} = \frac{20.6501}{t+1} - 14.2655 \qquad (1)$$

as the functional relationship between c and t. This is readily transferred into

$$(\sqrt{c} + 14.2655)(t+1) = 20.6501 \qquad (2)$$

This is the equation of a rectangular hyperbola between t and $\sqrt{c}$ with the asymptotes displaced from the axes at -14.2653 and -1. Another simple transformation gives

$$t = \frac{1.4476}{1 + 0.07010\sqrt{c}} - 1 \qquad (3)$$

The value of t at each concentration used in our experiments was then computed from this equation and is given in the second line from the bottom of Table I. The difference between the computed and observed values of t is given in the last line of Table I. As will be seen, the maximum deviation is +0.00052 in Expt. 24 and even here the computed result agrees exactly with the determination from the anode side, so that this deviation is clearly less than the possible experimental error. The average deviation is less than 0.0002. In view of the fact that most experimenters on transference numbers record their results only to the third decimal place this agreement is highly satisfactory. It should be noticed that the greater deviations occur in the dilute solutions where the experimental error is the greatest. Moreover, this equation holds exactly over the entire range of concentration from 0.01 to 1.035 mole per liter with no indication of systematic deviations in the more concentrated solutions. An additional reason for satisfaction is that the form of the function is such that there is no rapid change in slope as c approaches zero. It may therefore be used with considerable confidence for interpolation to obtain the value of the transference number at rounded concentrations and for extrapolation to infinite dilution. The values thus obtained are recorded in Table II. The value at infinite dilution is 0.4476.

TABLE II

TRANSFERENCE NUMBERS OF BARIUM IN BARIUM CHLORIDE SOLUTIONS AT 25° AT VARIOUS CONCENTRATIONS

c	0.000	0.001	0.005	0.01	0.025	0.05	0.10	0.25	0.5	1.0

Having discovered a new hyperbolic relationship between the transference number and the square root of the concentration which holds exactly in the case of barium chloride over a hundred-fold range in concentration, it becomes of much interest to determine whether or not this relationship is a general one. In the case of barium chloride one of the asymptotes of the hyperbola is at −1, but this may not be the case with other salts. An examination of the available data on transference numbers reveals very few cases in which the transference numbers have been determined over a wide range of concentration by the same method and at the same temperatures and by the same experimenter so that the data are comparable. The principal exceptions are the work of MacInnes and Reattie[6]

---

[6] D. A. MacInnes and J, A. Beattie, THIS JOURNAL, 42, 1117 (1920).

on lithium chloride, that of Lucasse[7] on barium chloride, strontium chloride and calcium chloride, that of Pearce and Gelbach[8] on barium chloride and that of Ferguson and Schlucter[9] on sodium hydroxide, all computed from the electromotive force of concentration cells with and without liquid junction. The transference numbers computed by these authors from their data do not show the same hyperbolic relationship between the transference number and the square root of the concentration which we have found for barium chloride. The results of Lucasse on barium chloride are shown in Fig. 1, Curve IV and, as will be seen, are widely different from the results which we obtained by the analytical method.

Experimental

Electromotive-Force Method.—In order to determine, if possible, the cause of the discrepancy, we undertook to measure the electromotive force of concentration cells with liquid junction similar to those used by Lucasse. The cells were of the flowing junction type used by Lamb and Larson.[10] In all of the experiments one-half of the cell contained 0.05 molal solution and the solution in the other half was varied in successive experiments from 0.001 to 1.000 molal. The electrodes were prepared by depositing silver chloride by a current of 1 milliampere for ten hours on a foundation of spongy silver formed by the pyrogenous decomposition of silver oxide. Electrodes when prepared in this way, then allowed to stand for several hours in a solution of potassium chloride or of barium chloride, nearly always agree within 0.00001 volt. We found that these electrodes could be transferred from one solution to another of different concentration and after standing for about one hour they gave definite and reproducible results.

For our final measurements a set of four electrodes was used. Two electrodes remained in the 0.05 barium chloride solution and the other two were used successively in the other solutions. These electrodes were allowed to stand for at least twenty-four hours in the solution under investigation in a thermostat before measurements were made. The difference between the pair in the same solution never exceeded 0.00003 volt and rarely exceeded 0.00001 volt. After this long-continued use in many different solutions they were all four put into a 0.05 molal solution of barium chloride and then the maximum difference between any two of the four was only 0.00003 volt.

Computation of Transference Numbers from the Electromotive Force of Concentration Cells.—The results shown in Table III were used in

preparing Fig. 2, in which $E_2 - E_1$ is plotted against log c_2 (points enclosed in circles). Then Lucasse's measurements (points enclosed in squares) were placed on the same plot by adding 0.02280 to each of his readings,

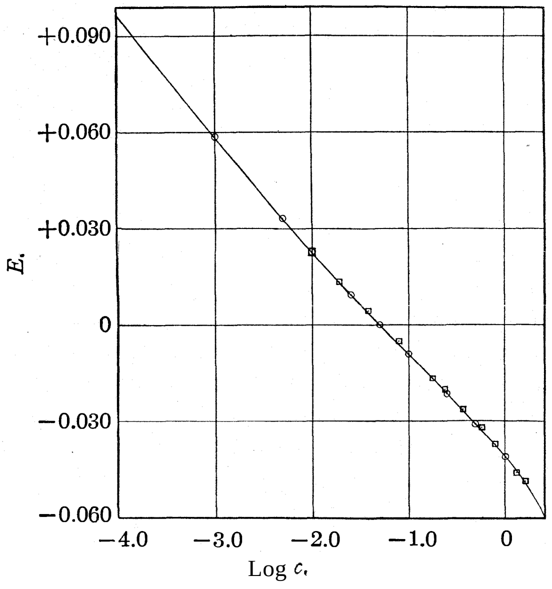

Fig. 2.—Electromotive force of barium chloride concentration cells with liquid junction, $E_2 - E_1$, against log c_2, all measurements being made against a solution having c_1 = 0.05 mole per liter. Points in circles represent our data. Points in squares represent Lucasse's data. The solid curve is the plot of Equation 16 which is derived from Equation 15 by substituting values of A and B determined from our analytical data and the values of N and P determined from Lucasse's data on concentration cells without liquid junction.

which refers them to the same arbitrary reference electrode ($c = 0.05$) as was used in our measurements instead of $c = 0.009968$ used by Lucasse. As will be seen, both sets of data fall on the same curve so well that the deviations are barely noticeable even on a large plot 50 cm. square, although Lucasse's data do not fit the curve as well as ours. We thus find ourselves in substantial agreement with Lucasse as to the experimental data. We have not verified his data on cells without liquid junction but in view of subsequent developments this seemed to be unnecessary.

The next step was a critical study of the method of computing transference numbers from the electromotive force of concentration cells. Lucasse employed a method modeled on that of MacInnes and Beattie for lithium chloride but modified disadvantageously so as to make it more dependent on plotting and less dependent on algebraic analysis. Lucasse first used his data on the electromotive force of concentration cells without liquid junction of the type Ag, AgCl, $BaCl_2$ (c_2), $BaHg_x$ —— Hg_xBa, $BaCl_2$ (c_1), AgCl, Ag to prepare a plot of activity coefficient against the square root of the concentration. From this plot he obtained by interpolation the activity coefficient at each of the different odd concentrations which were used in the measurements on concentration cells with liquid junction. The activity, a, was then computed and hence the quantity, A, which is arbitrarily defined as $1000a$. Then the electromotive force of concentration cells with liquid junction was plotted against log A. Up to this point he used the procedure of MacInnes and Beattie in principle, but with the difference that MacInnes and Beattie used identical concentrations in their cells with and without liquid junctions and therefore did not have to rely on values interpolated on plots. MacInnes and Beattie found that E could be expressed analytically as a binomial function of log A. This on differentiation gave a linear relationship between the transference number, t, and log A, which they used to compute t at any concentration within the range of their data. But this linear relationship cannot be applicable over the entire range of concentration because it leads to the result that as the concentration approaches zero the transference number must approach infinity.

Lucasse found that his curve between E and log A could not be expressed as a binomial and indeed was so complicated that he was unable to find the equation of the curve. He was therefore compelled to carry out by geometrical means the steps equivalent to those carried by MacInnes and Beattie by analytical methods. Lucasse measured the slope of his curves at various points and by dividing each value of the slope by the appropriate constant factor obtained a set of values for the transference number at various concentrations. These results are shown graphically in our Fig. 1 in the curve marked IV and, as will be seen, are not in agreement with our results obtained by the analytical method. Having confirmed the approximate reliability of Lucasse's measurements on the electromotive force of concentration cells with liquid junction, it seemed to us probable that the cause of the discrepancy was to be sought in errors introduced in the complicated method of plotting used by Lucasse. In this case the transference numbers must be inferred from the slope of the curves. The slope and especially the variation of the slope with concentration is greatly influenced by slight differences in judgment in drawing the complicated curves through the experimental points. We therefore undertook to develop an analytical procedure for computing transference numbers at any concentration from the data on electromotive force of concentration cells with and without liquid junctions.

The differential equation for the electromotive force of a concentration cell with liquid junction of the type Ag, AgCl, $BaCl_2$ (c + dc), $BaCl_2(c)$, AgCl, Ag is

$$dE = -\frac{3RT}{2F} t \, d \ln a \tag{4}$$

where t is the transference number of the barium ion at the concentration c and temperature T and a is the geometric mean activity of the ions in the same solution. The problem therefore is to express t and a as functions of the concentration and then integrate the resulting equation between the limits of concentration used in the measurements of electromotive force of concentration cells with liquid junction. If the values so computed agree with the observed voltages over a considerable range of concentration, the reliability of the expressions for t and a as functions of c may be regarded as confirmed.

It has been shown that for barium chloride we may write

$$t = \frac{1.4476}{1 + 0.0701\sqrt{c}} - 1 \tag{3}$$

or in generalized[11] form that

$$t = \frac{A}{1 + B\sqrt{c}} - 1 \tag{5}$$

The determination of the activity, a, as a function of the concentration, c, may be based on the measurement of the electromotive force of concentration cells without liquid junction. In a very important paper Hückel[12] has attacked the general problem of the variation of activity coefficient with concentration. He derives an equation (his Equation 97) for the

---

[11] This form is not fully generalized, as it may be necessary with other salts to replace the term —1 by another constant. The introduction of another constant would complicate the ensuing mathematical derivation and computations but would introduce no change in principle.

[12] E. Hückel, Physik. Z., **26**, 93 (1925). *See* also T. H. Gronwall, V. K. LaMer, and K. Sandved, *Physik.* Z., 29, 358 (1928), for another attempt to solve this general problem.

variation of activity coefficient with concentration which for a monovalent salt has the form

$$\log f = \frac{-0.354\sqrt{2c}}{1 + N\sqrt{c}} + Pc \qquad (6)$$

where N and P are constants for any given salt.[13] Hiickel gives computations and curves showing that this formula is consistent with the data of Allmand and Polack[14] on the electromotive force of sodium chloride concentration cells without liquid junction up to a concentration of 5.4 molal; and also consistent with similar data of MacInnes and Beattie[6] on lithium chloride up to *3* molal. For a divalent salt Hückel's equation reduces to the form $\log f = -1.734\sqrt{c}/(1 + N\sqrt{c}) + Pc$. The first step is to endeavor to select values for N and P which would be consistent with Lucasse's actual data. As first approximations for N and P we have used the values $N' = 2.175$ (taken from Harned's paper)[15] and $P' = 0.1475$.

The electromotive force of a concentration cell without liquid junction having a divalent salt such as barium chloride and electrodes reversible with respect to the anion such as Ag, AgCl electrodes is given by the equation

$$dE = -\frac{3RT}{2F}\,d\ln a = -\frac{3RT}{2F}\,2.3026\,d\,(\log c + \log f) \qquad (7)$$

$$dE = -\frac{3RT}{2F}\,2.3026\,d\left(\log c - \frac{1.734\sqrt{c}}{1 + N\sqrt{c}} + Pc\right) \qquad (8)$$

Integrating between the limits c_2 and c_1 gives

$$E_2 - E_1 = -3.4539\,\frac{RT}{F}\left[\left(\log c_2 - \frac{1.734\sqrt{c_2}}{1 + N\sqrt{c_2}} + Pc_2\right) - \left(\log c_1 - \frac{1.734\sqrt{c_1}}{1 + N\sqrt{c_1}} + Pc_1\right)\right] \qquad (9)$$

As a convenient abbreviation we will write $E = \phi(c, N, P)$, and refer to this as the Phi function. By the use of this equation $E_2 - E_1 = E_{\text{comp.}}$

---

[13] There are in use three methods of defining the concentration: mole fractions, moles per 1000 *g*. of water and moles per liter—with corresponding definitions of the activity coefficient. In Huckel's Equation 97 the activity coefficient is on the mole fraction basis, but owing to the uncertainty in the polymerization of water the mole fraction basis is inconvenient for practical use. Huckel uses the moles per liter basis in his practical numerical calculations to test his general formulas and this is the basis which we have adopted. It is easy to show by the use of Huckel's Equation 30 that if the activity coefficient is defined as the activity divided by the concentration in moles per liter, no change in the form of Equation 97 is necessary and that the only change required is a slight change in the numerical value of the coefficient of the term containing the first power of *c* (our P). But *P* is an empirical constant anyway. The mathematical steps in this transformation must be omitted to save space. See Harned, THIS JOURNAL, 48, 338 (1926), for some discussion of this question and for the corresponding transformation in terms of moles per 1000 g. of water.

[14] A. J. Allmand and W. C. Polack, *J. Chem. Soc.*, 115, 1020 (1919).

was computed for the actual values of the concentration used by Lucasse (after changing from m to c by the use of the following equation for the density of barium chloride solutions at 25° based on our own measurements: $d = 0.99707 + 0.1821c - 0.00407c^2$). These computed values were near enough to the observed values, $E_{\text{obs.}}$, to be encouraging but they probably were not within the experimental error and the deviations $\Delta E = E_{\text{obs.}} - E_{\text{comp.}}$ were apparently systematic. This indicated that N and P should be changed by some finite amount, ΔN and ΔP, and these values were found as follows. The rate of change of E with change in N and in P can be found by taking the partial derivatives of

$$E_2 - E_1 = \phi(c, N, P)_{c_1}^{c_2} \tag{10}$$

with respect to N and to P. Then

$$\Delta E = \left[\frac{\partial\phi\,(c, N, P)}{\partial N}\right]_{c_1}^{c_2}\Delta N + \left[\frac{\partial\phi\,(c, N, P)}{\partial P}\right]_{c_1}^{c_2}\Delta P \tag{11}$$

Each cell measured thus gives a linear equation between ΔN and ΔP with numerical coefficients and these equations can be solved by the method of least squares for ΔN and ΔP. The second approximations for N and P are then given by $N'' = N' + \Delta N$, and $P'' = P' + \Delta P$.

The values of $E_2 - E_1$ may then be recomputed and if the deviations are reduced but still significant and systematic, the process outlined above may be repeated. In this particular case the deviation equation takes the form

$$\Delta E = -\frac{3 \times 2.3026RT}{2F}\left[\left(\frac{1.734\sqrt{c_2}}{(1 + N\sqrt{c_2})^2} - \frac{1.734\sqrt{c_1}}{(1 + N\sqrt{c_1})^2}\right)\Delta N + (c_2 - c_1)\Delta P\right] \tag{12}$$

In this manner (using the points up to $m = 0.97$, only) we found $\Delta N = +0.052$ and $\Delta P = +0.0052$ and hence $N'' = 2.175 + 0.052 = 2.227$ and $P'' = 0.1475 + 0.0052 = 0.1527$. A repetition of the calculations gave $\Delta N = +0.0048$ and $\Delta P = -0.00004$ and hence $N''' = 2.227 + 0.0048 = 2.2318$ and $P''' = 0.1527 - 0.00004 = 0.15266$. Then f and E were computed with the equation $\log f = -1.734\sqrt{c}/(1 + 2.2318\sqrt{c}) + 0.15266c$, with the results shown in the following table.

TABLE IV

TEST OF HÜCKEL'S ACTIVITY FUNCTION FOR BARIUM CHLORIDE SOLUTIONS AT 25°

$$\log f = \frac{-1.734\sqrt{c}}{1 + 2.2318\sqrt{c}} + 0.15266c$$

Having a new exact relationship between t and c from our own measurements by the gravimetric method and Hiickel's relationship between a and c, we are in a position to integrate the fundamental differential equation. Neither of these relationships was known at the time when MacInnes and Beattie published their important improvement over Nernst's method of computing transference numbers from the electromotive-force data.

$$dE = -\frac{3RT}{2F}\,t\,d\ln a \tag{4}$$

but

$$t = \frac{A}{1 + B\sqrt{c}} - 1 \tag{5}$$

and

$$\ln a = \ln c + \ln f = 2.3026(\log c + \log f) = 2.3026\left(\log c - \frac{1.734\sqrt{c}}{1 + N\sqrt{c}} + Pc\right) \tag{13}$$

$$-\frac{2F}{6.9078RT}\,dE = \left(\frac{A}{1 + B\sqrt{c}} - 1\right) d\left(\log c - \frac{1.734\sqrt{c}}{1 + N\sqrt{c}} + Pc\right) \tag{14}$$

By substituting $x = \sqrt{c}$, which simplifies the form of the integral, and integrating between the limits $x_2 = \sqrt{c_2}$ and $x_1 = \sqrt{c_1}$

$$Ez - E_1 = \frac{3RT \times 2.3026}{2F}\Big[-\frac{2APx}{B} + Px^2 - (2A - 2)\log x + \left(\frac{2}{2.3026} + \frac{}{(N - B)^2} + \frac{2AP}{B^2}\right) 2.3026 \log(1 + Br) - \left(\frac{1.734A}{N - B} - \frac{1.734}{N}\right)\left(\frac{1}{1 \mp Nx}\right) - \frac{}{(N - B)^2}\,2.3026 \log(1 + Nx)\Big]_{x_1}^{x_2} \tag{15}$$

As a convenient abbreviation we will write $E = \psi(x, A, B)$ and refer to this as the Psi function.

This equation, although complicated, is as rigid as the equations connecting t and a with c. If we substitute at 25° $3RT/2F$ 2.3026 = 0.088731 and $A = 1.4476$, $B = 0.07010$, $N = 2.2318$ and $P = 0.15266$; Equation 15 reduces to

$$E_2 - E_1 = +0.088731\Big[-6.30489x + 0.15266x^2 - 0.89512 \log x + 210.082 \log(1 + 0.0701x) - \frac{0.38420}{1 + 2.2318x} - 0.0867026 \log(1 + 2.2318x)\Big]_{x_1}^{x_2} \tag{16}$$

$E_2 - E_1$ was then computed for each of the barium chloride concentration cells with liquid junction measured by us and by Lucasse with the results shown in Tables V and VI.

These computed values against 0.05 molal barium chloride were then plotted ($E_2 - E_1$ against $\log c_2$) and are shown in the solid curve drawn in Fig. 2. This method of plotting was chosen because it gives a curve which is approximately a straight line, but when it is drawn on a large scale it is easily apparent that it is concave for small values of c, has a point of inflection near the middle and is convex for the higher values of c. As will be seen from Fig. 2, our experimental points and those of Lucasse

fit the theoretical curve closely and follow the complicated curvature throughout the entire range in a way which supports the validity of our new function and shows that there is no real discrepancy between our data on the transference of barium chloride and by the analytical method and the electromotive-force data.

Although the deviations between the observed and computed voltages (ΔE of Tables V and VI) are so small as to be scarcely visible on a plot 50 cm. square, nevertheless computation shows that there are deviations which are apparently greater than the experimental error of the electromotive-force measurements. It will be seen from Table V that our deviations are apparently systematic, being positive in dilute solutions, negligible in middle concentrations and negative in the concentrated solutions, and that those of Lucasse are predominantly positive and larger than ours.

It now becomes of interest to reverse the computation described above and compute transference numbers from electromotive force alone and compare the results with the transference numbers obtained analytically. The numerical value of N and P is first computed from the voltage of concentration cells without liquid junction in the manner described above. Then as a matter of mathematical theory it would only be necessary to measure two different cells with liquid junction to make it possible to compute A and B and hence compute t at any concentration. But in practice it will be advisable to measure many cells covering the desired range of concentration and this requires that the data be treated by the method of least squares to find the best values of A and B. Moreover, the form of the function is so complicated that a simple numerical solution is not feasible. The problem can be solved, however, in a manner similar to that indicated above. First assume some value of A' and B' as a first approximation. Then compute E $= \psi(x, A', B')$ for each value of x used in the experiments and hence the deviation $AE = E_{\text{obs.}} - E_{\text{comp.}}$ Then

$$\Delta E = \left[\frac{\partial\psi\ (x,\ A',\ B')}{\partial A'}\right]_{x_1}^{x_2}\Delta A + \left[\frac{\partial\psi\ (x,\ A',\ B')}{\partial B'}\right]_{x_1}^{x_2}\Delta B \qquad (17)$$

Each cell measured thus gives a linear numerical equation with two unknowns, ΔA and AB, and these equations can be solved by the method of least squares. This gives a second approximation: $A^N = A' + \Delta A$ and $B'' = B' + \Delta B$.

This process can be repeated as often as is necessary, but unless the first approximation were greatly in error the third approximation will not differ from the second by a significant amount. In this particular case the partial derivatives take the form shown below

$$\begin{aligned}\Delta E = &+\frac{3RT}{2F}2.3026\Big[-\frac{2Px}{B} - 2\log x + \frac{2}{(2.3026} + \frac{}{(N-B)^2} + \frac{2P}{B^2}\Big)2.30261og\ (1+Bx)\\ &- \frac{1.734}{(N-B)(1+Nx)} - \frac{1.734B}{(N-B)^2}2.3026\ \log\ (1+Nx)\Big]_{x_1}^{x_2}\Delta A\\ &+\frac{3RT}{2F}2.3026\Big[+\frac{2APx}{B^2} + \Big(\frac{1.734B}{(N-B)^2} + \frac{2\times 1.734AB}{(N-B)^3} - \frac{4AP}{B^3}\Big)2.3026\log\ (1+Bx)\\ &+\Big(\frac{2A}{2.3026} + \frac{1.734AB}{(N-B)^2} + \frac{2AP}{B^2}\Big)\frac{x}{1+Bx} - \frac{1.734A}{(N-B)^2(1+Nx)}\\ &-\Big(\frac{1.734A}{(N-B)^2} + \frac{2\times 1.734AB}{(N-B)^3}\Big)2{,}3026\log\ (1+Nx)\Big]_{x_1}^{x_2}AB \qquad (18)\end{aligned}$$

By substituting $A' = 1.4476$, $B' = 0.0701$, $N = 2.2318$ and $P = 0.15266$, this reduces to the form

$$\begin{aligned}\Delta E = &+0.088731\Big[-4.35554x - 2\log\ x + 145.129\ \log\ (1+0.0701x) - \frac{0.802146}{1+2.2318x}\\ &- 0.059896\ \log\ (1+2.2318x)\Big]_{x_1}^{x_2}AA + 0.088731\Big[+89.9424x - 5907.46\\ &\log\ (1+0.0701x) + \frac{91.2374x}{1+0.0701x} - \frac{0.537147}{1+2.2318x} - 1.31704\log(1+2.2318x)\Big]_{x_1}^{x_2}\Delta B \qquad (19)\end{aligned}$$

By using the values of AE from Column 5 of Table V and solving the resulting deviation equations by the method of least squares, it was found that $AA = +0.00240$ and $AB = +0.00125$. Hence $A'' = 1.4476 + 0.00240 \doteq 1.4500$ and $B'' = 0.07010 + 0.00125 = 0.07135$. Then, using these second approximations for A and B, the values for $E_2 - E_1$ were recomputed by means of Equation 15, with the results shown in Table V. The corresponding deviations are shown in Col. 7. The average deviation, disregarding the sign, is only 0.09 millivolt. The only deviations exceeding 0.1 millivolt are for the 0.005 and 0.001 molal solutions and these solutions are so dilute that the measurements are not so reliable as for the more concentrated solutions, as will be apparent from Table II. Moreover, the deviations are about equally positive and negative, so that the sum, including the sign, is only -0.00004 volt. This equation was plotted in Fig. 1, Line II. The deviations being now within the experimental error, there is nothing to be gained by further computations by the method of successive approximations. Therefore our data on the electromotive force of barium chloride concentration cells with liquid junction and Lucasse's data on concentration cells without liquid junction lead to the conclusion that the transference number of the barium ion in barium chloride solutions at 25° is

$$t = \frac{1.4500}{1 + 0.07135\sqrt{c}} - 1 \qquad (20)$$

The hyperbolic form of the function $(t + 1)(\sqrt{c} + 1/B) = A/B$, which was found to be in accord with our data by the analytical method, is confirmed by the electromotive-force method and extended down to $c = 0.001$. The values of the transference number obtained by the electromotive-force method agree with those obtained by the analytical method to within 0.0024 throughout the entire range of concentration up to 1.0 molal. However, we believe that the results obtained by the analytical method are the more accurate.

In an exactly analogous manner the calculations were carried out with Lucasse's data on cells with transference and the results are shown in Table VI. The first deviations computed with $A' = 1.4476$ and $B' = 0.07010$ (based on the analytical data) are substantially greater than the corresponding deviations in our work and are predominantly positive. Then by the method described above it was computed that $AA = -0.0104$, and $AB = -0.01601$; hence $A'' = 1.4476 - 0.0104 = 1.4372$, and $B'' = 0.07010 - 0.01601 = 0.05409$. In these calculations the values for cells in which c is greater than 1 were not used because Hiickel's formula for the activity does not hold above 1 molal. Line III in Fig. 1 gives the corresponding plot of this equation.

The values for $E_2 - E_1$ computed with these values of A and B are shown in Table VI. The deviations, although larger than in Table V, are no longer systematic and the plus and minus deviations offset each other so nearly that no significant improvement can be made by repeating the calculations by successive approximations. Lucasse's data lead to the conclusion that the transference number is given by the equation

$$t = \frac{1.4372}{1 + 0.05409\sqrt{c}} - 1 \tag{21}$$

Line III in Pig. 1 gives the plot showing our interpretation of Lucasse's data. Curve IV in this figure is drawn by using the values of the transference number computed by Lucasse from the same data that were used in drawing Line III. We believe that Lucasse's computations of transference numbers from his data are erroneous and that when his data are properly interpreted they support rather than contradict our new hyperbolic relationship between the transference number and the square root of the concentration.

Further experiments on other salts to test the generality of our new hyperbolic relationship are under way.

Grateful acknowledgment is made of a grant from the Milton Fund of Harvard University for the expenses of this investigation.

Summary

1. Improvements have been made in the details of Washburn's analytical method for the determination of transference numbers of chlorides which make it more precise, especially with dilute solutions.

2. The transference number of the barium ion in barium chloride solutions has been measured by the analytical method at 25° at many different concentrations in the interval from 0.01 to 1.035 molal and found to vary from 0.4378 to 0.3514 over this range.

3. The results can be expressed within the limits of the experimental error by a hyperbolic equation between the transference number of the barium ion, t, and the square root of the concentration, $\sqrt{c}$, as follows: $(t + 1)(\sqrt{c} + 14.2655) = 20.6501$, or its equivalent form

$$t = \frac{1.4476}{1 + 0.07010\sqrt{c}} - 1$$

4. The limiting value of the transference number of the barium ion in barium chloride solutions at infinite dilution at 25° is 0.4476.

5. The mean activity coefficient of the ions of barium chloride solutions varies with the concentration in accordance with the equation

$$\log_{10} f = \frac{-1.734\sqrt{c}}{1 + 2.2318\sqrt{c}} + 0.15266c$$

This function has the form derived by Hiickel.

6. The computation of transference numbers from the electromotive force of concentration cells with and without liquid junction is discussed.

7. Measurements have been made on the electromotive force of

concentration cells with liquid junction containing barium chloride covering the range from 0.001 molal to 1.0 molal. These data when combined with Lucasse's data on concentration cells without liquid junction lead to the conclusion that

$$t = \frac{1.4450}{1 + 0.07135\sqrt{c}} - 1$$

Transference numbers computed by this formula agree with those obtained by the analytical method within 0.0024 over the entire range of concentration up to 1.0 molal.

THE SYSTEMS: STRONTIUM OXIDE-PHOSPHORUS PENTOXIDE-WATER, AND BARIUM OXIDE-PHOSPHORUS PENTOXIDE-WATER AT 25° (ACID REGION)

BY HERMAN V. TARTAR AND JAMES R. LORAH[1]

RECEIVED NOVEMBER 7, 1928 PUBLISHED APRIL 5, 1929

No investigation of the systems $SrO-P_2O_5-H_2O$ and $BaO-P_2O_5-H_2O$ has been reported in the literature. Investigation of the closely related system $CaO-P_2O_5-H_2O$ has been made by Cameron and his co-workers[2] and by Bassett.[3] Fairhall[4] has studied the system $PbO-P_2O_5-H_2O$.

Each system is one of three components. By working at a constant temperature, such a system may be made univariant, in which case the existence of a single solid phase is indicated by a variation in the composition of the solution. The formation of a second solid phase produces an invariant system, the solution being constant. Analyses of the solid and liquid phases of a series of empirical mixtures which have been permitted to attain equilibrium afford the data necessary for defining the conditions under which the different compounds exist in solid form.

For this investigation only those conditions under which at least three phases—gas, solid and solution—exist in equilibrium were of interest and the isotherms at 25° were determined. The composition of the solid phases was found by extrapolation, using Schreinemaker's[6] residue method. Analyses were made of the saturated solution and of the solid residue together with the adhering mother liquor. The values from the two analyses when plotted on a coordinate system lie on straight line, which when projected passes through a point representing the composition of

the solid phase. Similar lines located by the analyses of different mixtures at equilibrium pass through a common point which represents the composition of the solid phase.

Owing to the fact that phosphoric acid is very soluble, while strontium and barium oxides are only sparingly so, the entire range of experiments cannot be carried out easily in the same way; adsorption by the solid phase in alkaline solution is another complicating factor. The acid region only is treated in this paper. Further information regarding the compounds which exist in the basic region is given in the paper which follows.

Experimental **Part**

1. Preparation of Materials.—All of the materials used in the preparation of various salts were high grade "C. P. Analyzed" chemicals. The sirupy phosphoric acid (85%) gave negative tests for hydrochloric and sulfuric acids, heavy metals and reducing substances. The water used was the "conductivity water" of the laboratory, specific conductance approximately 2×10^{-6} mhos.

The monophosphates of strontium and barium were prepared by dissolving the hydroxides with an excess of moderately concentrated phosphoric acid, evaporating until crystals began to appear on the surface of the solution and then cooling rapidly with stirring to produce small crystals. The density of these solutions was so great that it was found advisable to use some means of stirring during their evaporation. The crystals were filtered by suction and washed with alcohol and then with ether. The alcohol and ether employed were anhydrous to prevent hydrolysis of the salts. The salts contained no water of hydration and analyses gave the following values: monostrontium phosphate, 36.60% SrO, 50.13% P_2O_5, ratio P_2O_5/SrO, 1.370 (theoretical, 1.371); monobarium phosphate, 46.69% BaO, 42.65% P_2O_5; ratio, P_2O_5/BaO, 0.933 (theoretical, 0.926).

Distrontium phosphate was made by adding slowly to a solution of 50 cc. of sirupy phosphoric acid per liter of water, solid powdered strontium hydroxide until *a* small amount remained undissolved, meanwhile keeping the solution rapidly stirred. The solid material was removed by filtration. The filtrate was next slowly heated and rapidly stirred. At about 60° a very fine precipitate of distrontium phosphate began to form, due to the hydrolysis of the monostrontium phosphate in solution. The precipitation was nearly complete when 75° was reached. The precipitate was filtered by suction and washed with alcohol and ether.

A different procedure was necessary for the preparation of dibarium phosphate. To a solution containing approximately 50 g. of barium oxide and 60 cc. of sirupy phosphoric acid per liter, dilute carbonate-free ammonium hydroxide (5%) was added drop by drop, the solution being thoroughly stirred. The gelatinous particles of tribarium phosphate which formed when the drops of ammonium hydroxide came in contact with the solution rapidly dissolved when stirred. The dibarium phosphate separated in crystalline form. The acidity of the solution at the end of the precipitate varied from PH 5 to 6.5.

2. Methods **of** Analysis.—(a) Strontium.——The sample was dissolved in 25 to 50 cc. of distilled water with the addition of 1 to 2 cc. of concentrated hydrochloric acid. Then an amount of alcohol exactly equal to the combined volume of aqueous solution and dilute sulfuric acid (1:20) used as the precipitating agent was added. Next, 5 to 10 cc. of the sulfuric acid solution was run in drop by drop while the solution was stirred. After standing from six hours to overnight at 10°, the precipitate of strontium sulfate, which meanwhile became crystalline, was filtered in a Gooch crucible, washed with 50% alcohol and moderately ignited.

(b) Barium.—The determination of barium was made in the usual manner in the form of the sulfate.

(c) Phosphorus.—The phosphorus determination was made using the filtrate from the strontium and barium sulfate precipitations. The filtrates were boiled to expel alcohol and then evaporated to small volume. Often the filtrates were diluted to a given volume and an aliquot portion taken. The solution was made slightly acid, as shown by the indicator brom thymol blue. Then phosphorus was precipitated by the addition of magnesia mixture,[6] followed by slowly adding dilute ammonium hydroxide until the precipitate of magnesium ammonium phosphate had completely formed. After half an hour concentrated ammonium hydroxide was added to the extent of one-eighth the volume of the solution. After standing overnight the precipitate was separated by filtration and dissolved in hydrochloric acid. The phosphorus was then reprecipitated as magnesium ammonium phosphate, filtered and finally ignited to constant weight as magnesium pyrophosphate.

3. Experimental Procedure.—To aqueous solutions of phosphoric acid of varying concentration were added the solid phosphates, the solid mono- and diphosphates to saturation. This was done by adding one phosphate until the solution was almost saturated and then adding the other phosphate in small quantity; for example, if the monophosphate was first used a small quantity of the diphosphate was used to "seed" the solution. After "seeding," the bottles containing the solution were tightly stoppered and carefully sealed. The bottles were then placed either in an oven maintained at 35°, or placed directly in a thermostat maintained at 25 ± 0.03°. Final equilibrium was attained in all cases at the latter temperature.

Series A and C were made up with monostrontium phosphate, Series D with distrontium phosphate, Series E and F with monobarium phosphate and Series G with dibarium phosphate. Series C and E were kept at 35° for three weeks in order to saturate them at that temperature. The former (Series C) was then allowed to stand at 25° for five weeks with thrice daily shakings while the latter was shaken constantly for one week at the same temperature. None of the others was ever heated to a higher temperature, since they were more dilute in phosphoric acid and hydrolysis would probably occur at the higher temperatures. Series A, D, F and G were allowed to stand at 25° for three weeks with thrice daily shakings. A and F were then shaken constantly for two weeks and D and G for three weeks at this same temperature. At the end of the period of shaking the solid and liquid phases of all samples were analyzed.

To obtain the samples for analysis the bottle containing the desired solution was removed from the thermostat, quickly wiped dry, opened and about **25 cc.** of the solution filtered by suction into a small vial. In order to prevent evaporation by drawing air through the moist residue, the suction was turned off just as all of the liquid had passed through the filter. The Gooch crucible used in this filtration had a thin layer of asbestos on the bottom to keep any small crystals from going through. On top of this was a Witt plate to protect the thin asbestos mat and on top of all was a small disk of hardened filter paper. The solid could be easily removed from the filter paper without tearing or damaging it in any way. In very concentrated phosphoric acid solutions the paper was not used.

The clear filtrate was used for the density determination and for the sample for the analysis of the liquid phase. During the filtration and density determination, the room temperature was maintained near 25°. The entire wet solid was analyzed. The

evaporation of water from either the liquid or solid phases was almost entirely prevented by placing the samples in tared, stoppered weighing bottles immediately after filtration. All the samples were then weighed within the following ten minutes.

Duplicate determinations on separate weighed portions of the solution were made in almost all cases, while a single determination on the solid phase was deemed sufficient; in many cases there was not sufficient material for duplicate determinations. The results are given in tabular form in Tables I and II, and graphically in Figs. 1 and 2.

Fig. 1, representing the system $SrO–P_2O_5–H_2O$, shows two stable phases, distrontium phosphate, Sr_2HPO_4, and monostrontium phosphate, $SrH_4(PO_4)_2$. The region in which the former is stable is bounded by A B C, and the latter by C D E. The area A C E represents the region which is not saturated and where no solid phase can be in equilibrium. Any region above the area A B C D E represents a state of supersaturation. At the point C, approximately, the two solid phases are in equilibrium with the solution. It is unfortunate that in experiment A C (Table I)

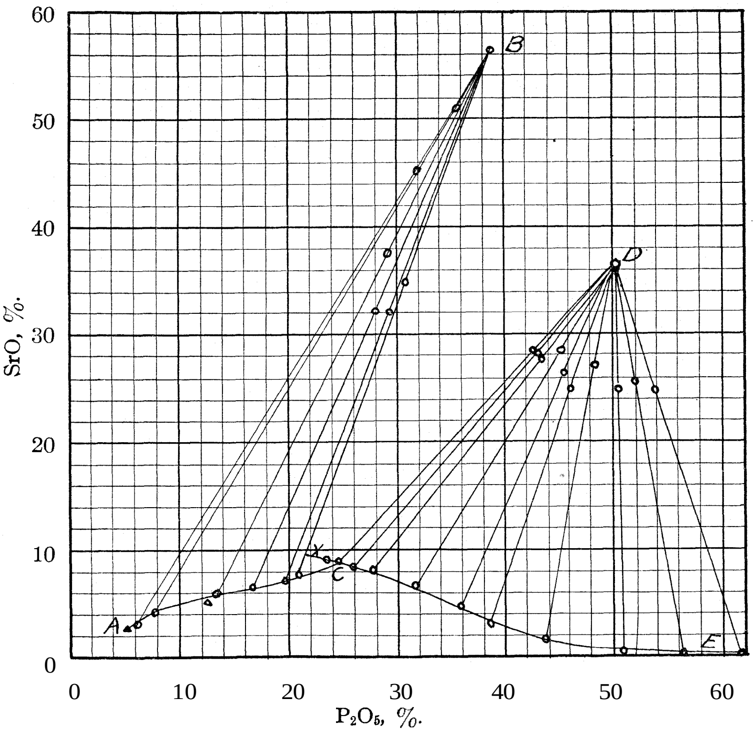

Fig. 1.—The system $SrO–P_2O_5–H_2O$.

the solid phase was too small for analysis; these data would show more conclusively the exact location of the invariant point. The extension C X probably represents a state of supersaturation with respect to distrontium phosphate as the solid phase. The lines A C and C E may be regarded as the solubility curves of di- and monostrontium phosphate, respectively, with respect to solutions of varying content of phosphoric anhydride.

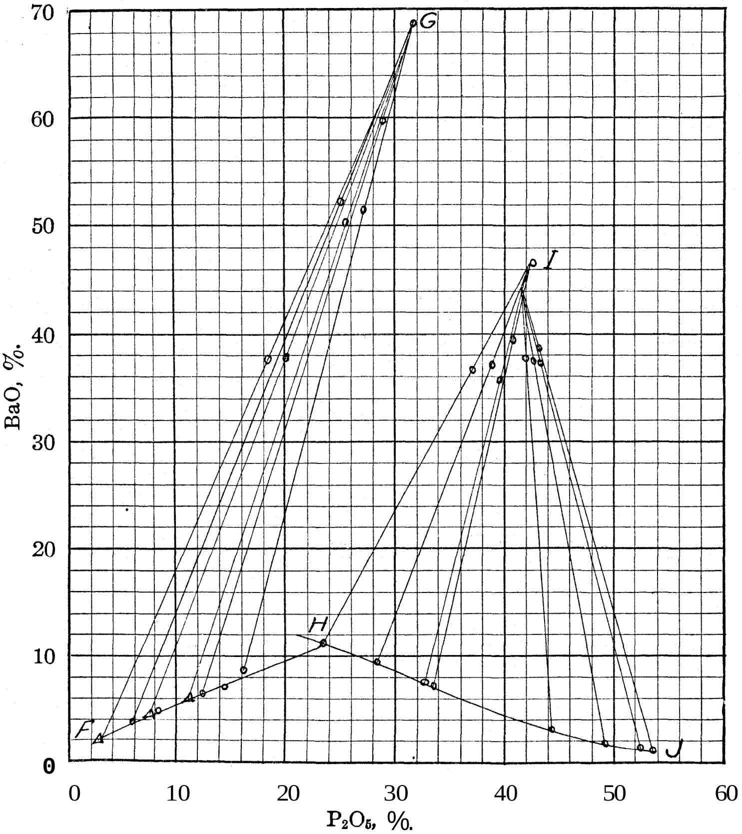

Fig. 2.—The system $BaO-P_2O_5-H_2O$.

The system $BaO-P_2O_5-H_2O$, represented in Fig. 2, is very similar to the $SrO-P_2O_5-H_2O$ system. Within the range of acidity of the system studied there are two stable solid phases. These are anhydrous di- and monobarium phosphates, represented by points B and I. The line FH represents the solution in stable equilibrium with dibarium phosphate and the line H J the stable equilibrium with monobarium phosphate. The point represented by H is the solution which can be in stable equilibrium with both di- and monobarium phosphates.

Summary

1. A phase rule study has been made of the system $SrO-P_2O_5-H_2O$ in the acid region. The limits at 25° have been defined for the two solid phases, monostrontium phosphate and distrontium phosphate.

2. A similar study has been made of the system $BaO-P_2O_5-H_2O$, in which the limits are defined for the solid phases, monobarium phosphate and dibarium phosphate.

A BASIC PIPOSPHATE OF CALCIUM AND OF STRONTIUM AND THE ADSORPTION OF CALCIUM HYDROXIDE BY BASIC CALCIUM PHOSPHATE AND BY TRICALCIUM PHOSPHATE

BY JAMES R. LORAH,[1] HERMAN V. TARTAR AND LILLIAN WOOD[2]

RECEIVED NOVEMBER 7, 1928 PUBLISHED APRIL 5, 1929

The purpose of this research was to clarify somewhat the confusion regarding the existence of phosphates of calcium more basic than the tertiary phosphate, $Ca_3(PO_4)_2$. To make the investigation more comprehensive the existence of basic phosphates of barium and of strontium was included.

Basic phosphates of calcium, strontium and barium have been mentioned frequently in the literature but apparently they have never been prepared in pure form.

Blarez[3] reported analyses of basic phosphates of calcium, strontium and barium which showed an excess varying from one-third to one-half molecule of the oxide over that required for the tertiary phosphates. Bertholet and Longuinine[4] had previously obtained similar results for barium phosphate.

Warington[5] found that when tricalcium phosphate is boiled with water the solution becomes distinctly acid. He made a series of experiments by boiling tricalcium phosphate with water for varying lengths of time, twenty-four to fifty hours, the water being renewed at frequent intervals. His analytical results do not show a final solid phase of constant composition; he concluded that the formula $3Ca_3(PO_4)_2 \cdot Ca(OH)_2$ "is the one which agrees best with the analyses." He further states, "We have, however, no certain ground for concluding that the action of boiling

water finally results in the formation of such a hydrated oxygen apatite, since we do not know what the further prolonged action of boiling water might effect."

Cameron and Seidell[6] noted in the precipitation of tricalcium phosphate that "when the supernatant liquid was alkaline, however, the precipitate always contained a larger proportion of lime than is required by the formula for tricalcium phosphate." Cameron and Bell[7] prepared a series of mixtures by adding lime water or dicalcium phosphate to phosphoric acid, which were agitated for three months at 25°. They obtained a series of solid phases which gave ratios, P_2O_5/CaO, varying from that of dicalcium phosphate to one much below that secured by Warington. They postulated a series of solid solutions intermediate between dicalcium phosphate and calcium hydroxide.

The solid solution explanation of Cameron and his co-workers has been criticized by Bassett,[8] who performed a series of experiments in which he shook mixtures of calcium oxide, dicalcium phosphate and water for eighteen months at 25°. He points out the serious experimental difficulties involved and states, "There seems little doubt that in spite of the length of time allowed, equilibrium had not been maintained in many cases." In one range he obtained solid phases with ratios, P_2O_5/CaO, varying from 0.881 to 0.831, which approximate "to the 0.845 for tricalcium phosphate, and it seems legitimate to conclude that in the main these solids do actually consist of this compound." In another group he obtained solid phases with ratios ranging from 0.798 to 0.763 "which are not far removed from the 0.761 of oxyapatite $(Ca_3P_2O_8)_3 \cdot CaO$, of which they appear to consist." With an excess of calcium hydroxide Bassett reports a solid phase with a ratio as low as 0.549.

Kolthoff,[9] from his results on the titration of phosphoric acid with calcium hydroxide using phenolphthalein indicator, was of the opinion that he had obtained a quaternary compound.

Jolibois[10] claims that from certain mixtures of calcium hydroxide and phosphoric acid he quickly obtained a new crystalline phosphate, $P_2O_5 \cdot 2CaO{-}P_2O_5 \cdot 3CaO{-}10H_2O$. In a later paper Jolibois and Maze-Sencier[11] have shown that calcium hydroxide is very strongly adsorbed by tricalcium phosphate when the latter is precipitated in the presence of the former. Hayashi and Matsui[12] report that the amount of calcium hydroxide required for the complete precipitation of the phosphate ion

from an alkaline sodium phosphate solution greatly exceeds the theoretical requirement for the formation of tricalcium phosphate.

Experimental Part

1. Preparation of **Materials.**—Tricalcium phosphate, $Ca_3(PO_4)_2$, was prepared from monocalcium phosphate, $CaH_4(PO_4)_2 \cdot H_2O$, which was produceci in a manner precisely analogous to that given in the preceding paper for monostrontium phosphate. Twenty grams of the monocalcium phosphate was dissolved in four liters of water and then carbonate-free ammonium hydroxide was added with constant stirring until the solution was distinctly alkaline. The amorphous, gelatinous precipitate was washed with water by decantation, allowing several hours between washings for the precipitate to settle. The washing was continued until the phosphate-ion content of the water had decreased to a minimum. The small amount of phosphate ion in the wash water came from two sources: (1) the solubility of the tricalcium phosphate and (2) the slow hydrolysis of the tricalcium phosphate, which will be discussed later.

Tricalcium phosphate "has an inherent slowness of precipitation."[13] When sufficient ammonium hydroxide for complete precipitation was added at once, the solution was quite alkaline and a small amount of basic calcium phosphate was formed. Practically it was found desirable to add the ammonium hydroxide at such a rate that the solution never became more than faintly alkaline. Theoretically the hydrogen ion should not be allowed to decrease beyond the point at which the tricalcium and basic calcium phosphates are in equilibrium. Although this point is not definitely known, it is on the acid side of neutrality. Consequently, the tricalcium phosphate prepared by the method given above contained a small amount of basic calcium phosphate. Analysis of a dried sample gave the ratio P_2O_5/CaO, 0.835 (theoretical for tricalcium phosphate, 0.845).

Tristrontium phosphate was prepared by a method analogous to that employed for the preparation of tricalcium phosphate. A portion of the moist material was washed with alcohol, then with ether and dried at 80°. Analysis gave the ratio P_2O_5/SrO, 0.458 (theoretical 0.457) and showed 4.75% of moisture (calculated by difference).

A different procedure was required for the preparation of tribarium phosphate. When a moderate excess of ammonium hydroxide was added to a dilute solution of monobarium phosphate, the precipitate was a mixture of dibarium phosphate and tribarium phosphate, the former being present in much greater quantity. By adding drop by drop a very dilute solution of barium chloride to a boiling, dilute solution of sodium phosphate, Na_2HPO_4, which was made strongly alkaline with carbonate-free sodium hydroxide, a precipitate of tribarium phosphate was obtained. Analysis gave the ratio P_2O_5/BaO, 0.295 (theoretical, 0.309).

2. Analytical Methods.—Strontium and barium and most of the phosphorus determinations were made by the methods given in the preceding paper. A portion of the phosphorus determinations was made in the usual way; the sample was dissolved in nitric acid, the phosphorus precipitated with ammonium molybdate, this precipitate was dissolved

---

[13] Holt, La Mer and Chown, J. *Biol. Chem.*, 64, 509 (1925).

in ammonium hydroxide and the phosphorus precipitated twice as magnesium ammonium phosphate, ignited and weighed as the pyrophosphate.

Two methods were used for the estimation of calcium. A limited number of the determinations was made by precipitating with ammonium oxalate from a solution of the sample made slightly acid with acetic acid; then dilute ammonium hydroxide was added until the solution was only faintly acid, as shown by the indicator bromothymol blue. After standing hot for one hour the precipitate was filtered and titrated with standard potassium permanganate in the usual manner. This procedure is not quite as accurate as the usual one in which the precipitate is formed in ammoniacal solution; calcium oxalate is slightly more soluble in the acid solution.

The greater part of the calcium determinations was carried out by precipitating the calcium as sulfate. The sample was dissolved in 15 cc. of water, 2 cc. of concentrated hydrochloric acid and an amount of 95% alcohol equal to four times the volume of the aqueous solution were then added; finally, dilute (1:20) sulfuric acid was added drop by drop with constant stirring. After standing at 10° overnight, the calcium sulfate was filtered in a Gooch crucible, washed with 70% alcohol and gently ignited.

3. Hydrolysis Experiments.—A series of experiments was made treating the tertiary phosphates of calcium, strontium and barium with boiling water and with carbonate-free sodium hydroxide solution. A separate batch of phosphate was prepared for each experiment, which was carried out as follows. Approximately 10 g. of the moist phosphate which had not been dried was suspended in 4 liters of distilled water contained in a 5-liter Pyrex flask connected to a reflux condenser, the inner tube of which was also Pyrex glass. When hydroxide was present in the aqueous phase, the system was protected from the carbon dioxide of the air by a soda lime tube. The contents of the flask were boiled for eight hours each day. Every morning the supernatant liquid was carefully siphoned off and fresh water or solution added. At intervals a sample of the solid phase for analysis was removed with a pipet. The sample was washed with water and sometimes finally with alcohol and ether. The results of the hydrolysis experiments are reported in Table I.

All the samples were tested for the presence of carbonate with negative results.

The final product obtained from the hydrolysis of calcium phosphate gave a composition corresponding within experimental error to the compound $3Ca_3(PO_4)_2{\cdot}Ca(OH)_2$, for which the ratio P_2O_5/CaO is 0.760. The hydrolysis may be represented by the summary equation

$$10Ca_3(PO_4)_2 + 6H_2O = 3Ca_3(PO_4)_2{\cdot}Ca(OH)_2 + 2H_3PO_4$$

The basic phosphate is very insoluble and the reaction proceeds to a definite hydrogen-ion concentration when equilibrium is reached. If

the acidic solution is removed by renewing the liquid in contact with the solid phase or by neutralizing the acid with alkali, the reaction proceeds to completion. After the solid phase reaches a composition giving the ratio P_2O_5/CaO, 0.76, it undergoes no change with further treatment.

The hydrolysis of the tristrontium phosphate took place more slowly than with the calcium salt. With water alone the conversion to the basic phosphate was very slow, only about half complete after forty-six days. In approximately half this time the material treated with dilute sodium hydroxide gave a solid phase corresponding in composition to the compound $3Sr_3(PO_4)_2\cdot Sr(OH)_2$ (theoretical P_2O_5/CaO ratio, 0.411). No change occurred upon further treatment with the sodium hydroxide.

Tribarium phosphate was difficult to prepare and the samples used for the hydrolysis experiments contained considerable amounts of dibarium phosphate; approximately two-thirds of the sample treated with water and one-half of the sample treated with alkali. With water only the hydrolysis of the diphosphate was exceedingly slow; with sodium hydroxide it was slightly more rapid. Even after twenty days' treatment with the alkali the ratio P_2O_5/BaO was 0.319, indicating that not all of the material was converted to the tertiary phosphate.

4. Precipitation from Alkaline Phosphate Solutions.—A series of experiments was made to prepare basic phosphates of calcium, strontium and barium by precipitation in alkaline phosphate solutions.

Ten grams of purified calcium carbonate was dissolved in dilute hydrochloric acid and the solution evaporated to dryness to remove the excess of acid. The residue was taken up in 2 liters of water. This solution was slowly added from a pipet to a boiling solution of 23 g of disodium phosphate (hydrate) and 95 cc. of saturated, carbonate-free sodium hydroxide solution in 2 liters of water. After standing overnight, the precipitate was washed with water until the wash water was practically free from chlorides. This required at least five washings with 3 liters of water each time, the solution being boiled for one hour to break up the large masses of precipitate, which was very gelatinous. Analysis of the dried precipitate gave the ratio P_2O_5/CaO, 0.781. Apparently the material was a mixture, largely the basic phosphate with some tricalcium phosphate.

The preparation of basic strontium phosphate was tried in a similar manner. A solution of 284 cc. of saturated strontium hydroxide (approximately 2.7 g. of $Sr(OH)_2$) was slowly added to a constantly stirred solution of 7.9 g. of disodium phosphate and 25 cc. of carbonate-free sodium hydroxide in 2 liters of boiling water. The flocculent precipitate was washed in the same manner as the calcium phosphate. Analysis gave the ratio, P_2O_5/SrO, 0 420, showing within experimental error that the material was the basic phosphate $3Sr_3(PO_4)_2 \cdot Sr(OH)_2$ (ratio, 0.411). The precipitate was then boiled for ten days longer with water (3 liters each day); after this treatment, analysis gave the ratio, P_2O_5/SrO, 0.423.

On adding drop by drop a very dilute solution of barium chloride to a dilute solution of disodium phosphate strongly alkaline with sodium hydroxide, a precipitate was obtained which gave the ratio, P_2O_5/BaO, 0.295, showing the material to be tribarium phosphate (theoretical ratio, 0.309). In all of the experiments no evidence has been secured of the existence of a basic barium phosphate.

5. Absorption Experiments.—In order to ascertain whether there is a reaction between the basic calcium phosphate reported above and calcium hydroxide or whether the basic substances often mentioned in the literature were materials produced by adsorption phenomena, some experiments were made on the adsorption of calcium hydroxide by the basic salt and by tricalcium phosphate. Two adsorption isotherms were determined for the basic salt, one after three days' and the other after six months' standing, and one isotherm for the tertiary phosphate after sixteen hours' standing.

(a) With **Basic** Calcium Phosphate.—Each experiment of the series was carried out in the following manner. The desired amount of recently boiled distilled water was placed in a dry, well-paraffined Pyrex bottle. To this was added two 25-cc. portions of a suspension of the basic calcium phosphate, the suspension being first thoroughly mixed by pouring from one flask to another. The use of a 25-cc. pipet twice, instead of a 50-cc. pipet once, reduced the error which might be due to any settling of the suspended material. The basic phosphate was prepared by the hydrolysis of tricalcium phosphate with water; ratio, P_2O_5/CaO, 0.765. The calcium hydroxide solution was then measured from a buret attached directly to the bottle, the system being carefully protected from the carbon dioxide of the air. The stopper of the bottle was then sealed carefully with paraffin. About 10 cc. of air space was left in the bottle so that the contents could be shaken. The bottle was then kept at 25 ± 0.03" and frequently shaken.

A blank was prepared in the same manner except that distilled water was substituted for the basic phosphate suspension.

The analysis of the basic phosphate suspension was made by determining the calcium and phosphorus in a weighed portion. From these data the weights of the basic calcium phosphate and of water in the suspension were calculated.

The concentration of the calcium hydroxide solution was determined by titration with carefully standardized hydrochloric acid with phenolphthalein indicator; the same acid was used for all the titrations. To determine the calcium hydroxide in the solution after adsorption, the bottle was allowed to stand for a day to allow the solid phase to settle. The seal was then broken and a 100-cc. portion of the solution rapidly removed and titrated. The blank was titrated in precisely the same manner. The data from the experiments with the basic phosphate are presented in Table II and in Figs. 1 and 2.

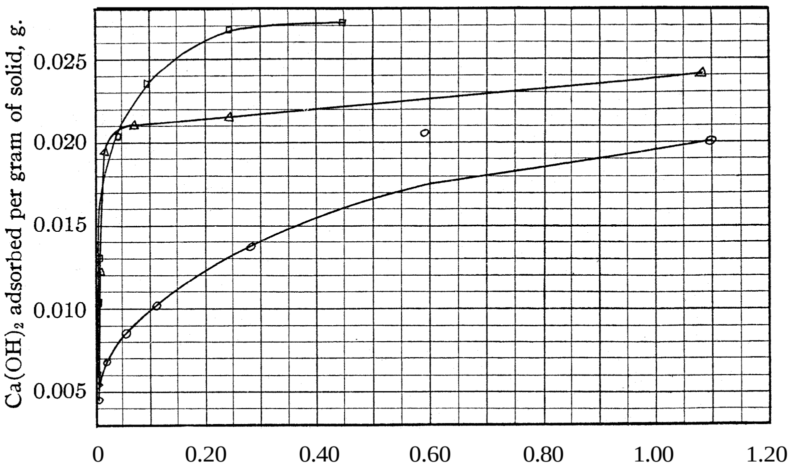
TABLE II

ADSORPTION OF CALCIUM HYDROXIDE BY BASIC CALCIUM PHOSPHATE AT 25°

0.8614 g. of basic calcium phosphate present in each bottle

Bottle number	Init concn. of $Ca(OH)_2$, g./l.	Final concn. of $Ca(OH)_2$, g /l.	Total vol. of soln., cc.	$Ca(OH)_2$ adsorbed per g. of solid, g.
		After Three Days' Standing		
25	1.176	1.099	224.69	0.0201
24	0.6706	0.5910	224.69	.0207
23	.3335	.2805	224.69	.0138
21	.1514	.1130	224.69	.0100
15	.0907	.0579	224.69	.0085
10	.0470	.0207	224.69	.0069
1	.0205	.0029	221.69	.0045
		After Six Months' Standing		
7	1.1760	1.0827	224.69	.0243
8	0.6706	0.5392	224.69	.0343
5	.3335	.2403	224.69	.0217
4	.1563	.0727	217.69	.0211
3	.0954	.0169	213.69	.0195
2	.0470	.0004	224.69	.0122
8	.0210	.0000	216.69	.0053

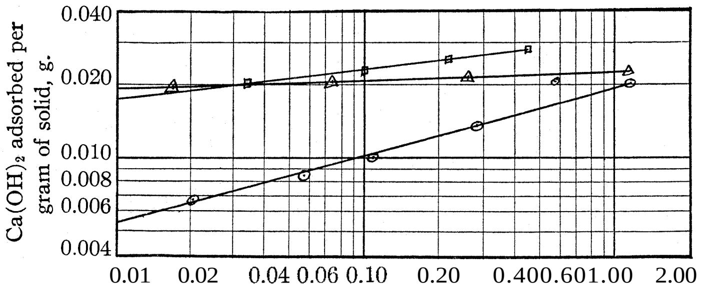
The curves from the two series of experiments (Fig. 1) are similar to the usual adsorption curve. When plotted logarithmically (Fig. 2), nearly straight lines are obtained, thus showing that the data may be represented by the common adsorption isotherm formulation proposed by Freundlich. There is no evidence of a reaction between basic calcium phosphate and calcium hydroxide. The two curves show that much more calcium hydroxide was taken up by the solid phase upon six months' standing. Usually adsorption equilibria are reached quickly and one might expect that if adsorption only took place there would be no further change after three days' contact. The change after this period may be due to the slow penetration of the calcium hydroxide into the interstices of the colloidal basic calcium phosphate. The writers are inclined to the opinion, however, that besides adsorption solid solutions were produced.



$Ca(OH)_2$ per liter after adsorption, g.

□, Tricalcium phosphate; △, six-month basic calcium phosphate; O, three-day basic calcium phosphate.

Fig. 1.—Adsorption of calcium hydroxide by calcium hydroxide.



$Ca(OH)_2$ per liter after adsorption, g.

□, Tsicalcium phosphate; A, six-month basic calcium phosphate; O, three-day basic calcium phosphate.

Fig. 2.—Adsorption of calcium hydroxide by calcium phosphates.

The data confirm the varying ratios obtained by Bassett[S] and by Cameron and Bell,[7] and apparently corroborate for this region the solid solution explanation proposed by the latter investigators.

(b) With Tricalcium Phosphate.—The series of experiments with tricalcium phosphate was run in precisely the same manner as that with the basic phosphate except that the contact between the solid and calcium hydroxide was limited to sixteen hours to minimize the change due to the slow reaction between these substances to form the basic phosphate. The tricalcium phosphate was prepared in the manner previously described. The results are reported in Table III and in Pigs. 1 and 2.

TABLE III

ADSORPTION OF CALCIUM HYDROXIDE BY TRICALCIUM PHOSPHATE AT 25° AFTER SIXTEEN HOURS

0.3838 *g.* of tricalcium phosphate present in each bottle

Bottle number	Init. concn. of $Ca(OH)_2$, g /l.	Final concn. of $Ca(OH)_2$,	Total volume of soln., cc.	$Ca(OH)_2$ adsorbed per g. of solid, g.
24	0.4990	0.4525	224.69	0.0272
23	.2848	.2388	224.69	.0269
15	.1390	.0989	212.69	.0234
10	.0699	.0348	224.69	.0205
1	.0278	.0043	224.69	.0131
47	.0188	.0011	224.69	.0103
48	.0110	.0002	224.69	.0064

The curves (Figs. 1 and 2) show that the data may be represented by the common adsorption isotherm formulation. The strong adsorption of calcium hydroxide by tricalcium phosphate affords at least a partial explanation of some of the basic materials which have been reported in the literature. Further experiments would be required to show whether solid solutions are possible in the range between tricalcium phosphate and the basic calcium phosphate.

Summary

1. The final product of the hydrolysis of tricalcium phosphate by water is a basic phosphate, the calcium and phosphorus contents of which correspond to that of the compound $3Ca_3(PO_4)_2 \cdot Ca(OH)_2$. This compound is similar to the mineral apatite, the calcium fluoride or chloride of the latter being replaced by calcium hydroxide.

2. The point of equilibrium between tricalcium phosphate and basic calcium phosphate lies on the acid side of neutrality.

3. Tristrontium phosphate boiled with an aqueous solution of sodium hydroxide hydrolyzes to form a basic strontium phosphate, $3Sr_3(PO_4)_2 \cdot Sr(OH)_2$, analogous to the basic calcium phosphate.

4. The hydrolysis of tricalcium and of tristrontium phosphate proceeds more rapidly with a sodium hydroxide solution than with water.

5. The basic strontium phosphate may be prepared by direct precipitation from an alkaline phosphate solution.

6. A method has been given for the preparation of tribarium phosphate.

7. No evidence has been obtained to indicate the existence of a barium phosphate more basic than tribarium phosphate.

8. The isotherm for the adsorption of calcium hydroxide shows that in most concentrated solutions approximately one-third of a mol of calcium hydroxide was adsorbed per mol of basic phosphate. Comparison of the curves for the three days' and six months' period indicates that either the calcium hydroxide penetrates the interstices of the solid phase very slowly or solid solutions are formed.

9. The adsorption of calcium hydroxide by tricalcium phosphate is slightly greater than by the basic phosphate.

10. The strong adsorption of calcium hydroxide by tricalcium phosphate and by basic calcium phosphate affords a basis for an explanation of many statements in the literature regarding basic phosphates of calcium.

THE EQUILIBRIUM IN AQUEOUS SOLUTION BETWEEN AMMONIUM ACETATE, ACETAMIDE AND WATER

BY EDGAR E. LINEKEN AND GEORGE H. BURROWS

RECEIVED NOVEMBER 7, 1928 PUBLISHED APRIL 5, 1929

Introduction

The general reaction between ammonium salts of organic acids, the corresponding amides and water, though complicated by ionization and hydrolysis phenomena, in many instances runs smoothly and is adapted to studies in equilibria. In particular, it permits a comparison in equilibria among members of a homologous series.

E. E. Reid[1] has measured the benzamide formed upon heating until establishment of equilibrium of solutions of ammonium benzoate. Menschutkin[2] has studied the formation of amides on heating in closed glass tubes the pure ammonium salts of acids from formic to caproic, and also of benzoic and anisic acids. Other studies have been made purely from the standpoint of amide preparation.

E. A. Brodie, in this Laboratory, has measured the equilibrium between ammonium acetate and acetamide in aqueous solutions of several concentrations and at two temperatures. He heated the solutions to be brought to equilibrium in sealed pyrex glass tubes and analyzed the equilibrium mixtures through determination of their refractive indices. The present experiments are essentially repetitions of those of Brodie, substituting, however, for index of refraction, electrical conductance, thus lessening errors of analysis.

[1] Reid, *Am. Chem.* **J., 44, 76 (1910).**

[2] Menschutkin, **J.** ***prakt.*** *Chem.,* **[2] 29, 422, 436,** (1884).

Experimental

The acetamide used was twice crystallized from benzene, with centrifugal draining, and was dried at 50–70°, yielding odorless crystals.

The ammonium acetate was crystallized from absolute alcohol, centrifuged. washed with absolute ether, or alcohol, and dried for several hours at 40° in an atmosphere of dry ammonia gas. The crystals were kept in well-filled, tightly stoppered bottles.

Conductivity water of uniform quality was used in preparing all solutions. In the work of Mr. Brodie equilibrium was approached from both sides, and shown to be attained within two days, at 184 and at 193°. In most of the present experiments equilibrium was approached from the amide side only, this substance being less subject to change during weighing.

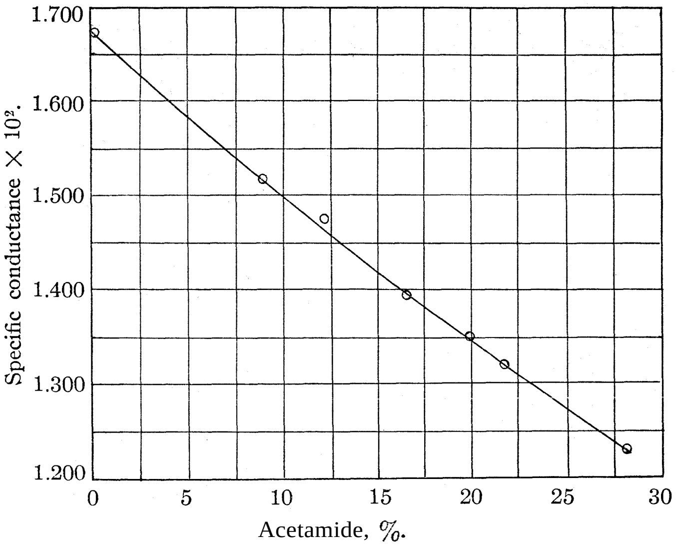

Fig. 1.

To attain equilibrium, solutions of acetamide were sealed in pyrex glass tubes of 5–10-cc. content, so that when hot the tubes would be closely full, and were heated in vapor-baths of dimethylaniline (193°), aniline (184") or secondary butylbenzene (172°), for the necessary length of time. After this they were plunged into cold water, opened and the contents of each tube, if not already of this concentration, were brought to a concentration of 0.2 mole of total solids (amide plus acetate) to 1000 g. of solution. Analysis was then effected by measuring the specific conductance of the solution and referring this to a curve (Fig. 1) plotted from conductance measurements on synthetic mixtures. The plot permitted reading to the nearest 0.1% of amide.

The data for the curve plotted are given in Table I. In this table the specific conductances are those of a series of synthetic solutions of ammonium acetate and acetamide, each of which holds the same total solute concentration of 0.2 mole of acetate plus amide to 1000 g. of solution.

The results of the analysis of the equilibrium mixtures studied are given in Table II. They are shown graphically in Fig. 2

TABLE II

RESULTS OF ANALYSES

Tube	Concn. (moles amide + acetate in 1000 g. soln.)	Temp., °C.	Time of heating, days	Spec cond. at 0.2 *M* concn.	Total solute in form of amide, %
14	0.5	172	5	1.527×10^{-2}	8.4
15	0.5	172	5	1.521×10^{-2}	8.7
6	1	172	5	1.474×10^{-2}	11.6
7	1	172	6	1.474×10^{-2}	11.6
18	2	172	5	1.356×10^{-2}	19.3
19	2	172	5	1.356×10^{-2}	19.3
10	0.5	184	2	1.514×10^{-2}	9.2
11	0.5	184	2	1.514×10^{-2}	9.2
4	1	184	2	1.441×10^{-2}	13.8
5	1	184	2	1.437×10^{-2}	14.0
1	2	184	2	1.305×10^{-2}	
2	2	184	2	1.319×10^{-2}	21.9
3	2	184	2	1.319×10^{-2}	21.9
16	0.5	193	2	1.470×10^{-2}	11.9
17	0.5	193	2	1.467×10^{-2}	12.1
8	1	193	2	1.407×10^{-2}	15.9
9	1	193	2	1.407×10^{-2}	15.9
12	2	193	2	1.289×10^{-2}	24.0
13	2	193	2	1.289×10^{-2}	24.0

Identity in composition of Tubes 6 and 7 indicates that equilibrium was established within about five days at 172°, a temperature not used by Mr. Brodie.

For comparison, part of the data obtained by Mr. Brodie, through use of the refractometer as a means of analysis, are quoted. He determined the percentage of amide and of ammonium acetate at equilibrium by comparing the refractive index of the mixture with those of pure amide and pure acetate solutions of the same concentration. A refractive index–concentration curve for acetamide solutions and for ammonium acetate solutions, each plotted in the same coordinate frame, gave two converging and almost straight lines. The value for any mixture, of

Approached from opposite sides, solutions of the same total solute concentration and at the same temperature always gave, at equilibrium, identical refractive readings, giving confidence in the purity of the amide and acetate used, and in the absence of side products.

Full treatment of the system under consideration would involve a knowledge of the ionization and of the hydrolysis of ammonium acetate at the concentrations and temperatures used. A. A. Noyes and co-workers[3] have determined such data for ammonium acetate in less concentrated solutions, at highest, approximately 0.01 molar.

An attempt was made to measure the equilibrium at this lower concentration. This failed, the results being quite irregular. In this attempt, refinements were made in the method of attaining equilibrium that will be mentioned.

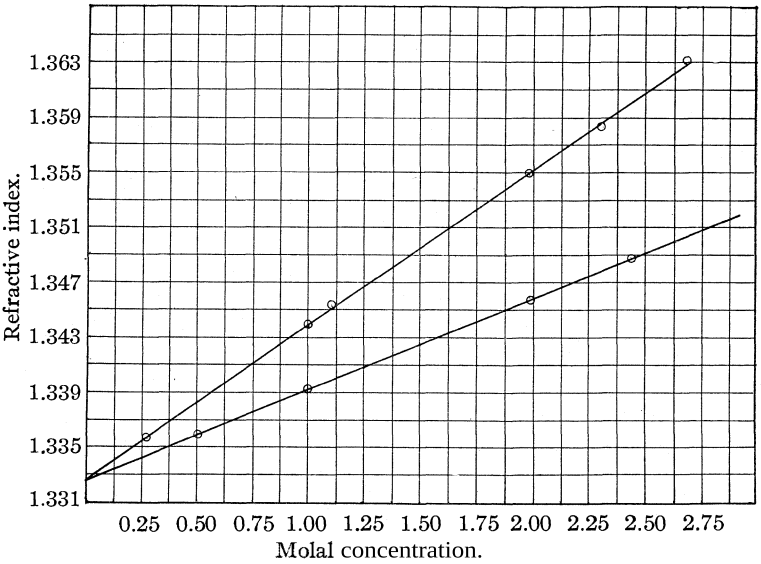

Fig. 3.

Though nothing of quantitative sort is known of the effect of the dissolved glass on the reaction itself, or of the effect of the reacting substances on the solubility of the glass, a brief study was made of the change

TABLE V

[3] A. A. Noyes, "The Electrical Conductivity of Aqueous Solutions," Carnegie Institute, 1907.

in conductivity of water when sealed in pyrex glass tubes of 5 to 10 cc. capacity and heated. The results are given in Table V.

The errors in the results due to this glass solubility at such concentrations as those recorded in Table II would be small, and likely within other errors of the method.

To minimize the effect of the solvent action on the glass, and that of the necessary residual gas space in the reaction tube, a different form of tube was designed, shown in Fig. 4. The glass tube A contains the loosely covered platinum cylindrical vessel D. The cover is kept in place by the platinum wire E. Tube A is connected to Tube B, and Tube B to Tube C by capillary tubing. The solution fills the apparatus to a suitable level in C, thus limiting to C any change in concentration due to evaporation into the gas space. The portion of the solution subjected to analysis is that contained in the platinum vessel. These precautions did not avail to give consistent results with solutions as dilute as 0.01 molar. A 2 molar solution of amide heated for two days at 184° in such a tube, then diluted to 0.2 molar, had at 25° a specific conductance of 13.36 X 10^{-4}, corresponding to 20.7% of amide remaining, and agreeing fairly well with the 21.9% of Table II.

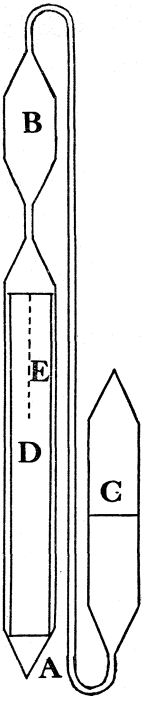

Fig. 4.

Examination of the data of Table II brings out that the ratios of the equilibrium concentrations of amide to those of ammonium acetate, including in the latter its dissociation and hydrolysis products, show, at a given temperature, no tendency to constancy. Such tendency is shown when the concentrations of amide are divided by the squares of the acetate concentrations (Table VI), indicating that the amide is formed through the interaction of the ammonium and the acetate ions.

TABLE VI

RELATIONS OF AMIDE AND ACETATE CONCENTRATIONS

Temp , °C.	Concn. of amide	Concn of acetate	$\frac{\text{Concn of amide}}{(\text{Concn. of acetate})^2}$
172	0.043	0.457	0.200
172	.116	.884	.148
172	.386	1.614	.148
184	.046	0.454	.2231
184	.139	.861	.1875
184	.438	1.562	.1795
193	.06	0.44	.31
193	.159	.841	.225
193	.48	1.52	.208

In Table VI the compositions are in moles per 1000 moles of solution.

Owing to the small concentration of amide, the first value for each temperature is the least accurate.

The conclusion that the amide is formed through the ions is in accord with such results as those of Walker and Hambly,[4] who show that the transformation of ammonium cyanate into urea is bimolecular

Summary

Results are given of measurements of the equilibrium between ammonium acetate, acetamide and water in aqueous solution at several temperatures and at several concentrations.

Evidence is presented that the amide is formed through the ions of the salt.

THE ACTIVITY COEFFICIENTS OF IONS IN VERY DILUTE METHYL ALCOHOL SOLUTIONS[1]

BY JOHN WARREN WILLIAMS[2]

RECEIVED NOVEMBER 7, 1928 PUBLISHED APRIL 5, 1929

The fundamental equations of the activity theory of Debye and Hückel[3] have been amply verified in solutions in which pure water was used as the solvent. The validity of the fundamental equations with respect to the effect of the variation of the dielectric constant of the medium has not been sufficiently investigated, although it has been attempted in a number of cases.[4] For the work to be reported in this article the papers by Kraus and Seward[4e] and by Robinson[4f] are perhaps of greatest interest because they have used the same method to determine their activity coefficients and have used non-aqueous solvents. The purpose of these articles, as well as of the present one, is to attempt a verification of the

---

[4] Walker and Hambly, J. *Chem. Soc.*, ***67,*** 753 (1895).

[1] The work reported in this article was carried out during the months of November and December, 1927, under the direction of Professor J. N. Brönsted. At that time the work could not be continued and extended; therefore, it was withheld from publication In the meantime articles by Kraus and Seward and by Robinson, to which references will be made, have appeared which make it desirable to publish the results to date. The continuation and extension of the work has now been begun at the University of Wisconsin.

[2] National Research Council Fellow in Chemistry.

[3] Debye and Hückel, *Physik.* Z., 24, 185 (1923).

[4] ((a) Scatchard, THIS JOURNAL, ***47,*** 2098 (1925); (b) Noyes and Baxter, *ibid.*, ***47,*** 2122 (1925); (c) Nonhebel and Hartley, *Phil.* Mag., 50, 729 (1925); (d) Baxter, THIS JOURNAL, 48, 615 (1926); *(e)* Kraus and Seward, J. *Phys. Chem.*, **32,** 1294 (1928); (f) Robinson, *ihid.*, **32,** 1089 (1928); (g) Bronsted and Williams, THIS JOURNAL, 50, 1338 (1928).

manner in which the activity coefficient of the ions varies with the dielectric constant of the solvent in solvents whose dielectric constants differ from that of water by a considerable amount. According to the theory, it will be recalled that in a sufficiently dilute solution

$$-\log f_i = \frac{3}{2.3}\,\alpha z_i^2\sqrt{\mu}$$

and

$$-\log f_s = \frac{3}{2.3}\,\alpha z_1 z_2\sqrt{\mu}$$

where α is a constant depending only upon the dielectric constant of the solvent, D, the absolute temperature, T, and a numerical constant. The quantity f_i is the activity coefficient of an ion of the i^{th} sort, while f_s is the activity coefficient of the salt itself.

The activity coefficient of either ion or salt varies inversely with the product of the dielectric constant of the solvent by the absolute temperature, raised to the three-halves power.

$$-\log f \sim \frac{1}{(DT)^{3/2}}$$

Kraus and Seward conclude that their results are not at all in agreement with the interionic attraction theory. The activity coefficients were determined by means of the effect of solvent salts, sodium nitrate and ammonium nitrate, on the solubility of sodium chloride in *iso*-propyl alcohol, and by means of the effect of the solvent salt sodium nitrate on the solubility of sodium bromide in acetone. Kraus and Seward state, "The divergence of the experimental results from those required according to the interionic attraction theory bears no apparent relation to the dielectric constant. In order to bring the observed values in the more dilute solutions into conformity with the theory, it would be necessary to assume for the dielectric constant the value 5.3 for acetone with sodium bromide and sodium nitrate; 7.2 for isopropyl alcohol with sodium chloride and sodium nitrate, and 11.4 with sodium chloride and ammonium nitrate." Robinson, in studying the effect of four solvent salts of two valence types on the solubility of potassium bromide in acetone, finds that the observed solubilities are all greater than those demanded by the theory. The increases in solubility are, however, of the right order of magnitude to be expected from the Debye-Hückel theory, and Robinson suggests that traces of water in his acetone may account completely for the differences found. The dielectric constant of these solvents, acetone and isopropyl alcohol, is in the neighborhood of twenty.

The measurements to be reported in this article were made in pure methyl alcohol at 20°. Using the value 30 for the dielectric constant of the alcohol at this temperature,[4c] the equation for the activity coefficient of the salt, f,, becomes

$$-\log f_s = 2.02122\sqrt{\mu}$$

where z_1, z_2 = valence of the ions in question; μ = ionic strength. The more complete Debye-Hückel equation which takes into account an atomic diameter has not been used in the discussion to follow.

Experimental

The activity coefficients were determined by means of the effect of solvent salts of two valence types on the solubility of highly insoluble saturating salts, also of two valence types. An apparatus of the usual type for solubility work was used for the preparation of the saturated solutions. The following systems were studied: (I) solvent, methyl alcohol; saturating salt, croceo chloride; *solvent* salts, sodium benzenesulfonate, potassium sulfocyanate, barium chlorate, strontium benzoate;—(11) solvent, methyl alcohol; saturating salt, chloropentammine cobalt nitrate; solvents salts, potassium sulfocyanate, barium chlorate;—(III) *solvent*, methyl alcohol; saturating salt, xantho chloride; solvent salts, potassium sulfocyanate, barium chlorate, strontium benzoate.

The analyses were made by measuring a fixed quantity of the saturating solution, adding sufficient sodium hydroxide solution and distilling the ammonia liberated on boiling into a known quantity of standard acid through a quartz condenser tube. Brom cresol purple served as indicator in making the titrations.

The methyl alcohol used was purified by the method described by Bjerrum and Zechmeister.[5] The various complex cobalt ammine salts were prepared and purified according to directions given in the original works of Jorgensen and Werner. The various solvent salts used, with the exception of the strontium benzoate, were Kahlbaum chemicals of "C. P." grade. The strontium benzoate was specially prepared in this Laboratory. These solvent salts were tested for ammonia before use.

Results

The solubility relations of the saturating salts in the various solvents are given in Tables I to III. The solubility is given in a great majority of the cases as either the average of two or four independent determinations, of which the individual values do not differ from their mean by more than 0.4 of 1% in any case. The concentrations in the tables are moles per liter.

Discussion

The values of the logarithm of the solubility ratio, log S/S_0, obtained directly from the analytical data have been plotted against the square roots of the ionic strengths and the limiting slopes of the resulting curves determined. In order to show the type of curves obtained, the data of Table I are represented graphically in Fig. 1.

The comparison of the limiting slopes obtained for the different systems with those predicted on the basis of the Debye-Hückel theory is interesting. These data have been collected to form Table IV.

TABLE IV

COMPARISON OF EXPERIMENTAL AND THEORETICAL SLOPES

Saturating salt	Valence type	Solvent salt	Obsd lim. slope	Theor. slope	Agreement
Croceo chloride	1–1	$C_6H_5SO_2ONa$	1.7	2.0	Satisfactory
Croceo chloride	1–1	KSCN	1.7	2.0	Satisfactory
Croceo chloride	1–1	$Ba(ClO_3)_2$	2.5	2.0	Approximate
Croceo chloride	1–1	$Sr(C_6H_5COO)_2$	1.7	2.0	Satisfactory
Chloropentammine cobalt nitrate	2–1	KSCN	4 0	4.0	Satisfactory
Chloropentammine cobalt nitrate	2–1	$Ba(ClO_3)_2$	8	4.0	Very poor
Xantho chloride	2–1	KSCN	4.0	4.0	Satisfactory
Xantho chloride	2–1	$Ba(ClO_3)_2$	6	4.0	Poor
Xantho chloride	2–1	$Sr(C_6H_5COO)_2$	6	4.0	Poor

An inspection of the table shows that in sufficiently dilute solutions the limiting law of Debye and Hückel is obeyed. In the case of the simplest type salt, croceo chloride, the value observed for the slope in the case of three solvent salts, namely, 1.7, must be considered to be in satisfactory agreement with the theoretical slope, 2.0. It may be recalled that in water solution a salt of this type gives a slope of the order of magnitude 0.45 instead of 0.50 as demanded by the theory.[6] Thus a slope is found in methyl alcohol solution, which, as is the case in water solution, is from 10 to 15% lower than that demanded by the theory.

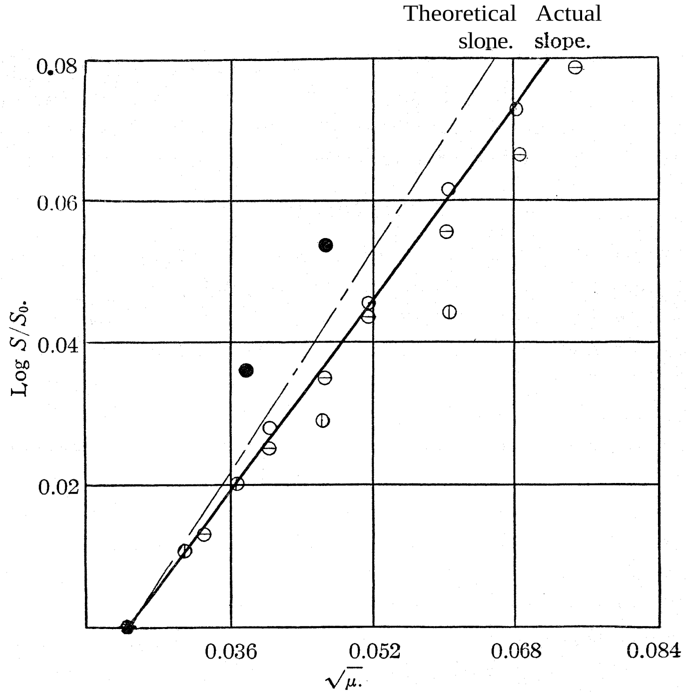

Fig. 1.—Solubility relations of uni-univalent salt croceo chloride in methyl alcohol at 20". Solvent salts: ○, KSCN; ⊖, $C_6H_5SO_2ONa$; ⦶, $Sr(C_6H_5COO)_2$; ●, $Ba(ClO_3)_2$.

The slope found when barium chlorate is used as solvent salt is considerably higher than that demanded by the theory, not only in the case of the 1–1 valence type salt but also in the case of both 2–1 valence type salts used. The explanation appears to be that either barium chlorate is not suitable for use as a solvent salt with any of the saturating salts used, or specific interactions of the ions interfere in the solubility effects produced. It may be mentioned that this substance was used as a solvent salt in less exact measurements on the solubility of the bi-univalent salt rhodanopentammine nitrate, and it was found that the resulting slope was of the order of magnitude 3 to 3.5, a value which is much more nearly that predicted by the theory. Rhodanopentammine nitrate is soluble

[6] Bronsted and Brumbaugh, THIS JOURNAL, 48, 2018 (1926).

only to the extent 0.00005 mole per liter and analyses could not, with the means available at the time of these experiments, be made with the same degree of accuracy as those for which results are given in the tables above. Therefore, the fact that slopes in closer agreement with the theory were not found when barium chlorate was used as solvent salt is not considered to be due to a failure of the theory.

In the case of salts of valence type 2–1, the theory is exactly obeyed when potassium sulfocyanate is used as solvent salt, but less exactly when strontium benzoate is used. However, it is probable that with salts of higher valence types, the theory will not be obeyed at concentrations of the order of magnitude reported in this communication.

Conclusions

The important fact indicated by the work which has been done to date is that if the solutions are made sufficiently dilute, the Debye and Hiickel theory will be obeyed in methyl alcohol solutions, at least for saturating salts of the simpler valence types. The range of applicability of the theory will probably depend upon the solute as well. It is not possible with the data available at the present time to discuss this point.

Further, it appears that as the dielectric constant of the solvent medium decreases, the highest concentration at which the simple activity theory will be obeyed also decreases. Thus in the case of a saturating salt of valence type 1–1, dissolved in water, and using a solvent salt of like type, the Debye-Hückel limiting law is obeyed to a total salt concentration of approximately 0.01 molal, but when suitable salts of the same valence types are dissolved in methyl alcohol, the limiting law is obeyed only to a total salt concentration of 0.002 molal. If acetone or isopropyl alcohol is used as a solvent, it would then be expected that an agreement with the theory could be obtained only if a total salt concentration of something less than 0.001 molal is used. It must be remembered, too, that the saturating salts which are suitable for the purpose under discussion must meet a number of criteria, not only as regards their own solubility but also in relation to the solvent salts which can be used with them.

These results indicate the importance of studying the interionic attraction theory in media whose dielectric constants are between that of water and of methyl alcohol. In this manner the limiting concentrations for which the theory will be obeyed for each of the different valence type salts will be ascertained. It is evident also that the study of the effect of various solvent salts on the solubility of a given saturating salt in the various media is of importance, particularly from the standpoint of the principle of the specific interaction of ions proposed by Brönsted.[7]

The author takes this opportunity to thank Professor J. N. Bronsted for facilities placed at his disposal and for his constant advice and encouragement during the course of the work. It is also a pleasure to thank Mr. E. Güntelberg, also of this Laboratory, for discussions of the subject matter.

Summary

1. The activity coefficients of several slightly soluble complex cobalt-ammine salts of the simpler valence types have been determined in pure methyl alcohol by the solubility method. These data have been utilized to test the validity of the simple Debye and Hückel equations.

2. The important conclusion to be drawn is that in sufficiently dilute methyl alcohol solution and using saturating and solvent salts of the simpler valence types, the general ideal equations of Debye and Hückel are obeyed. It seems probable that the range of applicability of the theory will depend also upon the solute used.

DIFFERENTIAL POTENTIOMETRIC TITRATION. III. AN IMPROVED APPARATUS AND ITS APPLICATION TO PRECISION MEASUREMENTS

BY DUNCAN A. MACINNES AND MALCOLM DOLE

RECEIVED NOVEMBER 8, 1928 PUBLISHED APRIL 5, 1929

Introduction

Since the first paper on this subject by MacInnes and Jones[1] several articles have appeared[2] which contain criticisms of the method or offer suggestions as to changes in the apparatus. An objection to the original arrangement has been that the electrode and shield as used by MacInnes and Jones is complicated and difficult to construct. There are, we have found, additional disadvantages. In the first place, as originally designed

---

[1] (a) MacInnes and Jones, THIS JOURNAL, 48, 2831 (1926); (b) MacInnes, *Z. physik. Chem.*, (Cohen-Festband), 217 (1927).

[2] (a) W. A. Roth, *Z. Electrochem.*, 33, 127 (1927); (b) Rabinowitch and Kargin, *ibid.*, 34, 311 (1928); (c) Hall, Jensen and Baeckström, THIS JOURNAL, 50, 2217 (1928). In two recent papers Erich Muller [(d) *Z. physik. Chem.*, 135, 102 (1928); (e) *Z. angew. Chem.*, 41, 1153 (1928)] claims first publication of the idea of a retarded electrode and, by implication at least, of the method of differential titration. As evidence he refers to a paper [(f) *Z. Electrochem.*, 31, 323 (1928)] in which data on pairs of bimetallic titrations are given. In one of each pair one electrode was wrapped with asbestos, thus hindering diffusion. We consider Müller's claim to priority on this evidence as rather fantastic. The first differential titrations were performed by Cox, THIS JOURNAL, 47, 2138 (1925).

it is difficult to make a shield in which the retained solution will not be disturbed by vigorous stirring. Also quite a number of up and down movements of the cap shielding the retarded electrode are necessary, after a reading, to make sure that the concentration of the solution around the two electrodes is the same. This has the effect of slowing up a determination. A still more serious disadvantage is that the sheltered electrode is permanently attached to the apparatus with the result that it cannot be changed if "poisoned," or if it is necessary to change the type of electrode used.

The New Apparatus

In order to overcome these defects we have designed and tested the differential apparatus shown in Fig. 1. The retarded electrode E is surrounded by a tube A having a capillary outlet C at the bottom. Solution from the beaker is circulated over the electrode by means of a simple gas lift L operated by a stream of gas passing through the tube G. By stopping the gas stream the portion of the solution in the tube A is isolated from the bulk of the solution, and does not react when the titrating solution is added from the buret B. On restarting the gas stream the solution in A is soon mixed with that in the beaker and the composition of the solution in this tube is made uniform with the bulk of the solution. The construction of the gas lift pump is easily within the powers of the amateur glass blower. The small hole H prevents the solution from running over the top of Tube A in case the gas stream is too rapid. The capillary C may be quite fine, but should not be small enough to be readily clogged. An advantage of this arrangement is that the electrodes E and E′ can be of any convenient form, are not attached to the apparatus, and can be changed, even, if necessary, in the course of a titration. The two electrodes may be fastened together using a small separator, and can then be placed astraddle the tube A.

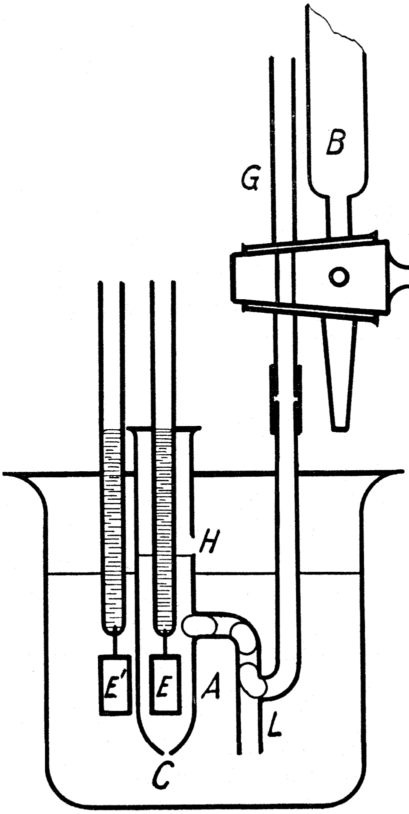

Fig. 1.

An additional convenience, but not altogether necessary for the operation of the apparatus, is the type of buret stopcock S as shown in Fig. 1. This stopcock is arranged so as to regulate the gas stream as well as the titration fluid. As shown the buret is closed and the flowing of the gas stream is producing circulation through the tube A. If, however, the stopcock is turned through a small angle the gas stream is turned off, thus isolating the solution in **A.** On turning still further the titrating fluid runs out of the buret. If the stopcock is turned back just enough to stop the flow of titrating fluid, the gas stream will not start and a reading of the potential between the electrodes E and E′ may be made. **A** short turn further causes the gas to flow again and renews the circulation.

Since this circulation soon produces uniformity in concentration throughout the apparatus the potential difference between the electrodes E and E′ should rapidly reach zero. If the electrodes are well adapted to the titration in hand this is found to be the case, except in the immediate region of the end of the titration where a short delay in attaining zero difference may be observed. We have found that observations of the speeds with which the zero is reached are of greatest use in determining the relative advantages for a particular titration of electrodes of different designs.

Titrations can be much more rapidly carried out if the operator does not have to set a potentiometer for each reading. The potential can be read directly in deflections of a galvanometer without polarizing the electrodes by means of one of the various forms of apparatus involving radio tubes. Arrangements for carrying out titrations in this manner have been described by Goode,[3] Treadwell[4] and others. A difficulty with most arrangements of this kind is that the zero is constantly shifting due to the sensitiveness of the radio tubes to slight changes in the current used for heating the filament. We have, however, found that the amplifier for ionization currents designed by Wynn-Williams[5] largely overcomes this difficulty and has far more than the necessary sensitivity for our measurements. Some measurements were also carried out with a potentiometer in the usual way.

The Combined Direct and Differential Procedure

An unexpected advantage of the apparatus shown in Fig. 1 is that the tube A can serve as a temporary reservoir for a small portion of the solution while a rough idea of the end-point is being obtained. To find this preliminary end-point the gas stream is stopped and the titrating solution is added until a large potential difference is found between the electrodes E and E′. This amounts to making a preliminary non-differential titration in the manner described by Müller.[2d] The potential during the titration, for instance, of an acid by a base follows a course like that shown by the dotted line O–x–a in Fig. 2. Now if the titration has not been carried too far beyond the point of inflection x of this curve and the solution has not become too basic it can be brought back to the acid side of the end-point by starting the gas stream. The material in the tube A will

---

then mix with the bulk of the solution and the difference between the two electrodes will return to zero. The exact end-point can then be found by the differential method as described above. At the final end-point the potential goes through a sharp maximum, as shown by the typical curve b–c–d. This procedure unites the advantages of the direct and differential methods, since the great bulk of the solution can be added rapidly and the precision and convenience of the newer method are retained. Ordinary titrations carried out by this method take very little more time than titrations involving the usual indicators, the limiting factor being the rapidity with which the electrodes respond to changes in concentration.

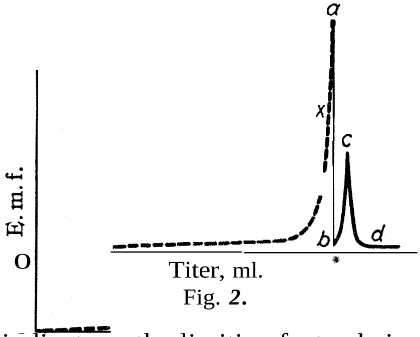

Fig. 2.

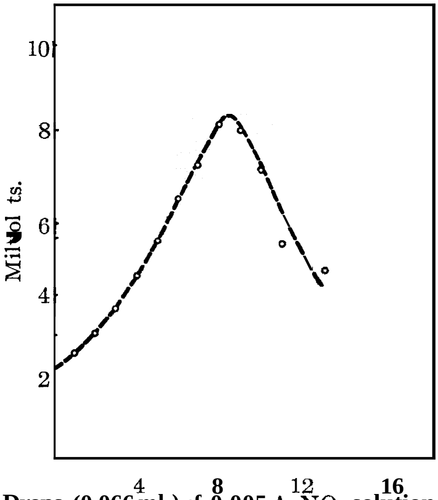
The Method Adapted to Precision Measurements

The main object of this investigation was, however, to continue the study commenced by MacInnes[1b] of the differential method as a means of making titrations of high precision. In such measurements the solution to be titrated was accurately weighed out into the beaker from a weight buret. With the gas stream stopped the titrating fluid was run from another weight buret until a point corresponding to a of Fig. 2 was attained. The titration was then continued by means of the differential procedure using, in the buret B of Fig. 1, the titrating fluid diluted in a known ratio, say 1 to 10 or 1 to 20. The success and accuracy of this procedure can best be judged by the results from the two different types of titrations outlined below.

The Titration of Ferrous Sulfate with Potassium Dichromate.—In a previous paper[1b] a failure was reported in the attempt to get accurate titrations of solutions containing ferrous ions, using the earlier differential technique, although the method yielded results of high accuracy for iodimetry and for the reaction between oxalic acid and potassium permanganate. The difficulty was probably due to an oxidation, catalyzed by the platinum electrodes, of the ferrous ions by atmospheric oxygen. We have, however, obtained excellent results by carrying out the titrations in an atmosphere of carbon dioxide. To this end a stream of that gas operated the lift pump and another stream bubbled through the solution to be titrated. A tall beaker was used in order to have a layer of the heavy gas between the solution and the air. The solution titrated was approximately 0.1 N ferrous ammonium sulfate. This was kept strongly acidified in an atmosphere of carbon dioxide during the measurements, and the volume of the solution drawn out of the container was replaced by that gas which was not, however, specially purified. The electrodes E and E′ were of smooth platinum gauze. Sixty to eighty grams of the acidified solution was weighed out into the beaker and 0.1 *N* potassium dichromate was added from a weight buret until the point a of Fig. 2 was obtained. The gas lift was then started and the titration continued with 0.01 N potassium dichromate, using increments of 0.1 cc., each of which corresponds to about 0.01%. However, the curve b–c–d is, in this case, extraordinarily sharp and definite, so that the true maximum could readily be interpolated to 0.002 or 0.004%. The data from a series of titrations are given in Table I, which is mostly self-explanatory. The figures in Col. 5 are the corrections to the weight of potassium dichromate solutions obtained from readings of the volumetric buret. The figures in Col. 6 show that there is a gradual increase in the ratio of the weight of the iron solution to the corrected weight of the dichromate solution. However, if these ratios are plotted against the times at which the individual titrations were carried out, a remarkably straight line is obtained. This result would follow if a slow oxidation of the ferrous sulfate solution occurred under the conditions of our experiments.



Drops (0.066 ml.) of 0.005 $AgNO_3$ solution.

Fig. 3.

TABLE I

TITRATION OF FERROUS SULFATE BY POTASSIUM DICHROMATE

Expt.	Time, hours	Weight of ferrous soln., g	Weight of $K_2Cr_2O_7$, g.	Corr. to wt. of (4)	Ratio, wt. $Fe/K_2Cr_2O_7$	Ratio at zero, time
1	0	86.064	76 284	0 067	1.12722	1.12722
2	26	62.070	54.694	.266	1.12937	1.12702
3	30	63.081	55 673	.115	1.12991	1.1271_9
4	31.5	66429	58.740	.048	1.12998	1.1271_2
5	122	60.500	53.115	.044	1.13810	1.1270_3
6	123.5	65.119	57.180	.031	1.13822	1.1270_2
7	126	76.718	67.331	.051	1.13855	1.12712

An idea of the accuracy of the measurements can be obtained by correcting all the ratios to zero time by means of the slope of the line just described. The ratios thus corrected, given in Col. 7 of the table, show a maximum variation of 0.02%. Apparently no rapid reaction with the oxygen of the air took place during a determination, as was found in the earlier experiments.

The Titration of Chloride Solutions with Silver Nitrate.—We have, however, been more interested in developing a rapid, convenient method for titrating chlorides as the necessity for this analysis occurs frequently in our work. Lange and Schwartz[6] describe, in a most excellent paper from which we have obtained many useful suggestions, a research in which they carried out direct electrometric titrations the results of which showed mean variations of only 0.003%. To get this precision required, however, elaborate precautions to prevent diffusion of chloride from the calomel half cell, and of the solution to be titrated into the salt bridge. They found it necessary to use an opposing flow of chloride-free ammonium nitrate solution to overcome the effects of these diffusions.

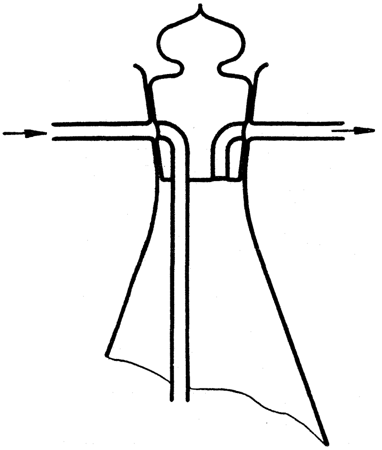


Fig. 4.

The procedure in our titrations followed that already described for the ferrous sulfate solutions with necessary changes to be outlined below. The solution to be titrated was an accurately prepared tenth (weight) normal potassium chloride solution made from the fused sodium-free salt. The titrating solution was approximately 0.1 N silver nitrate. The last part of the titrations was carried out with this solution diluted in the ratio 1 to 20. Following the suggestions of the authors just mentioned the titration was made with the beaker immersed in an ice-bath, and the solution in it was kept down to the smallest possible volume. Some of the electrodes used in this titration were made by coating a platinum wire with a paste of silver oxide and heating,[7] and with others the platinum was silver plated. The latter form of electrode is apparently the better for this purpose. To prevent slowing up of the electrode reaction due to an adherent coating of precipitated silver chloride, the upper part of the electrodes was given a vigorous tapping from the hammer of an electric bell. This tapping was also found necessary to keep the gas lift pump from clogging by the precipitated silver chloride. The entry tube of the solution to the gas lift was also given a slight constriction for the same reason. In these titrations a potentiometer was used instead of the Wynn-Williams bridge. A typical series of readings around an end-point are plotted in Fig. 3, indicating the magnitudes of the potentials and the definiteness of the curve.

[6] Lange and Schwartz, *Z.* Electrochem., 32, 240 (1926).

[7] Lewis, THIS JOURNAL, 28, 166 (1906).

The solutions were kept in two-liter Erlenmeyer flasks the necks of which were arranged as shown in Fig. 4. These flasks are particularly useful if it is desired to control the atmosphere above a solution. If the gas enters in the direction of the arrow it will bubble through the solution and eventually displace the air originally in the flask. To transfer the solution to another container the stopper is given a half turn. A flow of the gas in the same direction as before will then iorce the solution out of the flask. A quarter turn of the stopper will prevent the flow of either gas or solution. In the present work the air used to displace the solution was first bubbled through a solution of the same composition as that in the flask.

(a) The Titration of Potassium Chloride Solution.—The results of a series of titrations are given in Table II, with the ratios of the weights of the potassium chloride and silver nitrate solutions in the last column.

TABLE II

THE TITRATION OF 0.1 *N* POTASSIUM CHLORIDE WITH 0.1 *N* SILVER NITRATE

No.	Wt. KCl soln., g.	Wt. $AgNO_3$ soln , g.	Corr. to $AgNO_3$ soln.	Ratio $\frac{\text{wt. KCl soln.}}{\text{wt. AgNO}_3\text{ soln.}}$
1	38.858	39.441	0.030	0.98447
2	31.399	31.807	.088	.98445
3	39.875	40.359	.142	.98455
4a	25.589	25.970	.022	.98449
4b	25.639	25.970	.069	.98464
5	38.5304	39.0203	.1138	.98458

Of these determinations, that numbered 4b was made by adding more potassium chloride solution to the beaker and then going once more through the end-point, after the determination 4a had been made. Determination 5 was made with a separately prepared potassium chloride solution. The average of the last four figures was used in the computations which follow. The mean deviation (0.003%) is the same as that of Lange and Schwartz's measurements.

(b) The Analysis of Constant-Boiling Hydrochloric Acid.—Since we have, in this Laboratory, made much use of constant-boiling hydrochloric acid as a source of acid of known strength, it seemed desirable to determine whether the acid as we were preparing it had the strength assigned to it by the research of Foulk and Hollingsworth.[8] We have repeatedly proved the reproducibility of the concentration of successive distillations of the acid by means of conductance measurements. These showed that variations are not greater than 0.01%. The still, however, differs from that of the authors named in that it has a greater capacity (2 liters) and a larger condenser tube (1 cm. internal diameter). Also the rate of distillation was somewhat greater (7 cc. per min.) than they

---

[8] Foulk and Hollingsworth, THIS JOURNAL, 45, 1220 (1923).

used. The rate per unit of surface of acid is, however, within their recommended range.

Titrations of the middle fraction of the acid were carried out using the technique described in the last section, except that the acid had first to be neutralized. For this purpose a very nearly chloride-free alkali was prepared by recrystallizing sodium hydroxide twice from water. The resulting material, when neutralized, gave a barely perceptible turbidity with silver nitrate, certainly too little to affect the result. For analysis the constant-boiling acid was first diluted to 0.1 N and weighed portions of the dilute solution were titrated with the silver nitrate solution, standardization of which, against fused potassium chloride, is decribed in the previous section. The results of two titrations are given in Table III.

TABLE III

ANALYSIS OF CONSTANT-BOILING HYDROCHLORIC ACID

				% HCl	
No.	Wt. const.-boiling acid, g.	Wt. $AgNO_3$ soln., g.	Corr.	765.2 mm.	Corr. to 750 mm.
1	0.74385	41.8985	0.0823	20.2051	20.249
2	.71066	40.0368	.0676	20.2034	20.247
				Av.	20.248
				From Foulk and Hollingsworth	20.245

The column headed "weight of constant-boiling acid" is computed from the weight of the 0.1 N solution used by the accurately known factor of dilution. The last two columns contain the percentage of hydrogen chloride in the constant-boiling acid at 768 mm. and at 750 mm., the latter being obtained from the former by means of the factor (−0.0024%/mm.) used by Foulk and Hollingsworth. The usual corrections were applied to our barometer readings. The average of our determinations agrees remarkably closely with the value 20.245 given by those authors, whose measurements, however, ranged 0.004% above and below this. Foulk and Hollingsworth analyzed their solutions gravimetrically using the precautions, including the use of a nephelometer, developed at Harvard for atomic weight determinations. The outcome of this comparison of the gravimetric method with the differential potentiometric method is gratifying.

Conclusions and Comment

The differential potentiometric method using the improved apparatus has thus been shown to be suitable for rapid titrations of ordinary accuracy, and also for titrations of high precision. We feel sure that, using the technique already developed, still greater accuracy can readily be obtained.

Unless the counter-current method of Lange and Schwartz is used to overcome diffusion or convection of solution into the salt bridge, accuracy such as we have demonstrated cannot be obtained by the direct potentiometric method. Even with that device the solution is continually gaining in concentration of the solution used for the salt bridge. It is a desirable feature of the differential procedure that it introduces no extraneous material into the solution to be titrated. Another paper from this Laboratory will deal with the method as modified for the use of hydrogen electrodes.

From published comment[zb] it appears that there is uncertainty in the minds of some readers concerning the error involved in retaining a small proportion of the solution in the space around the retarded electrode, as, for instance, in Tube A of Fig. 1. A short consideration will show that the error E cannot be greater than

$$\frac{AT}{T} \times \frac{v}{V} > E$$

in which AT is the last increment of titrating solution, T is the total volume of this solution used and v and V are, respectively, the volume retained around the retarded electrode and the total volume. This is true because the final portion of titrating fluid reacts with all of the solution except a small proportion given by v/V. However, this small proportion of solution is only the fraction $\Delta T/T$ removed from the end-point. Thus if 50 ml. of solution are used with 0.1-ml. increments, and the tube A holds 4 ml. out of the 200 ml. in the beaker, the error will be

$$\frac{0.1}{50} \times \frac{4}{200} \times 100 = 0.004\%$$

Since such measurements are ordinarily made to one drop of solution, or about 0.1%, this error is negligible. In our work with weight burets the ratio $\Delta T/T$ is around 1/10,000 and the corresponding error is about 0.0002%, which is, of course, well within the experimental error.

Summary

An improved apparatus for differential potentiometric titration, involving a simple gas lift pump, is described. The usefulness of the method in analyses of high precision is shown in the titration of ferrous sulfate with potassium dichromate and of potassium chloride with silver nitrate. An analysis of constant-boiling hydrochloric acid, which agrees closely with the results of Foulk and Hollingsworth, has also been carried out.

APPLICATIONS OF CERIC SULFATE IN VOLUMETRIC ANALYSIS. V. POTENTIOMETRIC STUDY OF THE REACTION BETWEEN FERROCYANIDE AND CERIC IONS

BY N. HOWELL FURMAN AND OLIVER M. EVANS

RECEIVED NOVEMBER 10, 1928 PUBLISHED APRIL 5, 1929

Introduction

In previous papers of this series[1] it has been shown that solutions of ceric sulfate, containing sulfuric acid, are suitable for use in volumetric analysis, especially with the aid of the potentiometric method of determining end-points. Independently of this series of studies, H. H. Willard and Philena Young[2] and I. A. Atanasiu[3] have studied some of the uses of ceric sulfate in volumetric analysis. H. Rathsberg[4] has recently employed the reagent in the determination of antimony and arsenic as did Willard and Young[2] and Furman and Wallace (unpublished).

In addition to the advantages of ceric sulfate that have already been pointed out by the investigators whom we have cited, *viz.*, (a) stability, (b) high normal oxidation–reduction potential, (c) simplicity of valence change as contrasted with the relations in case of permanganate, there is another that is of some interest: (d) ceric salts are almost unique among the stable powerful oxidizing agents in having a cation as the primary active constituent.[5] In most of the other cases, that is, permanganate, dichromate, chlorate, bromate, iodate, etc., the active constituent is an anion, or at least can only be liberated by the destruction of an anion. Owing to mutual attraction of oppositely charged ions, ceric salts might therefore be expected to be somewhat more effective, other things being equal, in the oxidation of anions than dichromate, or even permanganate. This appears to be true in the oxidation of nitrite, for example.

The Reaction between Ceric Sulfate and Ferrocyanide.—The reaction $Ce^{++++} + Fe(CN)_6^{----} \rightleftarrows Ce^{+++} + Fe(CN)_6^{---}$ proceeds quantitatively from left to right in acid solution and quantitatively from right to left in alkaline medium (30% potassium carbonate solution). Browning and Palmer[6] used the latter reaction as a basis for the volumetric de-

termination of cerium. Tomiček[7] has shown that the end-point may be determined potentiometrically.

Atanasiu and Stefanescu[3] have published data on but a single titration of ferrocyanide with ceric solution, and give no test analyses regarding the accuracy of the method. They state that the concentration of sulfuric acid does not alter the inflection in any way. We find that there is a fairly definite upper limit of acidity. We have also studied the reverse titration.

Experimental

The potentiometric titration apparatus did not differ in any essential respect from that which was used in the earlier investigations of this series. The indicator electrode was a bright platinum wire; the reference electrode, a normal calomel electrode.

The ceric solutions which were used in this investigation were prepared from commercial rare earth oxides[8] containing 45% of CeO_2 (44.94 and 45.24% of CeO_2 [bismuthate method)].

Prior to ignition the material dissolves readily and practically completely in dilute sulfuric or nitric acid. After ignition it is readily decomposed by heating with concentrated or dilute sulfuric acid (1 vol. acid of sp. gr. 1.84 : 1 vol. water). Over 90% of the available cerium is found to be present in the ceric condition in the resulting solutions. A solution approximately 1 N in sulfuric acid and others from 3–4 N in acid were prepared; the latter solutions were found to be stable, whereas the former decreased slowly in strength.[9]

The ceric sulfate was standardized potentiometrically against pure sodium oxalate. Addition of hydrochloric acid as suggested by Willard and Young[10] makes the potentiometric standardization convenient, whereas in sulfuric acid solution the standardization is accurate, although extremely tedious.[11]

[7] O. Tomiček, Rec. *trav. chim.*, 44, 410 (1925).

[8] We are indebted to Dr. H. S. Miner of the Welsbach Company, Gloucester, N. J., for this material, which is a commercial rare-earth oxide mixture that is available in quantity. The mixture usually contains about 55% per cent. of CeO_2 on a dry basis, the other oxides being chiefly those of lanthanum and neodymium, with smaller quantities of praseodymium and samarium oxides. We have found this to be the best available raw material for the preparation of ceric sulfate solutions. *Cf.* also Willard and Young, THIS JOURNAL, 51, 149 (1929).

[9] The decrease in strength is not due to reduction but to the gradual precipitation of ceric ion in part, at least, in the form of phosphate. The phosphate occurs in the crude rare-earth oxides and is brought into solution by the more concentrated acid which is first used to dissolve the oxide. Upon dilution a gradual separation of ceric salt begins and may continue for a week, or even longer, depending upon the conditions of acidity and dilution of the ceric salt.

[10] Willard and Young, THIS JOURNAL, 50, 1325 (1928).

[11] Furman, ibid., 50, 761 (1928).

Potassium permanganate solutions were standardized potentiometrically against the pure sodium oxalate.[12]

Approximately 0.1 or 0.05 *N* potassium ferrocyanide solutions were prepared. The content of the solution was checked at frequent intervals by potentiometric titration with the potassium permanganate.[13] The data thus obtained were used as a basis of judging the accuracy of the titration of ferrocyanide with ceric sulfate.

Titration of Perrocyanide with Ceric Sulfate.—The titrations were made at room temperature (20–25"). Appropriate quantities of the ferrocyanide solution and of acid and water were measured out. The rate of addition of ceric salt had little effect upon the accuracy of the titration. The results are summarized in Tables I and II.

TABLE I

TITRATION OF APPROXIMATELY 0 05 *N* FERROCYANIDE WITH 0.05 *N* CERIC SULFATE

	1	2	3	4	5	6
Initial acid concn , N	...	1.5	5 0	...	0.5	0.8
Ceric soln. found, cc.	25.30	2531	25.34	25.11	25.11	25.08
Ceric soln. calcd., cc.	25.32	25.32	25.32	25.09	25.09	2509
Error, cc.	−0.02	−0.01	+0.02	+0.02	+0.02	−0.01

The total initial volume was 100 cc.; in Nos. 2 and 3 the acid was hydrochloric, in 5 and 6, sulfuric.

Weighed portions of a dried specimen of "C. P." commercial potassium ferrocyanide required, respectively, 0.13, 0.17, 0.17, 0.14, 0.13 and 0.10% less than the calculated quantity of ceric sulphate. Unpurified potassium ferrocyanide would probably serve as a secondary standard in much the same way as does "C. P." Mohr's salt.

[13] E. Muller and H. Lauterbach, *Z.* anal. *Chem.*, 61, 398 (1922); I. M. Kolthoff, *Rec.* trav. *chim.*, 41, 343 (1922).

The general nature of the titration graph in the neighborhood of the end-point is indicated in Fig. 1. The character of the reverse titration is also indicated. The potential readings become steady almost at once except in the immediate region of the end-point, where the establishment of a steady potential reading requires one to three minutes, depending upon the conditions.

The concentration of acid should not be too high. With a ceric solution that is 1 N in sulfuric acid the initial concentration of sulfuric acid in the ferrocyanide solution should not exceed 5 N. If the initial acid concentration is too low, and if the acidity of the ceric solution is low, a white precipitate may be formed during the titration. With much more than 5 N original acid concentration, the end-point potential readings are established sluggishly, and some decomposition of the ferro- or ferricyanide may occur. With hydrochloric acid the results are excellent in the range 0.5–2 N. If the acid concentration is as high as 4 *N* at the end-point the rise in potential is not sharp.

The jump in potential at the end-point usually amounted to 0.15–0.25 volt per 0.05 cc. of 0.05 *N* solution, or 0.2–0.3 volt per 0.05 cc. of 0.1 N ceric solution.

The titration appears to be very accurate and much less circumscribed than the permanganate titration, where a very limited range of acidity is essential.

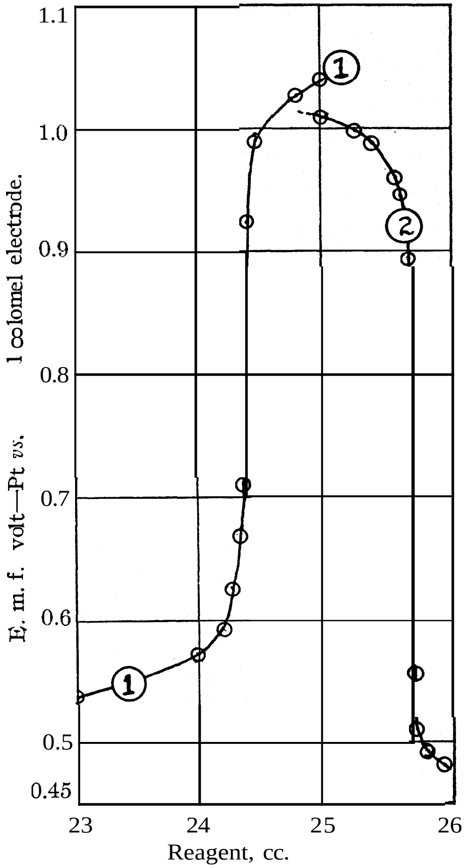

Fig. 1.—Curve 1, titration of 25 cc. of 0.1002 N ferrocyanide with 0.1027 N ceric sulfate. Initial volume, 60 cc. 1 N in sulfuric acid. Found, 24.36. Calcd., 24.37 cc. of ceric sulfate. Curve 2, the reverse of (1). Initial volume 75 cc., about 1 N in sulfuric acid. Calcd., 25.65 cc. Found, 25.66 cc. of ferrocyanide.

Visual End-Point.—During the titrations with ceric sulfate a greenish coloration is formed during the progress of the titration. This is apparently due to the formation of ferric ferrocyanide with a trace of iron that is found to be present in the ceric solution (thiocyanate reaction). Apparently the excess of ferrocyanide aids in keeping the ferric ferrocyanide in colloidal form.[14] The greenish coloration disappears quite sharply at the end-point when the last traces of ferrocyanide are oxidized.

It is possible to use the disappearance of the greenish color as a visual indication of the end-point. During the potentiometric studies the color end-point was observed to precede the potentiometric by 0.03, 0.00, 0.03, 0.00, 0.00, 0.04, 0.03 and 0.02 cc. The background was not very satisfactory for observation of the color change in these cases. A series of determinations was made by the visual method using a white tile background: found, 23.47, 23.48, 23.50, 23.49 cc. of approximately 0.1 N ceric solution per 25 cc. of ferrocyanide. Twenty-five cc. portions of the ferrocyanide were then titrated potentiometrically: found, 23.47, 23.47, 23.51, 23.49 cc. of ceric solution. The two methods are therefore in excellent agreement.

A portion of the ceric solution was treated with a slight excess of hydrogen peroxide and then boiled to decompose the latter. After appropriate dilution and withdrawal of an aliquot portion, the iron was estimated colorimetrically to be 1.00 ± 0.05 mg. per 25 cc. of ceric solution.

If a trace of ferric iron is added to a ferrocyanide solution that is being titrated with permanganate, the same greenish coloration forms and is destroyed in the same manner at the end-point.

Titration of Ceric Sulfate with Ferrocyanide.—This titration is only practicable under very limited conditions. The most important single factor is speed of titration. If the rate of titration is too small some ceric sulfate is apparently consumed by a side reaction, probably with ferricyanide, and too little ferrocyanide is used. For example, if the titration was interrupted after addition of 10 and 20 cc. of ferrocyanide, respectively, in order to take potential readings, only 25.53 cc. of ferrocyanide was required instead of 25.65 cc., the calculated quantity. The erratic nature of the results is indicated by the following figures, cc. of ferrocyanide (0.1002 N) found:

1	2	3	4	5	6	7	8	9
25.17	25.34	25.27	25.44	25.41	25.51	25.55	25.53	25.57

The amount theoretically required was 25.65 cc. in each case. In No. 1 the rate of addition was 5 cc. per minute. In instances 2–5 a relatively large number of interruptions was made for potential readings. In cases 6–9 only two readings were taken, one after rapid addition of 10 cc. and the other after 10 cc. more of ferrocyanide had been added. The titrations were then finished slowly. Under like conditions of operation the results are quite reproducible but seriously in error.

If from 80 to 97% of the theoretical amount of ferrocyanide is added very rapidly (fifteen to twenty-five seconds) the titration may be finished in the usual manner and the results are accurate, as is indicated in Table III.

---

[14] *Cf.* G. Rossi and M. Marzari, *C. A.*, 22, 1262 (1928).

TABLE III

TITRATION OF 0.1028 *N* CERIC SULFATE WITH 0.1002 *N* FERROCYANIDE

Initial vol., cc.	55	50	50	50	75	75	100	100
Ferrocyanide soln., cc.	25.60	25.60	25.65	25.67	25.66	25.68	25.63	25.65
Error, cc.	−0.05	−0.05	±0 00	+0.02	+0.01	+0.03	−0.02	±0.00

In each case 25.65 cc. of ferrocyanide should have been used The initial acid concentration ranged from 1 to 2.5 N. In the first instance 20 cc. of ferrocyanide was added, within about fifteen seconds, to the well-stirred ceric solution; in the other cases from 24.5–25 cc. was added rapidly before any potential readings were taken. The break in potential per 0.03 cc. of ferrocyanide at the end-point amounted to 0.23–0.34 volt. The readings were steady except in case of the drop that caused the large break in potential. Prom one to three minutes were required before the reading was steady. A drop of ferrocyanide in excess caused the appearance of the greenish coloration and was a reliable indication that the end-point had been passed. The general character of the potential curve is indicated in Fig. 1.

Summary

The potentiometric titration of ferrocyanide with ceric sulfate has been found to be accurate throughout a wide range of conditions and can be recommended for precise work.

The reverse titration is only accurate if the major portion of the ferrocyanide is added very rapidly. This method cannot therefore be recommended for general application.

The presence of a small quantity of ferric iron in the ceric solution causes a greenish coloration (ferric ferrocyanide) which disappears sharply at the end-point of the oxidation of the ferrocyanide. This visual end-point is practically identical with the potentiometric one.

SINGLE CRYSTALS OF SILVER

BY E. W. R. STEACIE AND F. J. TOOLE

RECEIVED NOVEMBER 13, 1928 PUBLISHED APRIL 5, 1929

A large number of metallic single crystals have been prepared. Hauser[1] has obtained symmetrical etch figures on spherical single crystals of copper and silver which show the crystallographic form of the metal. Various other workers have obtained rods or wires which consisted of one crystal. As far as we are aware, however, large single metallic crystals possessing the characteristic external form have not been previously prepared.

Experimental

During the course of another investigation[2] some very pure silver was prepared. The method of preparation was to dissolve silver nitrate in water and allow the solution to settle: Silver chloride was precipitated from the filtered solution by the addition of hydrochloric acid. It was then reduced to the metal by boiling with invert sugar and sodium hydroxide. The precipitate was thoroughly washed with hot distilled water and fused to a button in a crucible under borax. Analysis of the purified silver showed 0.003% of copper, **0.001%** of lead and a trace of iron.

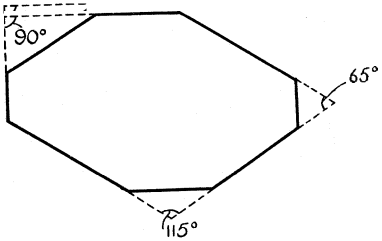

Fig. 1.—Cross section through prism.

A sample of this, weighing about **30** g., was accidentally fused owing to the failure of a thermostat, and was then cooled very slowly and kept just below the melting point for several days. The ingot, which was about 4 cm. long and **1** cm. in diameter, was treated with dilute nitric acid. After the action had continued for some time it was noticed that faces had appeared on the metal, and on examination it was found to be an octagonal prism weighing about 7 g. The crystal form is described later.

Apparently the original bar of silver consisted of a single crystal and the acid attacked the different faces in a specific manner, finally yielding an octagonal prism.

The fact that a well-defined crystal was obtained was undoubtedly due to the high degree of purity of the silver, which prevented any local electrolytic action such as would take place if impurities were present.

Hauser's crystals, prepared similarly by slow cooling, were turned into spheres on a lathe and then etched superficially with acids. The crystal-

---

[1] Hauser, *Ber. Siemens Konzern,* 1927.

[2] *Proc. Roy. Soc., London,* **117A, 662 (1928).**

line form was inferred from the shape of the resulting etch figures; in no case was the external form characteristic of the crystal obtained.

The preparation of crystals in this manner was repeated. Twenty grams of silver was placed in a quartz bulb in an electric furnace. The silver was melted and thoroughly evacuated to prevent spitting on solidification. It was necessary to shake the bulb during evacuation in order to prevent small bubbles of gas from sticking to the walls below the surface of the silver and causing irregularities in the ingot. The metal was then slowly cooled (about 5" per hour) and kept at a temperature of 940° for forty-eight hours. On treating with dilute nitric acid a crystal similar to the previous one, weighing about 4 g., was obtained.

In order to prepare satisfactory crystals it is necessary that the cooling should be slow and preferably from the bottom of the tube in order to avoid a pit at the surface. The presence of oxygen must be avoided.

We are indebted to Dr. R. P. D. Graham, Professor of Mineralogy at McGill University, who kindly examined the crystals and reported as follows.

> "The two crystals examined are prismatic in habit. Each has a diameter of about $^1/_4$ inch, and they are, respectively, $^7/_8$ inch and $^5/_8$ inch in length.
>
> "On both, there are eight faces in the prism zone, and some of them are surprisingly flat, although none are sufficiently so to yield images on the reflecting goniometer. Other faces are somewhat concave and irregularly pitted.
>
> "The longer crystal is terminated at one end by four ill-defined planes of the latter type, which form a pyramid whose apex is replaced by a tiny smooth face at right angles to the prism. The relation of these terminal faces to the eight faces of the prism zone is such as to suggest that the crystal is a combination of cube and dodecahedron elongated in the direction of a cubic axis. If such is the case, however, the crystal is highly distorted, as the angle between adjacent faces in the prism zone is not 45°, as it should be if they represent faces of the cube and dodecahedron.
>
> "Of these faces in the prism zone, four, taken alternately, are inclined to one another at 90°, and assuming the four terminal faces to be faces of the dodecahedron, these four prism faces also belong to the dodecahedron.
>
> "The remaining four faces in the prism zone are symmetrically disposed with regard to the first set, and together they would form a prism having an angle of about 65°. If, therefore, they arc faces of the cube, the crystal is much distorted. There is nothing, however, to indicate that the crystals are twinned. It is possible that the faces represent the development of two pairs of faces belonging to a four-faced cube (tetrahexahedron). The angle $hk0:kh0$ for the four-faced cube (510)is 67° 23′, and for the form (410) it is 61° $55^3/_4$′. The latter form has been observed on crystals of native silver."

Summary

Single crystals of silver can be prepared by slow cooling of the molten metal. Dilute acid attacks the faces in a specific manner, yielding prismatic crystals.

REACTIONS WITH VERY LARGE APPARENT TEMPERATURE COEFFICIENTS

BY LOUIS S. KASSEL[1]

RECEIVED NOVEMBER 27, 1928 PUBLISHED APRIL 5, 1929

During the last few months three reactions, of widely different types, have been reported to exhibit a dependence upon temperature considerably greater than is usual. R. P. Bell[2] studied the oxidation of benzoyltoluidine by potassium permanganate; the reaction taking place at a benzene–water interface; he reported a temperature coefficient of **13** for this reaction. The present author[3] has been unable to duplicate his results, and finds instead a value of about 2. Topley and Hume[4] investigated the dehydration of calcium carbonate hexahydrate crystals in the presence of liquid water; the reaction is apparently propagated throughout the separate crystals from active centers and the linear rate of propagation has a temperature coefficient of about 12. Patterson and McAlpine[5] have published measurements on the rate of decomposition of bornyl naphthalene-β-sulfonate, menthyl benzenesulfonate and menthyl naphthalene-β-sulfonate in toluene, nitrobenzene, ethylene dibromide, pyridine and methyl, ethyl, n-propyl, n-butyl and *sec.*-butyl alcohols. They did not investigate the effect of varying concentration or varying time of reaction (all their runs were for one hour), but only the dependence of percentage decomposition upon temperature. For the alcohols and pyridine they found a normal temperature coefficient, for toluene a very low one, while for ethylene dibromide and nitrobenzene the apparent temperature coefficient starts at a low value and increases rapidly; in a typical case, it increases from 1.5 to 150 in a 20° temperature range.

The purpose of the present paper is to discuss these latter measurements, to show how they may be accounted for by reactions with normal values for their separate temperature coefficients, and to make such other remarks upon the general nature of chemical reactions as the experiments suggest.

The Decomposition of Calcium Carbonate **Hexahydrate.**—Topley and Hume[4] have interpreted their experimental results to mean that the reaction is propagated throughout any given small crystal from reaction centers which arise on its surface; they have determined the approximate linear rate of propagation which this hypothesis requires and find

that at 0° the reaction front advances 0.135 layer of molecules per second. If we attempt to find a mechanism which will give this rather rapid rate, and at the same time account for the high temperature coefficient, considerable difficulty is encountered. By assigning a reasonable value to the vibration frequency, Topley and Hume calculated the fraction of the vibrations, β, which resulted in decomposition; they found 2.7×10^{-14}. They then pointed out that if reaction followed upon activation at a single degree of freedom, the expected value of β would be 10^{-33}, and even if, in analogy to the theory of unimolecular gas reactions, it was supposed that every molecule which acquired sufficient energy in 11 degrees of freedom (22 energy terms) decomposed, they found a value of β of only 2×10^{-25}.

It is possible to extend these calculations somewhat, on the basis of the more satisfactory form of the unimolecular reaction theory which has been given by Rice and Ramsperger and the author.[6] First it is found that, if the classical form of the theory is to be used, the number of degrees of freedom is to be taken as not more than half of the theoretically possible number; now $CaCO_3 \cdot 6H_2O$ has 23 atoms and therefore 63 internal degrees of freedom. Hence in our calculations we will take 30 degrees of freedom instead of the 11 used by Topley and Hume. We may now distinguish two possible courses which the reaction could take. It might be that practically every activation resulted in decomposition, that is, that during the time of a single vibration an activated molecule was almost sure to decompose. In this case the rate of reaction is equal to the rate of activation, and the fraction β of all vibrations resulting in reaction is simply the fraction W_E of the molecules which contain energy in excess of the critical energy E at any instant. If we have 30 degrees of freedom, $E = 41{,}300 + 29RT$, approximately. This gives $E = 57{,}000$, and at 0° $W_E = 10^{-18}$. This is still less than β by a considerable factor, which could not be changed much by any reasonable increase in the number of degrees of freedom.

A second possibility is that only a few of the activated molecules decompose. Then if the specific reaction rate depends upon the total energy in the way that the author has given for gas reactions, the mathematical theory of these reactions may be used without change. In particular, the simple relation $d \ln K/dT = E/RT^2$ is approximately restored. We calculate that $W_E = 5 \times 10^{-10}$, which is actually large compared to β. Thus the theory is self-consistent. There is nevertheless a very serious objection to this interpretation. If we consider only the molecules in the reaction front, and write for their reaction rate $K = Ae^{-E/RT}$, we calculate that $A = 10^{32}$. This value should be comparable with that

---

[6] **Rice** and Ramsperger, THIS JOURNAL, 49, 1617 (1927); 50, 617 (1928); **Rice,** *Proc. Nat. Acad. Sci.*, *14*, 113, 118 (1928); Kassel, *J. Phys. Chem.*, 32, 225, 1065 (1928).

of the same quantity in the unimolecular gas reactions. For the eight such reactions now well established, A ranges from 3×10^{11} to 9×10^{15}.[7] It seems rather unlikely, therefore, that a value as great as would be required here is acceptable. It is possible to say roughly what the physical meaning of A is; a large value of A means that the rate of transfer of energy within a molecule from one part to another is high; in terms of the quantum mechanics, this seems to mean that the interaction energy of the various oscillators is large. One would expect, from a general chemical standpoint, that the interaction energy would be less for a rather unstable coordination compound such as calcium carbonate hexahydrate than for a stable organic molecule. Azo-*iso*propane, with 22 atoms, is directly comparable with calcium carbonate hexahydrate, with 23; and azo-isopropane has $A = 4 \times 10^{14}$. On this basis it seems to the author necessary to reject the foregoing mechanism.

Thus it does not seem satisfactory to regard this dehydration as a single reaction with an energy of activation of approximately 40,000 calories. An alternative view is that the reaction occurs in steps. Now Topley and Hume have stated that there is no evidence for the existence of intermediate hydrates, but this only means that they do not occur in very large amount. We are dealing here with a surface reaction, and it would seem quite possible for an appreciable amount of the reaction front to consist of lower hydrates without any direct evidence of their existence being obtained. It remains to be seen whether a stepwise dehydration offers a satisfactory explanation of the temperature coefficient.

It is perhaps rather unlikely that the actual dehydration should require as many as six steps; partly for this reason, but more for the sake of simplicity, we shall consider the simpler case of a compound AB_3. We assume that the following reactions occur: (1) $AB3 = AB_2 + B$; (2) $AB_2 = AB + B$; (3) $AB = A + B$; (4) $AB_2 + B = AB_3$; (5) $AB + B = AB_2$. B corresponds to the water, which is always present during the experiments, and we may take its concentration to be constant and absorb it into the reaction rate constants. 'She other substances are all solids. We shall suppose that the reaction starts at an active center, perhaps a fault in the crystal, and is propagated from it in the following way: the layer of molecules surrounding this center is at liberty to react according to the scheme given above. When the reaction in this layer has acquired a definite degree of completion, the next layer starts to react; and this process continues until the entire crystal has decomposed. We further suppose that the first three reactions above all have the rate constant p, and that the last two have the constant q, where $p \ll q$. It is possible to carry through the analysis using different constants for each reaction, but there does not seem to be any profit in such a complication.

[7] Kassel, THIS JOURNAL, **50,** 1351 (1928).

Now for a layer just beginning to react we may write down the following equations

$$\frac{dx}{dt} = -px + qy \tag{1}$$

$$\frac{dy}{dt} = px - (q+p)y + qz \tag{2}$$

$$\frac{dz}{dt} = py - (q+p)z \tag{3}$$

$$\frac{dD}{dt} = pz \tag{4}$$

$$x(0) = a, \quad y(0) = z(0) = D(0) = 0 \tag{5}$$

where

$$x = [\mathrm{AB_3}], \quad y = [\mathrm{AB_2}], \quad z = [\mathrm{AB}], \quad D = [\mathrm{A}]$$

The symbol [ ] here means a *surface* concentration. To solve these equations for D it is most convenient to solve the first three of them for x. We differentiate (2) once, and (3) twice, and eliminate x and y and their derivatives from the six equations (1), (2), (2′), (3), (3′) and (3″). The resulting equation is

$$\frac{d^3z}{dt^3} + (2q+3p)\frac{d^2z}{dt^2} + (q^2+2pq+3p^2)\frac{dz}{dt} + p^3 = 0$$

It is well known that the general solution of (6) is

$$Z = Ae^{-m_1t} + Be^{-m_2t} + Ce^{-m_3t}$$

where m_1, m_2, and m_3 are the roots of

$$m^3 + (2q+3p)m^2 + (q^2+2pq+3p^2)m + p^3 = 0$$

The exact expressions for these roots are too unwieldy to use; it is more convenient to make use of the fact that $p \ll q$ and write down the approximate values.

$$m_1 = -p\left[\frac{p^2}{q^2+2pq+3p^2} + \text{terms in } \left(\frac{p}{q}\right)^5\right]$$

$$m_2 = -q\left[1 + \frac{3}{2}\frac{p}{q} - \sqrt{\frac{p}{q} - \frac{3}{4}\left(\frac{p}{q}\right)^2} + \text{terms in } \left(\frac{p}{q}\right)^{5/2}\right]$$

$$m_3 = -q\left[1 + \frac{3}{2}\frac{p}{q} + \sqrt{\frac{p}{q} - \frac{3}{4}\left(\frac{p}{q}\right)^2} + \text{terms in } \left(\frac{p}{q}\right)^{5/2}\right]$$

If we adopt the notation

$$\frac{p^2}{q^2+2pq+3p^2} = F \qquad 1 + \frac{3}{2}\frac{p}{q} = S \qquad \sqrt{\frac{p}{q} - \frac{3}{4}\left(\frac{p}{q}\right)^2} = R$$

these become, to the same approximation as before

$$m_1 = pF + \dots \qquad \begin{aligned} m_2 &= -q[S - R + \dots] \\ m_3 &= -q[S + R + \dots] \end{aligned}$$

It remains to evaluate the constants A, B and C. We know that at $t = 0$, $z = 0$, and it may also be shown that the initial conditions require $dz/dt = 0$. These conditions will be satisfied if

$$A + B + C = 0 \qquad -pFA - q(S-R)B - q(S+R)C = 0$$

Hence

$$C = \frac{S-R}{2R}A; \quad B = \frac{S+R}{2R}A$$

It is now easy to get D by integration; we find

$$\frac{D}{A} = \frac{1}{F}\{1 - e^{-pFt}\} - \frac{S+R}{S-R} \times \frac{p}{2qR}\{1 - e^{-q(S-R)t}\} + \frac{S-R}{S+R} \times \frac{p}{2qR}\{1 - e^{-q(S+R)t}\}$$

For small values of t all the terms must be considered, but when t is larger the first one becomes dominant; in fact, during almost the entire course of the reaction the other two terms are entirely negligible. The course of the reaction is shown in the following table for the special case $p = 0.01q$.

TABLE I

COURSE OF THE REACTION

qt	T_1	T_2	T_3	D/A
0.1	0.001	−0,00535	0.00438	0.00003
1.0	.01	− .03664	.02770	.00106
10.9	.10	− .06111	.04122	.08011
1000.0	10.00	− .Of3111	.04122	9.980
100000.0	952.9	− .06111	.04122	952.9
∞	10203	− .06111	.04122	10203

Here $T_1 = \frac{1}{F}\{1 - e^{-pFt}\}$

$$T_2 = -\frac{S+R}{S-R} \times \frac{p}{2qR}\{1 - e^{-q(S-R)t}\} \qquad T_3 = \frac{S-R}{S+R} \times \frac{p}{2qR}\{1 - e^{-q(S+R)t}\}$$

It is evident from this table that for all practical purposes, except when we are interested in the initial stage of the reaction, we need consider only the first term; but this term corresponds to a reaction with a rate constant given by

$$k = pF = p^3/(q^2 + 2pq + 3p^2)$$

We wish now to see whether this mechanism is in agreement with the experimental facts for the case of calcium carbonate hexahydrate. First we notice that it is possible to account for the temperature coefficient. If we put $p_1 = 0.01\,q_1$; $p_2 = 3p_1$; $q_2 = 1.5q_1$, where the subscripts 1 and 2 refer to temperatures 10° apart, we find $k_2 = 11.76\,k_1$. That is, if the dissociations have a temperature coefficient of 3, and the associations a temperature coefficient of 1.5, that of the overall reaction will be 11.76.

We must next show that it is possible for the dissociations to take place fast enough. The reaction front passes over 0.135 layer of molecules per second at 0°. If we suppose that the reaction begins in the next layer when the hydrate has been reduced to $1/e$ of its original concentration, and also that $p = 0.01\,q$, we can easily calculate that $p = 1350$. Then, writing $p = Ae^{-E/RT}$, and choosing E to make the temperature coefficient 3, we get E = 16,200 calories and $A = 10^{15}$. This value for A is reasonable and our experience in calculating the rates of unimolecular gas reactions convinces us that there will be no difficulty in producing activation fast enough.

It is also worth noticing that the reverse reactions can occur as fast as we have postulated. A temperature coefficient of 1.5 corresponds to an energy of activation of 6000 calories, and if we calculate the bimolecular rate in the manner used so successfully by Hinshelwood for gas reactions we find that 10^{-5} of the collisions could lead to combination. The actual bimolecular rate that we have assumed is 135,000; it seems reasonable to take the number of collisions per second equal to the vibration frequency, which Topley and Hume estimated as 5×10^{12}; if we do this we find that the fraction of successful collisions need only be 3×10^{-8}. It is, of course, not a source of difficulty that there are fewer successful collisions than would seem possible; if there had been an inequality in the other direction the scheme would have required modification.

It thus appears that the foregoing tentative explanation of the decomposition of calcium carbonate hexahydrate is perfectly consistent. There is no direct evidence supporting it, and it would seem very difficult to obtain any. Its chief merit is that it is one way, and the only way known at present, to account for the experimental results in this reaction; it shows that these results do not require any additions to the general reaction rate theory, as might at first sight be supposed.

The Decomposition of Menthyl and Bornyl Esters.—The work of Patterson and McAlpine was more from the organic than from the kinetic standpoint. They did not determine the order of the reactions and therefore did not calculate any reaction rate constants. In our analysis of their data we will first suppose that there is a homogeneous unimolecular decomposition, and calculate constants on that basis. For each ester–solvent combination we obtain a series of constants, one at each temperature. The results are of three types, illustrated by the following tables.

TABLE II

DECOMPOSITION OF MENTHYL BENZENESULFONATE IN TOLUENE

Temperature, °C.	85		90		95		100		105
% Decomp. = x	0.98		1.04		1.06		2.23		2.37
Log 100/(100 − x)	0.00428		0.00454		0.00463		0.00979		0.01042

Log 100/(100 − x)	0.01042		0.01211		0.02632		0.05983		0.74836
E_0		7870		40800		45600		140000	

TABLE IV

DECOMPOSITION OF MENTHYL BENZENESULFONATE IN BUTYL ALCOHOL

Temperature °C.	75	80	85	90	95	100	105
% Decomp. = x	4.10	6.77	10.85	17.27	28.15	45.14	60.23
Log $100/(100-x)$	0.01818	0.03044	0.04988	0.08234	0.14367	0.26074	0.40044
E_0		25200	24800	26000	29600	32600	24000

In these tables the first two lines are taken directly from the paper of Patterson and McAlpine; the numbers in the third line are proportional to the calculated unimolecular constants and those in the last are the values of the energy of activation calculated from the constants at two successive temperatures by the Arrhenius equation. Before proceeding further it may be well to point out that if constants were calculated for a bimolecular reaction, they would increase more rapidly at the higher temperatures where the reaction goes nearly to completion. Thus, if the data in Table III are calculated on the basis of a bimolecular reaction, the heat of activation for the first interval is unchanged, while that for the last is increased from 140,000 to 200,000, this latter value corresponding to a 31-fold increase in the rate for 5°. There are other cases in which the change is still more marked.

There does not seem to be any trend in the values of the heat of activation in Table IV. Similar results are found for each of the three esters whenever the solvent is an alcohol or pyridine. The average value of the energy of activation for each of the ester–solvent combinations of this type comes out 25,000 to 27,000 calories, which is to be considered as constant within the experimental error. It therefore seems altogether likely that the reaction is truly unimolecular in these solvents.

With nitrobenzene and ethylene dibromide as solvents, the results follow the type of Table III, in several cases with still more startling increases in the energy of activation. When an apparent increase in the energy of activation with increase in temperature is observed, it is usually to be ascribed to two reactions, either simultaneous or successive. Then in the normal case the energies of activation observed will be intermediate between the true energies of activation of the separate reactions; but since an energy of activation of 140,000 calories, corresponding as it does to a temperature coefficient of about 150, is utterly out of the question, it becomes necessary to seek some other explanation of the results. It occurred to the author that the reaction in these solvents might be autocatalytic. Investigation proved that it was actually possible to account for the type of result observed by a mechanism of this sort. If we write $dx/dt = a(A - x) + b(A - x)x$ and solve for x at $t = 1$, we find $x/A = (P - 1)/(P + R)$, where $R = bA/a$ and $P = e^{a(R+1)}$. Now if we assume appropriate values of a and R and let them vary with the temperature in the normal way, we can get x/A to have the type of temperature coefficient found experimentally. Two ways in which this may be done are shown in Table V.

TABLE V

CALCULATED RESULTS

(a)				(b)			
a	*R*	*Ab*	*x/A*	*a*	R	*Ab*	*x/A*
0.027	2.5	0.067	0.0275	0.027	10.24	0.276	0.0306
.036	5.0	.180	.0386	.036	17.92	.645	.0491
.048	10.0	.480	.0589	.048	31.36	1.51	.1033
.064	20.0	1.28	.1189	.064	54.88	3.51	.3834
.0853	40.0	3.41	.4385	.0853	96.04	8.19	.9739
.1137	80.0	9.10	.9920				

If it is supposed that the intervals in this table represent 5°, then the 10" temperature coefficient for the uncatalyzed reactions is $(4/3)^2$ or 1.78 in both cases; in (a) that for the catalyzed reaction is $(2\ X\ 4/3)^2$ or 7.11, while in (b) it is $(7/4\ X\ 4/3)^2$ or 5.44. It is not impossible that the catalyst should enter into the equation as a square, in which case somewhat smaller temperature coefficients for the catalyzed reaction would suffice; but there is no great objection to a value of 5 or so, and here again it must he urged that no importance attaches to the details of the calculation, only the general result being significant. It thus appears possible to account for the experimental results in nitrobenzene and ethylene dibromide by a combination of an uncatalyzed, probably unimolecular decomposition with a temperature coefficient in the neighborhood of 2, with a simultaneous decomposition, catalyzed by one of the reaction products, with a temperature coefficient that may be as great as 5 or 6, but may be somewhat lower.

It is hard to draw any definite conclusion about the decomposition in toluene; the sudden increase in rate between 95 and 100° shown in Table II is surely due to accumulated experimental error, and the table as a whole suggests a temperature coefficient of about 1.5; the other two esters have been studied over ranges of but 5 and 10°, respectively, and both show a temperature coefficient from 1.00 to 1.05. It is not at all certain whether the difference is real or not. A temperature coefficient of 1.2 or less would suggest heterogeneous catalysis, either by the walls or by dust particles, but there can be no certainty as to this without further data.

We have thus been able to account moderately well for all the experimental results by assuming three different types of decomposition: a heterogeneous catalyzed reaction, a homogeneous uncatalyzed one and a homogeneous catalysis by the reaction products. An explanation of this character cannot be considered satisfactory unless reasons can be produced for the changing importance of the various types as the solvent is changed. This is not hard to do; Patterson and McAlpine state that the products of the decomposition are a sulfonic acid and such substances as camphene and dibornylene as well as more complex hydrocarbon residues. Now hydrogen ion, and in particular unsolvated hydrogen ion, is the most notorious catalyst in all organic chemistry and it may well be the catalyst here. It is well known that pyridine and alcohol form complex ions with H^+ and the catalysis would thus be reduced in these solvents; the extent of the reduction is not easily predictable, but it is not surprising that the catalytic action is in fact practically stopped. Nitrobenzene and ethylene dibromide do not combine with H^+ to any appreciable extent, and thus in these solvents the catalysis is marked. We should expect it to be important in toluene also, but since in this solvent the decomposition obtained was always slight, it is impossible to tell whether this prediction is verified. The magnitude of the uncatalyzed reaction also varies in about the way we expect; it is greatest in the alcohols, which are the most polar solvents used, and greatest of all in methyl alcohol. In nitrobenzene, pyridine and ethylene dibromide the uncatalyzed rate is about the same, considerably less than in even butyl alcohol, while in toluene it is very much less than in any of the other solvents. The electric moment of the nitrobenzene molecule is known to be some 7 or 8 times that of toluene, so that the rate should be greater in nitrobenzene. Ethylene dibromide is symmetrical and should have a small or zero moment; there does not seem to be any available data as to this. If there is a wall reaction or a dust reaction it is probably independent of the solvent, but even though the entire reaction in toluene is due to this source, it would not be of importance in any of the other solvents. The qualitative variation of reaction rate with solvent for these decompositions is thus seen to be in agreement with theoretical predictions.

The remaining uncertainties as to the mechanism of these reactions could almost certainly be cleared up by a study from the kinetic standpoint. It does not appear to the author, however, of great importance that this should be done. The preceding analysis seems to leave little doubt that all the facts can be accounted for without introducing any new principles into reaction rate theory.

Summary

1. The possibility of regarding the decomposition of calcium carbonate hexahydrate crystals as a single reaction with a temperature coefficient of about 12 has been discussed; it appears that a reaction of this character is very improbable. It is then shown how the experimental results can be accounted for by assuming that the reaction occurs in steps, all but the last one being reversible.

2. The apparently strange behavior of the temperature coefficient of reaction rate in the decomposition of bornyl and menthyl sulfonates in certain solvents has been accounted for on the basis of autocatalysis by the resulting acid, and the general effect of the solvent upon these reactions bas been shown to agree with predictions based on the character of the solvent.

THE HEAT CAPACITIES OF ISOPROPYL ALCOHOL AND ACETONE FROM 16 TO 298°K. AND THE CORRESPONDING ENTROPIES AND FREE ENERGIES

BY KENNETH K. KELLEY[1]

RECEIVED NOVEMBER 28, 1928 PUBLISHED APRIL 5, 1929

The heat capacities of isopropyl alcohol and acetone have been studied by Parks and the author[2] from 70 to 298°K. Equilibrium measurements at several temperatures were also made for the reaction $CH_3CHOHCH_3 = CH_3COCH_3 + H_2$ in the gaseous state[3] in order to show that the third law of thermodynamics held, at least for all practical purposes, for this organic reaction. An exact test was not possible since heat capacity data for gaseous isopropyl alcohol and acetone were not available for extrapolating the results of the equilibrium measurements and since considerable uncertainty was involved in extending the heat capacity curves for crystalline isopropyl alcohol and acetone below 70°K. The present work, carrying the specific heat measurements to 16°K., was undertaken to remedy this latter defect. The temperature range covered before has been reinvestigated with increased accuracy and measurements have been obtained in the large temperature gaps which were omitted in the previous work. Details of the apparatus and methods used were given in a previous paper.[4]

Materials

Isopropyl Alcohol.—The best grade of isopropyl alcohol (99 to 100%) of the Special Chemicals Company was used. It was refluxed over lime for eighteen hours and carefully fractionated three times. The middle portion taken for the measurements had a volume of about 200 cc. and a boiling-point range of 0.03". The density was $d_4^{25} = 0.78095$, while Brunel[5] found $d_4^{25} = 0.78084$ for 100% *iso*propyl alcohol. The density determination corresponds to 99.95% of alcohol on the basis of purity adopted by Parks and Kelley.

[5] Brunel, *ibid.,* 45, 1336 (1923).

Acetone.—The acetone was an Eastman Kodak Company product. It was allowed to stand over calcium chloride for seven days, decanted off and carefully fractionated three times. The middle fraction used had a boiling point range of 0.05" and a volume of 150 cc. The density was $d_4^{25} = 0.78650$ which compares favorably with the values given in the literature.

The Specific Heats

In Tables I and II are given the results of the specific heat measurements expressed in 15° calories per mole (in vacuum). The same data are shown graphically in Figs. 1 and 2.

TABLE I

The isopropyl alcohol curves have no abnormalities and require no discussion. In the case of the acetone a curious hump occurs with the maximum at about 126°K. There can be little doubt but that some sort of a transition in the crystals involving a small energy change occurs here, for after passing through this region the material was kept at about 150°K. overnight, then rapidly cooled to 123° and the two determinations marked "x" in Table II and in Fig. 2 were obtained. During these two determinations the substance must have been in the high temperature form but supercooled somewhat. Immediately afterward the substance was further cooled to 118°K. and allowed to stand for several hours, after which the three determinations marked "a" in Table II were made. These three measurements agree very well with the previous ones around the hump and are about one calorie per mole higher than those marked "x," showing that on further cooling the substance passes into the low temperature form. A similar case has been discovered by Millar[6] in the heat capacity curve for manganese dioxide.

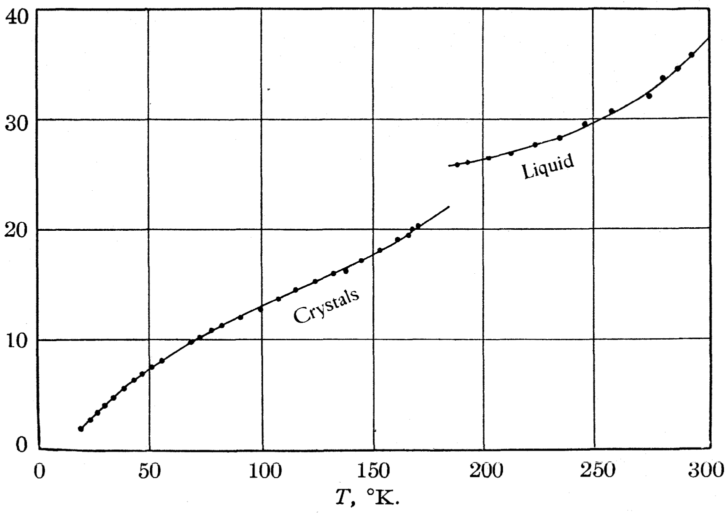

Fig. 1.—Heat capacity of isopropyl alcohol in calories per mole.

This phenomenon was missed in the work of Parks and Kelley since no measurements were made between 110 and 150°. A warming curve was taken through this region but was not accurate enough to indicate an increase in heat capacity of only 5%, though undoubtedly a transition involving a large energy change could not have escaped notice.

The facts or even a theory to explain the various types of transitions which have been found in specific heat curves would be very interesting but needless to say both are lacking at present.

[6] Millar, THIS JOURNAL, 50, 1875 (1928).

The specific heat of liquid acetone first decreases slightly just above the melting point and then increases, similarly to the behavior of water. This is usually attributed to association effects.

In an earlier paper[4] involving similar data for methyl alcohol a somewhat detailed discussion of the accuracy of the measurements was given which will also apply to the present results.

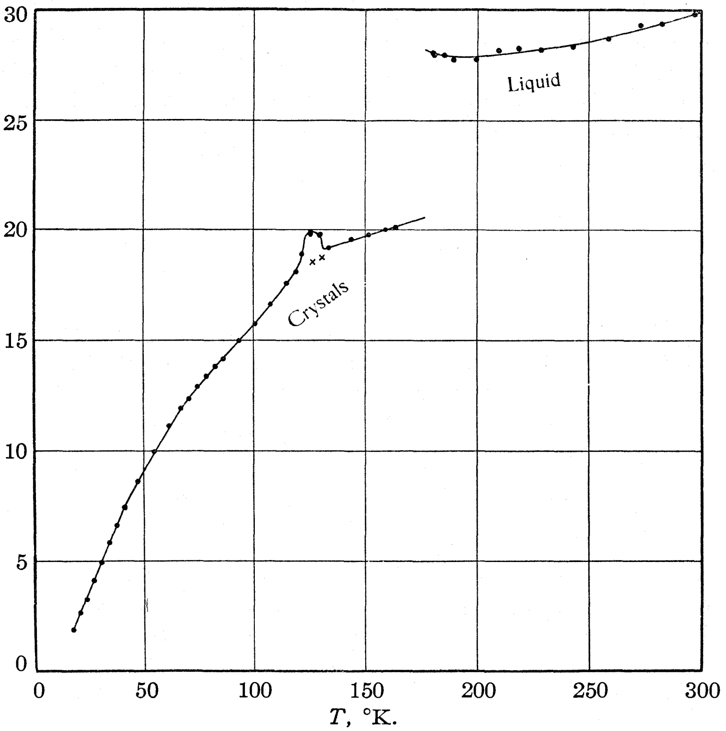

Fig. 2.—Heat capacity of acetone in calories per mole.

The Fusion Data.—The heats of fusion and the temperature of fusion were measured and the results appear in Table III.

TABLE III

HEATS OF FUSION OF *Iso*PROPYL ALCOHOL AND ACETONE

Substance	T, °K.	Heat of fusion in g.-cal.$_{15°}$ per mole 1st result	2nd result	mean
Isopropyl alcohol	184.67	1283	1285	1284
Acetone	176.62	1364	1368	1366

The mean values for the heats of fusion are considered accurate to 0.5% or better.

The Entropies.—The values of the entropies at 295.1°K. were calculated. The heat capacity curves for the crystalline substances were extrapolated from the initial temperatures of the lowest measurements to 0°K. by means of Debye functions with $\Theta = 108$ for *iso*propyl alcohol and $\Theta = 101$ for acetone. The results appear in Table IV.

TABLE IV

ENTROPIES

*Iso*propyl alcohol

0–16°K. (estrap.)	crystals	=	0.47
16–184 67	crystals	=	21.61
1284/184.67	fusion	=	6.95
184.67–298.1	liquid	=	13.99

$S_{298\cdot 1}$ for 1 mole of liquid =
43.0(±0 3) E. U.

Acetone

0–16°K. (extrap.)	crystals	=	0 56
16–176.62	crystals	=	24.67
1366/176.62	fusion	=	7.73
176.62–298 1	liquid	=	14.90

$S_{298\cdot 1}$ for 1 mole of liquid =
47.9(±0.3) E. U.

The entropy under the hump in the acetone crystals curve in excess of that due to the "normal" specific heat is 0.1 E. U. per mole.

The Free Energies.—The free energies of formation from the elements of the two substances may be calculated from the third law of thermodynamics and the thermodynamic equation, AF = AH − TAS.

There is no recent determination of the heat of combustion of *iso*propyl alcohol. Richards and Davis[7] have determined accurately the heat of combustion of the normal propyl alcohol and from this has been subtracted 5700 cal. per mole, which is the difference between the heats of combustion of the iso- and n-propyl alcohols found by Zubow.[8] Richards and Davis' value was corrected to 15° calories. The result of this procedure is 477,300 cal. per mole for isopropyl alcohol at 291°K. For the sake of consistency this value was corrected to 298°K., though the accuracy does not warrant it. Emery and Bennedict's[9] value for the heat of combustion of acetone has been utilized, correction being made to vacuum weighing and to 298°K. The final values appear in Col. 2 of Table V.

TABLE V

THERMAL DATA

The 15° g. calorie is used throughout

Substance	Heat of combustion at 298 1°K.	$\Delta H_{298\cdot 1}$	$\Delta S_{298\cdot 1}$, E. U	$\Delta F_{298\cdot 1}$
Isopropyl alcohol	477,100	−79,000	−103.7	−48,100
Acetone	430,500	−57,300	− 69.2	−36,700

Column 3 contains the values of $\Delta H_{298\cdot 1}$ which were calculated using the best available values for the heats of formation of carbon dioxide and water.[4] Column 4 contains the value of $\Delta S_{298\cdot 1}$ calculated from the experimental entropies of this paper and the entropies of the elements pre-

---

[7] Richards and Davis, THIS JOURNAL, 42, 1599 (1920).

[8] Zubow's values have been recalculated by Swietoslawski, *ibid.*, 42, 1092 (1920).

viously adopted.[4] In Col. 5 are the free energies of formation from the elements.

Discussion

The differences between the entropy values given here and those reported by Parks and Kelley[2,3] are largely due to the error in extrapolating the heat capacity curves by means of the "n" formula as was done in earlier work. The use of this formula below 90°K. causes an error of 2.1 E. U. or 17% in the extrapolation for isopropyl alcohol and 4.2 E. U. or 25% in the extrapolation for acetone. Similar results were reported for methyl alcohol[4] and for ethyl alcohol.[10]

We are now in a position to recalculate the entropy of the reaction, $CH_3CHOHCH_3(l) = CH_3COCH_3(l) + H_2(g)$, at 298.1°K. with considerably greater accuracy than was obtained by Parks and Kelley from their heat capacity measurements. We find $\Delta S_{298.1} = 47.9 + 29.6 - 43.0 = 34.5$ E. U.[11] while Parks and Kelley from the equilibrium measurements obtained 35.9 E. U. These values agree as well as could be expected in view of the fact that no heat capacity data for gaseous *iso*-propyl alcohol are available, so that a very accurate extrapolation of the results of the equilibrium measurements to 298°K. is not possible. Using the value of $\Delta H_{298.1} = 17,430$ cal. obtained by Parks and Kelley, the free energies of this reaction corresponding to the above entropy values are, respectively, 7150 cal. and 6720 cal.

Summary

1. The specific heats of isopropyl alcohol and acetone from 16 to 298°K. have been measured.
2. The heats and temperatures of fusion were determined.
3. The entropies and the free energies of formation from the elements have been calculated for 298°K.
4. The entropy and free energy of the reaction $CH_3CHOHCH_3(l) = CH_3COCH_3(l) + H_2(g)$ at 298°K. have been recalculated using the present thermal data and the third law of thermodynamics. These results are compared with previously reported data obtained by studying equilibria.

[10] Kelley, THIS JOURNAL, 51, 779 (1929).

[11] In a recent paper Giauque and Johnston [*ibid.*, 50, 3221 (1928)] consider that the entropy of hydrogen should be increased by 4.39 E. U. at 298.1°K. However, it is possible that only 1.63 E. U. of this need be considered for chemical reactions (Giauque, personal communication). Such a change would increase the third law value of the entropy of this reaction to 36.1 E. U., which agrees better with the equilibrium measurements.

GERMANIUM. XXVII. GERMANIUM DICHLORIDE[1]

BY L. M. DENNIS AND H. L. HUNTER

RECEIVED DECEMBER 1, 1928 PUBLISHED APRIL 5, 1929

Introduction

Winkler stated[2] in 1886 that germanium dichloride is formed when hydrogen chloride is passed over heated germanium. In the following year he announced[3] that the product of this reaction is germanium chloroform and not germanium dichloride. It has since been ascertained by Laubengayer[4] that in the reaction employed by Winkler both germanium chloroform, $GeHCl_3$, and germanium tetrachloride are formed, and that these two substances are not separable by long-continued fractionation in the vacuum apparatus.[5] Germanium chloroform was finally prepared by Tabern[4] by passing the vapor of germanium tetrachloride over heated germanium, which formed what was presumably germanium dichloride, and then causing this product to unite with hydrogen chloride. Tabern made a preliminary study of the germanium dichloride and the extension of our knowledge of this interesting substance was the objective of the present investigation.

Experimental

Germanium chloroform is readily hydrolyzed by water with the formation of hydrated germanous oxide (GeO) and hydrochloric acid, whereas silicon chloroform yields upon hydrolysis silicon dioxide and hydrogen. It was therefore thought possible to prepare germanium dichloride from the chloroform by removing from the latter an atom of chlorine and the atom of hydrogen. This was tried with a number of different substances but germanium dichloride was not obtained.

Attempts were next made to reduce germanium tetrachloride by various powerful reducing agents, but in no case was there definite evidence of the formation of the dichloride. Because of the negative character of these results, the method that was employed in the preparation of $GeHCl_3$ (see above) was then again taken up: $Ge + GeCl_4 = 2GeCl_2$.

Metallic germanium[6] was powdered and fused under salt to remove so far as possible traces of germanium dioxide that it might contain. The resulting button of metal was finely powdered.

[6] Prepared by the method of Tressler and Dennis, *ibid.*, 31, 1429 (1927).

Germanium tetrachloride[7] was freed from hydrochloric acid by first passing air through it at 40° and then distilling it over into a bulb containing solid sodium carbonate and calcium chloride. Some hours of contact with these substances removes water and the last traces of hydrogen chloride. The purified germanium tetrachloride was then distilled into the bulb M, while that bulb was still attached to the vacuum apparatus[5] by a "normal" interchangeable slip-joint.

The apparatus that was used for carrying out the reaction is shown in Fig. 1. The tube AB is of pyrex glass. All other parts are of soft glass. The ground slip-joints are "normal," interchangeable connections. The pyrex tube is joined to the soft-glass tubes by pieces of "varnished" rubber tubing which can withstand high pressures and is quite impervious to gases.

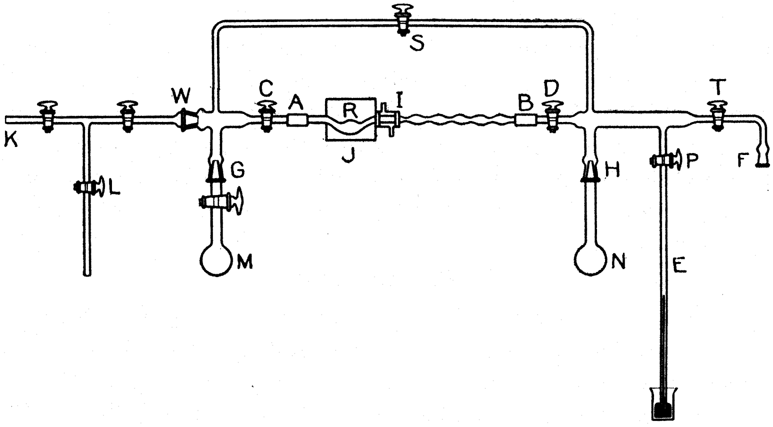

Fig. 1.

The metallic germanium was placed in a widened part of the tube, R, which is surrounded by an electric furnace, J. A short water-jacket, through which water can be run, surrounds the tube just beyond the furnace.

The germanium tetrachloride was solidified by cooling the bulb M with liquid air while it was still attached to the fractionating apparatus, the stopcock was closed and the bulb was then slipped off from that apparatus and attached to the chain (Fig. 1) by the "normal" joint at G. While the tetrachloride was kept frozen, the whole apparatus was exhausted by a pump through K. The stopcock S was then closed.

The current was now turned on the furnace, the temperature being measured by a thermometer or thermocouple throughout the experiment. When the furnace temperature had reached 300°, the stopcocks C and D were opened and the germanium tetrachloride was slowly distilled through the tube into the bulb N by surrounding the latter with a refrigerant and removing the liquid air from around M.

Reaction began at 350°, a white deposit appearing at I just beyond the water-jacket. The temperature of the furnace was held at about 430°. After all of the liquid had distilled over into N, the stopcocks C and D were closed, S was opened and the tetrachloride was returned to M by cooling this bulb and warming N. This

---

[7] Prepared by the method of Tabern, Orndorff and Dennis, THIS JOURNAL, 47, 2040 (1925).

procedure was repeated until a sufficient amount of the white deposit had collected in the tube between I and B. The excess of germanium tetrachloride was then removed from the tube by cooling the bulb M with liquid air and closing the stopcock of the bulb after condensation was complete.

Analysis.—Since germanium dichloride is instantly decomposed by moisture and is slowly acted upon by oxygen, the sampies for analysis were obtained by passing dry nitrogen through the tube, AB, and breaking off sections of the tube at the constrictions, dropping each segment immediately into a dry weighing bottle that stood in a desiccator filled with nitrogen. The bottle was stoppered and weighed, and the segment of tube was then dropped into a solution of sodium hydroxide to which had been added an amount of hydrogen peroxide sufficient to oxidize the sample. After solution was complete, chlorine was precipitated by silver nitrate, the excess of silver was removed from the filtrate by hydrochloric acid, sulfuric acid was added to the resulting solution until the acid concentration was 6 *N* and germanium was precipitated as the white disulfide.

Anal. Subs., 0.0695, 0.3101. Calcd. for $GeCl_2$: Cl, 0.03434, 0.1532; Ge, 0.0351, 0.1569. Found: Cl, 0.0343, 0.1530; Ge, 0.0350, 0.1558.

Properties.—At room temperature germanium dichloride in a thin layer is almost white; the color deepens through a cream to a light yellow tint as the layer becomes thicker. When some of the compound was caused to deposit on the sides of a thin-walled test-tube, and the tube was evacuated and then heated in an oil-bath, dissociation of the dichloride began at 74.6°, and as the temperature rose the substance became first cream-colored, then lemon-yellow, orange, reddish-brown, dark brown, and finally black at about 450°, at which temperature dissociation into $GeCl_4$ and Ge was complete. Because of this ease of dissociation, the compound cannot be sublimed either in a vacuum or in a current of an inert gas.

Germanium dichloride is insoluble in, or reacts with, many of the usual solvents that were added to it. It is not affected by 95% ethyl alcohol or by chloroform. It is fairly soluble in germanium tetrachloride. Water hydrolyzes it, and ammonium hydroxide converts it to an orange-colored substance. Concentrated hydrochloric acid changes it to a white solid which soon dissolves in the acid, with the probable formation of trichloromonogermane.

Dry oxygen slowly acts upon germanium dichloride. After about fifteen minutes' contact, the dichloride begins to turn white, due to the formation of germanium dioxide. A volatile substance that is simultaneously formed was identified as germanium tetrachloride (mol. wt., 213. Theoretical, 214.4). This reaction is, therefore, $2GeCl_2 + O_2 = GeO_2 + GeCl_4$.

When moist oxygen is passed over the compound, the reaction shown in the preceding equation probably takes place to a slight extent, but the moisture acts much more vigorously on the substance than does the oxygen. The first stage is doubtless $GeCl_2 + 2H_2O = Ge(OH)_2 + 2HCl$. The hydrogen chloride then instantly combines with unchanged germanium dichloride to form germanium chloroform, which is carried out of the tube by the current of oxygen.

Chlorine rapidly attacks germanium dichloride with the formation of pure germanium tetrachloride. Bromine forms a colorless liquid, which on fractionation was found to consist almost entirely of germanium tetrachloride and tetrabromide. Not more than a trace of a double halide was produced. Hydrogen sulfide acts at once upon germanium dichloride at room temperature. Quantitative examination of the products showed that the reaction is essentially $GeCl_2 + H_2S = GeS + 2HCl$.

Summary

This article describes the preparation and properties of germanium dichloride.

A CONDUCTANCE-DIFFUSION METHOD FOR STUDYING THE COAGULATION OF COLLOIDAL FERRIC OXIDE[1,2]

BY C. HARVEY SORUM

RECEIVED DECEMBER 3, 1928 PUBLISHED APRIL 5, 1929

Introduction

The knowledge that electrolytes will coagulate colloids dates back to the work of Thomas Graham.[3] The study of this particular phenomenon from all of its various angles has proceeded almost without a halt from Graham's time up to the present, with the result that an enormous amount has been written on the subject of coagulation. To review this mass of literature would only be repeating items already summarized in a number of modern books on Colloid Chemistry. Sufficient if, passing in review the most important experimental facts gleaned from the work of a great

---

[1] The substance of this article was included in a paper presented at the Midwest Regional Meeting of the American Chemical Society, University of Chicago, May 27–28, 1927. A preliminary version was submitted for publication in THIS JOURNAL, October 10, 1927.

[2] An extract from a thesis presented in partial fulfilment of the requirements for the degree of Doctor of Philosophy, University of Wisconsin, June, 1927. All work was carried out under the direction of Professors F. C. Krauskopf and J. H. Walton, to whom the author is deeply and gratefully indebted.

[3] Graham, J. Chem. *Soc.*, 15, 216 (1862); 17, 318 (1864).

many investigators, we mention four of the important current conclusions relating to coagulation. (1) Colloids may be coagulated by electrolytes, the ion of charge opposite to that of the colloid being the effective coagulant. (2) The coagulating power of an ion increases with the valency of that ion. (3) Each electrolyte appears to have a minimum concentration which must be reached before measurably rapid coagulation takes place.[4] (4) Coagulation is, in general, accompanied or preceded by adsorption of the coagulating ion.[5]

Even a cursory examination of the literature impresses one with the fact that there is great lack of agreement in the results upon which these and other conclusions are based. Due to the inherent nature of colloids and their apparent failure to conform to the laws which regulate the composition and behavior of pure compounds, we probably should not expect quantitative exactness in coagulation data, but a higher degree of accuracy and uniformity certainly is to be desired. Possibly the technique involved in making coagulation studies may be largely at fault. If so it should be intensely important to Colloid Science to correct this fault by substituting methods qualified to give more exact results.

If we inquire into the experimental technique employed by the numerous investigators in the field of coagulation, we find practical agreement in the methods employed. In most cases they have followed the general plan of adding varying amounts of the electrolyte in question to equal samples of the sol and noting the minimum amount required to bring about complete coagulation. The choice of electrolyte concentration seems to have been arbitrary, the only requirement being that it must be high enough to be capable of causing coagulation. Each worker has his own standardized concentration of sol and electrolyte and his own method of procedure. Some have used dilute sols, others concentrated. Some have added a concentrated solution of the electrolyte, others a rather dilute solution. The electrolyte has been added with stirring, without stirring, with agitation, without agitation, has been added rapidly and slowly. The time element has varied all the way from several minutes to several days. The decision as to the exact point of complete coagulation has, as a rule, rested on the appearance of the supernatant liquid obtained by centrifuging the treated sol, the absence of all color in the case of sols such as ferric oxide being taken as a positive index.

A combination of what seemed to him to be the best features of all past methods was employed by Ward[6] in connection with some unpublished

[5] Weiser, "Colloid Symposium Monograph," 4, **354** (1926); Bancroft, "Applied Colloid Chemistry," McGraw-Hill Book Co., Inc., New York, 1926.

[6] Doctorate "Thesis," University of Wisconsin, 1926.

studies made at the University of Wisconsin. Although primarily intended as a coagulation study, Dr. Ward's work really developed into a critical examination of the accuracy of the method which he employed, and it is interesting to note that his conclusion was that the coagulation values obtained were "an estimate, in error by ten or twelve per cent." If technique of the caliber displayed by Dr. Ward and by others who have preceded him is capable of giving only an "estimate," in error by 10 or 12%, then apparently some improvement in the method of making coagulation studies is necessary, or at least desirable, if we are ever to learn the true mechanism of coagulation.

A possible course which an attempt at improvement might follow is suggested in the third and fourth of the previously listed conclusions relating to coagulation. The third states that "each electrolyte appears to have a minimum concentration which must be reached before measurably rapid coagulation takes place." Granting the truth of this statement, the incidence of rapid coagulation should be a function of electrolyte concentration. There should be a critical concentration at which noticeable coagulation should begin to take place instantly and throughout the entire sol. If we could gradually bring the electrolyte concentration up to this critical value the sol should then cloud and coagulate very suddenly. By accurately catching the value of this critical concentration we should, theoretically at least, have a method for determining what we might then call "critical coagulation concentration." Possibly the third conclusion is not entirely correct. Perhaps there is no such thing as a "stable" colloid. Stability may be only relative, the most "stable" colloid eventually undergoing complete coagulation without the assistance or intervention of any electrolyte. Still, since experimental evidence points to the fact that noticeable and measurably rapid coagulation is dependent upon the attainment of a minimum electrolyte concentration, any means of accurately catching the point at which this rapid rate becomes noticeable should be of value.

'She fourth conclusion suggests a method by means of which we could catch this point. If "coagulation is, in general, preceded or accompanied by adsorption of the coagulating ion," the concentration of the electrolyte should experience an abrupt decrease at the coagulation point. The extent of this decrease would depend upon the degree to which the coagulating ion is adsorbed. If there is such a decrease we should have little difficulty in observing it because we have methods for following changes in electrolyte concentration. In the case of ferric oxide sols the conductance method would seem to be the only acceptable one. Using this method we could simply plot time against resistance as we brought the electrolyte concentration up to the "critical" value. The break in the time–resistance curve would represent the critical point.

To catch the "critical point" would then appear to be a simple matter. The main problem is to be able gradually and uniformly to bring the electrolyte concentration up to the critical value without getting preliminary coagulation. We cannot add the electrolyte directly, as past investigators have done, because that would give us local coagulation. This local coagulation would gradually deplete the supply of colloid and we would finally end up with a completely coagulated sol without having experienced the desired break in our curve. Obviously we must start with an electrolyte concentration too low to cause even the most minute trace of local coagulation and gradually increase it uniformly by evaporation; or else we must allow the electrolyte to diffuse in through a membrane, uniformly, slowly and in such minute quantities as to prevent any local effects. In this way we would get volume coagulation, that is, coagulation throughout the entire sol. Perhaps it may seem that we are frustrated at the very outset because there is no such thing as perfect volume concentration of a sol. Neither can there be diffusion without differences in concentration. But we should be able to come very close to the ideal state and get almost if not quite perfect volume coagulation. That, after all, is the best that we can hope for in any method.

Experimental

Concentration by evaporation was first resorted to, potassium nitrate being the added electrolyte. Twenty-five cc. of sol was diluted with 25 cc. of $N/200$ potassium nitrate, the mixture placed in a conductance cell consisting of a 2.5 X 20 cm. test-tube in the bottom of which was sealed two platinized platinum electrodes and the latter immersed in a bath of boiling water. A current of dry air was blown over the surface of the sol. The resistance of the solution was taken at frequent intervals up to and beyond the coagulation point. The time-resistance curves obtained from three runs showed slight but very noticeable "breaks." The sol clouded sharply at the same time as the break occurred; this was followed very shortly by the appearance of floccules of coagulum. Some localized coagulation took place at the surface in each run. In order to eliminate this, prooision was made for stirring by bubbling clean air through the sol. The air bubbles caused coagulation, as did nitrogen, oxygen and hydrogen.[7] A pyrex stirrer was then used.

The evaporation method served its purpose in that it indicated that the desired "breaks" could be obtained and that values could be checked. However, it was abandoned as unsatisfactory because it was too slow and tedious, about eight hours of constant attention being required for each determination.

The method of increasing the concentration by allowing the electrolyte to diffuse in through a membrane was then resorted to. The conductance–diffusion cell (Fig. 1) consisted of two platinum electrodes, D, sealed into glass tubes which were firmly embedded in sealing wax contained in the space between the inner, K, and outer, J, collars. The outer collar was flanged out at the lower edge to facilitate attachment of the collodion bag. The inner collar, being open at both ends, permitted introduction of the pyrex stirrer, C. The electrodes were protected by four solid glass guard posts,

---

[7] A detailed study of the coagulation of sols by gas bubbles is now under way in this Laboratory.

G, which were embedded in the sealing wax. These posts extended a short distance below the lower edge of the electrodes and prevented their coming in contact with the collodion bag.

The collodion bag, B, was molded in an ordinary 3-cm. pyrex test-tube of convenient length. It was slipped over the flanged edge of the outer collar to the position shown and was held in place by a rubber band. Fifty cubic centimeters of sol, or sol-electrolyte mixture, was then introduced by means of a pipet, after which the cell was clamped in the position indicated in the figure and lowered into a beaker, **A**, containing electrolyte of the same concentration as that used in the preparation of the sol–electrolyte mixtures. By means of a simple constant-level device the level of the electrolyte in **A** was adjusted and maintained about equal to that of the sol in the bag, B. Beaker **A** was kept in a water thermostat bath at 25°, all determinations being made at this temperature. The motor-driven stirrers, C and C', which were started as soon as the cell had been lowered to its proper position, were operated at 220 and 400 r.p.m., respectively.

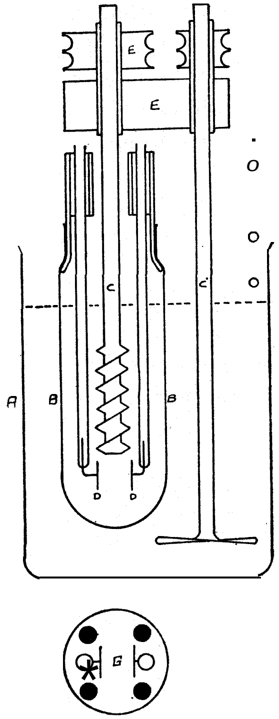

Fig. 1.

When the cell and its contents had come to the temperature of the thermostat, the desired electrolyte was introduced, drop by drop, at H from a water-jacketed buret whose temperature was kept constant at 25°. Time–resistance readings were then taken at frequent intervals until coagulation of the sol took place, the uniform drop-by-drop addition of electrolyte being continuously kept up. The location of the coagulation point was based on two criteria, the change in the appearance of the sol and the break in the time–resistance curve.

The break in the time–resistance curve having been properly located, the specific conductance corresponding to this break was calculated, and the electrolyte concentration corresponding to this specific conductance was read from an experimentally determined conductance–concentration curve. The final concentration was expressed in terms of normality and represented the critical coagulation concentration, that is, the concentration to which the electrolyte had to be raised before coagulation of the sol would take place.

The concentration of electrolyte run in at H was generally about ten times as great as that used in preparing the sol-electrolyte mixtures. The choice of this latter concentration was determined by elimination, a series of ranging concentrations being tried out and that one selected which just failed to show any signs of coagulation on twenty-four hours' standing.

The rate of addition of electrolyte at H was found to be important. If added too rapidly the high concentration gradient developed between the inside and outside of the membrane promoted such rapid diffusion into the sol that localized coagulation took place near the inner surface. Slower rate of addition was better since localized coagulation was then almost entirely avoided. However, regardless of how much care was exercised and how slowly diffusion took place, there was always some localized coagulation near the walls of the bag. Furthermore, the critical coagulation concentration was found to change with rate of addition of electrolyte, being greater with slow addition and less with rapid addition. When the rate of addition was kept constant, whether high, low or intermediate, results could be duplicated very closely.

The conductance–concentration curves from which the concentration of electrolyte at the "break" was read were drawn from values obtained from determinations made in aqueous solutions of the pure salts. Possibly it may seem that these curves should have been drawn from values obtained using ferric oxide sol as the diluent rather than conductivity water, but since we are interested in the effective electrolyte concentration at the coagulation point and not after coagulation has taken place, it is evident that the ordinary conductance–concentration curve is the one that should be used.

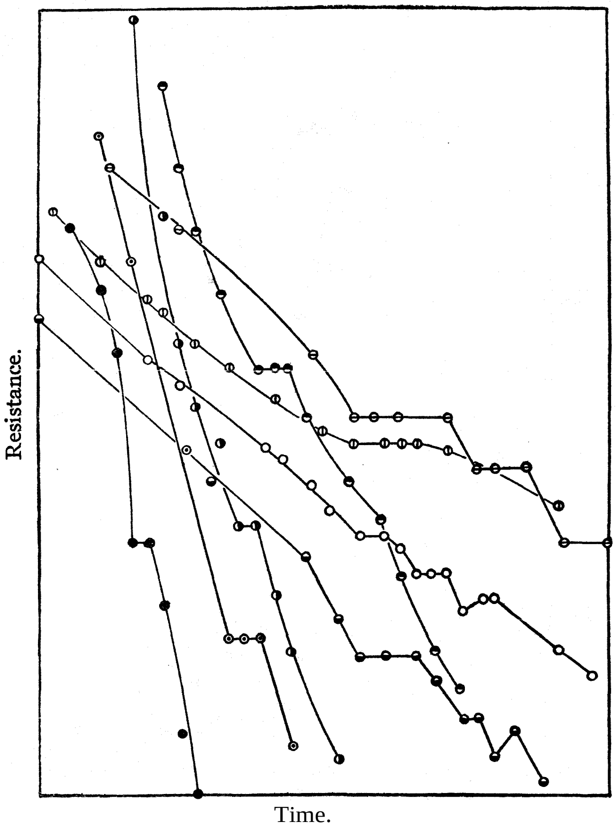

Fig. 2.

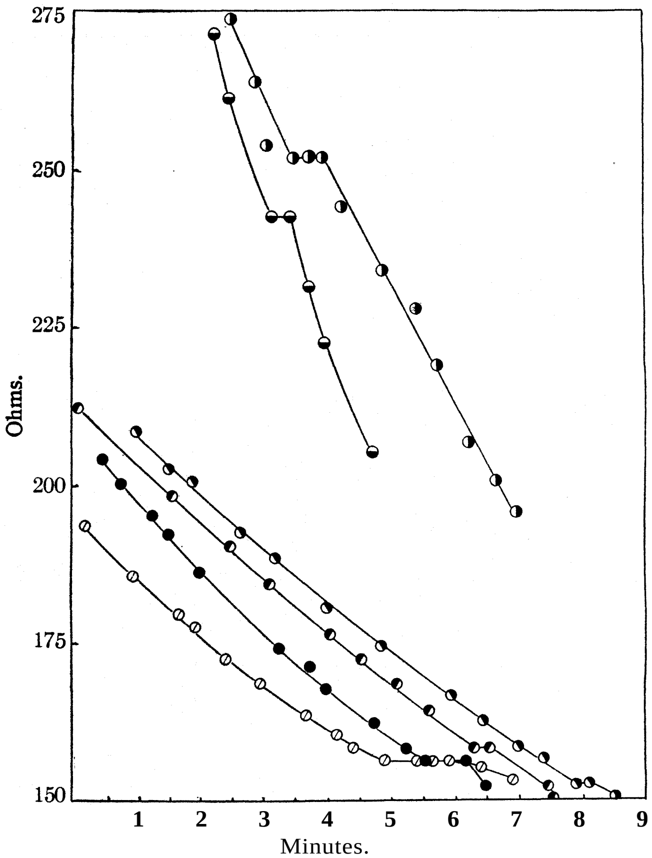
Coagulation studies were made with various electrolytes using various dilutions of sol. The particular sol employed was free from detectable amounts of chloride and was prepared in accordance with the method already described.[8] The iron content of the undiluted sol was 2.90 g. per liter.

Parts 1, 2, 3, 4, 5 and 6 of Table I show representative data obtained with six different electrolytes. Fig. 2 represents typical time–resistance curves, the resistance of the sol in ohms being plotted against time in minutes.[9] Parts 7 and 8, 9 and 10 and 11 and 12 of the table, with the corresponding curves (Fig. 3), show duplicate runs for potassium nitrate



Rapid addition: ◒, 7; ◑, 8. Slow addition: ●, 9; O, 10; ⊘, 11; ◔, 12.

Fig. 3.—Coagulation of ferric oxide by potassium nitrate.

---

[8] Sorum, This Journal, 50,1263 (1928).

[9] The conductance of the purified sol at 20° was found to be less than that of the conductivity water used in its preparation. This is in agreement with results described in a private communication from Dr. H. R. Kruyt, University of Utrecht, in whose laboratory purified sols with conductance lower than that of the water used in dialysis have been prepared.

with a sample of sol whose iron content was 1.45 g. per liter. These latter curves emphasize the fact that the critical coagulation concentration changes with rate of addition of electrolyte, being greater with slow addition and less with rapid addition. They show, further, that results can be duplicated quite closely when the rate of addition is kept reasonably constant.

Discussion

Since there is no standard by which the accuracy or inaccuracy of any method of making coagulation studies can be correctly judged, one cannot say that the conductance–diffusion method as outlined is capable of either greater or less accuracy than the classical method used by past investigators. Certainly the conductance–diffusion method does not give quantitative values, but when a standardized method of procedure is used results can be duplicated very accurately. The personal factor is largely eliminated since the location of the critical coagulation point is determined by the change in the course of a time–resistance curve.

The "break" in the time–resistance curve is an experimental fact, as the graphs will show. It was assumed at the outset that this "break" was due to the adsorption of electrolyte during coagulation. Such may or may not be the case. Perhaps the voluminous coagulation at the critical point impairs free diffusion, thereby creating a break in the curve. The fact that the majority of "breaks" are "plateaus" lends support to this view. The irregularities in the course of the curve following the first "break" lend further support, uniform diffusion of the electrolyte being impossible in the presence of a large volume of coagulum. This interference with free diffusion may also be the cause of the successive "breaks" that are to be observed in some of the curves.

Further study of the conductance–diffusion method is now under way in this Laboratory.

Summary

1. A conductance–diffusion method for studying the coagulation of colloidal ferric oxide by electrolytes has been described.
2. Data are presented to show the application of the method.

MADISON, WISCONSIN

NOTES

Dissociation and the Color of Free Radicals.—M. Gomberg and F. W. Sullivan, Jr.,[1] have determined the depression in freezing point caused by dissolving diphenyl-β-naphthylmethyl in the three solvents, benzene, nitrobenzene and cyclohexane, at various concentrations and have paralleled these measurements with colorimetric examinations of the same solutions. They observed that the deviation from Beer's law exhibited by these solutions was not proportional to the dissociation as measured by cryoscopic methods and decided that the color could not be due to simple dissociation of tetraphenyldi-β-naphthylethane. They concluded[2] that "the observed facts can best be explained by the assumption that we are dealing here with an equilibrium between benzenoid and quinonoid tautomers of the triarylmethyl, and that an increase in the proportion of the quinonoid tautomer (upon dilution) is the cause of the increase of color."

This conclusion is incompatible with the evidence upon which it is based, for such an increase in the proportion of the quinonoid tautomer could not occur in a system obeying the law of ideal dilute solutions which was implicitly assumed in calculating the degree of dissociation. In such a system the mass action law has a rigid thermodynamic basis and for a simple tautomeric equilibrium between two molecular species

$$C/C' = K \tag{1}$$

that is, the ratio of the equilibrium concentrations of the two tautomers is independent of the total concentration for an ideal solution. Gomberg and Sullivan necessarily assumed their solutions to be ideal in order to calculate the degree of dissociation from cryoscopic measurements. Therefore, if their calculations were valid, the tautomeric equilibrium constant could not vary upon dilution. Of course, this variation is possible in a real solution which need not behave ideally, but their calculations are not applicable to such a solution. Thus, the degree of dissociation, calculated from cryoscopic measurements by any known methods, *cannot possibly furnish any basis* for the conclusion that the equilibrium constant of a tautomeric process varies with dilution.

It is now pertinent to inquire what conclusions, if any, may be drawn from these measurements of Gomberg and Sullivan. The congruence of the cryoscopic data can be tested independently by calculating the equilibrium constant for a binary dissociation. This has been done by Walden,[3] who found that a satisfactory constant did not result. These cryoscopic measurements, therefore, do not give correct values for the dissociation of the ethane and, consequently, *they do not furnish a reliable basis for comparison with the colorimetric data.*

[1] Gomberg and Sullivan, THIS JOURNAL, 44, 1810–1833 (1922).

[2] Ref. 1, p. 1832, lines 18–22.

[3] Walden, "Chemie der freien Radikale," Leipzig, 1924, pp 200, 294 297

It is possible to test the colorimetric measurements, independently, to determine whether or not the dissociation and color are proportional, provided these measurements are sufficiently accurate. The law of mass action for a binary dissociation may be expressed.[4]

$$K = C\alpha^2/(1 - \alpha) \tag{2}$$

in which C is the molal concentration, α is the degree of dissociation and K is a constant. When the dissociation is proportional to the intensity of color (H)

$$\alpha = IH \tag{3}$$

and

$$K = CI^2H^2/(1 - IH) \tag{4}$$

The condition that K shall actually remain constant for two sets of experimental values, C_1, H_1 and C_2, H_2, is clearly

$$C_1I^2H_1^2/(1 - IH_1) = C_2I^2H_2^2/(1 - IH_2) \tag{5}$$

and the unique value of **I** which can satisfy this condition for any pair of measurements is given by

$$I = (C_1H_1^2 - C_2H_2^2)/(C_1H_1^2H_2 - C_2H_2^2H_1) \tag{6}$$

The values of **I** X 10^2 have been calculated from the data of Gomberg and Sullivan[5] and appear in Table I, where the values given under H represent the intensity of color in mm. of standard solution and those under V are the volumes of the solutions employed. These investigators made up their solutions by dissolving 0.25 g. of the substance in 5 cc. of solvent and then diluting to 10 cc. and 23 cc., respectively. Since the value of **I** is related to the ratio of the concentrations and is independent of their absolute value, the simple numbers 1, 0.5 and 0.2 may be substituted for C_1 and C_2 in Equation 6. Accordingly, the absolute values of C are not recorded in the table.

Table I

Dissociation and the Color of Diphenyl-β-naphthylmethyl

	Nitrobenzene		Benzene		Cyclohexane	
V	H	I X 10^2	H	I X 10^2	H	I X 10^2
5	13	2.5	11.5	0.6	10	0.5
10	17		16		14	
25	25	1.3	23	1.8	19	3.0

It is apparent from these values that Equation 3 is not established by the data. However, it is not disproved, either, for the values of H may obviously be in error by as much as 0.5 mm. By substituting 10.5 and 13.5 for the first two values of H in cyclohexane, for instance, the value 0.036 instead of 0.005 is obtained for **I**. Thus the large variations in the table are within the limits of accuracy of the colorimetric measurements."

---

[5] Ref. *1*, p. 1827.

[6] *In* fact, by choosing an optimum value of I from the table, much more satisfactory values of K are obtained than are furnished by the cryoscopic measurements

It follows, therefore, that *these measurements are not sufficiently accurate to test thoroughly the relation between the color and dissociation.*

The Confirmatory Test for Aluminum.—As a result of experiments carried out in this Laboratory last year, we were about to publish an account of a modified test for aluminum when a published account of practically the same test appeared.[1] Our procedure for carrying out the test was as follows. Pure asbestos fiber, one-half the size of a pea, was looped in a platinum wire, dipped into a solution of 0.05 N cobalt nitrate, ignited, then dipped into the solution of the aluminum hydroxide precipitate (dissolved in the least amount of nitric acid) and ignited.[2] We found that the test was easily sensitive to 0.2 mg. of aluminum, that the sodium salts did not interfere and that there was no danger of losing the test as with the fragile filter paper ash. This modified procedure is now being used successfully in our classes. Furthermore, we found that this procedure could he used for zinc, 0.5 mg. of the metal being detected with ease.

A Method for Determining Vapor Densities at Room Temperatures.—A summary of various methods for determining vapor densities is given by Biltz,[1] Windisch[2] and Arndt.[3] A method differing somewhat from any of these was developed and tried out to some extent. It can be carried out at room temperature and the apparatus can easily be built from parts found in any chemical laboratory.

Two two-liter round-bottomed flasks are connected by an oil manometer made of glass tubing of 5-mm. inside diameter. Means for evacuating the flasks simultaneously is provided by two stopcocks joined by a

glass tee and connected through a mercury manometer to a vacuum pump, which may be an ordinary aspirator. The liquid whose vapor density or molecular weight is to be' determined is sealed up in an ordinary Victor Meyer vapor density bulb and hung in a loop formed by one end of a stiff copper wire coil wrapped around the sealed end of the oil manometer, projecting four inches into the flask. A small hole is blown in the manometer tubing just below the rubber stopper. The flasks are now evacuated to about one centimeter of mercury pressure and the stopcocks closed. The bulb containing the liquid is crushed against the manometer tubing by an angle bent at the end of the stem of the stopcock, which can be turned from outside. In a few minutes, when the liquid has evaporated and equilibrium conditions have been reached, the increase in pressure indicated by the manometer is observed. This amounts to about 29 centimeters of oil when 0.1 g. of ethyl alcohol is used.

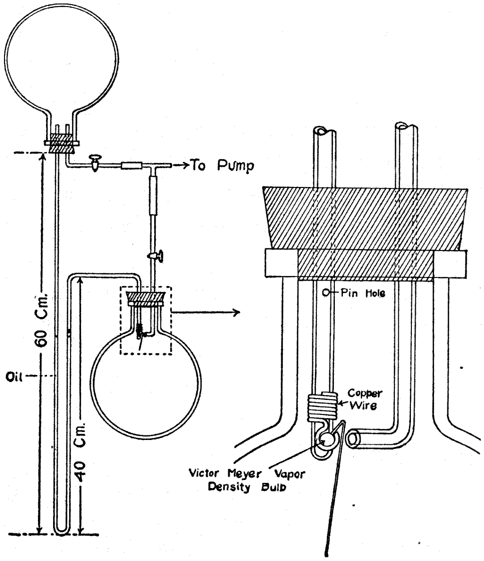

Fig. 1.

The temperature can be determined by a thermometer hung inside or near the flask. The volume of the flask, which must be determined, is made more uniform for different determinations by grinding a shoulder on a rubber stopper that is much too large at first. All the quantities in the familiar gas equation, $PV = WRT/M$, are known except M, which can be calculated.

The error in the pressure reading due to the decrease in volume in the upper flask and increase in the lower flask totals on the average 0.2 mm. of oil and may be neglected. The main precaution to be observed is not to warm the flask with the hands.

The approximate minimum vapor pressure which the substance exerts at room temperature should be 4 cm. of mercury or more. For substances of lower vapor pressure or small molecular weight, a small sample, a larger flask or higher temperatures would be required.

Of the data thus far obtained may be mentioned those taken by Trepp[4] for benzene, 79.7, 79.38, 81.0, 79.13, 79.64, 80.19, 79.42 and 80.23 and for ethyl alcohol 45.34, 44.30, 45.86, 45.99, 45.53, 45.48, 45.29 and 45.34.

[4] Senior Student, University of Michigan.

These determinations were made at 23–26°. The benzene was of high purity. The average value obtained for the sample of alcohol corresponded closely to that obtained for it by the Victor Meyer method.

DOUBLE SALTS OF ANILINE HYDROHALIDES WITH METAL HALIDES

BY GORDON D. BYRKIT AND WILLIAM M. DEHN

RECEIVED AUGUST 1, 1928 PUBLISHED APRIL 5, 1929

Aniline reacts in a great variety of ways with metallic salts to form molecular compounds, to yield oxidized and halogenated derivatives and to substitute amino or nuclear hydrogen by metal or metal–halide groups.[1] The object of this study is to review and extend the knowledge of molecular compounds of the types $n\text{An}\cdot n\text{HX}\cdot\text{MX}_n$, wherein An is aniline, X is halogen and M is metal. These and their hydrated forms are assembled in the following table. The asterisk indicates new compounds herewith contributed. The symbol of the metal is followed by its valence only where it is other than of the "ic" salt. The types of salts are arranged in the order of increasing complexity with respect to aniline hydrohalide. It will be noted that anhydrous salts are only numbered, while hydrated salts are lettered and correspondingly numbered. There are nine degrees of complexity of anhydrous salts and eight of hydrated salts, making seventeen types of complexity with respect to both aniline hydrohalide and water. In the absence of molecular weight determinations, the simplest formulas are used in the table. There is no evidence that these salts are not polymerized. For example, $\text{AnHCl}\cdot\text{HgCl}_2$ may be $(\text{AnHCl}\cdot\text{HgCl}_2)_x$.

Many of the compounds indicated by the blanks of the table were sought but could not be prepared. The known compounds, therefore, because they are most easily formed, roughly represent comparative capacities of the different metals to unite with aniline hydrohalide, their limits of capacity to enter into such union and the relative affinities of the three halogens.

As is shown in its greater number of types and its ability to form the ***octo-aniline*** compound, it is concluded that mercury has the greatest

capacity of all the metals to enter into such molecular combinations.[2] Ferric halide seems to approach mercury in this respect, and other metals

---

[2] This was observed also with the quinoline compounds, THIS JOURNAL, 48, 275 (1926); 48, 277 (1926).

in the order of lesser capacity seem to be tin, zinc and antimony. Chlorine seems to favor the greatest complexity; however, with quinoline, bromine was found to yield the greatest complexity. Iron, antimony and zinc are the most capable of forming hydrated salts with aniline hydrohalides: the bromides rarely form hydrated salts with aniline hydrohalides; the bromides rarely form hydrated salts; the iodides form none. Though magnesium bromide unites with 2, 4 and 6 moles of aniline, it could not be made to unite with aniline hydrobromide, either in hydrobromic acid or methylethyl ketone solutions.

Efforts to correlate these properties have in the past led to no certain conclusion, nor does it seem possible today to make any definite correlation.

All these compounds are double salts rather than complex salts, because they precipitate all of their halogen with silver nitrate, they liberate all of their metal with hydrogen sulfide or sulfuric acid and all of their aniline with sodium hydroxide or sodium carbonate.

That Werner's theory is inadequate to explain the constitution of these compounds[3] is especially evidenced by the existence of the iron-hexaniline compound and the octo-aniline compound of mercury. Furthermore, compounds of the table show no properties of the "inner zone."

In the preparation of heavy metal salts of the alkaloids and other bases for analytical purposes, it is usually assumed that the composition of the precipitate corresponds to Type 2, Base $HX\cdot MX_n$. That this assumption may lead to error is sufficiently indicated by this study, wherein it is especially shown that metals exercise a wide capacity to form salts of different types, under various conditions of solvent concentration, etc.

Experimental Part

In the preparation of these compounds, 0.08 mole of aniline hydrohalide and 0.01 mole of metal halide were weighed out, dissolved in the minimum amount of hot alcohol, methylethyl ketone or concentrated hydrohalogen acid, filtered and allowed to cool to room temperature. If no crystals formed, the solution was allowed to cool in a freezing mixture or the solvent evaporated spontaneously. Crystals formed were filtered out and washed with a small amount of the solvent from which they precipitated except that when too soluble the use of ether or benzene was found more satisfactory for washing. When the crystals appeared homogeneous and microscopically different from the original materials they were analyzed for metal, usually by precipitation of the sulfide. If the crystals were aniline hydrohalide or metal halide, they were re-

---

[3] Recent work with other bases also shows the inadequacy of Werner's theory [Scagliarini and Monti, *Atti Accad. Lincei,* [6] **1,** 582 (1925), [6] 2, 269 (1925); [A] **4,** 210 (1926)].

turned to the solution from which they precipitated, 0.01 mole of metal halide was added (with more solvent if necessary), the solution filtered and again allowed to crystallize. In case the double salt $4AnHX{\cdot}MX_n$ also failed to form, another 0.01 mole of metal halide was added and so on. If at any time a salt in other proportions was indicated, as, for example, Type **3**, an attempt was made to prepare it directly with the calculated quantities of material.

Often the expected salt did not form but one containing proportionately less aniline hydrohalide appeared. In cases of this kind the addition of a slight excess of aniline hydrohalide or of aniline over the theoretical quantity favored the formation of the more complex double salt.

The solvent used often had a marked effect on the complexity of the double salt formed. For example, when aniline hydrochloride and cobalt chloride were dissolved in concentrated hydrochloric acid, only aniline hydrochloride precipitated, but in methylethyl ketone $2AnHCl{\cdot}CoCl_2$ was formed.

Complex types tend to decompose to more simple types with rising temperature. This was found noticeable both in preparing the salts and in determining their melting points. Thus $2An{\cdot}HgCl_2$ softens at

[b] Prepared in hot alcohol.

[c] On heating the hydrochloric acid solution of this salt the solution darkens and precipitates pure gold in fern-like aggregates of short prisms. The reaction appears to be similar to that observed in the case of $2An{\cdot}HgI_2$. In each the metal halide is reduced and presumably the aniline is oxidized.

[d] Prepared in a large volume of hydrochloric acid with an excess of 2 moles of aniline.

[e] Mandal, Ber., 54, 703 (1921), gives a salt, $3An{\cdot}PbCl_2$, needles easily decomposed at 20–30° or by organic solvents.

about 130° with apparent loss of aniline and the formation of $An \cdot HgCl_2$, which then melts at 188°. In the preparation of the more complex types, the constituents were best dissolved in the minimum amount of solvent at room temperature and cooled in a freezing mixture.

Summary

Aniline exhibits a wide capacity to form compounds in combination with halogen and different metals. Seventeen types, including hydrated forms, are recognized. No correlation with properties can be made of all of these compounds on the basis of modern theories. The octo-aniline compound of mercury is easily prepared and is of special interest.

A METHOD FOR THE QUANTITATIVE DETERMINATION OF CYANIDE IN SMALL AMOUNTS

BY RALPH G. SMITH[1]

RECEIVED AUGUST 10, 1928 PUBLISHED APRIL 5, 1929

The following method is the application of an established reaction in organic chemistry for the quantitative estimation of cyanide in small amounts. The method depends on the development of a reddish-brown color due to the formation of the sodium or potassium salt of isopurpuric acid, which occurs when cyanide is added to an alkaline picrate solution. In the presence of an excess of alkaline picrate the development of the color is quantitative, making it possible to estimate the amount of cyanide present colorimetrically by comparison with a standard prepared with a known amount of cyanide.

Durien[2] applied such a method for the quantitative estimation of hydrocyanic acid in bitter almond water. Runne,[3] in a survey of the quantitative methods for the determination of cyanide, established the procedure of Durien as accurate to within one per cent. Waller[4] used a similar method in the analysis of tissue distillates for hydrocyanic acid. From a stock solution of alkaline picrate containing a definite amount of cyanide, color standards are prepared with which the unknown solution is compared. Furthermore, as Waller has pointed out, the reaction has been described previously as a qualitative test for cyanide, by various workers.[5]

However, since the method has been developed in a somewhat different manner and as some of its possibilities and limitations have been examined, it is considered to be of sufficient interest to report.

The details of the method which have been found to give satisfactory results are as follows. Into a test-tube with a 25-cc. graduation are pipetted *3* cc. of saturated picric acid solution, *1* cc. of *5%* sodium carbonate solution (which ensures an alkaline reaction) and *1* cc. of the cyanide solution to be determined. The tube is heated in a boiling water-bath for five minutes, then cooled in running water and the volume made up to *25* cc. The solution is then compared in a colorimeter with a standard prepared in an identical manner. The amount of cyanide which has been found satisfactory for the standard is *1* cc. of *N*/500 potassium or sodium cyanide, a depth of solution of *20* mm. being used in the colorimeter.

Using such a procedure Table I shows the results of a series of determinations of solutions of sodium cyanide of various concentrations. All solutions were prepared from the same stock solution (*N*/10 sodium cyanide) to avoid errors due to standardization. The results demonstrate the determination of sodium cyanide in amounts of the order of *0.1* mg. within 1% error.

In the boiling water-bath the color develops rapidly, about 90% of the intensity being present in two minutes. It gradually increases up to five or six minutes' heating and then fades slightly on further heating. After ten minutes in the water-bath there is a slight but definite decrease in the intensity and after twenty minutes this decrease amounts to approximately 5%. On heating for one hour the decrease in intensity approaches *20%.*

Although the color developed by heating on a water-bath for five minutes is approximately 90% of the intensity obtained by boiling to a small volume over an open flame, it has been arbitrarily adopted in the method as the procedure is more convenient, especially if a number of determinations are to be made. Moreover, it is permissible in that constant results are given. At room temperature the color becomes apparent within one minute after the addition of the cyanide to the alkaline picrate solution. It develops comparatively rapidly at first, reaching *50%* of its intensity in from one-half to one hour after the addition of the cyanide. It attains its maximum only after standing from twenty-four to forty-eight hours.

The color developed has been found to be permanent for at least one month.

A consideration which is of importance is the fact that a picric acid solution alkalinized with sodium hydroxide yields a reddish-brown color even in the absence of cyanide, the intensity of the color varying with the concentration of the alkali. Moreover, the intensity of the color developed by cyanide is decreased in the presence of sodium hydroxide. This appears to be rather a serious obstacle in that cyanide distillates are commonly collected in a solution of sodium or potassium hydroxide. However, such solutions neutralized with hydrochloric acid yield accurate results, so the difficulty may be obviated in this manner. In the presence of an appreciable quantity of the potassium ion there is a precipitation of potassium picrate due to the low solubility of that salt. However, on heating it is redissolved and remains in solution on diluting to the 25-cc. volume.

In the application of the method it must be remembered that the presence of certain reducing substances which cause the formation of a reddish color in alkaline picrate solutions will interfere with the validity of the test. Among these are sulfides, hydrosulfites, aldehydes and ketones, including the reducing sugars. However, these substances must be present in a concentration of a much higher order than that of cyanide before they become a factor. A number of compounds have been tested with a view to gaining some idea of this relationship. Table 11 shows the concentrations of the various substances necessary to produce a color of an intensity comparable with that of the standard when 1 cc. of the solution is used in the test according to the above procedure. It is evident from these results that in order to be a factor such substances must be present in very appreciable quantities. The possibility of obtaining furfural or its derivatives in tissue distillates was considered. On boiling liver and muscle tissue in 2% tartaric acid solution, a qualitative alkaline picrate test on the distillate was negative. In order to subject to a more crucial test the possibility of the formation of furfural compounds by the action of tartaric acid on carbohydrates, the following experiment was made. Gum arabic, a pentose which is more readily decomposed by acids than are hexoses, was boiled in 10% tartaric acid, a concentration much greater than that necessary for distilling cyanide from tissues.[6] The distillate gave a negative alkaline picrate test and a very faintly positive Molisch test. Consequently it was concluded that furfural compounds would not be an interfering factor in tissue distillates.

TABLE II

RESULTS OF TESTS

Substance	%	Substance	%[a]
Standard (potassium cyanide)	0.011	Formaldehyde (40%)	Color too pale to compare
Ammonium sulfide	0.4	Acetoacetic ester	
Dextrose	0.4	Ethyl acetate	No color developed
Acetaldehyde	15.0	Ethyl alcohol	
Acetone	20.0	Methyl alcohol	
Furfural	10–15	Acetic acid	

[a] Percentage of substance necessary to give color comparable with the standard.

---

[6] Bischoff, *Ber.*, 16, 1351 (1883).

Used qualitatively the test is very sensitive. By looking through the depth of a test-tube of solution against a white background and comparing with a control tube of alkaline picrate solution, the detection of very small amounts of cyanide is made possible. In the 25-cc. volume used in the test one in ten million (CN) is very easily distinguished, one in twenty million (CN) is quite distinct and one in fifty million is distinguished definitely but with more difficulty.

I wish to thank Dr. A. L. Tatum for the suggestion and direction of this research.

Summary

1. A method for the quantitative determination of cyanide in amounts of the order of 0.1 mg. within 1% error is described. The method depends on the formation of a reddish-brown color which occurs when cyanide is added to an alkaline picrate solution.

2. The effects of time and temperature on the development of the color are discussed.

3. The presence of certain reducing substances which cause the development of a red color in alkaline picrate solutions may invalidate the method. The concentration of such substances necessary to be an interfering factor is indicated.

4. Used qualitatively the test is sensitive to one part of cyanide (CN) in fifty million.

THE FORMATION OF PYRROLINES FROM GAMMA-CHLOROPROPYL AND CYCLOPROPYL KETIMINES[1]

BY JOHN B. CLOKE

RECEIVED AUGUST 24, 1928 PUBLISHED APRIL 5, 1929

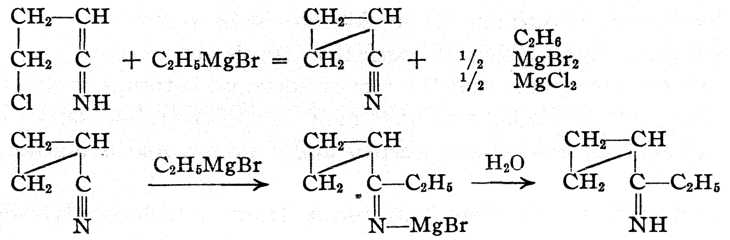
In a long, interesting paper appearing in 1923 de Booseré[2] reported the isolation of ethyl cyclopropyl ketimine and its hydrochloride with several other products following the action of magnesium ethyl bromide on γ-chlorobutyronitrile. The mechanism indicated by him for the origin of the ketimine follows closely an earlier one formulated by Bruylants[3] for an entirely analogous reaction. The equations follow.

---

[1] This paper is constructed from the first part of a dissertation to be presented by John B. Cloke to the University of Chicago in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] De Booseré, *Bull. soc. chim. belg.*, 32, 2651 (1923).

[3] Bruylants, *Bull. sci. acad. roy. belg.*, **12**, 1082–1084 (1908).



Ketimines react normally with water to give the corresponding ketone and ammonia, as follows: $R—C(=NH)—R' + H_2O = R—CO—R' + NH_3$. Ordinarily this change is greatly accelerated by acids. Until de Booseré's paper appeared, qualitative reports concerning the rate of this reaction, notably by Mignonac,[4] indicated that it increases as the substituted groups become more aliphatic in character, although no purely aliphatic ketimines have thus far been recorded.

In striking contrast with the generalization of Mignonac, de Booseré reported that his ethyl cyclopropyl ketimine hydrochloride does not appear to be altered either by cold water or even by the action of hot water for several minutes. This observation appeared especially notable in view of a further statement that the compound is decomposed by hot sodium hydroxide solution giving ammonia and an odor analogous to that of ethyl cyclopropyl ketone. The identity of the latter compound appeared to be established conclusively by the formation, but with some difficulty, of its semicarbazone.

In view of the striking resistance to hydrolysis reported for the ethyl cyclopropyl ketimine hydrochloride as opposed to the great sensitivity of its phenyl analog,[5] Professor Julius Stieglitz instituted four years ago a physico-chemical investigation of the ketimines as a class in order to ascertain precisely the relationship existing between their structure, their stability in water and their strength as bases. This line of attack, it was supposed, might connect the striking stability of the ethyl cyclopropyl ketimine hydrochloride with the presence of a large percentage of the enamic tautomer in the equilibrium $—C(=NH)—CH< \rightleftharpoons —C(NH_2)=C<$.[6] Although evidence of this type has been collected for certain ketimines, the investigation by redirecting attention to the preparation of the cyclopropyl ketimines has shown that the stable supposed

---

[4] Mignonac, *Compt.* rend., 170, 936–938 (1920).

[5] Bary, *Bull. soc. chim. belg.*, 31,404 (1922).

[6] The determination of sensitiveness to hydrolysis has been made the basis of a study of ketimine–quinoid–amine tautomerism of phenolic derivatives of benzophenone by J. Stieglitz and J. B. Culbertson (Doctorate "Dissertation," University of Chicago, 1927). Thus the tautomerism $HO—C_6H_3(OH)—C(=NH_2^+)C_6H_5 \rightleftharpoons O=C_6H_3(OH)=C(NH_3^+)—C_6H_5$ reveals itself in the rate of saponification of the ketimine as well as in color and other relations (J. S.).

ethyl cyclopropyl ketimine hydrochloride is in reality the isomeric 2-ethylpyrroline salt, which is perfectly stable in water. In addition the writer has also found that the real cyclopropyl ketimine hydrochlorides also undergo a molecular rearrangement to the pyrroline salts, whereby the unstable triatomic ring is opened and a new stable five-atom ring is closed.

The Formation of 2-Phenylpyrroline from **γ-Chlorobutyronitrile.**—In an attempt to prepare phenyl cyclopropyl ketimine by an extension of the reaction which de Booserk claimed gave ethyl cyclopropyl ketimine, γ-chlorobutyronitrile was treated with magnesium phenyl bromide. The addition product was decomposed by both the acetic acid–ammonia and the ice–ammonium chloride methods as described by Moureu and Mignonac,[7] and also by liquid ammonia as developed by the writer. The evaporation of the dry filtered ether solutions obtained by the foregoing methods on the water-bath gave mainly solid 2-phenylpyrroline hydrochloride accompanied by a variable amount of the free base and other products. It is to be noted that the evaporation and heating on the water-bath led to a chemical change, since the solid hydrochloride is insoluble in ether.

The Origin of the 2-Phenylpyrroline Hydrochloride.—It is clear that the 2-phenylpyrroline hydrochloride resulted from the rearrangement of phenyl y-chloropropyl ketimine. Thus, in the first place, theory would indicate that magnesium phenyl bromide would react normally with γ-chlorobutyronitrile, $Cl—(CH_2)_3—CN$, to give the bromomagnesium derivative of phenyl γ-chloropropyl ketimine, $Cl—(CH_2)_3—C(=NMgBr)C_6H_5$, which by careful decomposition as indicated above would yield the free ketimine, $Cl—(CH_2)_3—C(=NH)C_6H_5$, with certain by-products. It is well known, however, that compounds of the type of the aforementioned ketimine show a general tendency toward internal condensation. Thus, by analogy with the behavior of β-chloro-ethyl imidobenzoate[8] and y-chloropropyl imidobenzoate,[9] it would be expected that phenyl γ-chloropropyl ketimine would rearrange into 2-phenyl-A^1-pyrroline hydrochloride. If, however, the Δ^2 structure, which has been assigned by Gabriel and Colman[10] to the pyrroline hydrochloride finally obtained, is correct, the rearrangement of the ketimine into this compound could be readily understood by assuming the ketimine to be in equilibrium with its enamic tautomer,[11] also called an isoketimine,[12] and that the latter

---

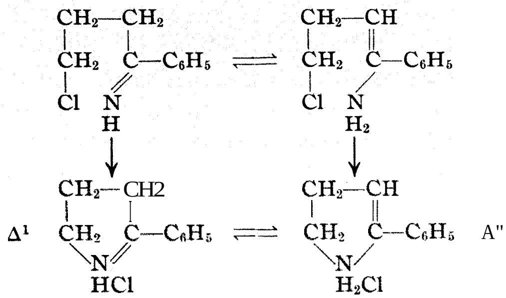
[10] Gabriel and Colman, *Ber*, 41, 517–518 (1908).

[11] Compare Thorpe and Best, J. *Chem. Soc.*, 95, 1506 (1909).

[12] Moureu and Mignonac, *Ann chim.*, 14,352 (1920).

then undergoes ring closure. These two possibilities and also a third involving a Δ^1–Δ^2 tautomerism are shown by the following equations[13]



In order to substantiate the foregoing theory, namely, that the action of magnesium phenyl bromide on y-chlorobutyronitrile gives phenyl y-chloropropyl ketimine as an intermediate product, which then rearranges into the phenylpyrroline hydrochloride, an attempt was made to isolate and identify the ketimine.

Phenyl y-Chloropropyl **Ketimine.**—On account of certain concurrent and consecutive reactions associated with the formation of the bromomagnesium derivative of phenyl y-chloropropyl ketimine, and because of the unstable character of the ketimine itself, it was not found possible by the method used to isolate the ketimine in a sufficiently pure state to establish its identity positively by analysis. That this compound was formed, however, is clear from the facts, first, that the bromomagnesium derivative, whose composition closely approximated the theoretical values, gave phenyl y-chloropropyl ketone on hydrolysis, and, second, that the impure ketimine hydrochloride, which was actually separated, gave in one experiment a velocity constant for its reaction with water at 0° whose value, *viz.*, $k, = 0.36 \pm$, was in complete harmony with the estimated order of reactivity, $k_v = 0.371$. The latter value was calculated upon the basis of an extensive comparative study of imido ester and ketimine stability which is being carried out in these Laboratories.

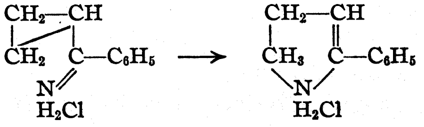
The Origin of the Free **2-Phenylpyrroline.**—The free 2-phenylpyrroline, which is formed in connection with all three decomposition methods, doubtless results from several concurrent and consecutive reactions. In the first place the free base is obtained with ammonium chloride by the action of ammonia on its hydrochloride, which is formed as described above. In the second place the free pyrroline would result from the decomposition of its N-bromomagnesium derivative, which appears to be formed to some extent. In addition a very small portion of the free

---

[13] Since Gabriel presented no critical evidence for the A^2 structure which he adopted, work is being continued on this phase of the problem in conjunction with the synthesis of other pyrrolines and related compounds.

base, which is obtained in connection with the ice–ammonium chloride decomposition method, would be formed by the action of ammonia on the hydrolysis product of the ketimine, namely, the ketone.

The Formation of 2-Phenylpyrroline Hydrochloride from Phenyl Cyclopropyl Ketimine Hydrochloride.—When it was found that phenyl cyclopropyl ketimine apparently could not be obtained directly from γ-chlorobutyronitrile, the original method followed by Bary for the preparation of this compound was employed. In studying the hydrochloride of this ketimine it was found that it melted fairly sharply at about 104–105°, but that it resolidified almost immediately, giving a compound melting from 195–200°. This change was found to be occasioned primarily by the rearrangement of the ketimine hydrochloride into the isomeric pyrroline salt as a result of the rupture of the cyclopropyl ring, as follows



All other cyclopropyl and cyclobutyl ketimine hydrochlorides thus far investigated behave in the same manner.[14]

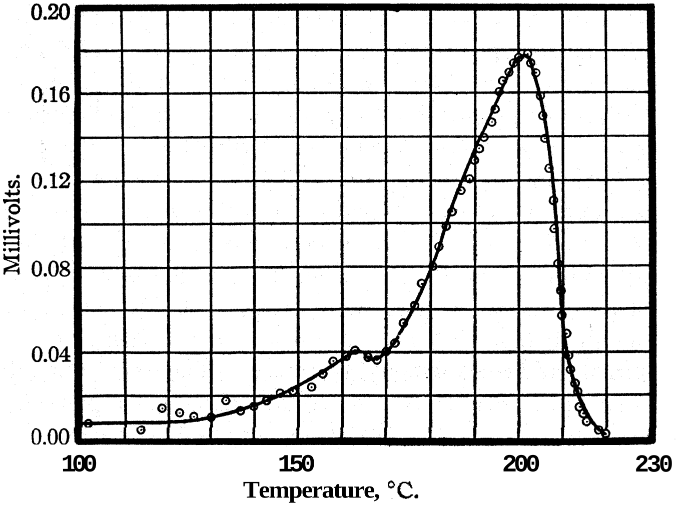


Fig. 1.

The Formation of 2-Phenylpyrroline from Phenyl Cyclopropyl Ketimine.—Although the discovery of the rearrangement of phenyl cyclopropyl ketimine hydrochloride into the isomeric pyrroline salt indicated that the free ketimine base would rearrange similarly, the experimental

---

[14] Baer, Robbins and Van Wyck, "Theses," Rensselaer Polytechnic Institute.

confirmation of this reaction came accidentally as the result of the distillation of a quantity of the free ketimine, which contained some chlorine compound, probably hydrochloride, as an admixture.

In order to avoid future loss of ketimine, comparative measurements were made to ascertain the effect of temperature and the presence of the hydrochloride on the sensitivity of the compound to rearrangement. On account of the scarcity of ketimine and in view of the fact that the ring rupture liberates heat, a differential chromel-constantan thermocouple was employed for the work. One leg of the thermocouple was immersed in the sample and the other in an equal amount of liquid petrolatum. The two tubes were then heated uniformly in a bath and simultaneous minute readings were taken on the thermometer and potentiometer.

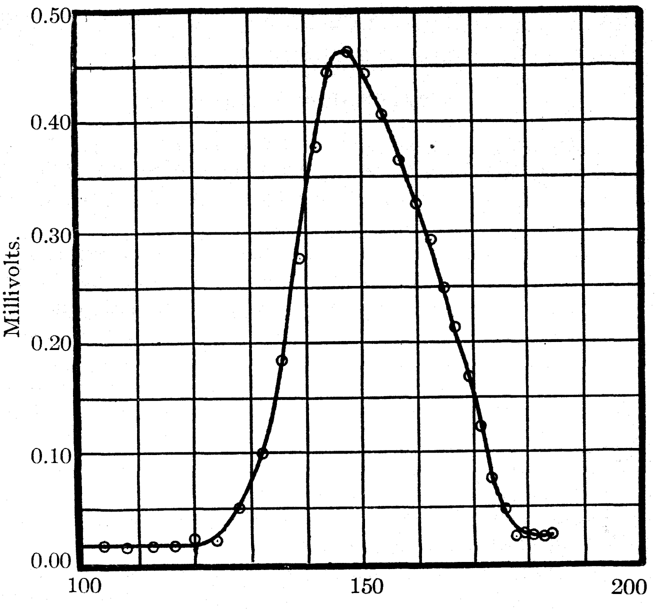

Fig. 2.

Figure 1 represents the effect of heating on the free ketimine, the heating being started at 91°. Exactly the same type of curve was obtained in the case of a second run which was started at 26°. Fig. 2 shows the catalytic effect produced by the addition of **0.0027** g. of the hydrochloride to **0.3483** g. of the free base. The same type of curve was given by the substitution of the same weight of the isomeric pyrroline salt for the ketimine hydrochloride but the maximum reached was somewhat lower, as would be expected. Ketimine free from all traces of hydrochloride would doubtless show a somewhat greater thermal stability than that indicated by Fig. 1.

The greater sensitivity of the phenyl cyclopropyl ketimine hydrochloride to rearrangement as compared with the free base is in complete harmony with the work of several investigators,[15] who have found that the cyclopropyl ring has an increased tendency to rupture in the presence of hydro-halogen acid.

Although practically all of the ketimine is converted into the pyrroline under the conditions mentioned above, other reactions occur. The most obvious of these is the probable formation of ammonia and diphenylcyclopropylcyclopropylidene ketisoketimine, the latter of which would probably undergo ring ruptures analogous to those previously described.

Experimental Part

Preparation of **Nitriles.**—Cyclopropyl cyanide, $\overline{\mathrm{CH_2—CH_2—C}}\mathrm{H—CN}$, was prepared by the action of sodium hydroxide on γ-chlorobutyronitrile, $\mathrm{Cl—CH_2CH_2CH_2—CN}$, which was obtained from trimethylene chlorobromide, $\mathrm{Cl—CH_2CH_2CH_2—Br}$, and potassium cyanide.

The trimethylene chlorobromide was made both by the action of moist hydrogen bromide gas on allyl chloride, $\mathrm{CH_2{=}CH—CH_2Cl}$,[16] according to the procedure described by Bruylants,[17] and also by the refluxing of trimethylene chlorohydrin,[18] $\mathrm{Cl—CH_2CH_2CH_2OH}$, while it was stirred with 48% hydrobromic acid according to the general procedure described by Kamm and Marvel.[19] This latter procedure is much to be preferred. The writer also succeeded in preparing the chlorobromide in one operation from trimethyleneglycol, $\mathrm{HO—CH_2—CH_2—CH_2—OH}$, by several methods, but the yields were comparatively unsatisfactory.

γ-Chlorobutyronitrile was prepared by Henry's method,[20] with the exception that 1.1 mole of potassium cyanide per mole of chlorobromide was found to be slightly more advantageous; moreover, the time of refluxing was increased and the nitrile and alcohol were distilled under diminished pressure.

The cyclopropyl cyanide was obtained by the action of powdered sodium hydroxide on γ-chlorobutyronitrile.[21] The reaction is quite violent and considerable ammonia is given off, the latter resulting from the hydrolysis of the nitriles by the water formed during the reaction. On account of the value of the cyclopropyl cyanide, several methods were studied for minimizing the hydrolysis. The admixture of powdered calcium oxide was of apparent value, but still better results were obtained by the use of anhydrous aluminum oxide, suggested by Dr. F. W. Schwartz. Subsequently it was found that sodamide works quite well. Although still better results may possibly be obtained by employing some of the technique developed by Nicolet and Sattler,[15] for the preparation of this compound, the following typical procedure for the sodium hydroxide–aluminum oxide method is given as a matter of record.

A mixture of 40 g. of powdered sodium hydroxide and 15 g. of freshly dehydrated powdered aluminum oxide was introduced into a 250-cc. distilling flask connected with an efficient water condenser. A weight of 75 g. of y-chlorobutyronitrile was then added all at once and the mixture well shaken, giving a uniform paste. The flask and contents were then heated in an oil-bath to about 154°, when a vigorous reaction occurred, necessitating the removal of the oil-bath. When the intensity of the reaction had subsided some hat., the bath wss returned and its temperature gradually raised to about 275°. Finally the receiver and distillate were replaced by a second receiver, when the application of diminished pressure gave a small additional quantity of distillate. The total distillate was washed once with water and then dried. Several similar runs were combined and fractionated with the aid of a special Vigreaux–Hempel column of small diameter and about two feet long, giving results similar to those reported by Bruylants and Stassens,[22] the main fraction boiling from 133–134° at 749 mm.

The Formation of 2-Phenyl Pyrroline, $C_3H_5{-}\overline{C{=}CH{-}CH_2{-}CH_2{-}NH}$, from γ-Chlorobutyronitrile.—Magnesium phenyl bromide was prepared from 8.4 g. of magnesium (2.42 mole), 56 g. of bromobenzene (2.5 mole) and 150 cc. of absolute ether, the procedure employed by Moureu and Mignonac being used.[23] To this ether solution 15 g. (1 mole) of γ-chlorobutyronitrile (b. p. 78–80° at 12 mm.), dissolved in its own volume of ether, was added slowly and with stirring. At the end of about nine minutes crystals separated out, accompanied by vigorous ebullition of the ether. The heating and stirring were then continued for four hours. During this time the material, which was originally crystalline and white, turned dark slowly and took on an amorphous appearance. The mass was then washed with anhydrous ether, when the residue was treated with 24 cc. of glacial acetic acid dissolved in 100 cc. of ether. Stirring and heating on the water-bath were then continued for ten hours, when the mixture was allowed to stand. At this point the yellowish residue was collected on a filter, washed with ether, suspended in more dry ether and then treated with a current of dry ammonia gas for several hours. The ether solution resulting was filtered from the residue (B), and distilled on the water-bath, leaving in the flask a yellowish solid, which was found to be the hydrochloride of a base. Up to this point the writer supposed that he was preparing phenyl cyclopropyl ketimine, but the appearance of the solid showed that some different change had taken place.

Since the residue (B), which was collected on a filter following the action of the ammonia, was found to contain undecomposed organomagnesium derivative, this was decomposed with shaved ice and ammonium chloride; the mixture was then extracted with ether and the ether solution dried over anhydrous sodium sulfate. The dry filtered solution was then evaporated under diminished pressure at a temperature below 0°, leaving a few cc. of a brownish oil. This liquid, contained in a flask, was then heated in a water-bath, when solidification occurred mainly in the vicinity of 85°, although a considerable fraction in this case failed to change.

The two hydrochloride residues thus obtained were dissolved in dry chloroform, the solution treated with dry ammonia gas and, after filtration, the chloroform was distilled off, leaving an oil, which gave about 5 g. of substance boiling between 117–125° at 12 mm. This product was later combined with similar material, which was obtained in the course of a second run not greatly different from the foregoing, and the mixture distilled, giving a liquid boiling for the most part at 124" at 15 mm. (In a subsequent run by a somewhat simplified procedure 8.5 g. of base, b. p. 125–125.5° at 15.5–16 mm., was obtained.) The distillate was colorless at first but it slowly developed a reddish

tint on standing. It was identified as 2-phenylpyrroline from a study of its hydrochloride.

The hydrochloride was obtained by the action of carefully dried hydrogen chloride gas on a solution of the free base in dry ether. The precipitated hydrochloride was collected on a filter, washed with dry ether and then left overnight in a desiccator containing sodium hydroxide and calcium chloride. The compound was recognized as 2-phenylpyrroline hydrochloride upon the basis of its stability in water, even on boiling, its chlorine content and its conversion into the characteristic picrate and the chloroplatinate of the base. The hydrochloride dissolves readily in chloroform, alcohol and water, but it is practically insoluble in ether and only slightly soluble in carbon tetrachloride.

Anal. Subs., 0.0454: 2.46 cc. 0.1 *N* $AgNO_3$. Calcd. for $C_{10}H_{12}NCl$: Cl, 19.52. Found: 19.24. *Anal.* of chloroplatinate. Subs., 0.0931: Pt, 0.0258. Calcd. for $C_{20}H_{24}N_2Cl_6Pt$: Pt, 27.87. Found: Pt, 27.71.

Isolation of Impure Phenyl **γ-Chloropropyl Ketimine,** $C_6H_5—C(=NH)—CH_2—CH_2—CH_2—Cl$.—An ether solution of magnesium phenyl bromide was prepared from 6.76 g. of magnesium (1.29 mole) and 44.8 g. of bromobenzene (1.33 mole). To this was added 22 g. of γ-chlorobutyronitrile (1 mole) dissolved in its own volume of ether; crystallization occurred as usual. The mixture was then heated for two hours on the water-bath and allowed to stand for twelve hours. At this time the precipitate was brought onto a filter, washed three times with anhydrous ether, decomposed with shaved ice and ammonium chloride, extracted four times with ether and the ether solution finally dried over anhydrous sodium sulfate. Two portions of this solution were next removed with the hope of being able to separate the free ketimine from the first portion and its hydrochloride from the second.

Free Base.—The ether was removed from portion No. 1 by evaporation under diminished pressure at less than room temperature. Since solid began separating as the result of a reaction almost as soon as the ether was removed, samples of the brownish liquid were taken immediately.

Anal. Calcd. for $C_{10}H_{12}NCl$: N, 7.71; Cl, 19.52. Found: 5.73; 16.12.

The amount of acid neutralized by the residue also was only in qualitative accord with the ketimine theory.

Hydrochloride.—A current of dry air was aspirated through the second ether portion in order to remove any ammonia. Pure dry hydrogen chloride gas was next passed into the cold ether solution, giving a yellow viscous mass which adhered to the flask tenaciously. The ether was poured off, the residue dissolved in dry chloroform and reprecipitated with dry ether, giving the same kind of viscous product as before. However, by repeating this procedure several times a product was finally obtained which solidified when rubbed with a glass rod. This solid hydrochloride, which was brought on a filter in dry air, was impure, as was shown by its melting incompletely in the vicinity of 85–88°, and also by its analysis.

Anal.[24] Calcd. for $C_{10}H_{13}NCl_2$: N, 6.42; Cl, 32.52. Found: N, 8.10; Cl, 32.40.

The most significant property of this hydrochloride was its remarkable rate of reaction with water at 0°. The procedure followed for the measurements was the same in principle as that developed by Stieglitz and Derby for the imido-ester hydrochlorides.[25] In the following table Col. 2 gives

[25] Derby, *Am.* Chem. J., 39, 439441 (1908).

the cc. of $N/10$ sodium hydroxide neutralized by the ketimine hydrochloride in *10* cc. of solution, containing *10.9* g. per liter, at the end of times t_1, t_2..... The constant k is calculated from the expression for a monomolecular reaction

$$k = \frac{2.303}{t_2 - t_1} \log \frac{v_1}{v_2}$$

where v_1, v_2 represent the cc. of $N/10$ sodium hydroxide in Col. 2, and the correction of t_1, t_2 from seconds to minutes is made.

TABLE I

DECOMPOSITION OF PHENYL γ-CHLOROPROPYL KETIMINE HYDROCHLORIDE

Time from start, sec.	30	76	145	180	
Vol. of $N/10$ NaOH, cc.	3.35	2.50	1.96	1.16	
k	..	0.386	0.280	0.425	Av. 0.363

Relatively large experimental errors were unavoidable on account of the exceedingly high reaction rate of the compound.

Analysis of Bromomagnesium Derivative of the **γ-Chloropropyl** Phenyl **Ketimine,** $(ClCH_2CH_2CH_2)(C_6H_5)C{=}NMgBr$.—Magnesium phenyl bromide was added to y-chlorobutyronitrile as previously described, but without any subsequent heating. A portion of the carefully washed crystalline mass was analyzed after several hours' exposure in a vacuum desiccator at 50°.

Anal. Subs., 0.1233: MgO, 0.0178. Subs., 0.03132: cc. of $N/100$ HCl, 9.85. Calcd. for $C_{10}H_{11}NClBrMg$: Mg, 8.54; N, 4.91. Found: Mg, 8.71; N, 4.40.

Previous analytical results indicate that the compound crystallizes with a molecule of ether.

Phenyl **γ-Chloropropyl** Ketone, $C_6H_5—CO—CH_2CH_2CH_2Cl$.—The above magnesium compound was decomposed with aqueous hydrochloric acid and the mixture extracted with ether. The ether solution was dried over calcium chloride and then treated with dry hydrogen chloride gas in order to precipitate any 2-phenylpyrroline as hydrochloride, some of this being obtained. After standing for a day the ether was removed from the filtered solution, leaving an oily residue. This was fractionated several times through a short column, giving a nitrogen-free oil which boiled mainly from 130–133° at 4 mm.

Anal. Subs., 0.1689: AgCl, 0.1256. Calcd. for $C_{10}H_{11}OCl$: Cl, 19.42. Found: Cl, 18.40.

Several further rectifications gave a liquid of boiling point 120–121° at 3 mm.; d_4^{20}, 1.149; n_D^{20}, 1.55433.

Anal. Calcd. for $C_{10}H_{11}OCl$: Cl, 19.42. Found: Cl, 16.79.

The lower chlorine content was probably occasioned by the loss of hydrogen chloride accompanied by the formation of phenyl cyclopropyl ketone.

Semicarbazone of Phenyl **γ-Chloropropyl** Ketone.—The semicarbazone separated out after a day in the form of colorless crystals melting at 136–137°. Prolonged heating leads to some decomposition, possibly to carbamyl-1-phenyl-3-tetrahydropyridazine.[26] The semicarbazone was analyzed according to Pregl's micro methods.

Anal. Subs., 9.98 mg.: N_2, 1.500 cc. (as measured at 16°, 765.9 mm.). Subs., 14.70 mg.: AgCl, 8.90 mg. Calcd. for $C_{11}H_{14}ON_3Cl$: N, 17.53; Cl, 14.80. Found: N, 17.54; Cl, 14.98.

[26] Compare Wohlgemuth, *Ann. chim.*, [9] 2, 454 (1914).

The Formation of 2-Phenylpyrroline from Phenyl γ-**Chloropropyl** Ketone.—Hielscher's preparation of 2-methylpyrroline by the action of ammonia on methyl γ-bromopropyl ketone[27] led Wohlgemuth[28] to attempt the extension of the reaction. He found, however, that the interaction of ammonia and γ-chloro-*n*-butyl ethyl ketone gave methyl cyclopropyl ethyl ketone, that is, methyl-1-propionyl-2-cyclopropane. He was unable to identify any pyrroline. The writer, on the other hand, has been partially successful in a similar case, as described below.

Phenyl y-chloropropyl ketone was treated with an excess of cold alcoholic ammonia for three weeks. The solution was dried over anhydrous sodium sulfate, filtered and the alcohol completely removed by evaporation at ordinary temperatures under diminished pressure after the addition of a little ether. The residue was dissolved in dry ether, treated with a slight excess of dry hydrogen chloride and allowed to stand until the 2-phenyl pyrroline hydrochloride had completely precipitated. The solid, obtained in about 10% yield, was identified as 2-phenylpyrroline hydrochloride upon the basis of its melting point and the formation of the picrate. The ether was removed from the remaining solution leaving an oily residue, apparently composed of the unchanged original ketone mixed with phenyl cyclopropyl ketone.

Since bases, in general, tend to form cyclopropyl derivatives from y-chloropropyl compounds, it follows that any free pyrroline base, for example 2-phenylpyrroline, must not be distilled in the presence of a y-chloropropyl ketone such as the y-chloropropyl phenyl ketone, which is a by-product of one method previously described for the preparation of pyrrolines. The heating results in the formation of the pyrroline hydrochloride which condenses in the flask neck.

The Formation of 2-Phenylpyrroline from Phenyl **Cyclopropyl Ketimine,** $C_6H_5—C(=NH)—\underline{CH—CH_2—CH_2}$.—Although the original object in the preparation of the phenyl cyclopropyl ketimine was to obtain the pure free base and its hydrochloride for certain physico-chemical measurements, lack of precise knowledge regarding the stability of the ketimine at that time led to the accidental synthesis of the isomeric pyrroline.

Phenylmagnesium bromide was prepared from 14.6 g. of magnesium (1.46 mole), 94.2 g. of bromobenzene (1.5 mole) and 250 cc. of anhydrous ether. To this solution 26.8 g. (1.0 mole) of cyclopropyl cyanide (b. p. 133–134° at 749 mm.), dissolved in its own volume of ether, was added over an interval of four minutes. After remaining quiescent for six minutes a light grey or slate-colored precipitate separated from the solution, occasioning such vigorous boiling of the ether that prompt cooling in water was necessary in order to prevent the expulsion of the mixture through the condenser. The ketimine was next liberated from the well-washed bromomagnesium derivative by the action of shaved ice and ammonium chloride; it was immediately separated by several extractions with ether, the extract being dried at once with calcium chloride followed by anhydrous sodium sulfate. By treating this solution with dry hydrogen chloride the ketimine was precipitated in the form of its hydrochloride, which was then dissolved in hot, dry chloroform and reprecipitated by ether as beautiful white crystals containing a molecule of chloroform. With the expectation of obtaining the pure free base and its hydrochloride for the physico-chemical measurements, the crystals containing the added chloroform were dissolved in warm chloroform; the solution was treated with an excess of dry ammonia gas, following which the precipitated ammonium chloride was removed by filtration and the chloroform by distillation on the water-bath. Since the free ketimine thus obtained was slightly colored, it was erro-

---

[27] Hielscher, *Ber.*, 31,277 (1898).

[28] Wohlgemuth, Ann. *chim.*, [9] 2,441 (1914).

neously decided to risk the distillation process in order to obtain a colorless product, but during the attendant heating under diminished pressure the ketimine rearranged into the isomeric pyrroline, as was conclusively demonstrated by the study of the hydrochloride described below. The rearrangement appeared to be accompanied by a peculiar color change associated with more vigorous boiling. About 90% of the ketimine was obtained as the pyrroline; the brownish-red residue was not examined.

In passing it may be noted that, although an excess of dry ammonia gas was employed in the foregoing procedure, a number of crystals of the hydrochloride of some base collected in the neck of the Claisen flask at the end of the distillation. These together with the excessive temperature, as was learned later, were responsible for the sensitivity of the ketimine to rearrangement. The crystals softened at 67° and melted from 71–73". The nature of this compound, of which only a few milligrams was obtained, may be cleared up in connection with work on other pyrrolines.

2-Phenylpyrroline Hydrochloride.—The distilled 2-plienylpyrroline, obtained as described above, was dissolved in dry ether, treated with dry hydrogen chloride and the salt removed by filtration.

Anal. Subs., 12.08 mg.: cc. $N/100$ HCl, 6.62. Subs., 0.4366: cc. $N/10$ $AgNO_3$, 23.96. Calcd. for $C_{10}H_{12}NCl$: N, 7.71; Cl, 19.52. Found: N, 7 67; Cl, 19.46. ***Anal.*** of chloroplatinate. Subs., 8.00 mg.: Pt, 2.23 mg. Calcd. for $C_{20}H_{24}N_2Cl_6Pt$: Pt, 27.87. Found: Pt, 27.87.

Phenyl Cyclopropyl Ketimine.—The ketimine which was employed in securing data for Figs. 1 and 2 was obtained by the evaporation of the ether at less than room temperature from a filtered dry ether solution obtained as described in the preceding section on the formation of 2-phenylpyrroline from phenylcyclopropyl ketimine with the single exception that the Grignard reagent was prepared in an atmosphere of dry hydrogen.

The Formation of 2-Ethylpyrroline Hydrochloride from γ-Chlorobutyronitrile.—By the action of magnesium ethyl bromide on y-chlorobutyronitrile, de Booseré, as stated previously, obtained the hydrochloride of a base, identified by him as ethyl cyclopropyl ketimine. This compound, which distilled from 160–170° (14–16 mm.), was very deliquescent and was apparently unattacked by water. When treated with sodium hydroxide solution, however, it was stated to decompose into ammonia arid ethyl cyclopropyl ketone, the presence of the latter being inferred upon the basis of odor and the formation of the semicarbazone. The free base, which was obtained from the hydrochloride, boiled from 127–128° at 759 mm. Although it appeared clear that the base was actually 2-ethylpyrroline,[29] in spite of the behavior with semicarbazide, the reaction has been reinvestigated.

Magnesium ethyl bromide was prepared from 8.4 g. of magnesium, 39 g. of ethyl bromide and 145 cc. of ether. To this solution 15 g. of y-chlorobutyronitrile dissolved in its own weight of ether was added, no permanent separation of solid occurring. The solution was then allowed to simmer gently for half a day, at which time the greenish-yellow liquid was poured into water containing ammonium chloride and the solution extracted with ether. Since distillation of the dried ether extract failed to give a constant-boiling fraction, the combined non-ethereal fractions were treated with alcoholic ammonia for a day, at which time the alcoholic solution was neutralized with anhydrous hydrogen chloride. The ammonium chloride was removed by filtration and the filtrate distilled, giving a substance which passed over mainly at 166° (18 mm.) and which solidified on cooling. The compound was so deliquescent that no accurate melting point could be determined by the capillary tube method, values being obtained ranging from 87–101°, these being surprisingly close to the melting point of the real ethyl cyclo-

---

[29] Dennstedt, German Patent 127,086; *Chem. Zentr.*, [1] 338 (1902).

propyl ketimine hydrochloride. Recrystallization from acetic anhydride and dry ether gave nice crystals but these deliquesced immediately when exposed to the outside air. The compound, like that of de Booseré, was not apparently altered either by hot or cold water. When treated with sodium hydroxide, an odor was at once developed which, indeed, resembled that of a mixture of ammonia and ethyl cyclopropyl ketone, as previously reported. That this was an olfactory error was shown by the fact that an alcoholic solution of the hydrochloride gave a precipitate with alcoholic platinic chloride, which, after resolution in boiling alcohol and reprecipitation by anhydrous ether, was found to be the chloroplatinate of 2-ethylpyrroline, m. p. 179–180° with decomposition.

Anal. of chloroplatinate. Subs., 9.33 mg.: Pt, 3.00 mg. Calcd. for $C_{12}H_{24}N_2Cl_6Pt$: Pt, 32.35. Found: Pt, 32.15.

Dennstedt, who first prepared the chloroplatinate in an impure form, found that it melted in the vicinity of 170°.

That the hydrochloride is not hydrolyzed to ammonia and ketone when distilled with a base was shown by the separation of the same chloroplatinate from an aqueous distillate, which was obtained by distilling the hydrochloride with aqueous sodium hydroxide.

The Formation of 2-Ethylpyrroline Hydrochloride from Ethyl Cyclopropyl Ketimine Hydrochloride.—Ethyl cyclopropyl ketimine was prepared from magnesium ethyl bromide and cyclopropyl cyanide by the acetic acid–ammonia process of Moureu and Mignonac. During the work certain unexpected difficulties arose which necessitated the exposure of the mixture to the outside air for a short time. Since this led to some hydrolysis of the very sensitive ketimine, the pure compound will be described later. Semi-quantitative work relating to its stability, however, shows that it is very rapidly hydrolyzed by water to give the ketone and ammonia. A portion of the ketimine was heated in a sealed tube up to 185° in order to learn how sensitive it is to rearrangement. No pyrroline, however, was separated.

A small amount of the impure ketimine was converted into its hydrochloride. This melted between 101–103°, decomposing shortly afterward. From a portion heated to 130° the chloroplatinate of the 2-ethylpyrroline was obtained.

Anal. of chloroplatinate. Subs., 7.33 mg.: Pt, 2.36 mg. Calcd. for $C_{12}H_{24}N_2Cl_6Pt$: Pt, 32.35. Found: Pt, 32.19.

In passing it may be added that the real ethyl cyclopropyl ketimine hydrochloride is decomposed normally by water, although it is more stable than was expected. This is being investigated further.

The writer is indebted to Professor Julius Stieglitz, under whose direction the work was undertaken, for criticism, inspiration and advice, and to President P. C. Ricketts and Professor A. W. Davison for their aid in providing materials and equipment.

Summary

1. 2-Phenylpyrroline can be obtained as a result of the action of magnesium phenyl bromide on γ-chlorobutyronitrile. By the procedure described most of the pyrroline is initially obtained in the form of its hydrochloride, which results from the rearrangement of phenyl γ-chloropropyl ketimine.

2. By heating phenyl cyclopropyl ketimine hydrochloride above its melting point it rearranges into 2-phenylpyrroline hydrochloride.

3. 2-Phenylpyrroline is formed by the action of heat on phenyl cyclopropyl ketimine. Curves are given which show the effect of temperature and the presence of the ketimine hydrochloride on the stability of the ketimine base.

4. The facts enumerated in 1, 2 and 3, together with a general study of ketimine stability, have led to the proof that de Booseré's so-called ethyl cyclopropyl ketimine hydrochloride, which is described as remarkably stable toward hydrolysis, is in reality a pyrroline derivative. The true ethyl cyclopropyl ketimine hydrochloride is sensitive to hydrolysis, as are the other true ketimine hydrochlorides.

PROCESSES INVOLVED IN THE DECOMPOSITION OF WOOD WITH REFERENCE TO THE CHEMICAL COMPOSITION OF FOSSILIZED WOOD[1]

BY SELMAN A. WAKSMAN AND KENNETH R. STEVENS

RECEIVED OCTOBER 1, 1928 PUBLISHED APRIL 5, 1929

Our information concerning the chemical processes involved in the decomposition (or so-called "decay") of wood, fossilization being merely a type of decomposition, is very meager. The question as to whether decomposition, which is never complete and which results only in a partial reduction in the bulk of woody substance, consists in the gradual utilization by microorganisms (fungi and bacteria) of all the chemical constituents of wood or whether certain complexes are decomposed more readily than others, has aroused considerable discussion. The nature of the processes involved in the decomposition of wood and other plant substances has found special application in connection with the recently proposed theories of the origin of coal and peat, largely centering upon the role of celluloses and lignins in this process.

It is commonly assumed that the disintegration of wood consists, first, in the chemical simplification of the various constituents from *a* greater to a lesser complexity, finally leading to their transformation into carbon dioxide, ammonia, water and, under anaerobic conditions, also into hydrogen and methane. The assumption that a number of intermediary substances are formed in this process has never been sufficiently substantiated.

Investigations reported elsewhere[2] on the decomposition of plant residues by microorganisms brought out the fact that the water-soluble plant constituents are the first to be attacked, long before the hemicelluloses

---

[1] Journal series paper of the New Jersey Agricultural Experiment Station, Department of Soil Chemistry and Bacteriology.

[2] S. A. Waksman and F. G. Tenney, *Soil Science*, 24, 275–284 (1927); 26, 155–171 (1928).

and celluloses are acted upon. No intermediary products at all or only in mere traces were found in the decomposition of celluloses by pure cultures of fungi[3] under controlled laboratory conditions; practically all of the carbon of the celluloses decomposed by these organisms was accounted for either in carbon dioxide given off or in the cell substance synthesized by the organisms. In view of the fact that this microbial cell substance frequently contains a large amount of cold and hot water-soluble material, the increase observed by Bray and Andrews in the water-soluble constituents as a result of decomposition of wood by fungi may be due to this cause rather than to the formation of intermediary products. The reasons submitted by Hawley and Wise[4] why these results must be considered in the light of the formation of intermediary compounds in the destruction of lignins and celluloses in wood are not very convincing. If one only recalls that large quantities of fungus mycelium are synthesized in the process of decomposition of the wood and that this mycelium is rich not only in water-soluble substances but also in various hemicellulose-like or gum-like substances, we can account even for the increase in the alkali-soluble materials as a result of wood decomposition.

In connection with a study[5] of the formation of "humus"-like substances from pure celluloses by microorganisms, it has been shown that the organic matter resulting from the repeated decomposition of celluloses, under controlled laboratory conditions and in pure sand but in the presence of additional inorganic nitrogen compounds and other minerals necessary for the growth of the microorganisms decomposing the celluloses, was a product which contained 23.4–30.2% of cold water-soluble, 6.9–13.4% of hot water-soluble and 23.8–25.4% of alkali-soluble (after cold and hot water treatment) material, all of which was a part of the cells of living and dead microorganisms.

There is no doubt that when celluloses are decomposed by anaerobic bacteria large quantities of organic acids and alcohols are produced, but these should be considered as final products of anaerobic metabolism rather than as intermediary products; these acids and alcohols will be decomposed further when conditions are made aerobic and the reaction is favorable.

We have no justification as yet for speaking therefore of the "simplification" of complex plant constituents when these plants are decomposed by fungi. There is more sound evidence that the chemical processes involved in the decomposition of wood by microorganisms consist merely in the complete destruction of the more readily available substances, followed

[4] L. F. Hawley and L. F. Wise, "The Chemistry of Wood," The Chemical Catalog Company, Inc., New York, 1926, p. 301.

[5] S. A. Waksman, *Cellulosechemie*, 8, H. 9/10 (1927).

by a slow but gradual disappearance of those that are less readily decomposed; the more resistant plant constituents contribute to the formation of the residual (or fossilized) material.

Chemists are willing to agree that the disintegration of wood is largely a result of the activities of bacteria and fungi and that the nature of decomposition depends upon the nature of the organisms that bring about the process. Unfortunately, the chemistry of wood, as well as of natural organic materials in general, still represents a series of complicated problems, and, unless these are first carefully worked out, one could not expect to unravel the chemistry of decomposed wood, as well as of the residual soil humus and peat, and understand the nature of the chemical and biological processes involved in their formation from the natural materials.

It is sufficient to call attention to the chemical composition of the lignins and celluloses in wood, which make up, in the form of lignocelluloses, 65 to 70% of the constituents of the wood. The chemical nature of these substances obtained from wood is influenced quite markedly by the method used in their preparation. When one attempts to determine lignin quantitatively, he is faced with an array of methods which give varying results not only quantitatively but even qualitatively, yielding substances which vary considerably in their chemical nature and their biological behavior. The quantitative determination of cellulose is also apt to give varying results, depending on the method employed, especially if one does not use sufficient care in accounting for the admixture of hemicelluloses, lignins and cutins. It is not remarkable therefore that the results obtained on the decomposition of plant materials are very conflicting, and it is only within very recent years that definite light has been thrown upon the chemical nature of the processes involved.

Rose and Lisse[6] have shown that when wood is rotted by fungi there is a gradual decrease in the cellulose and pentosan content and an increase in the lignin, *as* determined by the methoxyl content, and the amount of alkali-soluble materials. Lignin, which is more resistant to decomposition by microorganisms, gradually accumulates, while the celluloses and hemicelluloses disappear.

These results were utilized by Fr. Fischer[7] to prove his theory that coal originates from the lignins of plant materials, since they resist decomposition, while the other plant constituents, namely, the celluloses, hemicelluloses, proteins, etc., are gradually broken down by microörganisms.

Lamarlière[8] has shown previously that coniferous wood freshly removed from peat beds preserves, the microscopic structure, but a chemical analysis

[6] R. E. Rose and W. M. Lisse, *J. Ind. Eng. Chem.*, 9, 284–287 (1917).

[8] L. G. de Lamarlière, *Compt. rend. acad. sci.*, 131, 511–512 (1900).

shows that the celluloses are largely gone, while the amorphous residue dissolves rapidly, after treatment with chlorine, in alkalies.

The nature and rapidity of decomposition of wood depend upon the nature of the infecting organism. Bray and Andrews[9] found that certain hymenomycetes causing brown rot of wood may bring about a loss of **10** to 50% of the wood in six to ten months. The cellulose may be reduced from **60** to 6% in one year, while the loss in the lignins was only **3%;** this small loss all can be accounted for by a loss in the methoxyl content (2.8%).

However, although the lignins are not decomposed as rapidly as the celluloses, hemicelluloses and proteins, they will still undergo some decomposition, slow to be sure, under aerobic conditions. The existence of organisms capable of attacking lignins has now been definitely established.[10]

As a matter of fact, it has been demonstrated[10a] that decomposition of wood, under aerobic conditions and largely through the agency of fungi, can either consist in a rapid disintegration of the celluloses with the accumulation of lignins or in a gradual decomposition of both the celluloses and the lignins and frequently even in an accumulation of cellulose. These two processes were termed by Falck as "destruction" and "corrosion." They account for the differences observed in the chemical composition of the wood decomposed by the brown and white rot-producing fungi.

When a comparison is made of sound and decomposed wood, using the same method of chemical analysis, we can readily recognize the chemical changes that have taken place as a result of the decomposition of the various constituents of the wood by different groups of microörganisms. A typical analysis is given in Table I, where the chemical composition of healthy chestnut and cypress wood is compared with the composition of two samples of decomposed wood, one of which was non-fibrous in nature, having undergone the so-called process of "destruction," and the other fibrous in nature, having been decomposed by the fungi bringing about "corrosion," according to Falck's nomenclature. These results show that while in the case of certain processes of wood decomposition the celluloses have practically all disappeared (even more so than the hemicelluloses) and most of the decomposed wood consists of lignin which has resisted decomposition, in other cases both the lignins and celluloses, as well as the hemicelluloses, have all undergone a gradual decomposition. It is unfortunate that in this particular experiment the samples of decomposed wood were selected at random from decomposing trees in a New England forest and were not studied under controlled laboratory conditions. However, in other investigations on the decomposition of plant materials[11]

[b] Wood which has undergone the so-called process of "corrosion."

[c] Free from ash and nitrogen.

which were carried out under controlled laboratory conditions, it has been found that under anaerobic conditions lignins do not decompose at all or only in mere traces due to the absence of specific organisms, while, under aerobic conditions, the lignins are slowly decomposed, but here as well they are found to be the most resistant group of plant constituents.

It is interesting to observe in Table I the increase in the protein content of the decomposed wood over the sound wood; this is not necessarily due to the accumulation of the proteins because they are more resistant to decomposition by microorganisms than the celluloses, but to the fact that the products of protein decomposition are immediately reassimilated by the microorganisms bringing about the decomposition and are thus preserved. This has been amply demonstrated in this Laboratory for the decomposition of various plant substances by pure and mixed cultures of microorganisms under controlled conditions.

The chemical nature of the transformation of the wood constituents, especially the celluloses and lignins, has attracted considerable attention. According to Wehmer,[12] the wood-destroying fungus *Merulius* lacrymans brings about the decomposition of the cellulose and the transformation of the lignin of the wood into "humin," a part of which is soluble in alkalies and precipitated by acids.

According to Kürschner,[13] various wood-destroying fungi, such as *Merulius* lacrymans, attack largely the cellulose in the wood, while the lignins are transformed into a complex mixture of changed and unchanged depolymerized substances of a humic-like nature. Strache[14] analyzed the inner portion of a 1000-year old pine and found that only traces of cellulose

---

[12] C. Wehmer, *Ber.*, 48, 130–134 (1915); *Brennstoff-Chem.*, 6, 101–106 (1925).

[13] K. Kürschner, Z. *angew. Chem.*, 40, 224–232 (1927).

[14] H. Strache, *Brennstoff-Chem.*, 9, 21–22 (1927).

were left, while the lignin had changed, in the absence of oxygen, into "humic acid," which was thus considered to be the first step in the formation of lignite and brown coal. The residue of the action of *Merulius lacrymans* upon pine wood was found by Schwalbe and Ekenstam[15] to consist of 73% of lignin, 15% of cellulose, 8% of other carbohydrates and 4% of resins; the fats and pentosans were all destroyed; 64.2% of the lignin was soluble in 5% sodium hydroxide solution and it had less methoxyl (10.2%) than lignin of fresh wood. Brandl[16] recorded the presence of 24.90% of acid-hydrolyzable material, including 8.1% of cellulose, and 75.1% of non-hydrolyzable material in decomposed oak wood; the latter fraction was separated into lignin (36.35%) and humic acid (38.75%) on the basis of solubility in sodium bicarbonate solution.

Marcusson,[17] in an attempt to prove by chemical theories and facts the idea of the older botanists and geologists that coal originates largely from celluloses, claims that as a result of decomposition of plant materials the celluloses are changed to oxycelluloses by the action of air, light and moisture; the oxycelluloses are then transformed into "humic acids," which are soluble in dilute alkalies. The role of microorganisms in the processes of decomposition is not considered at all. According to Marcusson, the results of Rose and Lisse[6] could not be used in proving Fischer's theory concerning the role of lignins in coal formation, since the former did not determine the actual lignin content of the various forms of wood, but merely measured the methoxyl content and the amount of alkali-soluble material. Since the methoxyl content of various lignin preparations varies and since it is also present in other substances, as pectins, it need not be taken as an index of the lignin content of wood at various stages of decomposition. Marcusson found that when healthy and rotten wood were treated first with a 1% solution of sodium hydroxide and the lignin determined on the insoluble residue by the Willstatter method, the cellulose was found to decrease from 58% in healthy wood to about 6.0% in the fully rotted wood, while the lignin content was practically the same, ranging from 20 to 23%. The results of Rose and Lisse are explained by Marcusson by the fact that pectins present in the middle lamella and certain waxes also contain methoxyl groups, while the increase in the alkali-soluble materials is explained by the assumption that glucuronic acid, a constituent of oxycellulose, is thereby made soluble.

Without going into a detailed review of the extensive literature on the origin and chemistry of soil "humus," peat and coal, which is found elsewhere,[18] the results of some experiments will be presented here to show that

[16] A. Brandl, *Brennstoff-Chem.,* 9, 89–94 (1928).

[17] J. Marcusson, *Z. angew. Chem.,* 39, 898–900 (1926); **40,** 48, 1105 (1927).

[18] S. A. Waksman, *Soil Science,* 22, 123–162 (1926).

Marcusson's explanations will not stand any broad generalization and are merely isolated instances which have no application at all to the formation of "humus," peat and coal. The methods of analysis of the various plant constituents are reported in detail elsewhere.[19]

Table II gives an analysis of two samples of wood obtained from an undrained lowmoor peat bog, at Newton, N. J., at a depth of 7–8 feet, and of fossilized wood of the Pleistocene period kindly supplied to the authors by Dr. David White of the U. S. Geological Survey. The composition of these can be compared with that of healthy wood reported in Table I.

TABLE II

CHEMICAL COMPOSITION OF TWO SAMPLES OF FOSSILIZED WOOD

Percentage of dry material

Material	Wood from peat	Fossilized wood (oak)
Ether-soluble material	1.54	0.84
Cold and hot water-soluble organic matter	0.87	0.56
Alcohol-soluble	1.34	1.82
Hemicelluloses	8.15	3.79
Celluloses	6.12	3.38
Lignins (free from nitrogen and ash)	65.02	70.74
Protein	5.37	2.21
Ash	3.85	4.40
Total accounted for	92.25	87.74

The results show that in the wood from peat and in the fossilized wood there is a considerable reduction to an almost complete disappearance of the water-soluble substances; there is also a reduction in the ether-soluble substances and hemicelluloses and a marked decrease in the celluloses. The lignin and ash content have increased to such an extent that they account for three-quarters of the total wood material or of 80% of the constituents accounted for. The proteins also have increased very markedly, from about 0.6% in healthy wood to 2.21% in the fossilized wood and 5.37% in the wood from the lower layers of the peat bog. These results are in full accord with those obtained in this Laboratory experimentally, under controlled conditions, on the decomposition of natural plant materials by microorganisms, which can be summarized by a rapid reduction in the water-soluble substances, decomposition of hemicelluloses and celluloses as well as of certain ether-soluble substances, and an increase in the lignin, ash and protein content. The changes in the nature and quantity of the latter are especially illuminating, since they depend not only on the nitrogenous constituents but also on the nature and amount of the celluloses and hemicelluloses in the plant material, organisms active in the decomposition processes and the conditions under which decomposition is carried out.

[19] S. A. Waksman and K. R. Stevens, *Soil Science,* 26,113–138 (1928).

To demonstrate whether Marcusson is justified in assuming that, after treatment of rotted wood with an alkali solution to remove the so-called "oxycelluloses," the same percentage of lignin will be found in the decomposed as in the healthy wood, the wood from peat and the fossilized wood were subjected to treatment with ether for fifteen hours in Soxhlets, followed by 95% alcohol for one hour at boiling temperature, then boiling for five hours with a 2% hydrochloric acid solution. The lignin content was determined (by adding to a weighed quantity of dry residual material 10 volumes of 80% sulfuric acid, allowing to stand in the cold for two hours, then diluting with fifteen volumes of water and heating at 120° for one hour)[20] in the wood thus treated as well as in the original material and in the wood treated with a 2% sodium hydroxide solution for one hour on a water-bath. The lignin was filtered off, dried and weighed. The ash and nitrogen content of the lignin residue were determined and subtracted to give the amount of lignin.

The results presented in Table III show that the lignin content of untreated wood is somewhat higher than that of wood which has been previously extracted with ether, alcohol and dilute acid. The lignin content of the wood extracted with a 2% sodium hydroxide solution is considerably lower than the lignin of the wood not so treated; however, when the alkaline extract is neutralized with hydrochloric acid and the precipitate formed thereby dried and weighed, it is found that the sum of the weight of the precipitate and the weight of the lignin in the alkali-treated wood is almost the same as the weight of the lignin in the untreated wood. In other words, the alkali treatment merely removed a part of the lignin, or a modified form of lignin, as a result of the activities of microorganisms. Hawley and Campbell[21] found that when Sitka spruce is extracted with 1% sodium hydroxide solution on a boiling water-bath for one hour, the lignin content decreased from 29.3 to 27.7%. Others found that with the advance of decomposition there is an increase in the amount of lignin soluble in alkali bicarbonate or cold alkali hydroxide solutions (so-called "humic acids"). The accumulation of lignin as a result of disintegration of wood under anaerobic conditions is due entirely to its resistance to decomposition under these conditions and not to its formation in the process of decomposition.

TABLE III

LIGNIN CONTENT OF FOSSILIZED WOOD, SUBJECTED TO DIFFERENT PRELIMINARY TREATMENTS (PERCENTAGE OF TOTAL ORIGINAL DRY MATERIAL)

Material	Wood from peat bog	Fossilized wood
Untreated	72.76	84.58
Treated with ether, EtOH and 2% HCl	65.02	70.74
With 2% NaOH for 1 hour at 100°	54.52	56.61
Ppt. of alkaline extract with HCl	10.94	20.38

---

[20] It may be stated here that the lignin obtained by this method compares very well quantitatively with the amount of lignin found by the original hydrochloric acid method of Willstätter or any of its modifications.

[21] L. F. Hawley and W. G. Campbell, *Ind. Eng. Chem.*, 19, 742–744 (1927).

To study the effect of alkali treatment upon the acid lignin obtained from natural and from decomposed plant material, several plant-lignin and peat-lignin preparations were subjected to treatment with 2% sodium hydroxide solution, either in the cold for twenty-four hours, or for one hour on a steam-bath, or for thirty minutes at 120° (1-g. portions of lignin were extracted with 100 cc. of the sodium hydroxide solution). The solutions were then filtered and the residues washed, dried and weighed; hydrochloric acid was then added to the solutions and the precipitates formed were filtered, washed, dried and weighed. The results are reported in Table IV.

TABLE IV

INFLUENCE OF ALKALI TREATMENT UPON LIGNIN FROM STRAW AND FROM PEAT

One gram of lignin extracted with 100 cc. of 2% NaOH solution

		Acid lignin from rye straw	Lignin-like complexes from lowmoor peat treated with 2% HCl	Lipin-like complexes from lowmoor peat treated with Et_2O, EtOH and 2% HCl	Lignin-like complexes from highmoor peat treated with Et_2O, EtOH and HCl
24 hrs. cold	**Undis. res., g.**	0.420	0.496	0.420	0.757
	Acid ppt., g.	.428	.292	.428	.057
1 hr. 100°	**Undis. res., g.**	.212	.350	.271	.441
	Acid ppt., g.	.548	.332	.445	.327
30 min. 120	**Undis. res., g.**	.041	.389	.220	.193
	Acid ppt., g.	.663	.405	.523	.534

These results show that acid lignin prepared from rye straw can be dissolved almost completely in 2% sodium hydroxide solution if a sufficiently high temperature and pressure are used.[22] However, only 65 to 75% of the lignin which has been thus dissolved is reprecipitated from the alkali solution on neutralization with hydrochloric acid.

The lignin prepared from peat behaves in this respect very similarly to the lignin of rye straw, with the exception that in this case the amount recovered on acidification is somewhat less.

These results prove further that treatment of rotten wood with a hot alkali solution does not merely remove the oxycelluloses, as assumed by Marcusson, but has a decided effect in bringing the lignin itself, either in an unmodified or in a modified form, into solution.

The possible reason for the discrepancy in the results reported by Rose and Lisse, Bray and Andrews and others, as well as in this paper, on the one hand, and those of Marcusson, on the other hand, may be due to differences in the nature of the organisms concerned in the processes of decomposition. It has been definitely established that under aerobic conditions some fungi and other organisms[2,10a,23,] are capable of attacking

---

[22] M. M. Mehta, Biochem. J., 19, 958–978 (1925).

[23] A. W. Schorger, "The Chemistry of Cellulose and Wood," McGraw-Hill Book Co., New York, 1926.

lignins as well as celluloses. However, under anaerobic conditions no organisms have been found so far which would be capable of decomposing this group of chemical substances. This is largely the reason for the accumulation of lignins under the processes of formation of peat,[20] coal and fossilization of wood, but not in certain aerobic processes of rotting of wood by certain fungi belonging to the group of *Basidiomycetes*.

Although the results presented in this paper are not primarily concerned with the decomposition processes in peat bogs, it may be stated here that evidence will soon be submitted that peat bogs are teeming with life (largely bacterial) and are not sterile, as commonly assumed. The reason for peat formation and its chemical nature as well depend largely upon the nature of these organisms and their activities under anaerobic conditions.

Summary

Decomposition of wood under anaerobic conditions, as in peat bogs or in the process of fossilization, brings about the disappearance of the celluloses and hemicelluloses and a marked accumulation of the lignin complexes.

The nature of the chemical processes involved in the decomposition of wood under aerobic conditions depends largely upon the microorganisms concerned in the process.

There is no justification in assuming that in the decomposition (rotting) of wood, oxycelluloses are formed as an intermediary step in the formation of "humus" from celluloses.

Evidence presented in this paper, as well as by other investigators, definitely establishes the fact that the processes of decomposition of wood are largely microbiological in nature and the nature of decomposition will depend upon the organisms active in the process, as influenced by the environmental conditions and the chemical composition of the plant constituents.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF NORTHWESTERN UNIVERSITY]

THE PYROLYSIS OF BENZALDEHYDE AND OF BENZYL BENZOATE

BY CHARLES D. HURD AND C. W. BENNETT

RECEIVED OCTOBER 5, 1928 PUBLISHED APRIL 5, 1929

The pyrolysis of benzaldehyde appears to proceed essentially in one of two directions depending on the conditions of heating. At moderately high temperatures it changes slowly into benzyl benzoate by a polymerization process which involves the double bond of the carbonyl group. At elevated temperatures benzaldehyde rapidly decomposes into carbon monoxide and benzene. These primary effects were reported, respectively, by Lachman[1] and by Peytral,[2] and both appear to be well substantiated. However, certain secondary details in each case seemed open to question, and consequently it appeared expedient to give this subject further study.

A brief summary of the features of our work which contrast with the earlier results follows. Mlle. Peytral passed benzaldehyde vapors rapidly through a short platinum tube at 1150°. We obtained a decomposition similar to hers by using a pyrex combustion tube at 680°. She reported the formation not only of benzene, but also of diphenyl and of a solid, m. p. 213°, stated to be anthracene. Actually, we proved this to be 1,4-diphenylbenzene or "terphenyl," and not anthracene. Its formation is the result of continued pyrolysis of the benzene and diphenyl.

With two hours of heating in a sealed tube at 300°, our results showed much less decomposition of benzaldehyde than Lachman reported. In five such experiments our recovery of unchanged aldehyde was 88–95% as contrasted with 70%. The anticipated pyrolysis occurred, however, at 350–370°. For purposes of comparison, our results obtained at 350–370° are listed in Table I with Lachman's 300° data. Both sets of experi-

TABLE I

PYROLYSIS OF BENZALDEHYDE IN A SEALED TUBE

	Weight of benzaldehyde taken, Lachman, 50 g.		This investigation, 62.5 g.	
Products formed	Moles	Equiv. moles of benzaldehyde consumed	Moles	Equiv. moles of benzaldehyde consumed

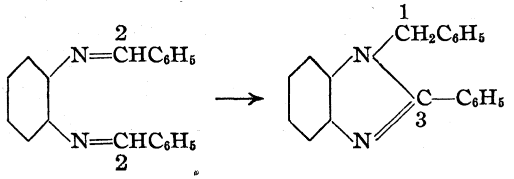
[1] Lachman, THIS JOURNAL, 46,720 (1924).

[2] Peytral, Bull. *soc. chim.*, [4] 29, 44 (1921).

ments were of two hours' duration and in both the recovery of undecomposed aldehyde was about 70%. We found no evidence for toluene or dibenzyl ether as reaction products and only slight evidence for benzoic acid.

From the present data it appears that the essential change at 350–370° is of the Cannizzaro type, giving rise to benzyl benzoate. A minor concurrent reaction, which becomes the major one at higher temperatures, is the pyrolysis into benzene and carbon monoxide.

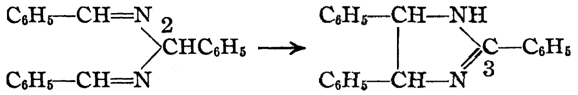
Ammonobenzaldehyde.—Hydrobenzamide and dibenzylidene-o-phenylenediamine may be regarded as analogs of benzaldehyde in the ammonia system. Just as with benzaldehyde, these substances undergo a Cannizzaro type of oxidation and reduction by moderate heating. Dibenzylidene-o-phenylenediamine[3] rearranges into benzaldehydine at 106°.



Atoms numbered (1), (2) and (3) in the equation represent, respectively, carbon atoms in the state of oxidation of alcohol, aldehyde and acid. With benzaldehyde the comparable reaction has been shown to be

$$C_6H_5\text{—}\overset{2}{C}HO + C_6H_5\text{—}\overset{2}{C}HO \longrightarrow C_6H_5\text{—}\overset{3}{C}O\text{—}O\text{—}\overset{1}{C}H_2C_6H_5.$$

Hydrobenzamide undergoes rearrangement[4] into amarine[5] by heating at 130° for three to four hours



Since the high-temperature decomposition of benzaldehyde leads to benzene and carbon monoxide instead of benzyl benzoate, it may be inferred that the high-temperature decomposition of "ammonobenzaldehyde" may also follow quite a different course from that which has just been outlined.

Benzyl Benzoate.—Since benzyl benzoate is a pyrolytic product from benzaldehyde at 350°, it was of interest to study the behavior of benzyl benzoate under similar conditions. The results show that about half of the ester is recoverable after two hours of heating. The products formed

---

[3] Hinsberg and Koller, *Ber.*, 29, 1497 (1896).

[4] Bertagnini, *Ann.*, 88, 127 (1853); Bahrmann, *J. prakt. Chem.*, 27, 296 (1883).

[5] Strain, THIS JOURNAL, 49, 1565 (1927), regarded this change as analogous to the benzoin condensation. That it cannot be analogous is evident from structural difficulties (noted by Strain), and also from the fact that benzoin is not a pyrolytic product of benzaldehyde.

are best explained by assuming an initial disproportionation into benzoic anhydride and dibenzyl ether, the former appearing as such and the latter decomposing[6] further into toluene and benzaldehyde. The reaction mixture was carefully searched for stilbene, phenanthrene, benzene, diphenyl and dibenzyl ether but none of these substances could be identified. The equation, therefore, which best represents the pyrolysis of benzyl benzoate is

$$2C_6H_5COOC_7H_7 \longrightarrow (C_6H_5CO)_2O + [(C_7H_7)_2O]$$
$$[(C_7H_7)_2O] \longrightarrow C_6H_5CHO + C_6H_5CH_3$$

A small amount of benzoic acid, in addition to the benzoic anhydride, was also formed. It may have been produced as a primary product, or it may have been produced secondarily from the benzoic anhydride or the benzaldehyde. At least, the absence of stilbene may be taken as evidence that phenylmethylene, $[C_6H_5CH=]$, did not appear even momentarily. Phenylmethylene is the residue obtained by detaching the elements of benzoic acid from benzyl benzoate. Possibly some of the benzaldehyde may have arisen by reversal of the Cannizzaro reaction, but the fact that toluene and benzaldehyde were isolated in roughly equivalent quantities is contra-evidence.

Esters with β-hydrogens in the alcohol part of the molecule, such as $RCO_2CR_2CHR_2$, are known to pyrolyze readily into acid, RCO_2H, and olefin, $R_2C=CR_2$. Benzyl benzoate has no such β-hydrogens and in this respect it is similar to methyl benzoate and benzohydryl benzoate. The former[7] of these is stable to 400°, but the latter[8] gives benzoic anhydride (among other things) on distillation. Presumably the primary effect is one of disproportionation.

$$2C_6H_5CO_2CH(C_6H_5)_2 \longrightarrow (C_6H_5CO)_2O + [((C_6H_5)_2CH)_2O]$$

Experimental Part

Benzaldehyde at 300–310°.—Benzaldehyde was freshly distilled *in vacuo* and was collected over a 2° range. About 50-g. portions were placed in pyrex bomb tubes. Air was excluded with benzaldehyde vapors by boiling prior to sealing. The tube was heated in a bomb furnace for two hours at 300–310° and left overnight to cool. Five such runs were made and the greatest non-recovery of benzaldehyde was 7 g. from 62 g. The percentage of recovery varied between 88–95%. Benzyl benzoate was the major product in the non-benzaldehyde portion, but there was always a small amount of benzoic acid. In no case was any other product isolated.

Pyrolysis of Benzaldehyde at 350–370°.—The details of a characteristic experiment will be related. A sample of benzaldehyde weighing 62.5 g. (freshly vacuum distilled)

---

[6] Benzoic anhydride is known to be stable at least to 400° [Anschiitz, Ber., 10, 1883 (1877); *Ann.*, 226, 15 (1884); Deninger, J. *prakt.* Chem., 50, 480 (1894); Staudinger, Ber., 44, 544, footnote (1911)], whereas dibenzyl ether decomposes rapidly at its boiling point, 295°, and slowly at 210–215° [Cannizzaro, *Ann.*, 92, 113 (1854); Lowe, *ibid.*, 241, 374 (1887); Lachman, THIS JOURNAL, 45, 2358 (1923)].

[7] Engler and Low, *Ber.*, 26, 1441 (1893).

[8] Linneman, *Ann.*, 133, 23 (1865); Anschiitz, *ibid.*, 235, 220 (1886).

was heated for two hours in a sealed tube at 350–370°. After cooling overnight and opening, considerable pressure of an inflammable gas was noted. On distillation of the red liquid, 30 g. was obtained from 110–176°, which, on redistillation, yielded 2 g. of a mobile liquid between 70 and 120°. This was chiefly benzene, as shown by nitration to dinitrobenzene (m. p. 88–89°) and confirmation by a mixed melting point determination with a known sample of dinitrobenzene. The mixture melted also at 88–89°. From this first fraction, and from that boiling from 176–196°, 43 g. of benzaldehyde was recovered. Half a gram of benzoic acid was extracted from the residue, thereby leaving 15.5 g. of a benzyl benzoate portion, b. p. 130–190° (6 mm.), and 1 g. of brown residue.

Fifteen g. of the 15.5 g. of liquid just mentioned, on hydrolysis with alcoholic potassium hydroxide (reflux one hour), gave 7 g. of benzyl alcohol, b. p. 75–80° (6 mm.) and 8.4 g. of benzoic acid. The theoretical yields for 15 g. of benzyl benzoate would be 7.6 g. of the alcohol and 8.6 g. of the acid. There was no high boiling residue and no indication of dibenzyl ether.

Pyrolysis of Benzaldehyde at 680–690°.—Forty-one g. of benzaldehyde was dropped from a stoppered-in dropping funnel into an upturned elbow of a nitrogen-filled pyrex combustion tube. The tube was about a meter long and was maintained at 680–690° (thermocouple measurement) by an electric furnace. The effluent end of the tube was connected to a smaller tube which led through a condenser into a receiving flask. The outlet of the flask was connected so that the gas formed could be collected over a saturated sodium chloride solution. After four hours all the benzaldehyde was added. Therefore, the rate of entry was $^1/_6$ g. per minute. The distillate weighed 31 g. and the volume of the gas was 5.8 liters (standard conditions).

The 31 g. of liquid, on fractionation, gave 11 g. of benzene, 13.5 g. of benzaldehyde and 2.5 g. of diphenyl. Diphenyl (m. p. 65°) was positively identified by chemical and physical properties. From the fraction boiling at 150–200° at 18 mm. about 0.3–0.5 g. of a white crystalline solid (m. p. 213°, corr.) was obtained after two crystallizations from alcohol. It was easily sublimed when distilled in a vacuum and was practically insoluble in cold alcohol or ether. It appeared to be the "anthracene" which Peytral found at 1150°, but no anthraquinone could be isolated from a chromic acid oxidation of a portion, nor could a picrate be made. A mixed melting point determination with anthracene (m. p. 210°) gave a melting point at 170°. Thus the substance was not anthracene. These properties are all those of "terphenyl" or 1,4-diphenylbenzene. In confirmation, a mixed melting point with a known sample of the latter showed no depression of the melting point; mixed m. p. 213° (corr.). Also, it dissolved characteristically in sulfuric acid with a green-blue color which changed to purple on boiling. Finally, a small amount of white powder which did not melt below 295° (terephthalic acid) was obtained from the chromic acid oxidation mixture.

The gas (5.8 liters, corrected volume) contained no methane or unsaturated hydrocarbons. By volume it analyzed as follows: carbon monoxide, 86.7%; hydrogen, 12.9%; carbon dioxide, 0.32%. This is calculated to a nitrogen-free basis.

Benzyl Benzoate, Preparation.—Benzyl benzoate was prepared by refluxing benzoyl chloride and benzyl alcohol for three hours by the method of Cannizzaro.[9] The yield of ester (alkali washed, and b. p. (23 mm.) 198–203°) was found to be 44.5%.

Pyrolysis of Benzyl Benzoate at 350°.—A sample of the ester weighing 42.5 g. (b. p. (21 mm.) 193–198°) was sealed in an evacuated tube and kept at 340–350° for two hours. After cooling overnight, the tube was opened and found to contain an apparently non-combustible gas under high pressure. The contents were black and the volatile portions were distilled off. Three g. of toluene and 2 g. of benzaldehyde

---

[9] Cannizzaro, *Ann.*, 90, 254 (1854).

were isolated. The toluene was identified as dinitrotoluene, which melted at 68–70" after two recrystallizations from alcohol. The same derivative similarly prepared from pure toluene melted at 69–70°, and a mixed melting point was 68–70°. The less volatile material was distilled under diminished pressure, thereby yielding 31.5 g. of distillate. It was dissolved in ether and extracted with alkaline solution, thereby removing 2 g. of benzoic acid. Test portions of the mixture absorbed bromine without the evolution of hydrogen bromide. Although indicative of unsaturated hydrocarbons such as stilbene, no such dibromide could be found. Actually the bromine absorption was caused by benzoic anhydride.[10] A known sample of benzoic anhydride behaved identically. The unused portion weighed 24.5 g. and 20 g. of this was saponified by refluxing with alcoholic potassium hydroxide for an hour and a half. This produced 7.5 g. of benzyl alcohol, b. p. (6 mm.) 75–80". The equivalent quantity of benzoic acid would be 8.5 g. but actually 12 g. (m. p. 120–122°) was isolated. The excess was produced from benzoic anhydride. These data indicate at least 15 g. of benzyl benzoate and about 3 g. of benzoic anhydride in the original 20 g. which was saponified. In terms of the 31.5 g. of distillate, this extrapolates to 23.6 g. of benzyl benzoate and 4.7 g of benzoic anhydride.

Summary

The decomposition of benzaldehyde is very slow at 300°, but about one-third of it decomposes, largely into benzyl benzoate, in two hours at 350°. A concurrent reaction of much less importance gives rise to carbon monoxide and benzene. No evidence could be obtained for toluene or dibenzyl ether as reaction products and benzoic acid is formed in negligible amounts.

By passing benzaldehyde through a pyrex tube at 700° at a rate of one-sixth g. per minute, it was about two-thirds decomposed. The major reaction was the formation of benzene by loss of carbon monoxide. Side reactions gave rise to diphenyl and 1,4-diphenylbenzene. Anthracene was definitely absent.

At 350" benzyl benzoate undergoes a reaction of disproportionation. After two hours' heating, the major products of change are benzoic anhydride, toluene and benzaldehyde. Smaller amounts of benzoic acid were also indentified. Negative searches were made for stilbene, phenanthrene, benzene, diphenyl and dibenzyl ether in the products of reaction.

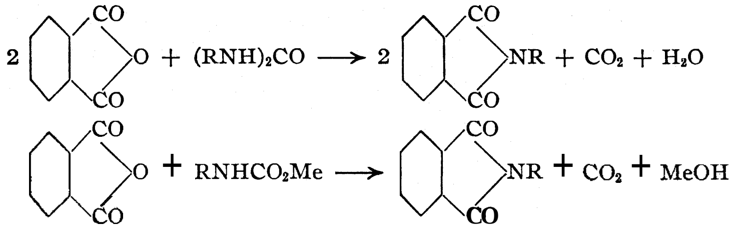
A MODIFICATION OF THE CURTIUS SYNTHESIS OF PRIMARY AMINES

BY RICHARD H. F. MANSKE[1]

RECEIVED OCTOBER 23, 1928 PUBLISHED APRIL 5, 1929

The usefulness of the Curtius reaction for the synthesis of primary amines is considerably decreased because of the difficulty frequently encountered in hydrolyzing the intermediate alkylureas and urethans. Di-p-phenylethylurea is hydrolyzed completely only after prolonged heating in a sealed tube with concentrated hydrochloric acid at high temperatures.[2] Such a procedure is likely to result in dealkylation when alkoxyl groups are present. The author observed that di-β-(3-indolylethyl)-urea was completely resinified on heating with hydrochloric acid even for a short time, while boiling with saturated alcoholic potassium hydroxide for twenty-four hours resulted in no change. Distillation with soda lime is generally to be avoided and is obviously too drastic in this case. The high temperature is conducive to decomposition and the yield of impure product is frequently very low.

When alkylureas are heated with phthalic anhydride, alkyl phthalimides are formed in excellent yield,[3] and the same reaction has now been applied to alkyl urethans. The reactions are represented as follows



and bring the methods of Gabriel and of Curtius into a common field. The subsequent hydrolysis of the alkylphthalimides may be quantitatively accomplished by the reaction of Ing and Manske.[4]

The examples described in the experimental section suffice to illustrate the generality of the reaction here discussed.

Experimental

1,8-Diphthalimido-octane.—A mixture of octamethylene-1,8-dimethylurethan[5] (4 g.) and phthalic anhydride (8 g.) was heated in an oil-bath at 230° until evolution of gases ceased (*ca.* thirty minutes). The reaction mixture which contained a small

amount of phthalic anhydride was cooled to 100°, treated with a small volume of alcohol and then neutralized with an excess of aqueous sodium bicarbonate. The precipitated diphthalimide compound crystallized almost at once. It was filtered off, thoroughly washed with water, dried and recrystallized from a small volume of alcohol, in which it is moderately soluble; yield, 7.4 g. It consists of colorless, glistening needles melting at 138°.[6]

Anal. Calcd. for $C_{24}H_{24}O_4N_2$: N, 6.93. Found: N, 6.43, 6.71.

In order to confirm the identity of this product a small amount was hydrolyzed with hydrazine hydrate.[4] The hydrochloride of the resulting base was identical in all respects with an authentic specimen of octamethylenediamine hydrochloride (mixed m. p. 277°).[5b]

Di-γ-phenoxypropylurea.—γ-Phenoxybutyric hydrazide, $C_6H_5OCH_2CH_2CONH\text{-}NH_2$, was prepared by heating a mixture of 70 g. of ethyl y-phenoxybutyrate, 20 g. of hydrazine hydrate (90%) and 50 cc. of ethyl alcohol under a reflux for ninety minutes. The greater portion of the alcohol was removed by distillation and the residue was heated under reflux for sixty minutes more. The cooled mixture yielded 55 g. of hydrazide which after two recrystallizations from alcohol had a melting point of 81–82°.

The crude hydrazide was converted into the azide by treating an iced solution of 19.4 g. in 200 cc. of water and 10 cc. of concentrated hydrochloric acid with 6.9 g. of sodium nitrite. The precipitated azide was thoroughly washed with iced water (it melted at room temperature to *a* pale yellow liquid) and decomposed by gradually heating it in 50 cc. of acetic acid and 300 cc. of water. The urea crystallized even while the liquid was boiling. It was filtered off, washed with water and recrystallized from alcohol, in which it is only sparingly soluble. The yield of purified product was 10 g. After another recrystallization from alcohol (charcoal) it melted sharply at 150°.

Anal. Calcd. for $C_{19}H_{24}O_3N_2$: N, 8.54. Found: N, 8.47.

γ-Phenoxypropylphthalimide.—Di-γ-phenoxypropylurea (16.4 g.) was heated with phthalic anhydride (16 g.) at 225° in an oil-bath until evolution of gases ceased (fifteen minutes). The excess phthalic acid was removed with aqueous sodium bicarbonate and the alkyl phthalimide recrystallized from alcohol; yield of pure product, 24 g. It melted alone or admixed with an authentic specimen at 91°.[7] Hydrolysis with hydrazine hydrate[4] yielded γ-phenoxypropylamine hydrochloride melting at 168° (alone or admixed with an authentic specimen).'

β-(3-Indolylethyl)-phthalimide, $(C_8H_6N)CH_2CH_2N(CO)_2C_6H_4$.—In the course of some experiments with the azide of indolylpropionic acid,[8,9] a small yield of di-β-(3-indolylethyl)-urea was frequently encountered. The exact conditions for obtaining this urea in good yield have not been investigated sufficiently and this subject together with some further work on indolylpropionic and indolylbutyric acids will form the substance of an early communication.

When the urea was heated at 225° with an excess of phthalic anhydride and the mixture worked up in the usual way, the phthalimide was obtained in excellent yield. After two recrystallizations from alcohol (charcoal) it consisted of pale yellow needles (readily soluble in hot alcohol) melting at 164–165°.

Anal. Calcd. for $C_{18}H_{14}O_2N_2$: C, 74.48; H, 4.83. Found: C, 74.32; H, 4.96.

On hydrolysis with hydrazine hydrate it produced tryptamine (β-3-indolylethyl-

amine) in quantitative yield. The hydrochloride consisted of colorless needles melting at 248°. The picrate had a melting point of 243°.[10]

Summary

1. It is suggested that the hydrolysis of alkylureas and urethans, when acid or alkali hydrolysis is impracticable, be accomplished by means of phthalic anhydride and subsequently with hydrazine hydrate.
2. This procedure has been utilized in the synthesis of tryptamine.

THE RELATION BETWEEN THE ABSORPTION SPECTRA AND CHEMICAL CONSTITUTION OF CERTAIN AZO DYES. I. THE EFFECT OF POSITION ISOMERISM ON THE ABSORPTION SPECTRA OF METHYL DERIVATIVES OF BENZENE-AZOPHENOL[1,2]

BY WALLACE R. BRODE

RECEIVED OCTOBER 27, 1928 PUBLISHED APRIL 5, 1929

The effect of position isomerism on the absorption spectra of similarly constituted aromatic compounds has been studied by Baly,[3] Purvis,[4] Klingstedt[5] and Henri[6] together with their co-workers in this field. In general it has been shown that substitution in the para position produces a stronger absorption band than substitution of the same group in either the ortho or meta position in the benzene ring. This effect, although not always mentioned, can be noted in the data of other observers. Recent work by Henri on the absorption spectra of isomeric xylenes and dihalogenated benzene compounds in the vapor phase has shown considerable variation in the fine structure of the absorption bands with a change in the position of substitution. The unstable nature of azo dyes, however, does not permit the study of their absorption spectra in a vapor state, so that data by this method are unobtainable on the compounds studied in this paper.

The object of this investigation is a fundamental quantitative study

of the relation between the absorption spectra and chemical constitution of simple derivatives of benzene-azophenol. The isomeric series of dyes selected for this study include, together with the parent substance, benzene-azophenol, all the possible mono- and dimethyl derivatives of benzene-azophenol in which not more than one methyl group occurs in a benzene ring. These dyes, prepared from c.p. intermediates, were recrystallized several times from alcohol and analyzed according to the Kolthoff[7] modification of the Knecht and Hibbert[8] titanous chloride titration method for azo dyes (see Table I).

Experimental

The data presented in this paper deal only with these dyes dissolved in a 3% aqueous solution of sodium hydroxide.[9] The alkaline dye solutions for spectrophotometric examination were prepared as follows.

The weighed amount of dye, 0.7200 g. of benzene-azophenol or 0.8450 g. of its various mono- and dimethyl derivatives, was dissolved in 500 ml. of alcohol (95%) at 20°. Fifty ml. of this solution were diluted to 250 ml. with alcohol and then 10 ml. of this latter solution and 10 ml. of a 30% solution of c.p. stick sodium hydroxide in distilled water were diluted to 100 ml. with distilled water. Thus the solutions which were measured contained 2.880 cg. per liter of benzene-azophenol or 3.380 cg. per liter of the mono- and dimethyl derivatives. It should be noted that the solutions as used contained a small amount of alcohol.

The experimental observations were made with a Hilger sector photometer and spectrograph.[10] This apparatus and the system of nomenclature used in the presentation of the data are described in previous papers published in THIS JOURNAL and elsewhere.[11] The data presented are plotted with $-\log_{10}$ transmittancy (intensity of absorption) as the ordinates and frequency in vibrations per 10^{-12} second as the abscissas. In Figs. 1 and 2 the concentrations are the same only when the molecular weights of the compounds are the same. In Table I, however: the absorption values have been corrected for analysis and weight so that all of the indicated values are for the same molecular concentration, that is, 1.5×10^{-4} g. mole per liter. The cell thickness used in all cases was 0.5 cm.

Discussion of Data

An examination of the absorption curves, Figs. 1 and 2, will show that all of these compounds exhibit the same general type of absorption.

1.64	1.86	1.52	1.42	2.94	.517	.73

[a] Approximate values.

There is a strong band between 670 and 750 f. and a weaker one between 1125 and 1200 f. The principal band is slightly asymmetric in form, the lower frequency side having a steeper slope than the higher frequency side. Further it is markedly deformed in the region of maximum absorption. Apparently it is composed of two overlapping bands. These components appear to be in equilibrium with each other, for where one of them is increased the other is diminished in intensity (see Table I). This suggests the presence of two slightly different modifications of the compounds in the solutions studied, the proportions of **which** are influenced by the position of the substituting group.

From a study of the absorption bands of these **and** similar compounds in various other solvents,[9,11d,11e] it may be seen that in any one solvent,

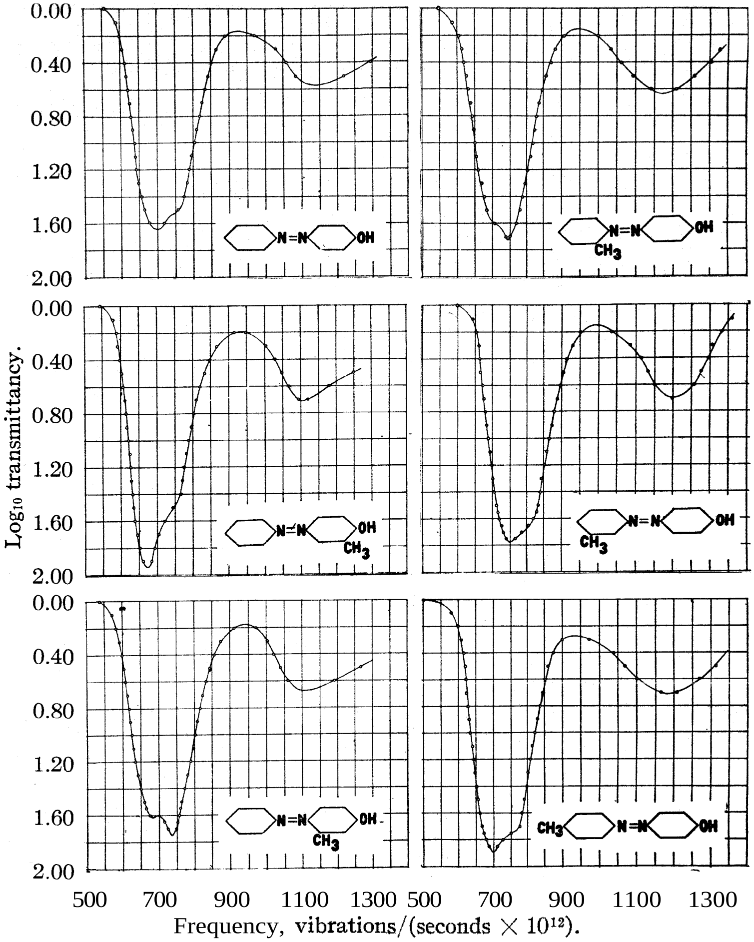

Fig. 1.—The absorption spectra of benzene-azophenol and its monomethyl derivatives in a 3% aqueous solution of sodium hydroxide. Concentration: benzene-azophenol, 2.88 cg. per liter; the monomethyl derivatives, 3.38 cg. per liter; cell thickness in all cases 0.5 cm. although the intensity or frequency may be shifted, the mathematical relation between the bands and their general shape when calculated to the same intensity of absorption is the same. Assuming that the two bands which make up the principal band in Figs. 1 and 2 have the same shape in all cases, an analysis of the curves into these components is possible and only one set of curves answering this requirement can be constructed.[12] It is found that approximately the same mathematical

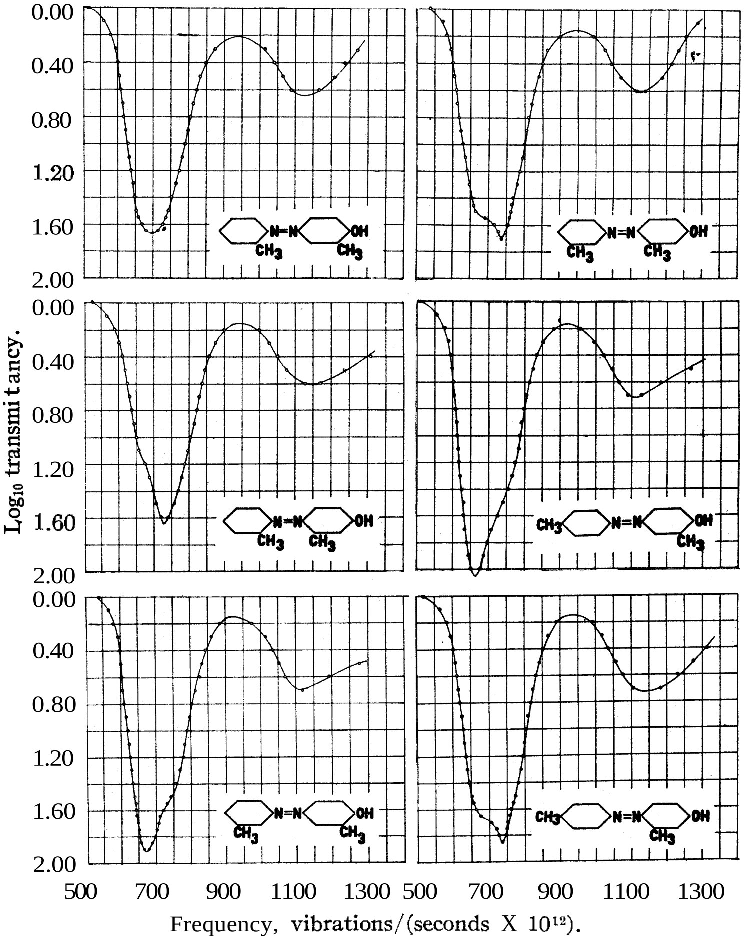

Fig. 2.—The absorption spectra of dimethyl substituted derivatives of benzene-azophenol in a 3% aqueous solution of sodium hydroxide. Concentration: **3.38** cg. per liter; cell thickness, 0.5 cm. relations with regard to frequency exist between the components of the principal bands. These facts tend to justify the assumption that the curves are composed of but two similar components. Whether or not

---

[12] Brode, Proc. Roy. *Soc.* London, **118A,** 290 (1928).

this assumption is true, their shape gives that appearance and the data obtained by the analysis afford a better expression of the changes in the principal bands than the curves themselves.

In Table I are given both the observed and calculated values of the components of the principal absorption bands. The observed values are indicated by A and B, corresponding to the low and high frequency

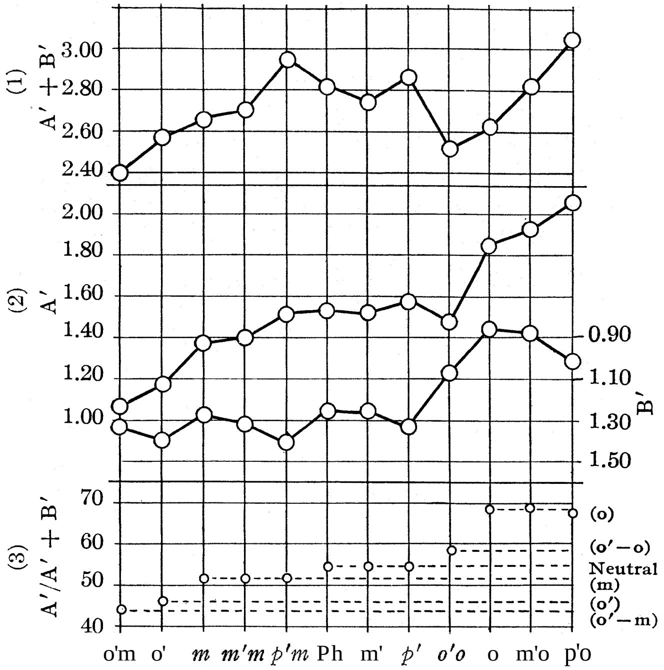

Fig. 3.—(1) Absorption intensities of the sum of the component bands (A' + B') of the principal band observed in a 3% aqueous solution of sodium hydroxide. Concentration, 1.5×10^{-4} mole per liter; cell thickness, 0.5 cm. Abscissas in $-\log_{10}$ transmittancy. (2) Absorption intensities of the principal band observed in a 3% solution of sodium hydroxide. A' = upper series, B' = lower series. Abscissas in $-\log_{10}$ transmittancy. (3) Percentage of the A' component of the principal band in a 3% aqueous solution of sodium hydroxide. (The abbreviated symbols for the compounds are explained in Table I.)

components, respectively, and the calculated values are similarly designated by A' and B'. It may be seen that the general direction of the deviations is the same in both cases. Fig. 3 (1) gives the sum of the absorption values of the components (A' + B'). As has been noted in other solvents and compounds, substitution in the *p'*-position results in an increase in the intensity of the absorption bands and this generalization holds equally true in the case of aqueous sodium hydroxide as a solvent. Also substitution in the o'-position tends to decrease the intensity of the bands as well as to influence the ratio between the A and B components.

In the absorption spectrum of benzene-azophenol, the parent substance of this series, in an aqueous solution of sodium hydroxide, there is what we may call a neutral equilibrium, in which band A is slightly more intense than band B. This neutral equilibrium does not represent an equal amount of the two forms and may undoubtedly be influenced by changes in the character of either the basic substance or the solvent.[9] For example, in the absorption spectrum of benzene-azophenol in an alcoholic solution of sodium hydroxide, the equilibrium has been shifted, with an increase in B and a corresponding decrease in A. Two other curves closely resemble the neutral curve of benzene-azophenol, namely, those of the *m'*- and *p'*-substituted compounds (Fig. 1). These two, together with the unsubstituted parent substance, constitute the neutral group or series. In the case of the *m'*-substituted compounds, there appears to be practically no effect of any kind on either the equilibrium or the intensity of the A and B bands. In the case of the *p'*-substituted compounds there is an increase in the intensity of absorption, but the relative shapes of the bands and the ratio between the components A and B are the same as in the original compound without the p'-substitution.

Substitution in the o-position (ortho to the hydroxyl group) (Fig. 1) causes a marked increase in the A band and a corresponding decrease in the B band or, in other words, a shift of the equilibrium toward the A state.

Substitution in the m-position (meta to the hydroxyl group) causes a shift of the equilibrium in the opposite direction, that is, an increase in the B band with a corresponding decrease in the A band. The degree of shift of this equilibrium from the neutral state, however, is not as great as in the case of the o-substitution.

Substitution in the o'-position causes an increase in the B component with a corresponding decrease in the A component, producing a relation differing from the neutral ratio by about the same amount, but in the opposite direction, as that caused by the o-substitution. In addition there is a suppression of both bands so that the sum of the intensities of A and B is considerably smaller than in the other cases (Fig. 3 (1)).

The general effect of disubstitution on the intensities of the two component bands is a combination of the effects produced by the two separate directing forces. In the case of the *o',o*-substituted compound (Fig. 2) the effects of the two substituting groups are opposite in character and to a large extent neutralize each other. The o-substitution appears to have a slightly stronger influence than the o'-substitution as the intensity of the A component present is slightly greater than in the neutral equilibrium. The effect of the o'-substitution, however, on the suppression of the bands seems to be only slightly influenced by the oppositely directed force of the o-substitution. In the o^1,m-substituted compound the substituting positions influence in the same direction from the neutral equilibrium or level, so that there is an addition of the two effects and a slightly greater suppression of the bands, due to the o-substitution. The effect of the introduction of the second substitution in the *m′*-position on the absorption spectrum of the compound is practically nil within the accuracy of the observations. There is possibly a slight increase in the intensity of the bands of the m^1,o-substituted compound above those of the o-substituted compound alone and a slight lowering of the ratio of A to B. In the absorption spectrum of the *m′*,*m*-substituted compound there is an indication of the same effect, although it is less prominent than in the *m′*,*o*-substituted compound. The influence of the substitution in the *p′*-position, as mentioned before, seems to be merely to increase the intensity of absorption, an effect quite independent of the solvent used.

In the graph (Fig. **3** *(2))* giving the intensities of absorption of components A' and B', those of B' are plotted on an inverted scale, since from general observation it may be seen that as one band increases the other decreases. It is to be noted that in cases which are normal, such as the unsubstituted, m-substituted and m^1-substituted compounds, approximately the same differences exist between the A′ and B′ values in the graph. Cases in which there is an intensification of the bands, *p′*-substituted compounds, show a difference greater than normal values, and cases with suppressed bands, o-substituted compounds, show differences smaller than the normal values.

A comparison of the sums of the calculated values of the intensities of the A' and B' bands (Fig. **3** (1)) with those of the principal bands of these same compounds in other solvents[8] shows that the same general relations exist in regard to the intensities of the absorption bands. This lends confirmation to the theory that, in any particular compound, the equilibrium between the concentration of the tautomeric forms represented by the bands A and B is directly proportional to the intensities of their absorption bands (A^1 and B').

The ratio of A′ to (A' + B') should, therefore, give approximately the percentage of the (A) tautomeric compound present and at the same time make the necessary corrections or allowances for the *p′*- and *o′*-effects on the intensities of both the component bands. (Fig. 3 (3)) gives these percentage values which, as may be observed, can be arranged in groups representing different stages or levels in the equilibrium. The highest percentage is about 68% of the A compound, which may be called the o-level. The next stage is that of a neutralized effect from two different levels which exert their influences in opposite directions from the neutral level; this is the combined effect of the o- and o'-substituting groups. The influence of the o-substitution is apparently somewhat stronger than that of the 0'-substitution, so that the level of this stage is still above the neutral level.

The next level is that of neutrality and is at about 55% of A under the conditions observed. As has been mentioned before, the use of other solvents for the alkaline reagent may shift this level or equilibrium. In the neutral level are the mono-substituted, *m'*- and *p'*-compounds, as well as the parent substance.

The effect of the m-substitution is not as strong as that of either the o- or the 0'-substitution. In the cases observed the equilibrium level has been lowered to about 51% of A.

The o'-substituted compound, when not influenced by other substitutions, produces an equilibrium at about 44% of A. The effect of the *o*-substitution on the 0'-substituted compound has been mentioned, and in the case of the *o'*,*m*-disubstituted compound, where both groups tend to lower the percentage of A in the equilibrium, the effect is additive, giving an equilibrium level at 41% of A.

The author wishes to express his appreciation of the help and suggestions given by W. D. Appel of the Dye Laboratory of the Bureau of Standards.

Summary

Benzene-azophenol and the eleven possible mono- and dimethyl derivatives, in which not more than one methyl substitution occurs in a benzene ring, have been prepared and their absorption spectra measured in a 3% aqueous solution of sodium hydroxide in the visible and ultraviolet regions of the spectrum to about 1250 to 1400 f.

From these data the following generalizations have been made.

1. The principal absorption bands appear to be composed of two component bands which, added together, produce the observed bands.

2. The equilibrium between the two components of a band is dependent on the nature of the solvent and the position of the substituting group. An o-substitution of the methyl radical in the benzene-azophenol molecule results in an increase in the lower frequency component, with a corresponding decrease in the higher frequency component. A m- or o'-substitution produces a reverse effect, while the equilibrium is not affected by either a m'- or *p'*-substitution.

3. Substitution of a methyl radical in the *p'*-position in benzene-azophenol causes an increase in the intensity of the absorption bands, irrespective of the type of solvent.

4. Substitution of a methyl radical in the 0'-position in benzene-azophenol causes a decrease in the intensity of the absorption bands.

The data suggest the possibility of a method of structural analysis for the determination of the position of a substituting group in a complex molecule, and a reverse of this in the prediction of the absorption spectra of compounds of known formula and structure. Additional data on the effects of substituting groups, including those of nitro,[13] chlorine and bromine substitutions, are now being collected with this object in view.

A METHOD FOR THE QUANTITATIVE ANALYSIS OF TIM IN ORGANIC COMPOUNDS

BY HENRY GILMAN AND W. BERNARD KING

RECEIVED OCTOBER 29, 1928 PUBLISHED APRIL 5, 1929

Introduction

In connection with studies on organotin compounds a need was felt for a convenient method for the quantitative estimation of total tin. The successful method described recently by Gilman and Robinson[1] for the estimation of total lead in organolead compounds suggested a similar technique for the analysis of tin. That method, applied to non-volatile organolead compounds, involved decomposition with concentrated sulfuric and nitric acids in the open. It was soon found to be without value when applied to a variety of alkyl tin compounds because of loss due to spattering and volatilization. We have shown that the method is applicable to the analysis of essentially non-volatile organotin compounds, and prior to our analytical studies Krause and Becker[2] used fuming sulfuric and fuming nitric acids for the analysis of some *aryl* tin compounds.

The obvious convenience of carrying out the analysis in open dishes directed efforts to find reagents that would decompose *all* organotin compounds without risk of losing any of the sample as a consequence of spattering or volatility due to vigorous decomposition incidental to the formation of stannic oxide. Several reagents were tried.[3] A satisfactory

[1] Gilman and Robinson, THIS JOURNAL. 50,1714 (1928).

[2] Krause and Becker, *Ber.*, 53, 178 (1920). In an article which has just appeared, Fichter and Herzbein, *Helv. Chim. Acta*, 11, 562 (1928), analyzed tin dichlorodiacetate by hydrolyzing the aqueous solution of the compound with ammonia and ammonium nitrate.

[3] One of these involved a *preliminary* decomposition by concd. hydrochloric acid, followed by the nitric–sulfuric acid oxidation to stannic oxide. In this method the compound is first dissolved in carbon tetrachloride, which is an excellent solvent for organotin compounds. The preliminary decomposition by hydrochloric acid is slower than the preliminary decomposition by bromine. However, satisfactory results were obtained by this method with the few compounds tried. We prefer the bromine method that is more fully described in this paper

reagent for non-volatile tin compounds, such as tetraphenyltin, was found in a mixture of one part by volume of concd. nitric and six parts of concd. sulfuric acids. This mixture with volatile compounds gave results that were barely acceptable, and the consistently low values indicated a loss of material.

The lesser volatility of organotin halides, their smooth oxidation to stannic oxide, and their ready formation by the addition of bromine to organotin compounds suggested a method based on a preliminary decomposition by bromine in carbon tetrachloride followed by a nitric–sulfuric acid oxidation to stannic oxide. This method has been successfully applied to a wide variety of organotin compounds and has been checked by several workers in this Laboratory. The total time required for an analysis is about six hours, but for a great part of this time (during evaporation and ignition) the analysis requires little or no attention.

Method of Analysis

About 0.5 g. sample of compound is placed in a previously weighed 60-cc. porcelain crucible.[4] The crucible is then partially immersed in an evaporating dish containing cold water.[5] A solution of bromine in carbon tetrachloride (of about 4% concentration) is added slowly with shaking.[6] Two cc. of a concd. nitric (one part) and concd. sulfuric (six parts) acid mixture is then added dropwise[7] with shaking or agitation. A reaction generally sets in with the first few drops of the acid mixture and a white precipitate forms and rises to the surface. After the first few drops of acid mixture have been added it is well to wait for a few minutes until a reaction begins. Thereafter the dropwise addition of acid is regulated by the subsidence of reaction.

In like manner there is then added 3 4 cc. of a 1:1 mixture of concd. nitric and concd. sulfuric acids. With the more volatile and reactive alkyl tin compounds it may be advisable at or prior to this point to replace the warm water in the evaporating dish by cold water. There is then added 2 cc. of concd. nitric acid and 4–5 cc. of fuming nitric acid.

The crucible is then covered by a small watch glass in a manner to permit the ready escape of fumes, and allowed to stand on a steam-plate or its equivalent for about half an hour. The contents are then heated[8] to expel the residual oxides of nitrogen and the carbon tetrachloride until a clear solution is obtained.

---

[4] Thorough shaking is difficult in a smaller-sized crucible.

[5] Such cooling is helpful in the decomposition of the more volatile compounds. Also it reduces the time required for the preliminary decomposition of all organotin compounds.

[6] The bromine should be added to a slight excess. The appearance of a brown color is not always evidence of an excess of bromine. The characteristic reddish color of bromine will appear when an excess has been added. The addition of bromine may be omitted with organotin halides of high molecular weight.

[7] The reagents are best added by keeping the tip of the pipet near the side of the crucible and above the edge of the material. During the addition, the contents of the crucible are agitated by a circular motion.

[8] This may be effected by heating in an air-bath, a convenient form of which is provided by placing a clay triangle on an evaporating dish and then heating the dish directly. Or, if time permits, the crucible may be allowed to remain on the steam-plate for a longer period than one-half hour.

The watch glass is now removed and the heat regulated until there is a slow evolution of sulfuric acid fumes. This heating is continued until all of the acid has been expelled. A grayish residue generally results. The crucible is then heated slowly by means of a small direct flame until the evolution of white fumes has practically ceased. A more intense heat is then applied, finally ending with ignition by a Méker burner. The crucible and contents are ignited to constant weight and the tin is estimated as stannic oxide.

The results of some representative analyses follow.

TABLE I

RESULTS OF ANALYSES

Compound	Sn %		
	Calcd.	Found	
Tetraethyl tin	50.53	50.66, 50.30	50.54, 50.13
Tetra-*n*-butyl tin	34.21	34.06	34.02
Tri-*n*-butyl tin bromide	32.14	32.39	32.26
Di-*n*-butyl tin dibromide	30.22	29.81	29.99
Triethyl-*p*-bromophenyl tin	32.81	32.33	32.12
Tetraphenyl tin	27.80	27.85	27.95
Triphenyl tin iodide	24.89	24.60	24.82
Triphenyl-*p*-chlorophenyl tin	25.72	25.81	25.74

The authors wish to acknowledge some check analyses carried out by C. C. Vernon and W. L. Wall.

Summary

A method has been described for the quantitative estimation of total tin in a variety of organotin compounds. The method consists of a preliminary decomposition by bromine in carbon tetrachloride followed by a nitric-sulfuric acid oxidation to stannic oxide.

NATURAL AND SYNTHETIC RUBBER. I. PRODUCTS OF THE DESTRUCTIVE DISTILLATION OF NATURAL RUBBER

BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

RECEIVED NOVEMBER 2, 1928 PUBLISHED APRIL 5, 1929

The destructive distillation of rubber has been studied by many investigators. Isoprene and dipentene have been isolated many times, identified and shown to be the predominating products. The existence of other products has often been detected and empirical names have been given to them. Ipatiew and Wittorf[1] have positively identified trimethylethylene; Harries[2] identified myrcene and also a terpene with a boiling point of 168–169°. Heveen (b. p. 252°) was found by Bouchardat[3]

and Staudinger[4] recently, has isolated two compounds which he believes to be dimethylbutadiene and tetrahydrotoluene. Staudinger and associates[4,5] also state that in the distillate from destructive distillation at reduced pressure only isoprene and dipentene are present in the fraction below 200°.

The present work was undertaken largely for the purpose of throwing light upon the structural formula of the rubber hydrocarbon and, although this objective has not been attained, it is hoped that an extension of the methods of prediction developed herein to the constitution of heveen, $C_{15}H_{24}$, may eventually yield constructive results.

Procedure

Two hundred pounds of light pale crepe were destructively distilled at atmospheric pressure, in 16-lb. batches in an iron vessel connected to a suitable condensing system. No attention was paid to temperature control, due to the large size of the batches; the temperature was always raised as quickly as possible to about 700°, in order to obtain a favorable yield of isoprene, which was desired for work on synthetic rubber. The distillate is a dark-colored oil. After removal of isoprene by fractionation, the residual oil was subjected to thorough fractional distillation in a carborundum-coated spiral column.[6] Cuts were made for every degree between 50 and 176°. The customary volume of an intermediate was 5 cc., except where components were detected within 4" of each other, in which case the intermediates were larger. Several components were present to the extent of 50 cc. or more, and in such cases accurate and positive identification could be made. In other instances, 10 or 15 cc. was the maximum amount to work with. Such cases are recorded in the data only when the identification was sufficient to be certain of the series to which the component belonged.

It was later discovered that the addition of magnesium to the rubber greatly increased the yield of materials other than isoprene and dipentene. Zinc, iron and aluminum have a similar effect but to a very much smaller extent; copper is without effect; brass equals iron. A batch of 16 lb. of rubber was destructively distilled in the presence of 850 g. of magnesium and the product separately investigated. The same components were found that had been identified in the distillation of rubber alone but the proportions were different. The material from the distillation with magnesium is richer in compounds of the aromatic series and poorer in chain compounds. The liberty has been taken only in the cases of a few of the chain compounds, which were present in both cases in extremely

small quantity, of combining the same cuts in order to obtain a sufficient sample to work with.

Wherever two or more components could not be separated to purity by fractional distillation, other methods of purification were used. Distillation from aniline proved to be very useful in separating chain from hydro-aromatic compounds. Compounds of the aromatic series were treated with bromine to eliminate the ethylenic impurities and steam distilled.

Cuts were considered suitable for identification: **(1)** when the Engler distilling range was less than 2°, (2) when special tests gave positive identification of the presence of a compound in the bulk, **(3)** when the compounds present could each be identified separately and the physical properties of the mixture checked this analysis (this has been done in only one case when more than two compounds were present) or (4) when continued purification failed to alter the physical properties.

In general, physical constants were relied upon for identification. These were augmented by titration of the unsaturation with a KBr–$KBrO_3$ mixture and by determination of the molecular weight. Quantitative hydrogenation with platinum black, followed by removal of the aromatic compounds by nitration, played an important part in many identifications. Special tests were used when found in the literature. Combustion was used in cases where the C–H ratio was in doubt.

Due to the small quantity of hydrocarbon left after other methods of identification had been exhausted, the location of double bonds with potassium permanganate was rendered impracticable. Consequently, where the comparison of physical constants is not sufficiently accurate to locate a double bond or where the constants are lacking in the literature, the exact position of the double bond remains in doubt. The location is actually being determined by ozonation and will be reported later.

In addition to the components which could be separated by fractional distillation, a substantial proportion of the original material polymerized, remaining as a jelly in the distilling flask. It may be safely assumed that the materials lost in this way consisted very largely of dienes which were too unstable to distil.

Results

Briefly stated, the materials found were olefinic, dienic, aromatic and hydro-aromatic compounds, and a single dicyclic olefin. No fully saturated compound was detected. Table I lists the names of the compounds, the degree of accuracy of their identification and the relative quantities present in the two types of distillates.

The following paragraphs describe more completely each compound listed in the table. The common or Geneva name is used to initiate the paragraph when positive identification has been secured. It is followed by the physical constants from "International Critical Tables" (abbreviated as I. C. T.) or other sources, which are then indicated. The next listed item is the method of purification, followed by the physical constants of the purified substance. Additional data include special tests, constants of the hydrogenated compounds, special observations, etc. Where no positive identification is possible, the paragraph is headed by the word COMPONENT, followed by the physical constants found and any other data bearing on the partial identification. The boiling point ranges refer to Engler distillation from the ten-to-ninety-per cent.-over points and unless otherwise stated densities are at 20°/20° and indexes of refraction at 20°.

3-Methyl-1-Butene.—B. p., 21°; d, 0.660; n not given; mol. wt., 70. Purified by fractional distillation: b. p., 19–20°; d_{20}^{15}, 0.645; n^{18}, 1.3897; mol. wt., 66.8; double bond, 1.35. Although the material obtained was impure, there can be no doubt that the major part of it was 3-methyl-1-butene. It probably contained a low-boiling diene as impurity.

Table I

Compounds, Identification and Quantities

Compounds	Degree of identification	% in distillate Straight	 With Mg

2-Methyl-1-Butene.—B. p., 32°; d_0^0, 0.667; n^{17}, 1.378. Purified by polymerization of the contained isoprene with sodium–potassium alloy, removal of the polymerized product, reduction of the remaining isoprene by sodium in liquid ammonia and subsequent fractional distillation: b. p. 30–31 °; d_{20}^{17}, 0.6645; n^{17}, 1.3752; double bond, 1.0.

Isoprene.—B. p., 34°; d, 0.679; *n*, 1.4221. Purified by fractional distillation, identified by polymerization to synthetic rubber: b. p., 33-34"; *d*, 0.671; *n*, 1.4103. Rromination indicates 1.82 double bonds per C_5H_8. Pentenes were present as impurities.

2-Methyl-2-Butene.—B. p., 38.4°; d^{13}, 0.668. Purified by fractional distillation: b. p., 36.8–38°; *d*, 0.666; *n*, 1.3927; double bonds, 1.25 per C_5H_{10}. Isoprene present as impurity.

Component 59–60°.—*d*, 0.730; *n*, 1.4117; 1.0 double bond per C_6H_{12}. Purified by fractional distillation. Hydrogenation and nitration gave a material, b. p., 60–61°; *d*, 0.654; *n*, 1.3728; mol. wt., 87. I. C. T. gives for 2-methylpentane: b. p., 60°; d, 0.654, *n*, 1.372; mol. wt., 86. These results identify the original material as a 2-methylpentene, position of the double bond unknown.

3-Methyl-2-pentene.—Isomer No. 1: b. p., 65.7"; d^{15}, 0.722; *n*, 1.4065. Isomer No. 2: b. p., 70.2°; *d*, 0.698; *n*, 1.401. Purified by fractional distillation: b. p., 62-65'; d, 0.694; *n*, 1.404; double bond, 1.07 per C_6H_{12}. Hydrogenation gave a compound b. p., 63.6–64.5°; *d*, 0.666; n, 1.3752; mol. wt., 86. I. C. T. gives for 3-methylpentane: b. p., 64°; *d*, 0.668, *n*, 1.377, mol. wt., 86.

Component 76–79°.—Purified by aniline fractionation: *d*, 0.742; n, 1.4346; double bonds, 1.58 per C_6H_{10}. Partially hydrogenated, then extracted with H_2SO_4; adding water to the acid liberates an oil which gave on redistillation: b. p. 67–68°; *d*, 0.712; *n*, 1.4060; mol. wt., 83. Bromine reacted slowly. I. C. T. gives for 3-methyl-2-pentene two isomeric forms of which the average is: b. p., 67.8"; d, 0.712; *n*, 1.4039; mol. wt., 84. The following deductions may be made: 1.58 double bonds shows the presence of a diene in the original material; the partial hydrogenation and the extraction show that the carbon structure of this diene corresponds to 3-methyl-pentadiene. The forms compatible with the experimental results are:  $C{=}\underset{\substack{|\\C}}{C}{-}C{=}C{-}C$,  $C{=}C{=}\underset{\substack{|\\C}}{C}{-}C{-}C$ and  $C{=}C{-}\overset{\substack{C\\\|}}{C}{-}C{-}C$. The only diene given in the literature boiling at 76–79' is 3-methyl-1,3-pentadiene, for which the constants by Abelmann are: b. p., 76–79"; d_4^0, 0.7576, $n^{16\ 5}$, 1.45427. *A* mixture of 64% of this diene, 31% of 3-methyl-2-pentene and 5% benzene will yield physical constants in close agreement with those of the original mixture. 3-Methyl-2-pentene and benzene are the adjoining and identified components. The identification is not considered as positive, despite the strong evidence.

Benzene.—M. p., 5.6"; b. p., 79.6"; *d*, 0.878; *n*, 1.5014.—Purified by aniline fractionation followed by a treatment with bromine and distillation: 2 cc. of purified material was obtained; m. p., +2°; n, 1.4995; characteristic odor of benzene.

Component 93-G°.—Purified by fractional distillation: d, 0.744, *n*, 1.422; 1.06 double bond per C_7H_{14}. Hydrogenation and nitration gave a compound: b. p., 92–95"; d, 0.723; *n*, 1.4032, which contained hexahydrotoluene as an impurity. The physical constants are not in sufficient agreement with anything in the literature to allow a possible identification. The nearest physical constants given are for d-3-methylhexane: b. p., 92°; d, 0.687. The physical constants of the hydrogenated product show that it contained a large proportion of a paraffinic hexane, the boiling point of which corresponds to the one given for 3-methylhexane. Identification considered incomplete.

Δ^3-Tetrahydrotoluene.—B. p., 103°; *d*, 0.799; n, 1.443. Purified by fractional distillation: b. p., 102–103°; d, 0.791; *n*, 1.444; double bond, 1.08 per C_7H_{12}. Hydrogenation gave a compound, b. p., 100–102°; *d*, 0.7671; n, 1.4225. I. C. T. gives for methylcyclohexane: b. p., 100.8°; *d,* 0.764; n, 1.4235. Nitration failed to detect aromatic compounds.

A²-Tetrahydrotoluene.—Not purified enough for identification; a sufficient intermediate persisted in the general distillation to suggest its presence.

Component **109–110°.—Purified** by aniline fractionation: d, 0.783; *n,* 1.4413; double bond, 1.13 per C_7H_{14}. Hydrogenation and nitration indicated toluene as an impurity. Further purification of the saturated compound by fractional distillation gave a small quantity of hexahydrotoluene and of iso-octane: b. p., 116"; d, 0.706; *n,* 1.397. I. C. T. gives for iso-octane: b. p., 116°; d_4^{15}, 0.704; *n,* 1.3964.

Δ¹-Tetrahydrotoluene.—B. p., 111°; *d,* 0.809; *n,* 1.4496. Purified by fractional distillation: b. p., 110–111°, d, 0.818; *n,* 1.4653. Special test (Beilstein): 3 drops of sulfuric acid added to an alcoholic solution of the hydrocarbon gave a green coior peculiar to A¹-tetrahydrotoluene. Double bonds, 0.75, indicating a large percentage of toluene. Hydrogenation and nitration yielded a large quantity of trinitrotoluene and hexahydrotoluene: b. p., 100°; *d,* 0.762; *n,* 1,423. I. *C.* T. gives for hexahydrotoluene: b. p., 100.8"; *d,* 0.764; *n,* 1.4235.

Toluene.—B. p., 110.5"; *d,* 0.866; *n,* 1.4962. Purified by aniline fractionation, treatment with bromine and steam distillation: b. p., 110° sharp; identified by its odor and nitration to mononitrotoluene, b. p., 220°, the latter also having a characteristic odor.

Component 121–122°.—*d,* 0.765; n, 1.4287; hydrogenation and nitration indicated the presence of a small amount of aromatic compounds and gave a material: b. p., 116–121°; d, 0.739; n, 1.4102; mol. wt., 112.4, indicating iso-octane with a small quantity of hexahydro-m-xylene as an impurity. A fraction 124–125" gave a hydrogenation product with a slightly higher boiling range, density and index of refraction, indicating another isomeric form of 2-methylheptene containing an increased quantity of hexahydro-m-xylene. Although the above two fractions were present in the distillation in sufficient quantity to indicate the presence of components, there was not enough for proper purification and identification; all indications were that they were isomeric methylheptenes, probably 2-methylheptenes, with the location of the double bond totally unknown.

Dihydro-m-xylene, Probably **Δ-1,3.**—No constants given in the literature. Purified by aniline fractionation: b. p., 129–130°; *d,* 0.795; n, 1.4451. Hydrogenation and nitration indicated the presence of a small quantity of xylene and of a compound, b. p., 122–129°, bulk at 125°; *d,* 0.764; n, 1.4208; mol. wt., 112.6. I. C. T. gives for hexahydro-m-xylene: b. p., 123.7'; *d,* 0.771; *n,* 1.425; mol. wt., 112. These properties identify hexahydro-m-xylene with a small amount of paraffinic compounds as impurity. **A** substantial part of the original cut obtained by fractional distillation containing the dihydro-m-xylene was treated with bromine; no dibromides were found, only tetrabromides.

***m*-Xylene.**—B. p., 139°; *d,* 0.865; n, 1.4973.—Purified by treating with an excess of bromine water, and steam distilling; redistilling several times to eliminate all traces of bromides gave a material, b. p., 137°; *d,* 0.866. Nitration to the trinitro compound gave white crystals melting sharply at 179.5°. **Mulliken** gives m. p. 180–181° for trinitro-m-xylene. It is thus shown that the xylene obtained was pure m-xylene containing no trace of either ortho or para derivatives.

***p*-Tetrahydro-Ethyltoluene.**—Beilstein gives for the Δ³-compound: b. p., 149°; d, 0.816; n^{16}, 1.453. Purified by fractional distillation: b. p., 144–145°; *d,* 0.813; *n,* 1.4529; double bond, 1.2 per C_9H_{16}. Hydrogenation and nitration gave a material: b. p., 147°; *d,* 0.784; *n,* 1.4335; mol. wt., 123. Beilstein gives for *p*-hexahydro-ethyltoluene: b. p., 147°; d_4^{15}, 0.788; n^{15}, 1.435; mol. wt., 126. There can be no question of the identification except for the position of the double bond, which may have been Δ^1 instead of A^3; no physical constants are available for the Δ^1-compound.

Component **158–159°.**—*d*, 0.834; *n*, 1.4665; double bond, 0.998. Purified by fractional distillation; composition by combustion, $C_{10}H_{16}$, establishing the presence of a dicyclic compound. I. C. T. gives for thujene: b. p., 151°; d, 0.830; *n*, 1.4515. Hydrogenation and nitration gave a material, b. p., 158–161°; *d*, 0.813; *n*, 1.4498; mol. wt., 133.5–134.8 (theoretical for $C_{10}H_{18}$, 138); double bond, 0. Combustion gave $C_{10}H_{18}$ within 0.2%. Beilstein gives for thujane: b. p., 157°; d, 0.814–0.819; *n*, 1.4376-1.44395. Off-hand it would appear that the identification of the original material, as an isomeric form of thujene, was as definite as many of the foregoing identifications, but more careful consideration indicates that such is not the case. Identification by physical constants requires not only that the physical constants of the unknown be in close agreement with those of likely possibility, but that all, or nearly all, of the possibilities be known and listed, and that the constants are not in agreement with any of the other possibilities. This has been the case with all the components positively identified in C_5, C_6, C_7, C_8 and C_9, but it is not so with the dicyclic compound in C_{10}. It was therefore decided to consider the identification of this component as unestablished.

***p*-Ethyltoluene.**—B. p., 162; d, 0.862; *n*, 1.4943. Purified by treating with bromine water and steam distilling: b. p., 160.5–163°; *d*, 0.866; n, 1.4832; mol. wt., 120.4, instead of 120, theoretical; saturated toward bromine; oxidation with permanganate yields terephthalic acid.

Component 162–163°.—*d*, 0.828; *n*, 1.46; mol. wt. 130.5; bromination indicated 1.0 double bond. Obtained only from rubber decomposed in the presence of magnesium. Hydrogenation and nitration gave a compound b. p., 162–164°; *d*, 0.794; n, 1.4407; saturated toward bromine; mol. wt., 135; combustion indicated a formula of $C_{10}H_{20}$ within 0.2%. This shows that the original material was of empirical formula $C_{10}H_{18}$. The hydrogenation was a quantitative check on the original bromination. It is evident that this is a single ring compound containing 1 double bond. It is impossible to identify this compound from any known data.

Component **162–163°.**—The distillate from rubber alone gave a component in this boiling range: d, 0.8105; *n*, 1.456; double bond, 1.4. Aniline fractionation failed to purify it further. Thus it is seen that the distillation of rubber alone gives a lighter material than the distillation with magnesium and that the unsaturation is 1.4 instead of 1.0 double bond, indicating the presence of a dienic compound. If this density be extrapolated to 100% diene, 0.783 is obtained. By a separate synthesis,[7] a mixture of 2,6-, 2,7- and 3,6-dimethyl-2,6-octadienes was obtained, the physical constants of which were: b. p., 163–164°; d, 0.773. Considered as not a positive identification, but as strong evidence that a dimethyloctadiene was present.

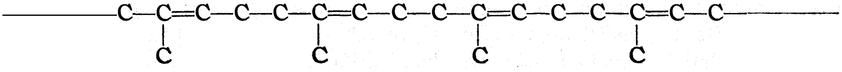
Dipentene.—B. p., 176°; d^{18}, 0.865; *n*, 1.471. The density given by I. C. T. is apparently an error; Schimmel and Company give 0.844; Brühl gives $d_4^{20.85}$, 0.8402; Staudinger, d^{20}, 0.841. Purified by fractional distillation: b. p., 176°; *d*, 0.8435; *n*, 1.4712; double bonds, 1.96. Hydrogenation gave p-menthane: b. p., 170–171.2'; *d*, 0.796; n, 1.4387. I. C. T. gives for p-menthane: b. p., 170°; d, 0.793; *n*, 1.437. No evidence was obtained of the presence of myrcene, or a terpene, b. p., 168–169°, or of dimethylbutadiene.[4]

Derivation of the Structural Formula of the Products from That of Rubber.—Prior to entering upon this investigation, a method had been developed for illustrating the mechanism by which isoprene and dipentene form during destructive distillation. After the above results were ob-

---

[7] Midgley and Henne, THIS JOURNAL, 51, 1294 (1929).

tained, it was felt that the method should be extended to include as many of the products as possible. A relatively simple solution is herewith presented which completely covers a majority of the cases, a few partially, and leaves only the formation of benzene without explanation. The long-chain structural formula for rubber hydrocarbon[8] is broken at single



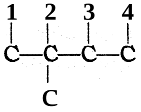
$$—C-\underset{\underset{C}{|}}{C}=C-C-C-\underset{\underset{C}{|}}{C}=C-C-C-\underset{\underset{C}{|}}{C}=C-C-C-\underset{\underset{C}{|}}{C}=C-C—$$

Staudinger formula for rubber

valences to give a section containing a given number of carbon atoms. The points of breakage are represented by partial valences and the double bonds are resolved into partial valence form. This is called the transient *form*. The following postulates are then observed: (1) adjacent partial valences may join to form double bonds (Thiele); (2) single partial valences six carbons apart may join to form rings; (3) any pair of partial valences may accept hydrogen, preferably those not adjacent to others; (4) partially hydrogenated aromatic compounds liberate hydrogen to yield the corresponding aromatic compounds; (5) partial valences not joining nor accepting hydrogen may migrate.

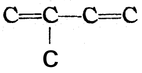
After having derived all of the combinations by applying the above assumptions to a transient form, the resulting stable forms are examined and those forms cast out which experimental data show do not form by pyrolytic decomposition. Predominant among these are molecules containing a carbon atom in a ring bonded to two other carbon atoms external from the ring and those containing a methylene group attached to a ring. The formation of dienic compounds has been disregarded, since no experimental data were obtained.

The mechanism of the reactions involving 5 carbon atoms (called compounds in C_5 for simplicity) may be represented as follows



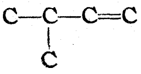
$$\overset{1}{\overset{|}{C}}-\underset{\underset{C}{|}}{\overset{2}{\overset{|}{C}}}-\overset{3}{\overset{|}{C}}-\overset{4}{\overset{|}{C}}$$

Transient form in C_5



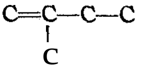
$$C=\underset{\underset{C}{|}}{C}-C=C$$

Isoprene



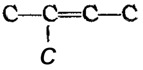
$$C-\underset{\underset{C}{|}}{C}-C=C$$

3-Methyl-1-butene



$$C=\underset{\underset{C}{|}}{C}-C-C$$

2-Methyl-1-butene



$$C-\underset{\underset{C}{|}}{C}=C-C$$

2-Methyl-2-butene

Because of the preponderance of isoprene(C_5), dipentene(C_{10}) and heveen(C_{15}) in the products of destructive distillation, it is held certain that the single bond furthest removed from the double bonds is the most easily broken by pyrolysis. The same conclusion is arrived at by C. D.

[8] Staudinger, *Ber.*, 44, 2212 (1911); 46, 2466 (1913); *Helv. Chim. Acta,* 5, 743 (1922); 5, 756 (1922); 5, 785 (1922); *Ber.*, 57, 1203 (1924); *Helv. Chim. Acta,* 7, 842 (1924); *Z. angew. Chem.,* 38, 226 (1926).

Hurd, starting from purely theoretical considerations,[9] and is found to hold when the other pyrolysis products of rubber are examined. Hence the transient form shown above predominates in C_5 to the practical exclusion of the two other possible forms. Four stable forms are derived from it: isoprene by the joining of 1 with 2 and 3 with 4, 3-methyl-1-butene by the acceptance of hydrogen on 1 and 2 and the joining of 3 with 4 and 2-methyl-1-butene by the acceptance of hydrogen on 1 and 4 and the joining of 2 with 3. Isoprene predominates, since it requires no hydrogen to produce a stable form.

In C_6, two transient forms are possible. Each case requires that a bond adjacent to a double bond be broken. The proportion of C_6 compounds should therefore be small. In neither case does a stable form result without either migration or hydrogen acceptance.

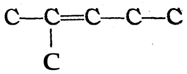
$$C-\underset{\underset{C}{|}}{C}=C-C=C$$

3-Methyl-1,3-pentadiene



$$C-\underset{\underset{C}{|}}{C}=C-C-C$$

3-Methyl-2-pentene

There is only one transient form possible in C_7. It requires the breaking of two single bonds adjacent to double bonds. It is obvious that valences 1 and 6 may either accept hydrogen to form 3-methyl-3-hexene or join to form Δ^1-tetrahydrotoluene, the dehydrogenation of which gives toluene.

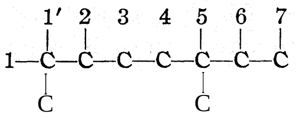
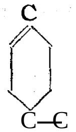
[9] C. D. Hurd, "The Pyrolysis of Carbon Compounds," American Chemical Society Monograph Series, The Chemical Catalog Co., New York, 1929.

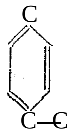
C_9 again presents two possible transient forms. The only evidence obtained covering the many possibilities in C_9 was in connection with transient form 1, which appeared to accept hydrogen by 1 and 1′, 2 joining with 7 and 5 with 6. The dehydrogenation of the resulting tetrahydro-*p*-ethyltoluene yields p-ethyltoluene. Other ring forms suggested as possible products of transient form 1 or 2 could not be detected.



Transient form
No. 1 in C_9

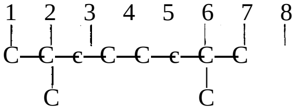


Tetrahydro-*p*-
ethyltoluene

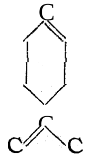


p-Ethyltoluene

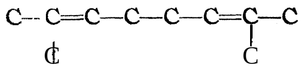
In C_{10}, as in C_5, three transient forms are possible, but since one of them is obtained by the rupture of only weak bonds, it should be predominant; it stabilizes without migration or hydrogenation by the joining of 3 with 8, 1 with 2 and 6 with 7, giving dipentene. By accepting hydrogen in 1,8 it stabilizes to dimethyloctadiene.



Predominating
transient form in C_{10}



Dipentene



Dimethyloctadiene

The other transient forms present an interesting speculation in connection with the component 158–159° (shown to be a dicyclic compound $C_{10}H_{16}$), and component 162–163° (shown to be a single ring compound $C_{10}H_{18}$). The development from transient form 2 serves as a suggestion of the mechanism of the formation of a dicyclic compound, while the development from transient form 3 is a suggestion, predicated on the behavior of form 1 in C_9, to show the acceptance of hydrogen and subsequent ring formation. Both derivations are only speculations. If these suggestions could be proved experimentally, an interesting generality might be derived, namely, that when a terminal carbon atom has two partial valences attached to it, dicyclic ring formation is favored, but when an internal carbon is in the same case, hydrogen acceptance is favored,

The identification of A^3-tetrahydrotoluene and the evidence for the existence of A^2-tetrahydrotoluene among the products is not predictable. It is felt, however, that migration of the double bond from the Δ^1-position should not be considered as unlikely, since the amounts of Δ^2- and Δ^3-compounds were exceedingly small.

Discussion

In view of the evidence at hand, it can scarcely be doubted that with the exception of benzene the compounds of the aromatic series present were all derived by dehydrogenation of the corresponding hydro-aromatic forms, since only those aromatic compounds are found whose hydro-derivatives are also present. Dihydro-m-xylene is the only predictable ring compound in C_8, hence if dehydrogenation occurs, only m-xylene should result. If, on the other hand, m-xylene is a primary pyrolysis product, small amounts of the ortho and para derivatives at least should be present. Particular care was taken to ascertain that no other xylene was present than the meta derivative. The same reasoning holds true in C_9 with respect to pethyltoluene. A reason for the dehydrogenation during destructive distillation is not apparent. It is well known that cyclohexane in the presence of nickel and at similar temperatures will dehydrogenate to benzene, but there was no catalyst present to account for a similar behavior during pyrolysis of rubber alone. It is significant that the presence of magnesium in the rubber increases decidedly the proportion of aromatic compounds.

The origin of benzene is obscure. It is not due to accidental contamination in the laboratory, since the presence of a metal in the rubber always increases the amount of benzene in the distillate. Extreme pyrolysis in locally overheated spots might account for its formation.

To sum up, of the **23** compounds identified, 12 were in perfect agreement with the postulated results, 5 were in agreement as far as their identification was possible and rational explanations of the other 6 are not at variance with the postulates. In C_5 all forms predicted were obtained, in C_6, C_7 and C_8 chain compounds only were missing from the predictions. In C_9 the only logical rings were obtained, in fact, and in C_{10} all normal predictions were fulfilled.

Relationship of the Results to the Structural Formula of Rubber.—The constitution of the ten-carbon section of rubber has been thoroughly established by oxidation and confirmed by many investigators, but assemblage of these units into the complete structural formula of rubber has been the basis of much work and argument. Harries originally interpreted the results of his oxidations as indicating the existence of an eight-sided ring. He was more or less driven from his original interpretation in later years. Staudinger and co-workers[4,8] support fa long-chain structure in which the ten carbon atom sections recur and are bonded together by ordinary valences, thus requiring no residual valences to account for the structure. Many intermediate speculations have been indulged in.

The results of this investigation throw no additional light upon the discussion. The use of the long-chain formula affords greater ease for interpretation, but the results do not contradict Harries viewpoint. Recently, E. A. Hauser[10] has supported the hypothesis that the rubber molecule is a long chain arranged in helix form, by interpreting the x-ray pattern of stretched rubber. The predominant formation of six-sided rings in C_7, C_8, C_9 and C_{10} appears to support this hypothesis, since to account for ring formation upon any other arrangement that has been advanced requires the joining of partial valences across the space occupied by six carbon atoms, whereas a helix may be so arranged that the carbon atoms, six apart in the chain, may be adjacent in space.

Conclusions

All of the products of the destructive distillation of natural rubber are directly derived, by simple reactions, from the rubber molecule. Those compounds predominate which represent sections of the rubber molecule occurring between the single bonds furthest removed from the double bonds.

Summary

Two hundred pounds of pale crepe rubber have been destructively distilled at atmospheric pressure. The distillate was fractionated and its components identified from C_5 to C_{10}, as shown in the table. Assuming that the Staudiiger formula is correct, that the single bonds furthest from the double bonds are the weaker spots and that the formation of six-carbon rings is favored, it has been shown that nearly all of the compounds actually isolated could be predicted. The experimental results, together with forthcoming experimental data, are expected to be used to throw light upon the formula of the rubber molecule.

THE ACTION OF THE GRIGNARD REAGENT ON HIGHLY BRANCHED CARBONYL COMPOUNDS[1]

BY J. B. CONANT[2] AND A. H. BLATT[3]

RECEIVED NOVEMBER 3, 1928 PUBLISHED APRIL 5, 1929

While a great variety of straight-chain aliphatic compounds of large molecular weight are known, the information in regard to many groups of branched aliphatic compounds is relatively meager. For example, of the 38 tertiary alcohols listed in the new edition of Beilstein's "Handbuch" (which covers the literature to 1910), 32 contain only primary alkyl groups. Of the remaining 6, four contain one secondary group and two primary groups, while only two contain a tertiary group; none contains more than one secondary or tertiary group. Although a great deal of work in aliphatic chemistry has been published in the last eighteen years, our information concerning branched compounds has not materially increased. Purely aliphatic carbinols of the type[4] $(R^3)_3COH$, $(R^2)_2R^3$-COH and $(R^2)_3COH$ appear to be still unknown.[5] In regard to the hydrocarbons our information is even more restricted. The only hexa-alkylethanes, $(R_3C–CR_3)$, that have been prepared are hexamethylethane[6] and tetramethyldiethylethane.[7] Hexa-alkylethanes containing branched alkyl groups are entirely unknown.

The facts which are available regarding branched aliphatic compounds indicate that these compounds possess highly interesting properties, and indicate further that predictions as to the behavior of branched compounds based on the behavior of their primary straight-chain analogs are likely to be quite misleading. For example, the reaction of *iso*propyl alcohol with the halogen acids to form the isopropyl halides is often given as a typical reaction of secondary alcohols. Now there are six

[3] American Petroleum Institute Research Fellow.

[4] We shall use R^1, R^2 and R^3 to represent primary, secondary and tertiary groups, respectively.

[5] A few alicyclic compounds are known of the type $(R^2)_3COH$; thus Murat and Amouroux, Bull. *soc. chim.*, [4] **15**, 159 (1914) prepared di-*iso*propylcyclohexylcarbinol, while Zelinsky, Ber., **60**, 713 (1927), has recently prepared tri-cyclohexylcarbinol.

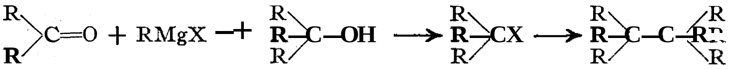
[6] Richards, Ann. *chim. phys.*, **21**, 323 (1910); Henry, Bull. *acad. roy. belg.*, **1906**, *256, 352; Compt. rend.*, **142**, 1075 (1906).

[7] Späth, *Monatsh.*, *34*, 1982 (1913).

different classes of secondary alcohols possible, according to whether the alkyl groups are primary, secondary or tertiary and alike or different. Examples of each of these classes are known. With members of five of these classes the behavior when treated with halogen acids has been studied and for only one class, that where both alkyl groups are primary is the behavior similar to that of *iso*propyl alcohol. The members of the other classes yield halides formed as a result of rearrangement, or yield oxonium salts and no halides.

In still another respect do branched alkyl groups differ from straight-chain groups, for recent work has shown that with the tetra-aryldialkylethanes[8] and the dialkyldixanthyls,[9] secondary alkyl groups are markedly more effective than primary in promoting the dissociation of carbon–carbon linkages.

Since the information regarding highly-branched aliphatic compounds, in particular tertiary alcohols and hexa-alkylethanes, is thus extremely meager, we have attempted to prepare complex tertiary alcohols and from them hexa-alkylethanes by the following general procedure



The peculiarities of highly-branched compounds became apparent earlier than expected and blocked the project at the first step. It was found that the typical addition reaction between ketones and the Grignard reagent ceases to be the main reaction as soon as highly-branched compounds are employed. We have studied a variety of branched compounds in this reaction and from our results and the data available in the literature it is possible to state the limits of usefulness of the Grignard reaction as a method of preparing secondary and tertiary alcohols (employing the procedures now available).

Besides the normal addition of Grignard reagents to carbonyl compounds three other important reactions have been noted. These are reduction, enolization and condensation. Which of these four reactions will predominate in a given case depends largely on the nature of the alkyl groups present in the Grignard reagent and in the carbonyl compound. When primary alkyl groups are present the addition reaction appears to prevail to such an extent that satisfactory yields of the desired carbinols may always be expected. Complications arise, however, when branched alkyl groups are present in the carbonyl compound or the reagent or in both. The following table gives a general summary of the phenomena. In it the letters A, R, E and C refer, respectively, to addition, reduction,

enolization and condensation. Yields are not given in exact figures because the results, taken from data of several workers, are not strictly comparable, but an approximate idea of the extent of the reaction is denoted by doubling the letter for yields greater than 50%.

The first and most striking fact shown by this table is that it has not been possible to prepare tertiary alcohols containing more than two secondary or tertiary groups. For when the simplest ketone containing two secondary groups, isobutyrone, is treated with the reagent from isopropyl bromide or *tert.*-butyl chloride the product, formed in an 80% yield, is di-isopropylcarbinol. There is no evidence of addition. When isopropyl *tert.*-butyl ketone or di-*tert.*-butyl ketone is treated with these same reagents reduction again occurs, the corresponding secondary alcohols being formed. Even in the case of aldehydes the reduction reaction is very evident when a secondary Grignard reagent acts on trimethylacetaldehyde and no addition occurs when *tert.*-butylmagnesium chloride is employed.

The special behavior of the methyl and benzyl reagents, a fact not shown in Table I, should be emphasized. Thus with isobutyrone and methylmagnesium iodide, addition to the extent of 78% takes place. In the course of some other work we found that this same ketone will add benzylmagnesium chloride, giving an 80% yield of tertiary alcohol. If now isobutyrone is treated with ethylmagnesium bromide[10] the yield of tertiary alcohol drops to 54% and is accompanied by 23% of reduction; with n-propylmagnesium bromide there is 30% of addition and 30% of reduction, while butylmagnesium bromide gives 40% of addition and 13% of reduction.

If we attempt to correlate structure and amount of reduction the facts of the preceding paragraph give a first clue that for a given carbonyl compound the amount of reduction increases with the size of the alkyl groups in the reagent. This same effect is also shown by pinacolone. With methylmagnesium iodide,[11] there is no reduction; with propylmagnesium chloride[12] there is 20% of reduction, and with butylmagnesium bromide over 30% of reduction. Much more important than the size of the alkyl group in the reagent is its complexity. The reduction of isobutyrone by n-butylmagnesium bromide amounts to 13%; with *tert.*-butylmagnesium chloride there is 80% reduction and no evidence of addition.

Just as an increase in the size and complexity of the alkyl group in the reagent promotes reduction, so also does an increase in the size and complexity of the alkyl groups in the carbonyl compound. Leroide[13] showed that while ethyl isobutyrate on treatment with n-propylmagnesium bromide gave a tertiary alcohol, ethyl pelargonate with the same reagent yielded a secondary alcohol. The effect of branching the carbon chain is shown by the behavior of diethyl ketone, isobutyrone and pinacolone toward n-butylmagnesium bromide. With the first ketone addition only is observed, with the second there is 13% of reduction and with the third 30% of reduction.

This effect of branching the alkyl groups in the carbonyl compound and reagent limits the usefulness of the Grignard reaction in preparing tertiary alcohols but it furnishes a convenient method for the reduction of highly branched ketones to the corresponding secondary alcohols. Thus isobutyrone, pentamethyl acetone and hexamethyl acetone are reduced by *tert.*-butylmagnesium chloride with excellent yields; the reduction is easily carried out and should be of use in working with branched compounds.

Besides reduction we have also encountered enolization and condensation. These two reactions seem to be limited to methyl ketones or to carbonyl compounds with a CH_2 group adjacent to the functional group, for they were encountered only with pinacolone and diethyl ketone.

[10] Stas, *Bull. soc. chim. belg.*, 35,379 (1926).

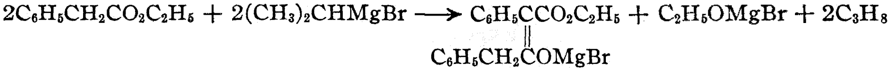
[11] Henry, *Bull. acad. roy. belg.*, 352, (1906).

[12] Leroide, *Ann. chim. phys.*, [9] 16,361 (1921).

[13] Leroide, ref. 12, p. 354.

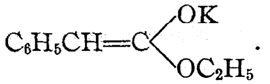
Our evidence for enolization was the recovery of the ketone from reactions where an excess of the reagent was present, coupled with the known enolizing effect of the Grignard reagent which has recently been pointed out by Grignard[14] and by Kohler.[15] By condensation in the above cases we refer to the formation of material of high boiling point.

Our most striking illustration of enolization and condensation is furnished by phenylacetic ester. When this ester is added to *iso*propylmagnesium bromide there is a steady evolution of gas (a saturated hydrocarbon) and on decomposing the reaction mixture the product is α,γ-diphenylacetoacetic ester, the acetoacetic ester condensation product of the original ester; the yield is over 90%.



$$2C_6H_5CH_2CO_2C_2H_5 + 2(CH_3)_2CHMgBr \longrightarrow C_6H_5\underset{\overset{\|}{C_6H_5CH_2COMgBr}}{C}CO_2C_2H_5 + C_2H_5OMgBr + 2C_3H_8$$

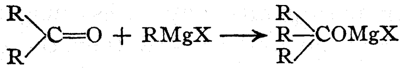
This condensation, effected only with difficulty by using dry sodium ethylate,[16] can also be carried out using metallic potassium and in this case Scheibler[17] has advanced evidence to show that the intermediate product is



$$C_6H_5CH{=}C\Big\langle\begin{matrix}OK\\OC_2H_5\end{matrix}.$$

One more Grignard reaction may be mentioned as illustrating the limiting case of the effect of branched alkyl groups. When ethyl trimethylacetate was treated with *tert.*-butylmagnesium chloride no reaction could be observed even after boiling the reaction mixture for ten hours; the ester was recovered unattacked.

Any discussion of the mechanism of these abnormal reactions must be at present largely a restatement of the experimental facts. The following seems to be the most satisfactory. With simple, straight-chain compounds the normal addition reaction takes place very rapidly



$$\begin{matrix}R\\R\end{matrix}\Big\rangle C{=}O + RMgX \longrightarrow \begin{matrix}R\\R\\R\end{matrix}\Big\rangle COMgX$$

As the alkyl groups present are increased in size and complexity, there is a decrease in the rate of this addition reaction. This would be expected in view of the known effect on the rate of bisulfite addition to carbonyl compounds of increasing the size and complexity of the alkyl groups in these compounds. When the normal addition reaction is slowed down sufficiently, other reactions, ordinarily too slow to be observed, and which are less subject to hindrance, become predominant. This is illustrated by the reduction of isobutyrone, pentamethyl acetone and hexamethyl

acetone and by the enolization and condensation of pinacolone when branched reagents are used. The limiting case, when all reactions are slowed down to such an extent as to be negligible in rate, is that of trimethylacetic ester and ter!?.-butylmagnesium chloride where no reaction takes place. When the hindrance to addition is great but reduction and enolization are not possible because of the structure of the ketone and reagent, there is no reaction; this is the case with phenylmagnesium bromide and hexamethyl acetone. The assumption that the rate of the enolization and reduction reactions is less affected than the addition reaction by what we may call steric factors is in accord with many rate measurements on a variety of organic reactions.

Experimental

Since essentially the same procedure was employed in all the Grignard reactions it will be economical of space to give here a general description of this procedure; then in the individual cases any variations used will be noted. The reagent was prepared in the usual apparatus, a flask fitted with a trident adapter in which were placed a condenser, dropping funnel and mercury-seal stirrer. Five hundred cc. of ether was used per mole of alkyl halide and magnesium. The average yields with the various reagents were as follows: n-butylmagnesium bromide, 80%; isopropylmagnesium bromide, 70–75%; *tert.*-butylmagnesium chloride, 50–55%. In preparing *tert.*-butylmagnesium chloride a solution of 5 cc. of *tert.*-butyl chloride and 50 cc. of ether was added to the magnesium plus a crystal of iodine. After the reaction had started (two or three minutes) an additional 75 cc. of ether was added at once and then the remainder of the ether and alkyl halide mixed and added slowly. After the reagents had been prepared they were chilled, then decanted into a second flask in order to separate any excess magnesium. The second flask was surrounded by an ice-bath and then the carbonyl compound, dissolved in dry ether, was added slowly. The ice-bath was removed, the mixture stirred at room temperature for several hours or left overnight and then boiled for one hour. Finally it was cooled, decomposed with ice and a bare excess of sulfuric acid[18] and the ether layer separated. The aqueous layer was extracted once with ether and the combined ether layers washed with water, sodium carbonate solution and water and then dried over sodium sulfate. The final working up of the products varied, of course, according to their properties. The practical distillations were carried out using a Widmer special column which was found very efficient.

The reagents in general were not analyzed, but knowing the yields to be expected, a large excess of the reagent was used. In the one case,

---

[18] If hydrochloric acid is used for the decomposition there is danger, with *tert.*-alcohols, of forming the ether-soluble chlorides.

tert.-butylmagnesium chloride, where the yield of reagent may vary within wide limits it is, fortunately, quite easy to detect poor preparations, for the magnesium chloride etherate formed in such cases is very slightly soluble in ether and the reagent is pasty. Well-conducted preparations of this reagent, which contained but little precipitate, when analyzed showed that about 50% of the magnesium had been converted into a Grignard reagent.

A. Grignard Reagents and Aldehydes

Acetaldehyde and *Tert.*-**butylmagnesium** Chloride.—Eleven grams (0.25 mole) of freshly distilled acetaldehyde dissolved in 50 cc. of ether was added to a theoretical 8 moles of *tert.*-butylmagnesium chloride. After working up, the ether was removed on the steam-bath and the residual material fractionated. There was obtained 1.3 g. of low-boiling material (85–115°), then 20.5 g. boiling at 115–119°, mostly at 116–118°, a yield of 80%. The residue was less than 1 cc. The main fraction, methyl-*tert.*-butylcarbinol, gave with phenyl isocyanate the well-known phenylurethan,[19] m. p. 75–76°.

Isobutyraldehyde and *Iso*propylmagnesium Bromide.—Pour-tenths of a mole (28.8 g.) of freshly distilled isobutyraldehyde in 50 cc. of ether was added to a theoretical 0.7 mole of isopropylmagnesium bromide. After removing the ether the residue, on fractionation, yielded 3 *g.* of low-boiling material (80–133°) and 36 g. of di-*iso*propylcarbinol, 134–138°; yield, 78%.

With phenyl isocyanate the di-isopropylcarbinol set to a solid mass. This phenylurethan crystallized from ether and petroleum ether in splendid long needles melting at 96–99°.

Anal. Calcd. for $C_{14}H_{21}O_2N$: C, 71.5; H, 8.9. Found: C, 71.6; H, 9.0.

Isobutyraldehyde and *Tert.*-**butylmagnesium Chloride.**[20]—Sixty-five grams (0.9 mole) of freshly distilled isobutyraldehyde in 100 cc. of ether was added to a theoretical 2.2 moles of *tert.*-butylmagnesium chloride. After removing the ether on the steam-bath the residual material was fractionated. On the fourth fractionation the following fractions were obtained: (1) 50–100°, 4.5 g.; (2) 106–114°, 13 g.; (3) 115–145°, 2.4 g.; (4) 148–152°, 57 g. The residue was less than 1 cc.

Fraction 2 consisted of isobutyl alcohol for with phenyl isocyanate it yielded within five minutes a solid cake of the phenylurethan of that alcohol.[21] The melting point of the phenylurethan and the mixed melting point with a known specimen was 85–86°; yield of reduction product, 20%.

Fraction- 4 consisted of *iso*propyl-*tert.*-butylcarbinol. With phenyl isocyanate it yielded the phenylurethan, m. p. 89°. This melting point, confirmed with other specimens, is exactly 10° higher than that given by Haller and Bauer,[22] yield of addition product, 44%. We could find none of the glycol which previously was reported to be formed in this reaction.

B. Grignard Reagents and Ketones

Diethyl Ketone and *n*-**Butylmagnesium** Bromide.—Forty-three grams (0.5 mole) of diethyl ketone in 100 cc. of ether was added to a theoretical 1.0 mole of *n*-**butyl**magnesium bromide. The reaction mixture yielded on fractionation 6 g. of material boiling from 106–113°, 2.5 g. boiling from 113–115" and 46 g. boiling at 119–121" at 110 mm. and 116–118" at 105 mm. This last fraction consisted of *diethyl-n-butyl carbinol,* yield, 60%; d_4^{20}, 0.8409; n_D^{20}, 1.4360; M_D, calcd. for n^2 formula, 45.05; n formula, 74.44. Found: n^2 formula, 44.79; n formula, 74.65.

Anal. Calcd. for $C_9H_{20}O$: C, 75.0; H, 13.9. Found: C, 74.7; H, 14.2.

The fraction boiling at 113–115° was heated with 3,5-dinitrobenzoyl chloride and pyridine. No dinitrobenzoate of diethylcarbinol was formed.

In order to secure a solid derivative of diethylcarbinol for identification we had previously treated a known sample of this carbinol with phenyl isocyanate. A solid phenylurethan was not formed. Consequently we had recourse to 3,5-dinitrobenzoyl chloride and pyridine. These yielded the 3,5-dinitrobenzoate of diethylcarbinol which melted, after crystallization from methyl or ethyl alcohol, at 101°.

Anal. Calcd. for $C_{12}H_{14}O_6N_2$: C, 51.1; H, 5.0. Found: C, 50.5; H, 5.1.

Diethyl Ketone and *Tert.*-**butylmagnesium** Chloride.—Four-tenths of a mole (34.4 g.) of diethyl ketone in 100 cc. of ether was added to a theoretical 1.0 mole of *tert.*-butylmagnesium chloride. On fractionation, the reaction mixture yielded 1.3 g. of material boiling from 70–105°, 10 g. boiling from 105–120° and 20 g. boiling from 30–100° at 5 mm. From this material no definite products could be isolated.

Pinacolone and n-ButylmagnesiumBromide.—Fifty grams (0.5 mole) of pinacolone was added to a theoretical 1.0 mole of n-butylmagnesium bromide. On fractionating the reaction product there was obtained 5.5 g. of material boiling from 95–117°, 16 g. boiling from 117–119" and 20 g. boiling from 84–87' at 13 mm. This last fraction was *methyl-n-butyl-tert.-butylcarbinol,* yield, 25%; d_4^{20}, 0.8487; n_D^{20}, 1.4409; M_D, calcd. from n^2 formula, 49.65; from n formula, 82.09. Found: n^2 formula, 49.16; n formula, 82.09.

Anal. Calcd. for $C_{10}H_{22}O$: C, 75.9; H, 13.9. Found: C, 75.6; H, 14.1.

The fraction boiling at 117–119° was shown to be the reduction product of pinacolone, pinacoline alcohol, by conversion to the phenylurethan, m. p. 79°, and a mixed melting point with a known specimen. The yield of reduction product was 30%.

Piacolone and *Iso*propylmagnesium Bromide.—Twenty-five grams (0.25 mole) of pinacolone was added to a theoretical 0.5 mole of isopropylmagnesium bromide. Much gas was evolved. On fractionation there was obtained 13 g. of material boiling from 105–115° and 8 g. of high-boiling material. The low-boiling material yielded no phenylurethan, but with hydroxylamine gave an oxime, m. p. 75°, which was identified as pinacolone oxime by comparison with an authentic specimen,[23] yield of recovered pinacolone, 50%. The high-boiling material on distilling in vacuo boiled at 60–95° at 3 mm. and evidently consisted of condensation products, for methyl-*iso*propyl-*tert.*-butylcarbinol (see later) boils at 56° at 6 mm.

Pinacolone and *Tert.*-**butylmagnesium** Chloride.—Thirty-five grams (0.35 mole) of pinacolone was added to a theoretical 1 mole of *tert.*-butylmagnesium chloride and the product fractionated twice. There was obtained 22 g. of material boiling at 100–117°, and 9.4 g. of high-boiling material. This latter consisted of condensation products, for on distillation in vacuo it boiled over a wide range, 65–100° at 5 mm. The material boiling at 100–117° was shown to be recovered pinacolone by the preparation from it of benzalpinacolone, m. p. 41–42°.[24]

Isobutyrone and *n*-**Butylmagnesium** Bromide.—From **57** g. (**0.5** mole) of *iso*-butyrone and a theoretical mole of reagent there was obtained on fractionation a small amount of low-boiling material, then **3** g. boiling from 128–137°, **8** g. boiling from 137–140° and **34** g. boiling at **115–118°** at **45** mm. This last fraction, consisting of di-*isopropyl-n-butyl carbinol,* which was obtained in a yield of **40%;** d **0.8487;** and n^{20}_{D}, 1.4435; M_D, calcd. from n^2 formula, 54.26; from n formula, 89.84. Found: n^2 formula, **53.78;** n formula, **89.86.**

Anal. Calcd. for $C_{11}H_{24}O$: C, **76.7;** H, **14.0.** Found: C, **76.6;** H, **14 2.**

The material boiling at 137–140° was shown to be di-isopropylcarbinol by conversion to the phenylurethan and mixed melting point with a known sample The yield of this reduction product was **13%.**

Isobutyrone and Isopropylmagnesium **Bromide.**[25]—From **28.5** g. (**0.25** mole) of isobutyrone and a theoretical **0.5** mole of isopropylmagnesium bromide, there was obtained **2.4** g. of material boiling from 80–134°, then **22.5** g. boiling at 135–138° and **3** g. boiling from 138–143°. The residue amounted to **2** cc. The fractions boiling at 135–138° and 138–143° consisted of di-isopropylcarbinol, for with phenyl isocyanate they set to a solid mass of phenylurethan, m. p. **95".** The identity of this phenylurethan was established by a mixed melting point. The yield of reduction product was 78%.

Isobutyrone and *Tert.*-**butylmagnesium** Chloride.—From 28.5 g. (**0.25** mole) of isobutyrone and a theoretical **0.8** mole of *tert.*-butylmagnesium chloride there was obtained **3** g. of material boiling at 70–110°, **2.1** g. boiling at 110–130° and **21.8** g. boiling at **136–138".** The residue amounted to **1** cc. The two latter fractions consisted of the reduction product, di-isopropylcarbinol, for with phenyl isocyanate they yielded the known phenylurethan (melting point and mixed melting point). The yield of reduction product was **80%.**

Pentamethylacetone and **Methylmagnesium** Iodide.—From **26** g. of pentamethylacetone and a theoretical **0 3** mole of methylmagnesium iodide there was obtained 4 g. of low-boiling material and then **18** g. of *methyl-isopropyl-tert-butylcarbinol,* b. p. 56–57° at **6** mm., a yield of 60%. This carbinol has d^{20}_{4}, **0.8564;** n^{20}_{D}, **1.4430.** M_D, calcd. from n^2 formula, **45.05;** from n formula, **74.44.** Found: n^2 formula, **44.59;** n formula, **74.49.**

Anal. Calcd. for $C_9H_{20}O$: C, **75.0;** H, **13.9.** Found: C, **75.2;** H, **13.9.**

In this reaction the intermediate magnesium compound separates as splendid colorless crystals.

Pentamethylacetone and Isopropylmagnesium Bromide.—From **19.2** g. (**0.15** mole) of ketone and a theoretical **0.29** mole of reagent there was obtained **0.8** g. of low-boiling material, to 149°, then **17.1** g. of reduction product boiling at 149–151°. The *iso*-propyl-*tert.*-butylcarbinol, identified through its phenylurethan, was obtained in an 88% yield.

Pentamethylacetone and *Tert.*-**butylmagnesium** Chloride.—From **19.2** g. (**0.15** mole) of ketone and a theoretical **0.5** mole of reagent there was obtained **1.3** g. of material boiling up to 149°, then **17.6** g. of reduction product, boiling at **149–151 .** The reduction product, *iso*propyl-*tert.*-butylcarbinol, yield 90%, was identified as the phenylurethan.

Hexamethylacetone and **Methylmagnesium** Iodide.—From **13** g. of hexamethylacetone and the Grignard reagent prepared from **4** g. of magnesium and **23** g. of methyl

---

[25] This reaction, already carried out by Stas, *Bull. soc. chim. belg.*, 34, **188 (1925); 35,379** (1926), was repeated because from the experimental data given in his article the yield of reduction product (50%) was not as large as we expected in view of our results with *tert.*-butylmagnesium chloride.

iodide there was obtained 11.4 g. of solid *di-tert.-butyl-methylcarbinol,* b. p. 184–191°, m. p. 39–41° and 0.9 g. of low-boiling material; yield, 78%. (The period of refluxing was four hours.)

Anal. Calcd. for $C_{10}H_{22}O$: C, 75.8; H, 14.0. Found: C, 75.4; H, 13.7.

Hexamethylacetone and Isopropylmagnesium Chloride.—From 13 g. of the ketone and the Grignard reagent from 4 g. of magnesium and 13 g. of isopropyl chloride (period of refluxing three and one-half hours) there was obtained 6 g. of unchanged ketone (b. p. 150–159°), 1.5 g. of b. p. 159–161° and 1.2 g. of b. p. 163–167". The last fractions solidified and were identified as di-*tert.*-butylcarbinol.

Hexamethylacetone and *Tert.*-butylmagnesium Chloride.—From 14 g. of the ketone and the Grignard reagent from 6 g. of magnesium and 23 g. of *tert.*-butyl chloride there was obtained (after four hours of refluxing) 9.9 g. of solid di-*tert.*-butylcarbinol, b. p. 159–167°; yield, 69%.

C. Grignard Reagents and Esters

Trimethylacetic Ester and *Tert.*-butylmagnesium Chloride.—One-tenth mole (12 g) of trimethylacetic ester was added to a theoretical 0.6 mole of reagent and the mixture boiled for ten hours. On working up the products there was obtained 9 g. of recovered ester boiling at 116–119°. No hexamethylacetone or *tert.*-butylcarbinol could be found.

Phenylacetic Ester and Isopropylmagnesium Bromide.—Three-tenths of a mole (49.2 g.) of phenylacetic ester was added to a theoretical 0.5 mole of isopropylmagnesium bromide chilled in an ice-bath. There was a steady evolution of saturated gas and the separation of a light gray magnesium compound. After standing overnight the reaction mixture was decomposed and the ether layer on evaporation gave 39.5 g. of crude diphenylacetoacetic ester; yield, 94%. The crude ester melted at 72–75°. After it was triturated in a mortar with cold alcohol, filtered and dried, it melted at 78°. This product may be recrystallized from alcohol with only slight loss.

The ester was identified by a mixed melting point and by the preparation of the pyrazolone on treatment with phenylhydrazine.[16b]

Summary

1. Besides the normal addition of the Grignard reagent to carbonyl compounds, three other reactions—reduction, enolization and condensation—may take place. The occurrence of these reactions has been correlated with the lengthening and branching of the alkyl groups in the carbonyl compound and reagent. The limits of usefulness of the Grignard reaction for synthesizing secondary and tertiary alcohols have been pointed out. The extreme case where no reaction at all takes place has been illustrated.

2. It is shown that ketones containing two secondary groups or one secondary and one tertiary group may be easily and conveniently reduced to the corresponding secondary alcohols with isopropylmagnesium bromide or *tert.*-butylmagnesium chloride.

3. A synthesis of α,γ-diphenylacetoacetic ester based on the enolizing and condensing action of isopropylmagnesium bromide is described.

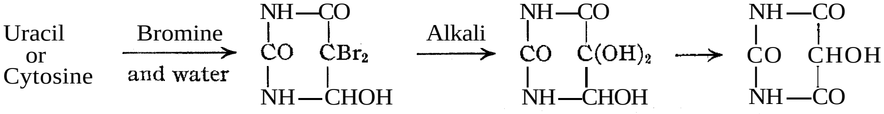
RESEARCHES ON PYRIMIDINES. CV. A NEW TEST FOR THYMINE AND 5-METHYLCYTOSINE IN THE PRESENCE OF URACIL AND CYTOSINE[1]

BY HENRY H. HARKINS[2] AND TREAT B. JOHNSON

RECEIVED NOVEMBER 7, 1928 PUBLISHED APRIL 5, 1929

Introduction

In 1907 Wheeler and Johnson[3] showed that when uracil or cytosine is treated first with bromine water, and then with an alkali, the following reactions take place



$$\begin{array}{l}\text{Uracil}\\ \text{or}\\ \text{Cytosine}\end{array} \xrightarrow[\text{and water}]{\text{Bromine}} \begin{array}{ll} NH & —CO \\ | & | \\ CO & CBr_2 \\ | & | \\ NH & —CHOH \end{array} \xrightarrow{\text{Alkali}} \begin{array}{ll} NH & —CO \\ | & | \\ CO & C(OH)_2 \\ | & | \\ NH & —CHOH \end{array} \longrightarrow \begin{array}{ll} NH & —CO \\ | & | \\ CO & CHOH \\ | & | \\ NH & —CO \end{array}$$

I II III

The dialuric acid formed, III, is characterized by its property of interacting with barium hydroxide to give a purple, insoluble barium salt.

Since 1907 this reaction has been used widely by biochemical workers as a practical test for these two pyrimidines. It was found that thymine, IV, would not give this purple barium salt, a fact which could be predicted from inspection of the structural formula of the pyrimidine. Johnson[4] later described a method for separating thymine from uracil by means of nitric acid, but this method of analysis was not proposed by him as a test for thymine in the presence of uracil. We have available, therefore, delicate tests for uracil and cytosine, and as thymine is also a normal constituent of many nucleic acids, it was very important to develop a correspondingly delicate test for this pyrimidine which would be applicable in the presence of either uracil or cytosine. The object of the research discussed in this paper was to develop, if possible, from known reactions a practical test for thymine which would meet these conditions.

The first attempt to perfect a specific test for thymine was made by Johnson and Baudisch,[5] who made a preliminary study of the oxidation products of thymine. It was found that the thymine molecule, in the presence of the system *ferrous sulfate* + *sodium bicarbonate* + air yields after acid hydrolysis urea, pyruvic acid, acetol and formic acid. Urea

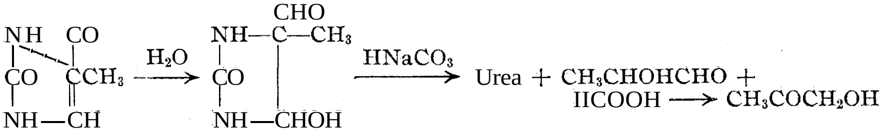
is identified by means of its xanthydrol derivative;[6] the pyruvic acid is converted to the dyestuff indigo by interaction with o-nitrobenzaldehyde, the acetol is identified as 3-oxyquinaldine formed by warming the acetol in alkaline solution with *o*-aminobenzaldehyde,[7] while formic acid is identified by its reducing action on silver nitrate in ammoniacal solution. It was found that pure thymine, IV, in quantities of milligrams only (2 to 5 mg.) may be detected by this procedure. No postulations were made regarding the mechanism of this interesting degradation of the thymine molecule. Deuel and Baudisch[8] later reported a modification of this test for the detection of thymine in the presence of carbohydrates.

This research was continued later by Baudisch and Bass,[9] who investigated the action of other oxidizing reagents on thymine, namely, (1) hydrogen peroxide, (2) hydrogen peroxide + ferrous sulfate, (3) sodium penta-cyano-aquo-ferroate + air, (4) ferrous sulfate + sodium bicarbonate + air and (5) iodine + sodium bicarbonate. They found that the five oxidizing agents except iodine were productive of urea, acetol and pyruvic acid when the products of oxidation are heated in aqueous solution with sodium bicarbonate. Acetol is formed as a direct hydrolytic product of thymine, while pyruvic acid is formed by the hydrolysis of an intermediate oxidation product of unknown constitution. Baudisch and Bass were apparently only interested in the mechanism of these various changes, and interpreted the course of the hydrolytic split of thymine as follows



IV V

With the first three oxidizing reagents the time required to carry out the complete operation is from twelve to forty-eight hours. The following quotation from the paper by Baudisch and Bass[8] reveals their method of oxidizing thymine with iodine "50 cc. of an approximately 0.1 *N* solution of iodine was added to a solution of 0.5 gram of thymine and 30 grams of sodium bicarbonate. The reaction mixture after dilution to one liter was allowed to stand overnight. The excess of iodine was then removed by blowing a rapid stream of air through the solution until it was decolorized (about four hours). The colorless solution was then distilled to a small volume. The distillate gave a strong acetol test. The residue gave a strong test for urea but no test for pyruvic acid. Al-

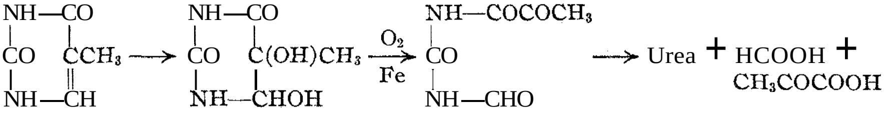
though this experiment has been repeated several times, a positive test for pyruvic acid has never been obtained." This quotation will serve to illustrate the technique of these tests as compared with that of the simplified test described in detail in the Experimental Part of this paper. Furthermore, the mechanism of change brought about by the action of iodine on thymine is undoubtedly identical in principle with our new procedure, but Baudisch and Bass were not conscious of this at the time of their work.

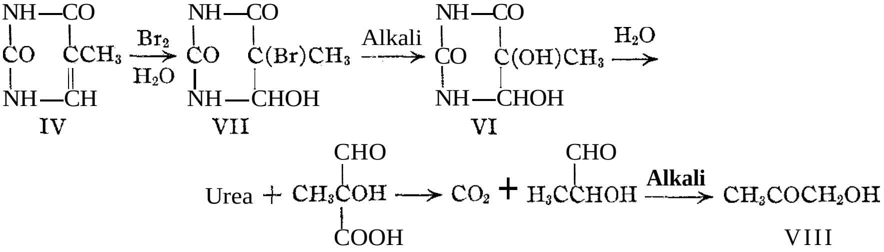
The correct formulation of the mechanism of the oxidation of thymine was worked out by Baudisch and Davidson.[10] They rejected the previous explanation postulated by Baudisch and Bass[8] and concluded that the mechanism of reaction leading to the formation of pyruvic acid is to be explained as follows



IV VI

In other words, they demonstrated that the different end-products resulting from degradation of thymine by oxidation and hydrolysis can result from the breakdown of an intermediate pyrimidine-glycol represented by Formula VI. But here again these workers emphasized only the mechanism of reaction in their work and did not point out any improved applications that could be made of their technique for the testing for thymine in the presence of other compounds. With these data at hand we have now been able to establish the basis of a very sensitive test for thymine applicable in the presence of uracil and cytosine.

Basis of the Thymine Test.—Thymine IV is converted quantitatively into 4-hydroxy-5-bromohydrothymine, VII, by the action of bromine water.[11] Baudisch and Davidson prepared this pyrimidine according to Jones' directions and showed that it undergoes hydrolysis easily with formation of carbon dioxide, acetol and urea. From these two observations we can now formulate reactions which lead to an important and intensively delicate test for thymine. The changes are expressed as follows



IV VII VI VIII

---

[10] Baudisch and Davidson, J. Biol. Chem., 64,233 (1925).

[11] Jones, Z. physiol. Chem., **29,** 20 (1900).

To carry out this simple test one treats thymine in aqueous solution with an excess of bromine and then removes the excess of halogen by boiling the solution. Barium hydroxide is then added in excess and the solution distilled, when acetol is carried over into the distillate. The acetol, VIIX, is then tested for according to the method of Baudisch.[7] The usefulness of this test is apparent if one bears in mind the fact that when uracil and cytosine are treated in a similar manner they both yield almost: quantitatively the purple barium salt of dialuric acid. Therefore, we now have available a procedure whereby these two pyrimidines can be detected easily in the same solution containing thymine, and can be removed from solution so as not to interfere with the acetol test for thymine. The reactions are easy to perform and the tests for the three pyrimidines in the same solution can be applied in a few minutes.

Application of the Acetol Test with **5-Methylcytosine.**—On account of the structural relationship existing between thymine and 5-methylcytosine and between uracil and cytosine, respectively, and since uracil and cytosine are both converted by action of bromine water and alkali into dialuric acid, it was logical to suppose that 5-methylcytosine would give the same end-products as thymine, IV. Experimentally this has been found to be the case and the detection of the four pyrimidines, uracil, thymine, cytosine and 5-methylcytosine, thus becomes a simple matter. The technique of this analytical procedure is discussed in detail in the Experimental Part of this paper. The investigation is being continued.

Experimental Part

Synthesis of Thymine.—Thymine was prepared by hydrolysis of 2-ethylmercapto-5-methyl-6-oxypyrimidine.[12] This mercapto-pyrimidine can be obtained in much better yields than according to the procedure described in the previous paper.

Sodium **Ethylformylpropionate.**—For the preparation of this salt the necessary reagents were used in the following amounts: 204 g. of ethyl propionate, 222 g. of ethyl formate, 1000 cc. of anhydrous ether and 46 g. of sodium. The two esters were mixed and then added slowly through a dropping funnel to ether in which was suspended the sodium. In order to accelerate the reaction the sodium was granulated by melting under the toluene and thoroughly shaking while cooling. The toluene was then decanted, the sodium washed with anhydrous ether and finally covered with dry ether in a large, round-bottomed flask connected to a reflux condenser. The ether solution of mixed esters was then dropped onto the sodium during a period of two days and the mixture allowed to stand for a third day to complete the reaction. Water was then added cautiously and the sodium salt of ethylformylpropionate dissolved. The water layer was separated and used in the condensations described below. Several preparations of this salt were made and in each condensation reaction the water layer was diluted to 1000 cc. and then divided into aliquot parts as required. Seven pyrimidine condensation reactions were then made using salt units corresponding to known weights of ethyl propionate (see Table I).

It may be concluded from the results of these experiments that the addition of

---

[12] Wheeler and Johnson, *Am. Chem.* **J.**, 31, 591 (1904).

alkali is not necessary in this condensation, and also that 102 g. of ethyl propionate is productive of sufficient condensation product—ethyl *sodium formylpropionate*—to interact with only 23 *g.* of pseudo-ethylthiourea hydrobromide (0.125 mole).

TABLE I

CONDENSATIONS WITH PSEUDO-ETHYLTHIOUREA

No.	Pseudo-ethylthiourea hydrobromide, *g.*	Ethyl propionate in form of sodium-formylpropionate, g.	Yield of mercapto-pyrimidine, g.	Sodium hydroxide, g.
1	185 (1 mole)	102	31	None
2	185 (1 mole)	102	26	40
3	92.5 (0.5 mole)	102	30	None
4	92.5 (0.5 mole)	102	20	20
5	46.0 (0.25 mole)	102	31.5	None
6	46.0 (0.25 mole)	102	36.00	None
7	23.0 (0.125 mole)	102	19.00	None

Theoretical yield for (Expt. 7) 31.00 g.

Preparation of **5-Methylcytosine.**—This pyrimidine was synthesized from 2-ethylmercapto-5-methyl-6-oxypyrimidine according to the method described by Wheeler and Johnson.[3] This process involves treatment of the 2-ethylmercaptopyrimidine with phosphorus pentachloride to obtain 2-ethyl-mercapto-5-methyl-6-chloropyrimidine and then heating this chloro compound under pressure with ammonia. The resulting mercapto-aminopyrimidine is then converted into 5-methylcytosine by hydrolysis with hydrochloric acid. Ninety-three grams of the 2-ethylmercaptopyrimidine were productive of 82 g. of the chloro compound boiling at 145–147° at 15–18 mm. By heating this chloride at 125–120° in alcohol saturated at 0° with ammonia nearly a quantitative yield of the corresponding aminopyrimidine was obtained. After digesting this mercaptopyrimidine for six hours with hydrochloric acid the evolution of mercaptan had ceased and on evaporating the solution the hydrochloride of 5-methylcytosine was obtained in excellent yield. Practically no thymine, IV, is produced in this hydrolysis. The free base was separated according to the directions of Wheeler and Johnson.

Application of the Acetol Test with Uracil, Thymine, Cytosine and **5-Methylcytosine:** Thymine.—To 0.0100 g. of pure thymine dissolved in 50 cc. of water, bromine is added until a red color is permanent. The excess of bromine is then removed by boiling and to the solution is added 1.0 g. of barium hydroxide crystals. The mixture is then refluxed for fifteen minutes and then distilled. The distillate is made strongly alkaline with sodium hydroxide and tested for acetol as follows.

"3.0 grams of crystalline *o*-nitrobenzaldehyde is mixed with 50 grams of crystalline ferrous sulfate and to this is added 75 cc. of concentrated aqueous ammonia solution. This ammoniacal solution is then heated on the steam-bath for one hour. It is then distilled with steam and several cubic centimeters of the distillate added to the alkaline solution containing acetol described above. This mixture is then evaporated by heating over a Bunsen flame to a volume of 25 cc. After cooling, hydrochloric acid is added until distinctly acid, and the solution then made alkaline by addition of sodium bicarbonate and the solution filtered. The solution thus obtained shows a deep blue fluorescence even in diffused daylight."[7]

In order to test the delicacy of this reaction successively smaller quantities of thymine were used and the solution containing acetol and *o*-aminobenzaldehyde was evaporated to a small volume, in some cases to a volume of 1 cc. It was observed that a blue fluorescence could be obtained with 0.001 g. of thymine. Although the characteristic fluorescence produced with this small quantity of pyrimidine is not observable in ordinary light, it can easily be seen in the light of a mercury arc lamp.

Baudisch[7] does not mention in his paper how to preserve the o-aminobenzaldehyde reagent. It was found that the aqueous solution containing o-nitrobenzaldehyde, ferrous sulfate and ammonia, heated as described above, could be allowed to stand in the laboratory for two weeks without destruction of the aminobenzaldehyde, *i. e.*, the steam distillate from such a mixture gave the fluorescence characteristic of 3-oxyquinaldine at the end of this time.

Uracil and Cytosine.—From inspection of the formulas of uracil and cytosine it can be seen that neither of these pyrimidines can give rise to acetol when treated with bromine and alkali. Uracil prepared by the hydrolysis of 2-methylmercapto-6-oxypyrimidine, when tested for acetol was found, however, to give a distinct, blue fluorescence, which persisted even when the uracil thus obtained was recrystallized several times from water. The same quantity of synthetic cytosine made by the pseudothiourea method3 was also found to give a distinct fluorescence. Apparently these pyrimidines contained a small trace of thymine and 5-methylcytosine, respectively, as impurity. The presence of these two impurities can be traced back to the original aliphatic ester used in the first condensation of the synthesis, namely, ethyl acetate. It is necessary that this reagent be absolutely free from ethyl propionate in order to obtain uracil or cytosine that will not respond to the acetol test.

In order to prove that uracil, when free from thymine, will not give the acetol test, this pyrimidine was synthesized from urea and malic acid according to the method of Davidson and Baudisch.[13] The uracil so obtained cannot contain thymine When 0.5 g. of this product was tested for acetol no fluorescence whatever could be detected thereby proving that uracil and cytosine cannot produce the blue fluorescence characteristic of thymine.

5-Methylcytosine.—5-Methylcytosine hydrochloride prepared as described above responds to the acetol test strongly. In order to make certain, however, that the test in this case is due to 5-methylcytosine and not to thymine, the methylcytosine was precipitated repeatedly as its phosphotungstate and the recovered methylcytosine then tested for acetol as before. A strong fluorescence was obtained, showing that 5-methylcytosine undergoes the same reaction with bromine and alkali as thymine. This is to be expected since uracil and cytosine yield the same product—dialuric acid—when treated with bromine and alkali.

Summary

1. An improved chemical or color test for detecting thymine, based on the experimental work of Johnson, Baudisch and co-workers, has been described.
2. The test is dependent on the formation of acetol by action of bromine and alkali on thymine.
3. The test applies equally well to 5-methylcytosine.
4. Both of these pyrimidines can be detected in quantities as small as one milligram.
5. The acetol test for thymine and 5-methylcytosine is applicable in the presence of uracil and cytosine.

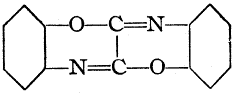
CONDENSATION OF ORTHO-AMINOPHENOL AND OXALIC ACID. PRELIMINARY COMMUNICATION[1]

BY ARTHUR A. LEVINE AND LESTER WEHMHOFF

RECEIVED NOVEMBER 9, 1928 PUBLISHED APRIL 5, 1929

In an investigation undertaken in this Laboratory it was desirable to prepare a number of substituted oxanilides of the general formula $XC_6H_4NHOCCOHNC_6H_4X$. These substances were prepared by fusing the substituted amine with the required quantity of oxalic acid and in each case the desired product was obtained. If o-aminophenol and oxalic acid were used, o-hydroxy-oxanilide was not obtained but another substance was formed melting at 271–272°. This new condensation product possesses a deep red color and will be designated as the "red condensation product."

o-Aminophenol condenses readily with monocarboxylic acids, giving benzoxazoles or β-substituted benzoxazoles depending on the acid used.[2] Kehrmann and Bener[3] have shown that oxalic acid reacts with *o*-aminophenol hydrochloride dissolved in molten benzoic acid, giving a product melting at 260" to which is ascribed the formula



Discussion

The red condensation product is formed on heating a mixture of two moles of o-aminophenol with one mole of anhydrous oxalic acid at 180–200" for thirty minutes. Two moles of water are evolved in the reaction and a small quantity of carbon dioxide (0.04 mole) due probably to partial decomposition of some oxalic acid. If the reaction was carried out at 130–140°, a small quantity of o-hydroxy-oxanilide was formed together with large amounts of the red product. At the higher temperature oxanilide could not be found in the reaction product.

Analysis of the red condensation product gave on calculation the same formula as for o-hydroxy-oxanilide ($C_{14}H_{12}O_4N_2$). Though certain reactions indicate that the molecular weight must be doubled, a direct determination of this has not been possible, as every effort failed to give concordant results due to the slight solubility in the solvents tried.

---

[1] Abstracted from a thesis by L. H. Wehmhoff presented to the Graduate Faculty of the State College of Washington in partial fulfilment of the requirements for the degree of Master of Science.

[2] Ladenburg, *Ber.*, 9, 1524 (1876); 10, 1124 (1877).

[3] Kehrmann and Bener, *Helv. Chim. Acta*, 8, 16 (1925).

If the red condensation product is heated a few degrees above its melting point decomposition occurs, giving carbon dioxide equivalent to one free carboxyl group and a tarry substance which could not be purified. On heating it to a higher temperature the red product decomposes completely into carbon dioxide, water, o-aminophenol and an unidentified substance melting above 300°.

With an alcoholic solution of sodium hydroxide, the red product forms *a* crystalline sodium salt. Analysis of this compound indicates that two atoms of sodium have entered the molecule. The sodium salt on treatment with dimethyl sulfate and an additional quantity of sodium hydroxide gives a crystalline substance containing three methyl groups.

The compound reacts with one molecule of aniline with the elimination of a molecule of water and the formation of a new substance. It gives an acetyl derivative by the action of acetic anhydride or acetyl chloride, which gradually decomposes on recrystallization from benzyl alcohol and yields the diacetate of o-hydroxy-oxanilide.

The red condensation product is not affected by acids but it is readily decomposed by alkalies. Toward oxidizing and reducing agents in an acid medium it is stable. Alkaline reducing agents such as zinc dust and sodium hydroxide convert it into a colorless, unstable reduction product which has not yet been obtained in a pure state.

Experimental

Numerous experiments were performed in order to determine the most suitable conditions for the formation of the red product. In some of these trials the relative quantities of o-aminophenol and oxalic acid were varied and in others the temperature at which the reaction was carried out. The following procedure has been found to be the most suitable.

One mole of oxalic acid and two moles of o-aminophenol were intimately mixed and transferred to an Erlenmeyer flask. This was immersed in an oil-bath and maintained at 180–200° for about one-half hour. The grayish red reaction product was pulverized and washed with dilute hydrochloric acid and water. The impure product (yield, quantitative) melted at 250–260°. It was crystallized first from nitrobenzene and subsequently from benzyl alcohol until a pure substance melting at 271–272° was obtained.

Anal. Subs., 0.2320, 0.3490: CO_2, 0.5270, 0.7934; H_2O, 0.0918, 0.1377. Subs., 0.4676, 0.2854: 33.05, 20.25 cc. of 0.1053 N acid. Calcd. for $C_{28}H_{24}O_8N_4$: C, 61.74; H, 4.44; N, 10.29. Found: C, 61.97, 62.02; H, 4.43, 4.42; N, 10.42, 10.46.

Properties of the Red Product.—It crystallizes in small, red plates from dimethylaniline, nitrobenzene and benzyl alcohol. It is insoluble in most solvents. It dissolves in concentrated sulfuric acid, from which it reprecipitates unaltered on addition of water. Concentrated and dilute alkalies on heating decompose it. On acidifying an alkaline solution that has been heated, carbon dioxide is evolved and a tarry substance is formed.

Determination of the Carbon Dioxide Evolved on Heating the Red Product to 280°.—A weighed quantity was heated in an Erlenmeyer flask immersed in an oil-bath maintained at a temperature of 280° for one hour. The flask was connected with a U-tube containing concentrated sulfuric acid and this to a weighed potash bulb. A slow current of air was passed through the apparatus.

Anal. Subs., 2.6420, 2.0300: CO_2, 0.2077, 0.1700. Calcd. for one carboxyl in $C_{28}H_{24}O_8H_4$: 8.09. Found: 7.86, 8.37.

Heating the substance to 320° decomposes it completely into carbon dioxide, water, o-aminophenol and an unidentified substance melting above 300".

The Sodium Salt of the Red Condensation Product.—This is formed on carefully warming the red product with an excess of 0.5 N alcoholic solution of sodium hydroxide. Long, needle-like crystals formed. These were recrystallized five times from 80% alcohol containing a small quantity of sodium hydroxide. The amount of sodium was determined by treating a weighed quantity with sulfuric acid and oxidizing the organic matter with nitric acid. Though somewhat high values were obtained, the results indicate that two atoms of sodium had reacted.

Anal. Subs., 0.2807, 0.7638: Na_2SO_4, 0.0775, 0.2026. Calcd. for $C_{28}H_{22}O_8H_4Na_2$: Na, 7.82. Found: Na, 8.94, 8.59.

The corresponding potassium salt was also prepared but was found to be even more difficult to crystallize. Both the sodium and potassium salt decompose readily on heating in aqueous or alcoholic solutions.

The Aniline Derivatives of the Red Product.—Ten grams of the red product were refluxed for one hour with 50 cc. of aniline. The resulting solution deposited well-formed crystals on standing. These were recrystallized from dimethylaniline and subsequently from nitrobenzene. The purified compound melts at 250°.

Anal. Subs., 0.2425, 0.1960: CO_2, 0.5850, 0.4724; H_2O, 0.1048, 0.0879. Subs., 0.4237, 0.2766: 31.18, 20.58 cc. of 0.1053 N acid. Calcd. for $C_{34}H_{29}O_7N_5$: C, 65.88; H, 4.72; N, 11.30. Found: C, 65.81, 65.75; H, 4.80, 4.98; N, 10.85, 10.97.

From this it follows that one mole of aniline has reacted with one mole of the original product. The aniline derivative is difficultly soluble in most organic solvents, though readily soluble in benzyl alcohol, nitrobenzene, aniline and dimethylaniline. It is not soluble in concentrated acids or alkalies.

Methyl Ester of the Red Condensation Product.—This was prepared by dissolving 10 g. of the product in 150 cc. of *2* N sodium hydroxide and adding 30 cc. of dimethyl sulfate in small portions with constant shaking. After about one-half of the dimethyl sulfate had been added, a crystalline precipitate formed. When all of the dimethyl sulfate had been added, the reaction mixture was heated on the water-bath for one hour. The product was recrystallized from benzyl alcohol until a constant melting point of 246–247° was attained.

Anal. Subs., 0.2245, 0.2832: CO_2, 0.5216, 0.6562; H_2O, 0.1118, 0.1351. Subs., 0.2240: 13.66 cc. of 0.1053 N acid. Calcd. for $C_{31}H_{30}O_8N_4$: C, 63.45; H, 5.33; N, 9.38. Found: C, 63.36, 63.20; H, 5.53, 5.36; N, 9.00.

The Acetyl Derivative.—Ten grams of the red condensation product was refluxed for four hours with 200 cc. of acetic anhydride. The acetic anhydride was distilled leaving a residue of about 50 cc. in the flask. This solidified on standing for a short time. The resulting product was transferred to a suction funnel and washed with about 10 cc. of glacial acetic acid, alcohol and finally with ether. The yield of impure product was 6.7 g. melting at 189°. Recrystallization from glacial acetic acid did not change the melting point. From this solvent it precipitates in well-shaped, red-colored plates, quite soluble in acetic acid, nitrobenzene and benzyl alcohol. Analysis for carbon and hydrogen gave values indicating that the substance was not pure. It was recrystallized from benzyl alcohol giving needle-like crystals lighter in color and melting at 183°. Evidently heating the substance with benzyl alcohol caused decomposition. Subsequent crystallization from the same solvent gave finally a perfectly white product, melting at 194°. This white substance is the diacetate of *o*-hydroxy-oxanilide, identified by analysis and a mixed melting point with a synthetic sample prepared by the method of Meyer and Seeliger.[4] These investigators give 201° as the melting point of the diacetate. This melting point is too high; a purified sample melted at 194° (corr.).

Anal. Subs., 0.2002, 0.1891: CO_2, 0.4461, 0.4203; H_2O, 0.0816, 0.0796. Calcd. for $C_{18}H_{16}O_6N_2$: C, 60.67; H, 4.50. Found: C, 60.77, 60.61; H, 4.52, 4.73.

The red acetate may be decomposed by dissolving in benzyl alcohol and heating for **a** few minutes. The solution is completely decolorized.

Summary

A new condensation product of o-aminophenol and oxalic acid has been isolated and some derivatives of it are described.

TRIMETHYLACETALDEHYDE AND DIMETHYLETHYLACETALDEHYDE

BY J. B. CONANT, C. N. WEBB AND W. C. MENDUM

RECEIVED NOVEMBER 13, 1928 PUBLISHED APRIL 5, 1929

Now that tertiary butyl and tertiary amyl alcohols are available, it becomes possible to prepare trimethylacetaldehyde and dimethylethylacetaldehyde in quantities suitable for synthetic work. These aldehydes promised to be of interest in connection with the study of highly-branched compounds which is being carried on in the Harvard Laboratories. In this paper we shall describe the preparation and behavior of these aldehydes in certain reactions. Although the hope of using these substances as a starting point in the synthesis of other branched compounds now seems dim, the results which have come to light are of some general interest.

The procedure we employed in the preparation of both aldehydes is outlined below

$$R_3COH \xrightarrow{HCl} R_3CCl \longrightarrow R_3CMgCl \xrightarrow{HCHO} R_3CCH_2OH \longrightarrow R_3CCHO + H_2$$

The last step, the dehydrogenation, is the same as that employed by Franke[1] in the most recent synthesis of trimethylacetaldehyde. We followed Bouveault's procedure instead of Franke's, however, and using copper at 250–300° obtained a 64–66% yield of aldehyde from both primary alcohols. The yield from the tertiary alcohol to the primary alcohol in both series was 40–50%, making the over-all yield for the four steps given above 25–33%.

---

[4] Meyer and Seeliger, ***Ber.***, 29, 2644 (1896).

[1] Franke and Hinterberger, *Monatsh.*, 43, 657 (1922).

One rather unexpected result was encountered in the preparation of the primary alcohols. If a considerable excess of gaseous formaldehyde is passed into the Grignard reagent, the reaction mixture decomposed and the product isolated in the usual way, as much as two-thirds of the product may be the acetal, $H_2C(OCR_3)_2$. The acetals are high-boiling liquids from which the tertiary alcohols may be obtained by heating with alcoholic hydrochloric acid. Although they are not appreciably decomposed by distillation with steam from 30% sulfuric acid, they appear to be decomposed to some extent by steam distillation of the reaction mixture. This procedure, together with a careful control of the amount of formaldehyde, results in relatively little high-boiling material and the maximum yield of carbinol. An alternative scheme is to employ an excess of formaldehyde and then boil the entire crude product with alcoholic hydrochloric acid, thus regenerating the carbinol from the acetal.

Dimethylethylacetaldehyde was prepared by Faworski[2] with very poor yields by chromic acid oxidation of the primary alcohol. Our product yielded a semicarbazone with the same melting point as that reported.

Autoxidation and Photochemical Decomposition.—Both trimethylacetaldehyde and dimethylethylacetaldehyde rapidly undergo autoxidation in the air. Samec[3] has shown that the final product in the first case is trimethylacetic acid and we have obtained as much as 82% of dimethylethylacetie acid by the autoxidation of the corresponding aldehyde. The phenomenon of the autoxidation of both these aliphatic aldehydes seems to be very similar to the autoxidation of benzaldehyde. After a short exposure to air, peroxide is present, as shown by the liberation of iodine from acidified potassium iodide solution. If a sample of aldehyde containing the peroxide is allowed to stand out of contact with air, the peroxide disappears, presumably because it is used up in the oxidation of a further amount of the aldehyde to acid. The autoxidation is retarded by the presence of hydroquinone. This was determined by following the process of oxidation by the titration of the acid formed; it was also found that the peroxide developed much more slowly. Although the rate of oxidation of pure trimethylacetaldehyde is of the same order of magnitude as that of pure benzaldehyde, the effect of the hydroquinone is much greater on the aromatic substance.

It was noticed early in our work that the liquid aldehyde slowly evolved gas and the evolution proceeded more rapidly in diffused daylight than in the dark. As much as 30 cc. of gas was evolved from 40 g. of aldehyde in the course of a day. The gas was found to be carbon monoxide. The

[2] Faworski, J. *Russ. Phys.-Chem. Soc.*, **50**, 43 (1918), Chem. Zentr., III, 667 (1923); Bouveault, *Bull. soc. chim.*, [3] 31, 1326 (1904), obtained the compound in traces and analyzed the semicarbazone.

[3] Samec, *Ann.*, 351, 259 (1907).

decomposition of aliphatic aldehydes by the action of ultraviolet light according to the equation $RCHO \longrightarrow RH + CO$ has been studied by Franke and Pollitzer.[4] The action of ultraviolet light on trimethylacetaldehyde was shown by Hinterberger[5] to cause the evolution of carbon monoxide, presumably as a result of the same reaction. We have been able to show that this is, indeed, the case since we isolated *iso*butane from a sample of pure trimethylacetaldehyde which was allowed to decompose for many weeks in daylight in the absence of oxygen.

A few preliminary experiments were performed to outline in a general way the photochemical behavior of these trisubstituted aldehydes. About 40 g. of aldehyde was employed and the rate of gas evolution per hour measured when illuminated by a quartz mercury arc lamp. The rate of decomposition was about the same in both quartz and pyrex flasks but was reduced to one-half by the interpolation of 1.45 mm. of soft glass and to about 20% by 1 mm. of mica. These facts enabled us to estimate the range of effective light from an inspection of photographs of the iron arc which were taken through our pyrex flask, glass plate and mica sheet. We are indebted to Mr. W. C. Root for these spectrograms. The limits of transmission were: pyrex, 2950 Å.; mica, 3020 Å. (3020 to 3150 Å. weak); glass, 3100 Å. (3100 to 3150 Å. weak). Since pyrex and quartz were photochemically equivalent in our reaction, whereas both mica and glass greatly diminished the effectiveness of the light, we conclude that it is primarily light of a wave length of 2950 to 3200 Å. that is responsible for the photochemical decomposition of trimethylacetaldehyde.

It is a well-known fact that the autoxidation of benzaldehyde is accelerated by ultraviolet light and we found a two-fold increase in the autoxidation of trimethylacetaldehyde when it was exposed to a quartz mercury arc. It is an interesting question for further research to decide what connection, if any, exists between the autoxidation reaction and the decomposition into carbon monoxide. That there is some connection is suggested by the facts just mentioned and also by our observation that the addition of 1 part in 500 of hydroquinone decreases to a third the photochemical decomposition in ultraviolet light.

Cannizzaro Reaction.—Although the Cannizzaro reaction is often supposed to be a general reaction of aldehydes which have no hydrogen in the a-position, Hinterberger[5] could obtain no evidence of this reaction with trimethylacetaldehyde. He used a concentrated solution of potassium hydroxide in water and some alcohol. Using 50% alcoholic potassium hydroxide containing a little water we obtained, after letting the homogeneous solution stand for one day at room temperature, a 59% yield of the carbinol and 55% yield of the acid. The Cannizzaro reaction

---

[4] Franke and Pollitzer, *Monatsh.*, 34, 797 (1913).

[5] Hinterberger, "Dissertation," Vienna, 1923.

thus does proceed with this aldehyde to at least 60% if alcohol is used as a mutual solvent for the alkali and the aldehyde. When we used aqueous alkali, however, we obtained chiefly unchanged aldehyde and indefinite higher boiling condensation products.

The Action of the Grignard Reagent.—The usual addition reaction between the Grignard reagent and an aldehyde is complicated in the case of aldehydes of the type R_3CCHO by the appearance of a reduction reaction which leads to the carbinols R_3CCH_2OH. Which of these two competing reactions predominates is determined by the nature of the hydrocarbon residue attached to the magnesium atom of the Grignard reagent. Thus with n-propylmagnesium bromide and dimethylethylacetaldehyde 15% reduction was observed, with isopropylmagnesium bromide 33% and with *tert.*-butylmagnesium chloride the reduction was 65%; in this last case there was no evidence of an addition reaction. With trimethylacetaldehyde, the process of reduction is slightly less pronounced than with its homolog; thus with the n-propyl Grignard reagent there was only a trace of reduction as compared with 15% with dimethylethylacetaldehyde, and the yield of addition product was 50% against 45%. With isopropylmagnesium bromide the figures were: trimethylacetaldehyde, reduction 10%, addition 33%; dimethylethylacetaldehyde, reduction 33%, addition 27%. The distinction between the two aldehydes thus seems to be just sufficient to be detected by our methods. Similar results have been obtained in this Laboratory in a study of the action of the Grignard reagent on ketones[6] and it is not necessary in this paper to discuss again this interesting effect of branching the chain in carbonyl compounds and Grignard reagents.

Experimental

(A) Preparation of **Trimethylacetaldehyde.**—*Tert.*-butylcarbinol was prepared from *tert.*-butylmagnesium chloride[7] and formaldehyde by a modified Courtot procedure.[8] The directions for the preparation of cyclohexylcarbinol by this procedure are given in detail in a recent volume of "Organic Syntheses"[9] and need only be briefly referred to here. Three moles of Grignard reagent was prepared and the passing in of the formaldehyde vapor required five to six hours. Some difficulty was encountered by the clogging of the entrance tube with solid paraformaldehyde. This was overcome by using a T-tube and running a rod down from time to time. The reaction mixture was hydrolyzed with dilute sulfuric acid, steam distilled and the carbinol purified by fractionation through a long column. The yield was 42 to 50% of the theoretical based on the magnesium. The product boiled at 112–114° and melted at 47–49°.

Di-*tert.*-butyl Acetal of Formaldehyde, $H_2C(OC(CH_3)_3)_2$—Small amounts of this substance were obtained as a high-boiling fraction in the *tert.*-butylcarbinol prepared as described above. In one experiment in which 4.2 moles of formaldehyde vapor

[9] "Organic Syntheses," John Wiley and Sons, Inc., New York, 6, 22 (1926).

was introduced into the reagent formed from 3 moles of magnesium, the yield of acetal was 40 g. (0.25 of a mole). The acetal distils at 182–185°. It was not affected by steam distillation from 80% sulfuric acid but was converted into *tert.*-butylcarbinol by heating with an equal weight of 95% ethyl alcohol containing 2 cc. of concd. hydrochloric acid.

Anal. Calcd. for $C_9H_{20}O_2$: C, 70.2; H, 12.8. Found: C, 70.3, 70.0; H, 12.4, 12.5.

Dehydrogenation of the Carbinol.—The method of Bouveault[10] was followed. A copper catalyst was placed in a vertical pyrex tube 2 cm. in diameter and 80 cm. long. This was attached directly to the flask containing the carbinol, the contents of which were kept boiling by means of a Bunsen burner. The tube containing the catalyst was heated electrically to a temperature of 250–300°. The vapors after passing from the flask up through the catalyst were fractionated by means of a long spiral column and the higher-boiling portion returned to the flask by means of a tube leading back from the bottom of the fractionating column. By controlling the rate of distillation with reference to the temperature at the top of the column it was possible to obtain a distillate consisting very largely of the aldehyde. On redistillation through a column, aldehyde boiling at 74–76° was obtained in a yield of 60–66%. The copper catalyst prepared according to Bouveault's directions was found satisfactory for the preparation of both trimethylacetaldehyde and dimethylethylacetaldehyde and was used in a number of runs. The catalyst is subject to poisoning rather easily, however, and in subsequent work many attempts to prepare an active catalyst failed for no apparent reason.

(B) Preparation **of Dimethylethylacetaldehyde.**—The *tert.*-amylcarbinol, $(CH_3)_2$-$C(C_2H_5)CH_2OH$, was prepared from *tert.*-amylmagnesium chloride and formaldehyde exactly in the same manner as the *tert.*-butylcarbinol. In preparing the Grignard reagent from *tert.*-amyl chloride it was noticed that if the amount of ether was insufficient a precipitate formed and the mixture became very thick. The following directions were satisfactory for the preparation of 3 moles of reagent. A 3-liter 3-necked flask was fitted with a stirrer, condenser and dropping funnel. Seventy-two g. of magnesium and a little iodine were placed in the flask. About 150 cc. of ether was added, then 30–40 cc. of chloride, with stirring. In a short time a vigorous reaction started, the flask was cooled and about 500 cc. of ether added as fast as possible. When the reaction slowed down the remainders of 1500–1600 cc. of ether and 360 g. of chloride were mixed and added slowly at such a rate that the mixture boiled gently; this required about six hours. The *tert.*-amylcarbinol boiling at 135–138° (Bouveault and Blanc[11] give 135°) was obtained in yields of 40–47%.

Di-*tert.*-amyl Acetal of Formaldehyde, $H_2C(OC_5H_{11}\text{-}tert.)_2$.—This acetal was obtained as a by-product from the preparation of the *tert.*-amylcarbinol. In one run a large excess of formaldehyde was used and the acetal was the principal product (the reaction mixture was not steam-distilled). The acetal distils at 220–224°. On boiling an alcoholic solution of it containing a little concd. hydrochloric acid it is converted into the *tert.*-amylcarbinol; 5 g. yielded 4 g. of carbinol and the presence of an aldehyde in the solution was shown by Schiff's reagent. The compound does not react with any of the following reagents: methylmagnesium iodide in amyl ether, alcoholic potassium hydroxide, phenyl isocyanate, *p*-nitrophenylhydrazine.

Dimethylethylacetaldehyde, $(CH_3)_2C(C_2H_5)CHO$.—The dehydrogenation of the *tert.*-amylcarbinol was carried out in the apparatus described above. The yield of aldehyde which boiled at 101–107° was 60–66%. The boiling point of the pure aldehyde is 104 ± 0.5°; this value was obtained both with a carefully refractionated material and with aldehyde regenerated from the bisulfite compound. The semihydrocarbazone melted at 153–155°, as reported by Faworski and by Bouveault.[2] A crystalline bisulfite compound was formed by shaking the aldehyde with an aqaeous saturated solution of sodium bisulfite also saturated with sulfur dioxide. The aldehyde was regenerated by the action of sodium carbonate solution. The bisulfite compound is oxidized by air rather rapidly.

Anal. Calcd. for $C_6H_{12}O$: C, 72.0; H, 12.0. Found: C, 71.1, 71.2; H, 12.1, 12.2. Refractive *Index*. $n_D^{22°} = 1.3975$; $d_4^{22} = 0.8040$; M_D (n^2 formula) = 29.99. Calcd., 29.92.

(C) **Autoxidation.**—It is known that the product of autoxidation of trimethylacetaldehyde is trimethylacetic acid. To prove that the dimethylethylacetaldehyde forms the corresponding acid the following experiment was made: Five g. of the aldehyde was placed in a 500-cc. flask fitted with a stopcock and full of oxygen. The flask was attached to a manometer. The stopcock was opened from time to time and the pressure read. It was noticed that the pressure in the flask fell considerably during the early part of the reaction. The flask was allowed to stand for twenty-nine days and then the material was removed. The acid content was determined by means of excess standard base and standard acid. It was found to be 82.1% acid by weight. The acid was then distilled. The major portion distilled between 180–188°, the boiling point of the acid being 186°.

The rate of oxidation of trimethylacetaldehyde to acid both in air and oxygen, with and without hydroquinone, was determined. One gram of the aldehyde was placed in a 300-cc. flask containing air or oxygen and from time to time a sample was removed and its acid content determined by dissolving in excess standard base and titrating back with standard acid, using phenolphthalein as an indicator. The inaccuracy of this method is probably in the neighborhood of 1%. The end-point in the case of the samples containing hydroquinone was rather uncertain. The amount of hydroquinone used in the protected samples was about 1 part in 500. The aldehyde employed contained only a trace of acid. Some typical results showing the percentage of oxidation at different times are as follows: (1) trimethylacetaldehyde in oxygen: 1.75 hrs., 44%; 5.75 hrs., 67%; 18.7 hrs., 83%; 24.9 hrs., 88%; 44.2 hrs., 87%—(2) trimethylacetaldehyde containing 1 part in 500 of $C_6H_4(OH)_2$ in oxygen: 1.75 hrs., 9%; 5.75 hrs., *22%;* 18.7 hrs., 57%; 25 hrs., 65%; 43.5 hrs., 73%; 48.75 hrs., 74%—(3) trimethylacetaldehyde in air: 7.75 hrs., 43%; 25 hrs., 60%; 32.25 hrs., 77%—(4) trimethylacetaldehyde with 1 part in 500 of $C_6H_4(OH)_2$ in air: 5 hrs., 3%; 20.75 hrs., 11%.

(D) **Photochemical Decomposition of** the Aldehydes.—When either of the aldehydes was sealed into a flask containing air connected to a manometer it was noticed that the pressure first fell off and then increased. The increase in pressure continued a long time, being continuously observed for over a month. This increase was not noticed when the flask was covered with black paper. The only logical explanation was that either the aldehyde or some oxidation product was being decomposed by light to a gaseous product. To decide this question about 40 g. of aldehyde was placed in a small flask which was connected to a gas buret filled with mercury. The leveling bulb was kept a little above the mercury level in the buret in order to keep a slight pressure on the system and to prevent leaks inward. After the apparatus had stood for a day or so, it was noted that gas came off, the rate of evolution seemingly increasing with time up to a more or less definite maximum. The amount seemed to be greater the brighter the day. It was noted that the gas was evolved whether the gas above it were air or nitrogen and whether or not the aldehyde had peroxide in it. In the case both of trimethyl- and dimethylethylacetaldehyde, amounts of gas as great as 30 cc. were given off in a day from 40 g., although the amount given off was generally much less than this. It was also noted that if the flask were covered with black paper, the evolution of gas stopped. It was also found that addition of hydroquinone stopped the formation of gas. The gas obtained was analyzed from time to time using the regular methods of gas analysis. The gas both from dimethylethylacetaldehyde and trimethylacetaldehyde had about the same composition. A typical analysis is as follows: CO_2, 0.9%; O_2, 1.0%; CO, 76.1%; material soluble in fuming sulfuric acid, 13.1% ; residue incombustible, 8.8%.

A sample of 30 g. of aldehyde which had been giving off gas to a closed system for several weeks (the evolution being most rapid on bright days) was connected to a gas buret through a return condenser and boiled under diminished pressure. About 345 cc. of gas was thus obtained (some air was introduced in connecting the apparatus); of this 7 cc. only dissolved in concd. sulfuric acid. Of the remainder, 25 cc. condensed to a liquid at −40°. This liquid on evaporation yielded a gas which was identified as *iso*butane by its liquefaction point, −9° to −14°, and its failure to react with concd. sulfuric acid or bromine water.

The action of ultraviolet light was studied using a Cooper-Hewitt Lab. Arc 105–125 V, 1 Amp., Type K 210,230. The results could not be exactly duplicated because the conditions and the output of the lamp could not be accurately controlled. It was found that if 38 g. of aldehyde in a pyrex flask was exposed to the rays from the arc located about 3 inches away, the gas evolved in the first hour (the aldehyde being taken from the dark) was approximately 20 cc., or of the order of the amount of gas given off in a day in good sunlight. The rate of evolution greatly increased during the time of exposure and after the light was turned off gas came off for the next half hour at a high rate. If the aldehyde was placed in quartz the amount of gas in the first hour was about 25 cc. The placing of one glass plate of 1.45 mm. thickness in front of the flask cut the amount of gas down to about 14 cc.; more glass plates had little effect. Passing the rays through 0.9 mm. of mica cut the rate down to 5 cc. in the first forty minutes; the use of only 0.17 mm. of mica gave almost the same result. The addition of hydroquinone in the proportion of 1 in 500 decreased the evolution of gas to approximately 8 cc. in the first hour.

(E) The **Action** of the Grignard Reagent.—The general procedure was to prepare the Grignard reagent from magnesium and the alkyl chloride or bromide in the usual way. Usually 0.4 of a mole of alkyl halide in a total of 225 cc. of ether was used. The aldehyde containing a trace of hydroquinone diluted with 4 to 6 times its volume of ether was run into the well-stirred solution of the Grignard reagent kept at 0°. The reaction mixture after standing overnight at room temperature was warmed to the boiling point of ether for about one hour and then decomposed in the usual way with ice-cold dilute sulfuric acid. With those reagents which caused reduction there was a vigorous evolution of gas when the reaction mixture was warmed; this gas was in part unsaturated hydrocarbons, since it decolorized bromine water. The crude product from the decomposition of the reaction mixture was separated as far as possible by fractional distillation through a spiral column of the Widmer type. The presence or absence of carbinols in the fractions was determined by adding phenyl isocyanate and obtaining the crystalline phenylurethans where possible.

The results are summarized below; unless otherwise stated the Grignard reagent in each case was prepared from 0.41 g. atom of magnesium and a slight excess of alkyl halide. There was thus a large excess of reagent in every case.

Trimethylacetaldehyde and n-Propylmagnesium **Bromide.**—0.12 Mole of aldehyde yielded 0.06 mole of $(CH_3)_3CCHOHCH_2CH_2CH_3$, b. p. 151–157"; phenylurethan, m. p. 69–71°.[12] The fraction at 120–151° was only 1 g. and gave a slight amount of the phenylurethan of $(CH_3)_3COH$.

Trimethylacetaldehyde **and *Iso*propylmagnesium Chloride.**—0.12 Mole of aldehyde yielded 0.04 mole of $(CH_3)_2CCHOHCH(CH_3)_2$, b. p. 140–150°, phenylurethan 87–88°.[13] The fraction at 110–125° gave the phenylurethan of $(CH_3)_3CCH_2OH$; a slight intermediate fraction at 125–140° yielded what seemed to be a mixture of the two phenylurethans. Neglecting the primary alcohol in this fraction the amount of reduction product was 0.01 mole.

Trimethylacetaldehyde and ***Tert*.-butylmagnesium Chloride.**—0.3 of a mole of Grignard reagent (by analysis) in 180 cc. of clear ethereal solution and 0.2 mole of aldehyde yielded 0.13 mole of $(CH_3)_3CCH_2OH$, b. p. 110–111°, which solidified. No other product could be found.

Dimethylethylacetaldehyde and ***n*-Propylmagnesium** Bromide.–4.10 Mole of aldehyde gave 0.015 mole of *tert*.-amylcarbinol, b. p. 130–140°, yielding the known phenylurethan, and 0.045 mole of $(CH_3)_2C(C_2H_5)CHOHCH_2CH_2CH$, b. p. 175–180°, 3,5-dinitrobenzoyl ester (from the chloride and pyridine), m. p. 70–71°. There was

---

[12] Haller and Bauer, *Ann. chim. phys.*, [8] 29, 317 (1913). We also synthesized the carbinol in 47% yield from n-butylaldehyde and *tert*.-butylmagnesium chloride.

[13] Haller and Bauer, ref. 12, give the melting point of the urethan as 79°, but this is probably a misprint for 89°, since this is the melting point of a pure sample prepared from the carbinol synthesized from *tert*.-butylmagnesium chloride and isobutyraldehyde.

a slight intermediate fraction. Since the carbinol was unknown it was also synthesized by the action of *tert.*-amylmagnesium chloride on *n*-butyraldehyde; the yield was only 25%. The pure carbinol boils at 177–178° and the phenylurethan is obtained with difficulty. The 3,5-dinitrobenzoyl ester is more useful for identification; it melts at 71.5–72.5°.

Analysis of *Tert.-amyl n-Propylcarbinol.*—Calcd. for $C_9H_{20}O$: C, 75.0; H, 13.9. Found: C, 75.5; H, 13.9.

Dimethylethylacetaldehyde and Isopropylmagnesium **Bromide.**—0.09 Mole of aldehyde yielded 0.030 mole of *tert.*-amylcarbinol, b. p. 133–134°, a small intermediate fraction, and 0.024 mole of *tert.*-amyl-*iso*propylcarbinol, b. p. 167–177° (Haller and Bauer give the b. p. as 170–171°; we were unable to obtain a pure crystalline phenylurethan from our product).

Dimethylethylacetaldehyde **and** *Tert.*-**butylmagnesium Chloride.**—0.05 Mole of aldehyde added to the reagent from 0.11 mole of magnesium yielded 0.03 mole of *tert.*-amylcarbinol, b. p. 130–137°; the higher and lower boiling fractions were very slight.

(F) Cannizzaro Reaction.—Ten g. of trimethylacetaldehyde was stirred with 15 cc. of 95% alcohol, 2 cc. of water and 7 g. of potassium hydroxide (the solution was cooled before the aldehyde was added) for a day. The mixture was homogeneous. The mixture was poured into water and ether extracted; the extract was dried and distilled through a short column. A strong smell of aldehyde was noticed in the ether distillates. The fractions collected were: 110–116°, 2.5 g.; 116–120°, 0.5 g.; residue 0.5 g. Both the 110–116" and the 116–120° fractions became solid in less than ten minutes on treatment with phenyl isocyanate, forming the phenylurethan of *tert.*-butylcarbinol. The potassium hydroxide solution was acidified and extracted with ether. The extract was dried and distilled: 155–163° (most at 159–164°), 3.3 g. or 55%; residue, 0.5 g.

Three attempts to carry out the Cannizzaro reaction with aqueous sodium hydroxide failed. An emulsion of the aldehyde in 50% aqueous sodium hydroxide for a day at room temperature yielded only a trace of *tert.*-butylcarbinol though a small amount of acid was formed. The chief neutral product boiled over a very wide range. Use of 30% sodium hydroxide, while keeping the emulsion stirred for two and one-half days, gave no evidence of carbinol formation and only a trace of acid which might have come from atmospheric oxidation. Evidently in all three cases large amounts of aldehyde remained unchanged and were contaminated with a mixture of higher boiling neutral substances.

Summary

1. A procedure is described for the synthesis of trimethylacetaldehyde and dimethylethylacetaldehyde from *tert.*-butyl and *tert.*-amyl alcohols.

2. Both aldehydes undergo autoxidation in the air. The process is retarded by the presence of traces of hydroquinone.

3. Both aldehydes undergo photochemical decomposition in bright daylight and in light from a mercury lamp. The effective wave lengths appear to be 2950–3200 Å. The products of the reaction are carbon monoxide and the saturated hydrocarbon.

4. The Cannizzaro reaction may be carried out with trimethylacetaldehyde if alcoholic potassium hydroxide is employed.

5. The action of the Grignard reagent from *n*-propyl, isopropyl and *tert.*-butyl halides on the two aldehydes has been studied. The reagent

from the primary and secondary halides gives addition and reduction products; with the *tert.*-butylmagnesium chloride only reduction occurred.

THE ISOELECTRIC POINT OF CRYSTALLINE UREASE[1]

BY JAMES B. SUMNER AND DAVID B. HAND

RECEIVED NOVEMBER 13, 1928 PUBLISHED APRIL 5, 1929

Introduction

In connection with our study of the properties of crystalline urease[1a] we have been especially interested in finding the isoelectric point inasmuch as it has never been determined for an isolated enzyme. We thought that a knowledge of this value would help to classify urease among proteins, would aid in improving the method of purification and might eventually throw light on the mode of action of the enzyme on urea.

References to the isoelectric points of enzymes are not lacking in the literature and some of these references are contradictory. Some enzymes have been stated to function as ions over the PH range at which they are active; other enzymes have been found to have isoelectric points coinciding with the PH of their optimum activity and consequently they are thought to react best when not ionized. Thus, pepsin was found by Michaelis and Davidsohn[2] to have an isoelectric point at *P*H 2.26. These authors state that pepsin must be positively charged to have a proteolytic effect. Northrop,[3] however, from a study of the distribution of pepsin and chloride and bromide ions between solid gelatin or coagulated egg albumin, concludes that pepsin is a monovalent ion from *P*H 1 to 7. Michaelis[4] states that with invertase the uncharged particles are active, that with trypsin, erepsin, lipase and maltase the anions are the active part, while with pepsin the cation is active. Michaelis and Pechstein[5] have found the isoelectric point of liver catalase to be at *P*H 5.37 and believe that the anions and uncharged particles are active, while the cations are not. Northrop[6] thinks it probable that the isoelec-

tric point of trypsin is at PH 10.2 and he finds trypsin to exist as a positive monovalent ion from *PH* 10 to 2. On the other hand, Sherman, Thomas and Caldwell[7] have reported that highly purified malt amylase is isoelectric at *PH* 4.3 to 4.5, which coincides with the *Pa* optimum for the action of this enzyme on starch.

Probably most of the enzyme preparations that have been employed to determine isoelectric points were far too impure to yield significant results. The presence of foreign proteins and other colloids must surely mask the ionic behavior of enzymes. It is of interest to note that in 1911 Pekelharing and Ringer[8] found that highly purified pepsin, which had a minimal solubility at *PH* 3.3, showed no direction of migration under the influence of an electric current unless albumin, or albumose, were added, when the enzyme assumed the electrical properties of the added substance. The apparent purity of crystalline urease suggests that its isoelectric point may be determined accurately.

Electrophoresis Experiments.—The first method employed with crystalline urease was that of electrophoresis. We used the Sherman, Thomas and Caldwell[7] modification of the apparatus of Michaelis[9]

The urease was prepared by methods already described and when obtained from meal low in enzyme activity was recrystallized. The media were phosphate, phthalate and acetate buffers, prepared from reagents which had been carefully purified. Cataphoresis experiments were run for periods varying from two to twenty-two hours, using a direct current of 110 volts. Various non-polarizable electrodes were tried in some cases and in others non-polarizable electrodes were not used. The amount of migration was tested by making determinations of the urease activity in all three chambers of the U-tube.

Our results showed that from *PH* 7 to about 5.5 the urease migrated toward the anode, but in solutions more acid than this very little migration occurred. Since urease is a globulin, the lack of migration in the vicinity of what we later showed to be the isoelectric point is probably due to the presence of salts. This property of globulins of being dissolved without electric charge by salts has already been reported.[10] We would have repeated the migration experiments, using urease solutions containing minimal amounts of buffer, but at present we are unable to procure satisfactory jack bean meal.

Precipitation by Phthalate and Lead Ions.—In the electrophoresis experiments the addition of phthalate buffer to urease caused a precipitation at PH 5 to 4. Since determination of the isoelectric point by migration had been unsatisfactory, we decided to find the PH of maximum

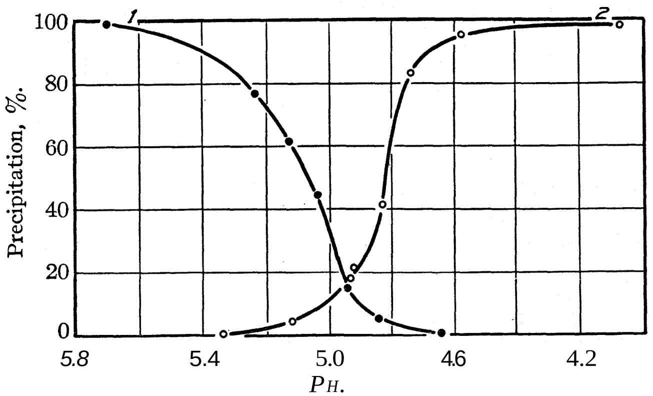
precipitation by phthalate buffer, expecting that this PH could be taken as the isoelectric point.

Experiments were conducted by adding 25 cc. of 0.04 M phthalate buffer, made up at different *PH* values, to 25 cc. of crystalline urease solution, containing 2500 to 3500 units of urease, mixing and allowing to stand in the ice chest for one hour. The material was then centrifuged until the supernatant liquid was water-clear. The centrifuging was continued for intervals of ten minutes with cooling in the ice chest before centrifuging again. In some cases it was necessary to centrifuge for a total of fifty minutes. The supernatant liquid was poured off as completely as possible, and in those cases where either very little, or nearly all of the urease had been precipitated, the centrifuge tube was freed of the last drop of supernatant fluid by a filter paper.

Both supernatant liquid and precipitate were analyzed separately for urease activity. The precipitate was dissolved in dilute neutral phosphate buffer before analyzing. The PH of the supernatant liquid was determined by the quinhydrone electrode. In these experiments very little of the urease was destroyed when the reaction was near PH 5, but at *PH* 4.07 the amount destroyed in one case was 21%. After determination of urease activity and *PH*, the remainder of the material was analyzed for total nitrogen by the macro-Kjeldahl method, using a refined technique suitable for small amounts of material.



1, Precipitation by lead 0.008 M in HAc–NaAc 0.12 M; 2, precipitation by phthalate, 0.02 M.

Fig. 1

The analyses demonstrated that precipitation of urease by phthalate is parallel to the precipitation of the protein and that no significant separation of urease from protein takes place. A curve was constructed, showing the percentage of total urease precipitated with change of PH. We had expected to find a point of maximum precipitation but there was none, as will be seen from Fig. 1. The curve shows that urease begins to precipitate at PH 5.3 and is almost all precipitated at PH 4.6.

Acetate buffer (Walpole's[11] 0.2 *M*) was substituted for the phthalate

buffer in order to study the precipitation of urease in more acid solutions but we were surprised to find the urease to be completely soluble in acetate buffer from *PH* 3.8 to neutrality. We concluded that the precipitation by phthalate is not a *PH* effect solely, but is caused by phthalate ions which unite with positively charged urease.

On account of the results with phthalate we decided to investigate the precipitation of urease with positively charged ions. For this purpose we employed lead acetate, since we had previously observed that lead acetate precipitates urease without much destruction and the insoluble precipitate actively decomposes urea.

The precipitation was carried out by adding to 5 cc. of phosphate-free urease solution, containing about 500 units, 10 cc. of 0 2 *M* acetate buffer, followed by 4 drops of 25.5% lead acetate. The lead acetate was Kahlbaum's and had been recrystallized three times. The material was mixed and allowed to stand for an hour in the ice chest; then it was centrifuged and the ureasc activity determined as was done with the phthalate precipitation. A few experiments were run using larger amounts of enzyme, and analyses for total nitrogen showed that the urease accompanied the protein in its precipitation. Treatment with lead was found to have very little destructive action on urease in the region of PH 5, but in more acid media some destruction occurred. However, even when the addition of lead acetate did not inactivate the urease, centrifuging down the lead precipitate did cause partial inactivation. The way in which the lead precipitate was redissolved apparently made a difference. Here the addition of gum arabic had a favorable effect. In no case in our experiments was more than 25% of the urease inactivated.

A curve was constructed showing the percentage of total urease precipitated with changing *PH*. As will be seen from Table I, urease begins to precipitate under these conditions at *PH* 4.7 and is almost completely precipitated at *PH* 5.6. The curves of precipitation of urease by phthalate and by lead clearly show the amphoteric nature of crystalline urease. On the acid side of *PH* 5 the colloidal particles bear a positive charge and are precipitated by negative ions such as phthalate. On the alkaline side of *PH* 5 the particles are negative and are precipitated by the lead ions. The two curves intersect at PH 4.95 and this value we thought might be taken as the isoelectric point. However, further experiments with lead precipitation have shown that the concentration of lead ions and of acetate buffer have a decided effect. Increasing the amount of lead acetate added was found to push the precipitation more toward the acid side, while increasing the concentration of the acetate buffer dissolved the lead–urease precipitate, or prevented its appearance. Hence it is evident that the accuracy of the isoelectric point established by these two curves can be questioned. The curves do give the isoelectric point approximately and they illustrate the precipitation of urease by certain electrolytes without destruction.

Mercuric and cupric ions precipitate urease over a much wider PH range than do lead ions and unlike lead cause complete inactivation if present in sufficient concentration. Here a portion of the urease can be reactivated by buffered hydrogen sulfide, but all of the urease cannot be reactivated.

Solubility Relationships.—As a result of further experiments we are able to summarize the solubility relationships of urease very simply. Urease is completely insoluble on the alkaline side of the isoelectric point in excess of lead acetate and on the acid side in excess of phthalate buffer. Urease is soluble in excess of phosphate buffer, acetate buffer and carbonic acid–bicarbonate buffer at all *PH* values, but is partly precipitated by these reagents over a narrow *PH* zone, provided a minimal amount of buffer is used. This range lies between *PH* 4.8 and **5.3.** On adding more of the buffer the precipitate immediately redissolves. Hence it is necessary to distinguish between the precipitating action of certain ions, such as lead and phthalate, and that of certain buffers which in small amount are able to precipitate urease by *PH* effect. However, these buffers have a solvent action and if present in sufficient quantity are able to dissolve urease at any *PH*. These findings confirm our previous statement that urease is a globulin.

Determination of Minimal Solubility.—Having an understanding of the solubility relationships of urease, it proved a simple matter to determine the isoelectric point by finding the minimal solubility in greatly diluted acetate buffer.

For this purpose 1-cc. portions of urease solution, containing about 150 units of enzyme, were pipetted into pyrex test-tubes and to each tube was added ***2*** drops of 0.2 *M* acetate buffer of various *PH* values. It was readily apparent that the heaviest precipitation occurred in tubes which were at PH 5.0 and 5 1, as was afterwards shown by testing with the quinhydrone electrode. Repetition of the experiment gave the same result. In a few instances the urease precipitate was centrifuged off and analyzed for its activity. The urease was found to be about 50% precipitated at PH 5.0 to 5.1. Below *PH* 4.8 and above *PH* 5 **3** no precipitate was produced. We were able also to precipitate urease by bubbling carbon dioxide through its solution. As nearly as could be found maximum precipitation by carbonic acid occurred at *PH* 5.0 to 5.1.

TABLE I

PRECIPITATION OF UREASE BY ACETATE BUFFER

Experiment 1		Experiment 2	
PH	Precipitate	*PH*	Precipitate
4.82	None	4.80	Faint
4.91	Moderate	4.88	Moderate
5.00	Heavy	4.98	Heavy
5.10	Heavy	5.10	Heavy
5.20	Moderate	5.18	Faint
5.30	Very faint	5.30	None

Accordingly we report the isoelectric point of crystalline urease as determined by the PH of minimum solubility to be at PH 5.0 to 5.1. The greatest possibility of error is dependent upon the purity of the urease employed. Our material is admitted not to be as pure as that which might have been prepared by several recrystallizations, starting with crystals obtained from jack bean meal of highest activity.

The isoelectric point is thus shown to be far to the acid side of the PH of optimum activity. We have previously found this for crystalline urease to be at *PH* 7.0. Urease is active on both sides of the isoelectric point with no sudden change in activity in passing from one side to the other. Indeed, the enzyme is still active in solutions as acid as PH **3.8,** although it is being steadily destroyed at this acidity.

Summary

1. Crystalline urease undergoes electrophoresis toward the anode in solutions of buffer varying from neutrality to about *PH* **5.5.** In buffer more acid than **5.5** no migration could be confirmed.

2. Urease begins to be precipitated by potassium acid phthalate at **PH 5.3** and the precipitation is almost complete at *PH* 4.6.

3. Urease begins to be precipitated by buffered lead acetate at *PH* 4.7 and the precipitation is almost complete at *PH* 5.6. The regions for precipitation by phthalate and lead overlap at *PH* 4.95, where 20% of the urease is precipitated by either ion. Urease is precipitated by mercuric and cupric ions over a much wider range than for lead ions.

4. Dilute electrolytes have three effects on the solubility of urease: ***a*** precipitation by certain ions such as phthalate and lead, over a certain range of PH; a solvent effect on urease; a precipitating action where the dilute salts bring the solution to the *PH* of the isoelectric point of urease.

5. The isoelectric point of urease as determined by the point of minimum solubility in dilute acetate buffer is at *PH* 5.0 to **5.1.** This point is far to the acid side of the *PH* of optimum activity for urease. Urease is active on both sides of its isoelectric point.

THE PREPARATION OF CERTAIN OCTADECANOIC ACIDS AND THEIR BACTERICIDAL ACTION TOWARD B. LEPRAE. XV[1]

BY W. M. STANLEY,[2] MARIAN S. JAY[2] AND ROGER ADAMS

RECEIVED NOVEMBER 15, 1928 PUBLISHED APRIL 5, 1929

In previous papers numerous series of organic acids of the general formula $RCH(CO_2H)R'$ in which R is a cyclohexyl, cyclopentyl, cyclopentenyl, or cyclopropyl group, or in which R is one of these groups substituted in the ω-position of the alkyl group, and in which R' is an alkyl group, have been prepared and studied for their bactericidal action toward B. leprae. The results indicated that there are no very marked differences between the acids containing the 3, 5 or 6-membered rings, and consequently the supposition that a ring is an important factor for the bactericidal action is probably incorrect. The acids which gave the best results in each of the series studied were those containing from sixteen to eighteen carbon atoms. When the two substituted groups in the acetic acids were of approximately the same number of carbon atoms, the products in general had the most pronounced bactericidal action.

The object of the present investigation was to determine whether acids not containing a ring might have a bactericidal action. A number of isomeric octadecanoic acids were synthesized which included a complete series of compounds with a chain of seventeen carbon atoms and a carboxyl group substituted in every possible position. The bactericidal properties are reported in Table I.

The results indicate conclusively that no ring in the molecule is necessary for bactericidal action. The marked difference between the acid with the carboxyl at the end of the chain and those with the carboxyl at any other position is particularly to be noticed. The individual members of the series do not show as regular a variation in bactericidal properties with change in constitution as was found in the previous series containing the rings. In fact, the variability resembles to a certain extent that found in the previously prepared ring-containing acids which had nineteen

to twenty-one carbon atoms. It seemed probable, therefore, that analogous acids of somewhat lower molecular weight, such as hexadecanoic acids, should prove more effective. A complete series of acids was synthesized which contained a chain of fifteen carbon atoms with the carboxyl in each possible position. The bacteriological results are given in Table II.

TABLE II

BACTERICIDAL ACTION OF HEXADECANOIC ACIDS

Analysis of the data indicates that the prediction was correct. The acids were in practically every instance more bactericidal than the octadecanoic acid homologs. Moreover, the regularity in the change of bactericidal property with constitution, which did not exist in the acids of eighteen carbon atoms, is apparent here. The marked difference between the acid with the carboxyl at the end of the chain and acids with the carboxyl in any other position again deserves notice.

The conclusion from the studies of the bactericidal effect toward acid-fast bacteria, and especially toward B. *leprae*, of the large number of acids described in this series of papers, is that the effect can hardly be attributed to a chemical specificity of the individual acids but must, probably, be due to a combination of physical properties common to many of these acids. The mechanism of the bactericidal effect may be looked upon as an adsorption or solution of the acid in the waxy coating of the bacteria, with a consequent smothering or suffocation of the organism. The physical properties of the effective acids are being studied in an attempt to correlate physical properties and bactericidal action.

Although occasional tests have been made to determine the bactericidal effect of some of these acids toward B. *smegmatis* and *B. tuberculosis,* no report of the results has as yet been published. The relative bactericidal action for B. *tuberculosis* and *B. leprae* of a few selected acids is recorded in Table III.

TABLE III

BACTERIOLOGICAL ACTION OF CERTAIN ACIDS TO B. *tuberculosis*

	Dilution of sodium salts in thousands									Max **eff. diln.** *vs.* B. *leprae* in thousands
	1	5	10	16	20	25	33	50	100	
$C_7H_{15}CH(CO_2H)C_7H_{15}$	—	—	—	—	—	—	—	±	+	155
$C_6H_{11}(CH_2)_2CH(CO_2H)CH_2C_6H_{11}$	—	—	—	—	—	—	—	—	+	100
$C_6H_{11}(CH_2)_2CH(CO_2H)C_7H_{15}$	—	—	—	—	—	—	—	±	+	220
$C_6H_{11}CH(CO_2H)C_{10}H_{21}$	—	—	—	—	—	—	—	±	+	180
$C_5H_7(CH_2)_2CH(CO_2H)C_{10}H_{21}$	—	—	—	—	±	+	+	+	+	192
$C_6H_{11}(CH_2)_3CH(CO_2H)(CH_2)_3C_6H_{11}$	—	+								25
$C_6H_{11}(CH_2)_4CH(CO_2H)(CH_2)_2C_6H_{11}$	—	+								***25***

It is obvious that the acids are in general only a fraction as effective toward B. *tuberculosis* as they are toward B. *leprae;* nevertheless they do have a similar action. The acids of too high molecular weight have a relatively low effect just as was found in the tests against B. *leprae.*

Strain 1 is a culture of B. leprae of unknown history obtained from the University of Chicago. It has been cultured on laboratory media for several years and is a very rapidly-growing strain. All of the tests made on the various acids have been with this particular organism. Strains 2 to 8 inclusive were obtained from the American Type Culture Collection and are listed as follows: No. 2, 65 Hyg. Lab., Washington, D. C., 365—"Duval," 1925; No. 3, 66 Hyg. Lab., Washington, D. C., 367—"rat 2," 1925; No. 4, 67 Hyg. Lab., Washington, D. C., 368—"rat 12, Dr. McCoy," 1925; No. 5, 68 Hyg. Lab., Washington, D. C., 361—"Needham," 1925; No. 6, 69 Army Med. School, Washington, D. C., 366—"rat 1," 1925; No. 7, 282 of American Type Culture Collection; No. 8, 283 of American Type Culture Collection.

In order to be certain that the acids are bactericidal toward strains of B. leprae other than that regularly used, a few tests were made and are recorded in Table IV. Three synthetic acids and the mixed acids from two natural oils were studied, using eight different strains of bacteria.

It can be seen that the synthetic acids are much more bactericidal than the mixed acids of the natural oils, and that the results run parallel with the different, more or less resistant, strains. Strain 4 is obviously much more easily killed than the others and too much significance should, therefore, not be attached to the results on this particular one.

The synthetic acids were prepared from the proper disubstituted malonic esters by saponification and decomposition of the malonic acids.

Experimental

The general methods of preparation of the various intermediates have been described in previous articles in this series.

Summary

1. It has been demonstrated that *a* ring structure is unnecessary in order that certain various organic acids have a bactericidal action.

2. A number of octadecanoic acids and hexadecanoic acids have been synthesized and their bactericidal actions determined.

3. A table of bactericidal values toward B. *tuberculosis* of a few selected acids is included. The effect is much less than toward B. *leprae.*

4. A table of bactericidal values of a few acids toward eight different strains of B. *leprae* is given.

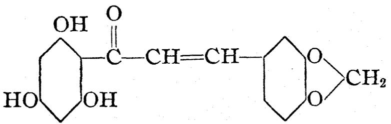
SYNTHESIS OF SOME CHALKONES

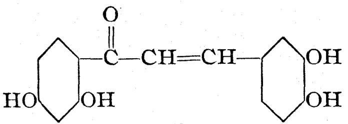
BY R. L. SHRINER AND E. C. KLEIDERER

RECEIVED NOVEMBER 19, 1928 PUBLISHED APRIL 5, 1929

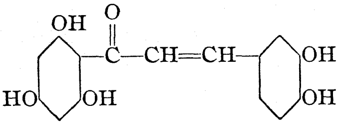
A yellow coloring matter, hyssopin, first isolated from *Herba Hyssopi* by Tunmann,[1] was shown to be a rhamnoside of a chaikone by Oesterie and Kueny.[2] Oesterle[3] also prepared it from *Capsella Bursa Pastoris* and studied its decomposition by 33% potassium hydroxide. Since piperonal, acetopiperone and phloroglucinol were obtained by this alkaline degradation, Oesterle decided that the chalkone was 2,4,6-trihydroxyphenyl-3,4-methylenedioxystyryl ketone (I). This structure was analogous to that assigned to butein (II) by Perkin and Hummel,[4] and Göschke and Tambor,[5] who have synthesized the latter compound. It is also similar to the structure given to eriodictyol (III) by Tutin.[6]



I



II



III

However, since only a small amount of piperonal was obtained and acetopiperone predominated among the decomposition products, it would seem that the chalkone should be 2,4,6-trihydroxystyryl-3,4-methylenedioxyphenyl ketone (VIII). The purpose of the present investigation was to synthesize the two isomeric chalkones represented by Formulas (I) and (VIII).

[4] Perkin and Hummel, J. *Chem. Soc.*, *85*, 1459 (1904).

[5] Göschke and Tambor, Ber., 44,3502 (1911).

[6] Tutin, J. *Chem. Soc.*, 97,2054,2062 *(1910)*.

The first isomer (I) was prepared by condensing 2,4,6-trihydroxyacetophenone (IV) with piperonal (V) by means of alcoholic potassium hydroxide. The 2,4,6-trihydroxyacetophenone was made by condensing phloroglucinol with acetyl chloride by means of aluminum chloride in nitrobenzene as a solvent.'

The second isomer (VIII) was synthesized by the condensation of phloroglucinaldehyde (VI) with acetopiperone (VII). The phloroglucinaldehyde was prepared by means of the Gattermann reaction using the modified procedure of Adams and Levine.[8] Dry hydrogen chloride was passed into a suspension of zinc cyanide in an ether solution of phloroglucinol. The resulting imidohydrochloride was then hydrolyzed to phloroglucinaldehyde. Acetopiperone was prepared by the ketonic hydrolysis of piperonyl acetic ester[S] obtained by condensing methyl piperonylate with ethyl acetate by the use of sodium. The chalkone was obtained by condensing together the above aldehyde (VI) and ketone (VII) with alcoholic alkali.

These chalkones decompose on heating and do not possess definite melting points. Their acetates, however, melt sharply and hence the triacetate of each of the isomers was prepared. The natural product decomposed at 262–263° and its triacetate melted at 196–197° according to Oesterle.[3] The synthetic chalkone corresponding to Formula (I) decomposed above 300° and yielded an acetyl derivative melting at 218–220°. Compound VIII decomposed at 265–270° and yielded an acetate melting at 205–206°. It will be noted that the synthetic chalkone (VIII) decomposed at very nearly the same temperature as the natural product. It also possessed properties which agreed with those given by Oesterle for his compound, but the triacetate of this synthetic chalkone melted ten degrees higher than the acetate prepared from the natural substance. Since it is very difficult to purify these natural coloring matters it may be that the natural product was not quite pure. It is very evident that chalkone I diiers markedly from the natural product. Its decomposition point and the melting point of its triacetate are very much higher than the values for the natural chalkone. Unfortunately, no sample of the natural product could be obtained for direct comparison.

Experimental

Piperonal.—The piperonal was a commercial product and was purified by vacuum distillation. It melted at 36°.

2,4,6-Trihydroxyacetophenone.—Fifteen grams of phloroglucinol and 20 g. of acetyl chloride were dissolved in a mixture of 200 cc. of dry nitrobenzene and 200 cc. of absolute ether. Thirty grams of aluminum chloride was then added in small portions

[9] Mauthner, *J. prakt. Chem.*, **116**, 321 (1917).

during a period of half an hour. The ether was distilled and an additional 30 g. of aluminum chloride was added to the solution. which was stirred vigorously and allowed to stand overnight. The mass was decomposed with ice and the nitrobenzene removed by steam distillation. The aqueous residue was filtered while still hot. On cooling the filtrate, trihydroxyacetophenone crystallized out. After two crystallizations from water with the aid of Norite, 5 g. of light yellow needles was obtained which melted at 213–214° (corr.). The compound gave a wine-red color with ferric chloride, which differentiates it from phloroglucinol, which melts at 217–218°.

Anal. Subs., 0.1341: H_2O, 0.0563; CO_2, 0.2819. Calcd. for $C_8H_8O_4$: H, 4.76; C, 57.14. Found: H, 4.69; C, 57.33.

2,4,6-Trihydroxyphenyl-3,4-methylenedioxystyryl Ketone (I).—This chalkone was obtained by mixing together 2 g. of piperonal, 2 g. of chloro-acetophenone and 20 cc. of 50% alcohol in which 5 g. of potassium hydroxide had been dissolved. The mixture was heated for one hour at 95–100°. After cooling, it was poured into dilute hydrochloric acid and the yellow precipitate filtered off. After recrystallization from 75% methyl alcohol, a yellow powder was obtained which decomposed around 300–310°.

Anal. Subs., 0.0986: H_2O, 0.0365; CO_2, 0.2309. Calcd. for $C_{16}H_{12}O_6$: H, 4.03 C, 64.00. Found: H, 4.13; C, 63.85.

The acetate was prepared by refluxing 1 g. of the above chalkone with 15 cc. of acetic anhydride and 1 g. of anhydrous sodium acetate for one hour. On pouring into water the acetate separated as a light yellow solid. It was recrystallized from 90% alcohol and consisted of light yellow needles melting at 218–220°.

Anal. Subs., 0.1071: H_2O, 0.0386; CO_2, 0.2419. Calcd. for $C_{22}H_{18}O_9$: H, 4.22; C, 61.97. Found: H, 4.03; C, 61.56.

Phloroglucinaldehyde.—Dry hydrogen chloride was passed into a mixture of 30 g. of phloroglucinol dissolved in 250 cc. of dry ether with 30 g. of zinc cyanide with vigorous mechanical stirring. At the end of two hours the imido-hydrochloride separated as an oil. The supernatant liquid was decanted and the crude imido-hydrochloride washed with ether. The product then solidified. It was boiled with 250 cc. of water for three minutes and the solution cooled. Orange-red crystals of the crude aldehyde separated and were purified by two crystallizations from hot water in the presence of Norite. Long, white needles were obtained which possessed no definite melting point. This compound gave a wine-red color with ferric chloride and yielded a phenylhydrazone melting at 120°; yield 18 g. or 49% of the theoretical.

Anal. Subs., 0.1268: H_2O, 0.0451; CO_2, 0.2521. Calcd. for $C_7H_6O_4$: H, 3.89; C, 54.50. Found: H, 3.98; C, 54.28.

Acetopiperone.—A mixture of 24 g. of methyl piperonylate, 3.1 g. of powdered sodium and 18 g. of ethyl acetate was heated on the steam-bath for two hours. At the end of this time an additional 2 g. of sodium and 10 g. of ethyl acetate were added and the heating was continued for another two hours, at which time 10 g. of ethyl acetate was again added and the heating allowed to continue for four hours. The addition of the ethyl acetate in this manner is necessary in order to get the methyl piperonylate to condense, since a considerable portion of the ethyl acetate condenses with itself to give ethyl acetoacetate.

The reaction mixture was decomposed with water and acidified with acetic acid. The oil which separated was crude 3,4-methylenedioxybenzoylacetic ester. This was washed with water and then hydrolyzed by refluxing with 300 cc. of 10% sulfuric acid for eight hours. After cooling, the solution was made alkaline with sodium hydroxide and extracted with ether. The ether was distilled and the acetopiperone recrystallized from 50% alcohol. Eight grams of white crystals was obtained which melted at 87–88°.

The compound yielded a *p*-nitrophenylhydrazone melting at 201–203°, which agrees with the value given by Mauthner.[9]

Anal. Subs., 0.1011: H_2O, 0.0457; CO_2, 0.2424. Calcd. for $C_9H_8O_3$: H, 4.88; C, 65.90. Found: H, 5.05; C, 65.45.

2,4,6-Trihydroxystyryl-3,4-methylenedioxyphenyl **Ketone** (VIII).—Two grams of phloroglucinaldehyde and 2 g. of acetopiperone were condensed by the method described above for the other isomer. Crystallization from 75% methyl alcohol yielded an orange powder which decomposed at 265–270°. In its decomposition point, color (deep orange) and also its insolubility in dilute ammonia, this compound resembled the natural product described by Oesterle.

Anal. Subs., 0.0770; H_2O, 0.0289; CO_2, 0.1798. Calcd. for $C_{16}H_{12}O_6$: H, 4.03; C, 64.00. Found: H, 4.20; C, 63.71.

The triacetate was prepared by refluxing 1 g. of the above ketone with acetic anhydride and sodium acetate for one hour. After decomposition with and crystallization from alcohol, light yellow needles were obtained which melted at 205–206°.

Anal. Subs. 0.0876: H_2O, 0.0328; CO_2, 0.1995. Calcd. for $C_{22}H_{18}O_9$: H, 4.22; C, 61.97. Found: H, 4.18; C, 62.08.

Summary

The two isomeric chalkones, 2,4,6-trihydroxystyryl-3,4-methylenedioxyphenyl ketone and 2,4,6-trihydroxyphenyl-3,4-methylenedioxystyryl ketone, corresponding to the possible structures for the chalkone previously isolated from natural sources, have been synthesized. A comparison of the properties of the natural chalkone with those of the synthetic isomers indicates that the natural compound is 2,4,6-trihydroxystyryl-3,4-methylenedioxyphenyl ketone. The other isomer, which possesses the structure originally assigned to the natural chalkone, differs markedly from the compound found in nature.

DIFURYLETHYLENE

BY PAUL F. BRUINS

RECEIVED NOVEMBER 19, 1928 PUBLISHED APRIL 5, 1929

In making a study of the disappearance of furfural in alcohol fermentation, Lintner[1] found that furfural in dilute aqueous solution reacts with hydrogen sulfide to form a milky emulsion of polythiofurfuraldehyde which has a peculiar penetrating bread-like odor. The emulsion which was formed could be coagulated to a rubbery mass on the addition of a few drops of sulfuric or hydrochloric acid.

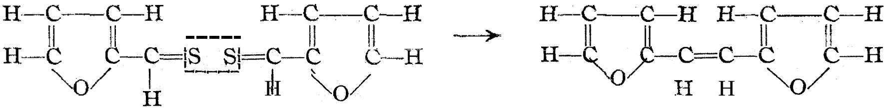
A study of this reaction has been made and an attempt to identify the product has brought about the discovery of a method whereby difurylethylene may easily be prepared. By the vacuum distillation of

---

[1] Lintner, Z. ges. *Brauw.*, 15,189 (1910); C. *A.*, 5,755 (1911).

the polythiofurfuraldehyde, difurylethylene is formed and is obtained almost pure in the distillate.

The mechanism of the reaction is probably of the following order:



The product of this reaction is one which should be of considerable value in the synthesis of furfural compounds. With the remarkable increase in the production of furfural and its accompanying low cost per pound, the synthesis of compounds made from furfural becomes increasingly interesting.

Experimental

The polythiofurfuraldehyde was prepared as follows: A 3% solution of furfural in water was placed in a large absorption bottle of about 4-liters capacity. A slow stream of hydrogen sulfide gas was passed through the solution for three hours. By raising the temperature of the solution to 50°, the absorption rate may be increased. The resulting emulsion was coagulated with a small amount of hydrochloric acid and the resulting mass dried as much as possible without warming.

One hundred grams of the polythiofurfuraldehyde was placed in a 500-cc. Claisen flask and slowly warmed with a low flame, maintaining a vacuum of from 10 to 15 mm. of mercury. At about 60° a slight amount of ebullition took place but the solid crystals did not begin to condense on the walls of the receiver until 90". The distillation was complete at 135°, leaving only a char. The product had a small amount of water with it and had a very penetrating odor due to a trace of sulfur compounds. The odor was entirely removed by petroleum ether, in which the compound which was formed was only slightly soluble.

The compound was purified by redistillation in *vacuo*. It was found that recrystallization from alcohol caused the compound to darken, indicating its rather unstable structure. It did not discolor farther on standing and the redistilled compound remained white. The yield was 18 g., or 18%.

Anal. Subs., 0.2076: CO_2, 0.5674; H_2O, 0.0960. Calcd. for C_5H_4O: C, 74.94; H, 5.09. Found: C, 74.55; H, 5.17.

The molecular weight determination using the freezing-point method with benzene as solvent was 162. The nearest theoretical weight would be 160.18, making the molecular formula $C_{10}H_8O_2$.

The compound melts at 100°. It is very soluble in acetone, soluble in benzene, ether, carbon tetrachloride, chloroform and hot alcohol, slightly soluble in petroleum ether and cold alcohol.

Summary

The vacuum distillation of polythiofurfuraldehyde, a compound prepared from furfural by treatment with hydrogen sulfide in dilute aqueous solution, yields what is believed to be difurylethylene.

AMES, IOWA

IDENTIFICATION OF AMINES. IV. METHANESULFONAMIDES

BY C. S. MARVEL, M. D. HELFRICK AND J. P. BELSLEY

RECEIVED NOVEMBER 21, 1928 PUBLISHED APRIL 5, 1929

The arylsulfonyl derivatives of primary and secondary amines have been carefully investigated and are very useful in the separation and identification of amines. However, very little work has been done on the alkylsulfonyl derivatives of this type. The work of Johnson and Ambler[1] shows that benzylsulfonamides are more easily hydrolyzed than are arylsulfonamides. It was thought that the simple alkylsulfonamides might hydrolyze even more readily than the benzyl derivatives and since ease of hydrolysis is a desirable property in sulfonamides if they are to be of value in the separation of amines, some of the methanesulfonamides were prepared and characterized.

Methanesulfonyl chloride has been prepared by the action of phosphorus pentachloride on methanesulfonic acid.[2] In this work the mixture of sodium methanesulfonate and sodium methyl sulfate obtained by the action of dimethyl sulfate on sodium sulfite was dried and treated directly with phosphorus pentachloride.

The methanesulfonamides could be prepared by the usual procedure using the sulfonyl chloride, the amine and aqueous alkalies. However, methanesulfonyl chloride is fairly easily hydrolyzed by water and the best yields of sulfonamides were obtained by working in benzene solutions. The methanesulfonamides were readily hydrolyzed by boiling them with 60% sulfuric acid for six hours.

Methanesulfonyl chloride has certain disadvantages as a reagent for the separation of amines. When an unknown mixture of primary, secondary and tertiary amines was treated with an excess of the reagent in the presence of cold aqueous alkalies, the primary amine was converted quite largely to the disulfonyl compound, which precipitated with the derivative of the secondary amine. Unless an excess of the reagent was used the tertiary amine was always contaminated with unchanged primary and secondary amine. When a known mixture of amines was treated with a known excess of the reagent, the amines were separated satisfactorily and the primary and secondary amines were recovered by hydrolysis of the derivatives.

Experimental Part

Methanesulfonyl Chloride.—In a 5-liter three-necked flask fitted with a reflux condenser, mechanical stirrer and a separatory funnel, were placed 1 kg. of anhydrous sodium sulfite and 2 liters of hot water (80–90°). The mixture was stirred and heated

---

[1] Johnson and Ambler, THIS JOURNAL, 36, 385 (1914).

[2] Carius, *Ann.*, 114, 142 (1860).

on the steam cone for about ten minutes to get as much in solution as was possible. The heating was discontinued and then 1 kg. of dimethyl sulfate was added at such a rate that the solution boiled gently. When all of the dimethyl sulfate had been added, the condenser was set for distillation and the water was distilled off under reduced pressure until a pasty mass just fluid enough to pour remained in the flask. This mixture was transferred to a large porcelain dish and dried in an oven at 120° until the mass was solid. This mass was then ground in a mortar and dried again far about six hours at 120°. The powdered mixture of sodium methanesulfonate and sodium methyl sulfate was transferred to a 5-liter flask and mixed thoroughly with 1.4 kg. of phosphorus pentachloride. About 2 liters of dry benzene was added to give better contact between the two reacting substances. This mixture was heated to gentle boiling under a reflux condenser for ten to twelve hours. The reaction mixture was cooled and filtered with suction. The salt cake was washed with 500 cc. of dry benzene. The benzene solution was then carefully fractionated using a good column. The yield of methanesulfonyl chloride boiling at 158–162° was 200–250 g. (21–27% of the theoretical amount based on the sodium sulfite).

Methanesulfonamides.—For the preparation of the pure amide it was found that the best results were obtained by treating a benzene solution of two molecular proportions of the amine with a benzene solution of one molecular proportion of methanesulfonyl chloride. The amine hydrochloride was filtered off, the benzene evaporated and the sulfonamide recrystallized from dilute alcohol until it had a constant melting point. The results of these experiments are given in Table I.

TABLE I

METHANESULFONAMIDES

Amine	M. p. of amide, °C.	Amine	M. p. of amide, °C.
Aniline[a]	100.5	2,5-Dichloro-aniline	174
o-Toluidine	103	α-Naphthylamine	125.5
p-Toluidine	102.5	β-Naphthylamine	153.5
o-Anisidine	115.5	6-Phenoxybutylamine	79.5
p-Anisidine	116	Methylaniline	76.5
p-Phenetidine	125	Ethylaniline	59
o-Chloro-aniline	90.5	n-Propylaniline	76
p-Chloro-aniline	148	n-Butylaniline	73
p-Bromo-aniline	136	Benzylaniline	122

[a] McGowan, J. prakt. Chem., [2] 30, 282 (1884), prepared this amide but does not list its properties; Duguet, Chem. *Zentr.*, [1] 854 (1902), gives 99° as the melting point of this compound.

The derivatives of N-ethyl-p-toluidine, N-ethyl-o-toluidine, l-menthylamine, *sec.* butylaniline, diethylamine, di-n-butylamine and di-n-propylamine were oils. Satisfactory nitrogen analyses were obtained on the solid compounds. The derivatives of the primary amines were soluble in 10% aqueous sodium hydroxide.

Hydrolysis of Methanesulfonamides.—A suspension of 9.3 g. of methanesulfone-N-methylanilide in a solution of 30 cc. of concentrated sulfuric acid (sp. gr. 1.84) in 30 cc. of water was boiled under a reflux condenser for about six hours. The solution was made alkaline and distilled with steam. The distillate was extracted with ether and the ether evaporated. The residual oil weighed 3.8 g. (about 71% of the theoretical amount) and was shown to be methylaniline.

The oily methanesulfonyl derivative prepared from 17 g. of di-*n*-butylamine was hydrolyzed by boiling under reflux for six hours with a solution of 30 cc. of concentrated sulfuric acid in 30 cc. of water. The solution was then made alkaline and extracted with ether. The ether was extracted with aqueous hydrochloric acid. This solution was then evaporated to dryness. The yield of di-n-butylamine hydrochloride was 7.8 g.

Separation of Amine Mixtures.—A mixture of 10 g. of aniline, 10 g. of methylaniline, and 10 g. of dimethylaniline was suspended in a 10% excess of cold 10% aqueous sodium hydroxide. To the cold suspension 27 g. (about 20% excess) of methanesulfonyl chloride was added during about ten minutes. The temperature was never above 25° and was usually about 10–15". When the methanesulfonyl chloride had reacted, the solution was extracted with ether. The ether was evaporated and this residue was again treated with methanesulfonyl chloride and aqueous alkali as before.

After the second treatment the derivative of the primary amine was obtained by acidifying the combined alkaline solutions. The yield was 10.2 g. (55% of the theoretical amount). The unchanged tertiary amine was extracted from the ether solution with hydrochloric acid and the ether was then evaporated. The residue weighed 10.5 g. (60% of the theoretical amount) and was the pure secondary amine derivative. The tertiary amine was recovered to the extent of about 95% from the acid solution.

When the composition of the amine mixture was not known the results were never as satisfactory as those described above. Prolonged action of the sulfonyl chloride converted the primary amines to alkali-insoluble derivatives. These are undoubtedly the disulfonyl derivatives although they were not isolated and characterized.

Summary

Several methanesulfonamides have been prepared and characterized. They make suitable derivatives for many amines and they are more readily hydrolyzed than most sulfonamides. Some difficulties are encountered when methanesulfonyl chloride is used as a reagent for the separation of unknown amine mixtures.

RESEARCHES ON PYRIMIDINES. CVI. LEUCO BASES OF A NEW CLASS OF DYESTUFFS CONTAINING PYRIMIDINE RINGS

BY TREAT B. JOHNSON

RECEIVED NOVEMBER 23, 1928 PUBLISHED APRIL 5, 1929

Certain representatives of the aniline dyes hold a place of great importance in the chemotherapy of bacterial diseases, and their practical use for the disinfection of tissues has received increased attention during recent years.[1] Some of these combinations, especially members of the triphenylmethane series, are highly bactericidal. Gentian violet and magenta, for example, have been shown to be able to inhibit growth of staphylococci and streptococci in culture media in dilutions as high as 1:100,000 to 1:1,000,000. It is important also to note that several of these dyestuffs

exhibit a remarkable variation in activity toward different bacterial organisms, a property which bears a close relationship to chemotherapy.

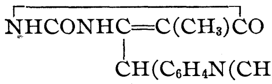
Notwithstanding the scientific interest that has been created in these compounds[2] and the increased attention that they have received by clinicians and bacteriologists, we have at present very little information regarding the relation of chemical constitution to their bactericidal and bacteriostatic properties, and also regarding the mechanism of their bactericidal activities. As a preliminary undertaking in the development of a new program of research on germicides the writer investigated, (with his co-workers) some new condensation reactions of certain pyrimidine aldehydes. The reactions reported at this time serve to illustrate the condensation possibilities of three typical pyrimidine aldehydes with aromatic bases under experimental conditions favoring the formation of leuco bases in the triphenylmethane series. The aldehydes thus far studied are derivatives of thymine as represented by Formulas I, II and III, respectively.

I $\overline{\text{NHCONHC(CHO)=C(CH}_3\text{)CO}}$ II $\overline{\text{NHCSNHC(CHO)=C(CH}_3\text{)CO}}$

III $\overline{\text{NHC(SC}_2\text{H}_5\text{)=NC(CHO)=C(CH}_3\text{)CO}}$

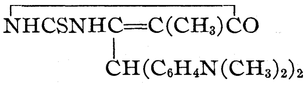
These aldehydes all condense smoothly with dimethylaniline in the presence of zinc chloride, giving the corresponding leuco compounds represented by Formulas IV, V and VI, respectively. These combinations

IV



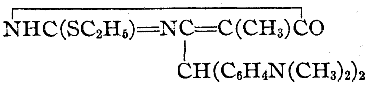
$$\begin{array}{l}\overline{\text{NHCONHC=C(CH}_3\text{)CO}}\\ \qquad\qquad\quad |\\ \qquad\qquad\quad \text{CH(C}_6\text{H}_4\text{N(CH}_3)_2)_2\end{array}$$

V



$$\begin{array}{l}\overline{\text{NHCSNHC=C(CH}_3\text{)CO}}\\ \qquad\qquad\quad |\\ \qquad\qquad\quad \text{CH(C}_6\text{H}_4\text{N(CH}_3)_2)_2\end{array}$$

VI



$$\begin{array}{l}\overline{\text{NHC(SC}_2\text{H}_5\text{)=NC=C(CH}_3\text{)CO}}\\ \qquad\qquad\qquad\qquad\quad |\\ \qquad\qquad\qquad\qquad\quad \text{CH(C}_6\text{H}_4\text{N(CH}_3)_2)_2\end{array}$$

are leuco pyrimidine–malachite greens in which one benzene cycle of leuco malachite green has been replaced by a pyrimidine ring. All three of these leuco compounds are colorless substances and undergo oxidation in acid solution, giving soluble dyestuffs which dye silk fiber with beautiful effects. It is our belief that a program of research involving the study of these combinations can be organized which will aid in advancing our present knowledge of the chemotherapy of dyestuffs. Structural changes can be incorporated easily in the pyrimidine cycle, which will enable us to synthesize new dyestuffs in an orderly manner.

Experimental Part

p-2-Tetramethyldiaminodiphenyl-2-thiothyminylmethane, V.—In order to prepare this leuco compound we used the following reagents: 1 gram of 2-thiothymine aldehyde[3]

(11), **3** cc. of dimethylaniline and **2** g. of fused zinc chloride. These reagents were mixed and heated in a flask at 100° for four hours. The mixture was stirred intermittently during the heating period. The excess of dimethylaniline was then removed by distillation with steam and the waxy residue left behind washed several times with water and finally dissolved in hot alcohol. On cooling, the leuco compound separated in the form of large, colorless blocks which melted at 212–214° to an oil. The leuco compound is practically insoluble in water. The yield was 1.6 g.

Anal. Calcd. for $C_{22}H_{26}ON_4S$: N, **14.2;** S, **8.1.** Found: **N, 14.1, 14.2;** S, **7.94.**

p-2-Tetramethyldiaminodiphenyl-2-ethylmercaptothyminylmethane, VI.—The procedure followed in preparing this new leuco compound corresponded exactly to that described in the previous experiment for the synthesis of the thio analog. The compound was insoluble in water but very soluble in warm alcohol. It crystallized from the latter solvent in long, colorless needles which melted at 218–219°. The yield was **1.8** g. from one gram of the aldehyde (III).

Anal. Calcd. for $C_{24}H_{30}ON_4S$: N, **13.2.** Found: N, **13.0, 13.1.**

The aldehyde used in this synthesis (III) has already been described in an earlier paper.[3]

p-2-Tetramethyldiaminodiphenylthyminylmethane, IV.—The aldehyde (I) used in the preparation of this compound has likewise been described in our earlier work.[3] The leuco compound was found to be insoluble in water but very soluble in boiling alcohol. It crystallized from the latter solvent in the form of flat prisms or plates and melted at 197–198°. The yield was **1.8** g. from one gram of the pyrimidine aldehyde.

Anal. Calcd. for $C_{22}H_{26}O_2N_4$: N, **14.8.** Found: N, **14.9, 14.8.**

Summary

1. Aldehyde derivatives of thymine condense smoothly with dimethylaniline in the presence of zinc chloride to give stable leuco pyrimidine bases corresponding to the leuco base of malachite green.
2. Their oxidation products will be investigated in this Laboratory.

EFFECT OF HEAT ON MALIC ACID[1]

BY FRED W. MORSE

RECEIVED NOVEMBER 23, 1928 PUBLISHED APRIL 5, 1929

During a study of the cranberry, samples of the fruit were dried before making the subsequent analysis. The berries were cut in halves, spread in thin layers on trays and placed in a large, steam-heated drying-oven, where the temperature ranged around 85°. They remained in the oven for about three days; then they were cooled in the air, weighed, ground in an iron mortar and preserved in bottles.

When total acids were determined in these samples, the results appeared to be low when compared with data obtained from fresh cranberries.

---

[1] Published with the approval of the Director of the Massachusetts Agricultural Experiment Station.

More samples of cranberries were procured. Portions of each sample were weighed, cut in small pieces, placed in volumetric flasks, digested for twenty-four hours with hot water, cooled and made up to volume. Aliquots were withdrawn and titrated. Other portions of the samples were weighed, cut in halves and dried as before. The dried material was pulverized, digested in hot water and aliquots titrated.

The standard alkali used was $N/10$ sodium hydroxide and the indicator was brom thymol blue. Titrations were stopped at the greenish blue tint. The results were calculated as percentages of citric acid in the fresh berries.

Five varieties of cranberries gave an average of 2.26% of total acid in the fresh berries, while the dried portions yielded the equivalent of 1.99% on the fresh basis. Prolonging digestion of the dried material did not change the discrepancy.

The acids of the cranberry have been shown to consist approximately of four-fifths citric acid and one-fifth malic acid[2] while benzoic acid[3] is present as less than 0.1% of the fresh berries.

Nothing has been found in chemical literature to show that citric and malic acids are affected in any manner by heating below 100". Benzoic acid does not account for the loss.

Aberson[4] and Walden[5] have shown that levo-malic acid is partially changed to the anhydride at 100 and 110".

To ascertain the effect of temperatures below 100" upon the principal acids of the cranberry, dilute solutions of citric and malic acids were prepared from selected crystals of each. Several aliquots of each acid were titrated directly. Other aliquots were measured into small beakers. The solutions were evaporated to dryness on the water-bath. Beakers with their films of solidified acids were then placed in ovens where the temperatures were maintained approximately at the following stages: 65°, 75°, 85" and 95°. After various periods of exposure to the respective temperatures, the beakers were removed from the ovens, their contents dissolved in water and the aliquots titrated. The same standard alkali and indicator were used that were described for the cranberries. All titrations were stopped at a light blue tint.

The variations in titrating the citric acid aliquots were within the limits of experimental error, and heating the dried crystals apparently had no effect on the constitution of citric acid.

The aliquots of malic acid yielded such differing results that the crystals appeared to be affected in proportion to both temperature and time of exposure.

[4] J. B. Aberson, *Ber.*, 31, 1432–1449 (1898).

[5] P. Walden, *ibid.*, 32, 1706–1721 (1899).

An aliquot of the original solution required 19.1 cc. of the standard alkali. Exposure of the dry acid to 65° for seventy-two hours made no change in the amount of alkali required for an aliquot. At 75° after forty-eight hours an aliquot was neutralized by 18.6 cc. of standard alkali, while another after ninety-six hours required 18.5 cc. At 85° after forty-eight hours an aliquot required 18.5 cc. and after ninety-six hours another was neutralized by 18.0 cc. At 95" 17.8 cc. neutralized an aliquot after twenty-four hours; 12.9 cc. was required after seventy-two hours and at the end of a week an aliquot was neutralized by 10.7 cc.

Walden obtained two anhydrides of I-malic acid. The anhydride obtained at 100° consisted of two molecules of the acid from which one molecule of water had been removed, forming a tribasic acid. The second anhydride was obtained at 180° and consisted of a double molecule with dibasic properties.

The malic acid employed in our experiments was found to be inactive to polarized light and should be regarded as dl-malic acid. A week's heating around 95° of a thin film of the dry acid caused an approach to the second anhydride of Walden, since the alkali required to neutralize the aliquot was but little more than half the amount required for the original solution. Under the conditions of the experiments no definite stages of dehydration were observed.

Walden found that the malic anhydride was restored to the normal acid by heating it with water in a sealed tube at 115°.

Some of the partly dehydrated aliquots were left in the beakers after titration and it was observed that the indicator tint changed to acid. Thereupon watch-glasses were placed on them and the solutions were boiled gently for a few hours with occasional additions of water to maintain the volume of solution approximately constant. The indicator tints were now strongly acid. The solutions were again titrated to the light blue tint. Enough additional standard alkali was required to bring the total for an aliquot up to 18.8 cc. in nearly every one. None could be carried above this figure.

Solutions from the five samples of dried cranberries were next heated after a preliminary titration and titrated a second time. The total alkali required by the two titrations was equivalent to 2.3% of total acid in the fresh berries, thus bringing the dried samples to equality with the undried berries.

Several other samples of dried cranberries were examined in a similar manner but not all of them could be made to yield a total acid equal to the result obtained from the corresponding undried fruit.

Summary

Summing up, malic acid is partly transformed to an anhydride when dried at temperatures between 75 and 95°, the amount of change being dependent on both temperature and time of exposure. Solutions of the partially dehydrated acid, when neutralized by alkali and then boiled for several hours are partially and sometimes completely restored to normal strength. In conclusion, when malic acid occurs in fruits the determination of total acid will be nearest the truth when it is made on undried samples.

CONDENSATION OF GLUCOSE AND FRUCTOSE. SYNTHESIS OF AN ISO-SUCROSE[1]

By James Colquhoun Irvine, John Walter Hyde Oldham and Andrew Forrester Skinner

Received December 7, 1928 Published April 5, 1929

The investigation of which the results are now communicated has been in progress for some years and was designed to effect the synthesis of sucrose by methods based on researches carried out in this Laboratory on the constitution of mono- and disaccharides.

Prior to the study of methylated sugars initiated by Purdie and Irvine in 1901, no evidence was available regarding the particular form of glucose or of fructose present in sucrose and, in the light of later discoveries, it is not surprising that all attempts to synthesize the disaccharide by the condensation of dextro-rotatory glucose with *levo*-rotatory fructose resulted in failure. In 1903, however, it was shown[2] that when sucrose is methylated and the product hydrolyzed, the form of tetramethylglucose then produced is the same as that obtainable from α-methylglucoside. This result established that one half of the sucrose molecule consists of a glucose residue of normal type but, even at the time, it was evident that the fructose residue was abnormal and differed from the levorotatory form of the sugar. This was obvious from the fact that, on hydrolysis, octamethylsucrose showed no "inversion"[3] and gave a methylated fructose which, contrary to expectation, was dextrorotatory. A further important advance in the chemistry of fructose was subsequently made by Purdie and Paul,[4] who proved that two isomeric tetramethylfructoses exist, one dextro- and the other levorotatory, the reasonable conclusion being that the parent sugar would also display the same isomerism. Some years later Irvine and Robertson[6] brought forward supplementary evidence

---

[1] The results described in this paper were communicated to the Institute of Chemistry (American Chemical Society) in the form of an address delivered on August 3,1928.

that fructose can exist in a dextrorotatory "y-form" and they expressed the definite opinion that sucrose must be regarded as a derivative of this variety of fructose. The above results were confirmed in the course of other researches conducted in this Laboratory on the constitution of sucrose.[6]

The synthesis of sucrose thus resolves itself into the union, through the loss of water, of equimolecular proportions of normal glucose and y-fructose, or, alternatively, of reducing derivatives of these sugars followed by elimination of the substituting groups. In condensations of this nature the following stereochemical possibilities must be taken into account so that, in all, four isomeric gluco-fructoses may be formed.

1. a-glucose (normal type) may combine with a-fructose (y-type)
2. a-glucose (normal type) may combine-with 0-fructose (γ-type)
3. β-glucose (normal type) may combine with α-fructose (γ-type)
4. β-glucose (normal type) may combine with 0-fructose (γ-type)

No difficulty presents itself in obtaining a convenient derivative of glucose of the desired normal type but it is otherwise in the case of fructose, owing to the uncrystallizable nature and instability of γ-fructose derivatives. However, in the course of examining the acetylation of fructose by the method of Hudson and Brauns,[7] it was shown by Steele[8] that whereas the crystalline fructose tetra-acetate belongs to the stable type, the sirup which yields the crystalline crop consists of a mixture of partially acetylated fructoses containing y-forms. It was hoped that this material although consisting of several compounds might be utilized as a reagent in the synthesis of sucrose [and this has subsequently been done by Pictet[g]] but in view of the importance of the problem we considered it in the highest degree desirable to use individual compounds in preference to mixtures of unknown and variable composition. The experimental obstacles encountered in realizing this program of work have been formidable. It is necessary to describe our experimental procedure in detail as, so far as can be judged, one of the methods traversed by us is precisely the same as that employed by Pictet save that we used a definite tetra-acetylfructose related to y-fructose in place of the mixture of fructose acetates referred to above. Further, the condensations, when successful, yielded an octa-acetate isomeric and not identical with sucrose octa-acetate as the sole crystalline product containing both glucose and fructose residues. We explored, however, more than one method of coupling glucose and fructose, and for these reactions required *(a)* tetra-acetyl-?-fructose and

---

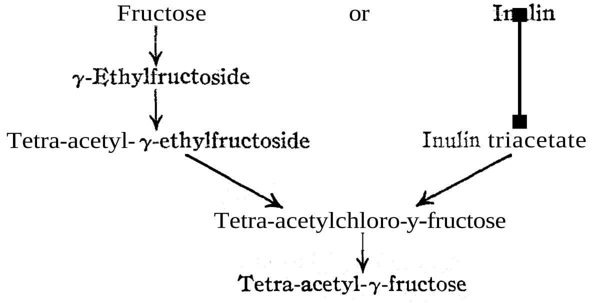
(b) tetra-acetylchloro-?-fructose; attention is therefore directed to the experimental part in which the preparation of these new reagents is described according to the following scheme:



At each stage the compounds formed in the above consecutive reactions were converted into tetramethylfructose in order to ascertain if the γ-type remained intact. The results were satisfactory, as the dextro-rotation and properties of the methylated ketose then isolated were in good agreement with the accepted standards for tetramethyl-?-fructose. We have accordingly retained the expression "γ" in the nomenclature of our reagents but wish to emphasize that, as the compounds under consideration are sirups, similarities in rotation and in properties are not sound criteria in establishing identity. The history of methylated sugars shows that fundamental mistakes have been made through hasty claims of this nature and it is undesirable to urge with absolute assurance that our reagents, despite their origin and properties, belong to the same y-fructose type as is present in sucrose.

Three distinct methods of condensation were attempted, *viz.;* A, reaction between tetra-acetylbromo- (or chloro-) glucose and tetra-acetyl-γ-fructose in the presence of a base; B, reaction between tetra-acetylglucose and tetra-acetylchloro-y-fructose in the presence of a base; C, reaction between tetra-acetylglucose and tetra-acetyl-y-fructose in the presence of a dehydrating agent.

It is remarkable that in Method A no condensation of the glucose and fructose residues took place. The halogen derivatives of glucose are conspicuously successful in the synthesis of @-glucosides and their failure to condense with such a reactive compound as tetra-acetyl-y-fructose is significant. On the other hand, the use of tetra-acetylchloro-y-fructose as the halogen-carrying reagent (Method B) was successful and the compound reacted with tetra-acetylglucose to give a crystalline octa-acetyl-*iso*-sucrose (m. p. 131–132°, $[\alpha]_D$ in chloroform + 20.3"). From this, in turn, by de-acetylation an iso-sucrose was isolated in the crystalline state (needles decomposing at 194°, $[\alpha]_D$ in water + 34.2"). The disaccharide, which had no action upon Fehling's solution under standard conditions but gave slight reduction on prolonged boiling, was characterized by greater instability toward acid hydrolysis than sucrose. During hydrolysis a characteristic optical inversion to give "invert sugar" took place.

Precisely similar results were obtained in the case of Method C, the same octa-acetate being formed and, in turn, the same disaccharide. Direct evidence was obtained that other gluco-fructoses were formed in both types of reaction, particularly when tetra-acetylchloro-y-fructose was used as a reagent. In no case, however, did we obtain any crystalline derivative of a gluco-fructose other than that referred to above.

The isomerism of our synthetic disaccharide with sucrose must lie in the stereochemical form (a or β) in which the monosaccharide components are bound together, provided the oxygen ring in the fructose component is actually in the same position as in sucrose. How far this point has been safeguarded has already been discussed. In the case of our tetra-acetyl-y-fructose, which is a sirup, both a- and β-forms are doubtless present and the same holds true for the sirupy form of tetra-acetylglucose used in the condensation, complications which are also present in Pictet's synthesis. As a general rule, however, halogen derivatives of sugars react as β-forms and this fact enables the configuration of iso-sucrose to be deduced with reasonable certainty. As stated, tetra-acetylchloro-γ-fructose yields the acetate of iso-sucrose, a result which presumably stamps the fructose residue as β. On the contrary, tetra-acetylbromoglucose, which is also β, fails to react with the acetate of y-fructose. This might be interpreted as meaning that the a-configuration of glucose is most favorable to condensation with y-fructose but the bulk of the evidence is opposed to this view. The reactions of tetra-acetyl-y-fructose are not exclusively those of a monohydric alcohol and this may be the factor responsible for its failure to condense with halogen compounds. Further, when tetra-acetylchloro-y-fructose is condensed with tetra-acetylglucose, in addition to the compound melting at 131°, a non-crystalline acetylated gluco-fructose is formed which is derived from a disaccharide showing a higher dextro-rotation than sucrose. On the basis of analogy this particular product is a derivative of α-glucoside-β-(γ)-fructose, and the compound melting at 131° must be a derivative of b-glucosido-6-(?)-fructose. Accepting this argument, sucrose must be either α-glucosido-α-(γ)-fructose or β-glucosido-α-(γ)-fructose, preference being given to the latter in view of the magnitude of the rotation of sucrose and the prevalence of β-glucosides in Nature.

Since our preliminary account of the new *iso*-sucrose was published,[10] Pictet[11] has described, under the name "Saccharose D," what may possibly be the same compound.

---

[10] Irvine, *J. Soc. Chem. Ind.*, **47**, 494 (1928).

[11] Pictet, *Helv. Chim. Acta*, **11**, 905 (1928).

	M. p., °C.	$[\alpha]_D$
Iso-sucrose octa-acetate	131–132	+20.3° (in chloroform)
"Saccharose D" octa-acetate	127	+19° (in chloroform)
Iso-sucrose	Sinters at 150° and decomposes without melting at 194°	+34.2° (in water)
"Saccharose D"	127	+19° (in water)

If the compounds are identical, Pictet's preparation must be less pure than that now described and, in any case, his allocation of the β-glucosido-β-(γ)-fructose configuration to "Saccharose D" by application of Hudson's Rule is not convincing. Calculation of the constants required to apply Hudson's Rule demands, for each form of a sugar, a knowledge of the specific rotations of pure crystalline derivatives. Such derivatives, so far as known to us, do not exist in the case of y-fructose.

As stated, we are of the opinion that iso-sucrose is β-glucosido-β-(γ)-fructose but no evidence on this point is afforded by the preparation of the compound by Method C. The condensation of tetra-acetylglucose and tetra-acetyl-y-fructose by shaking in solution with phosphoric anhydride undoubtedly proceeds smoothly and gives a mixture of acetylated disaccharides but has not, in our hands, yielded sucrose octa-acetate as a crystalline component. Consideration will show that each reagent used, in the form in which it is employed, will exist in α- and β-forms, which are capable not only of coupling but of undergoing auto-condensation. In such a reaction there is therefore the possibility that, in addition to the four isomeric glucosido-y-fructoses, there will be formed di-glucoses and di-fructoses, the total number of octa-acetates which may be produced being ten. If the tetra-acetylfructose employed contains the stable stereoisomeride (a factor which is absent in our experiments) this number may be increased to twenty-one. It is, of course, unlikely that all the possible stereoisomerides would react equally in such condensations, but that simultaneous reactions of the above nature can and do proceed is shown by our experience that considerable quantities of iso-trehalose octa-acetate, together with uncrystallizable isomerides, were formed in addition to *iso*-sucrose octa-acetate.

In the course of the research tetra-acetylchloro-y-fructose has been isolated for the first time and as this compound is obviously a valuable reagent in the study and synthesis of fructose derivatives, we desire to reserve its application and also those of the tetra-acetyl-y-fructose described by us.

Experimental

For the purposes of this investigation the following compounds were required: (1) tetra-acetyl-y-fructose, (2) tetra-acetylchloro-y-fructose and **(3)** tetra-acetylglucose.

Preparation of **Tetra-acetyl-γ-fructose** from Fructose. Stage I. **γ-Ethylfructoside.**—The following is an account of **a** typical preparation. Sixty-five grams of finely-powdered fructose was dissolved in 2285 cc. of hot absolute alcohol and, after cooling, 250 cc. of alcohol containing 26 g. of anhydrous hydrogen chloride was added. The progress of the condensation was followed polarimetrically, the rotation rapidly altering to dextro and attaining in about ten minutes the maximum value $[\alpha]_{\mathrm{D}} = +17^\circ$ (approx.). The reaction was arrested as closely as possible to this maximum value, absolute alcohol, in which 18 g. of sodium had been previously dissolved, then being added. Carbon dioxide was passed through the alkaline liquor, which was thereafter evaporated under diminished pressure and the sirupy residue dried at 100° (12 mm.). This was extracted repeatedly under a reflux condenser with a mixture of ethyl acetate and alcohol until the undissolved material disintegrated into a hard red powder. The solution was then taken to dryness and the residue extracted repeatedly with dry ethyl acetate at the boiling point. On standing overnight in a corked flask a sirup was deposited from the solution and on decantation and removal of the solvent, γ-ethylfructoside remained as a sirup. It is important to note that the subsequent acetylation of the ethylfructoside should be undertaken promptly, as if the material is allowed to stand for more than twenty-four hours the acetate subsequently obtained is a hard glass and is apparently a polymeride.

Stage **II.** Acetylation of **γ-Ethylfructoside.**—This reaction was carried out in the usual manner with acetic anhydride and sodium acetate, the acetylated mixture being poured into water and nearly neutralized with calcium carbonate. Thereafter the liquid was shaken with excess of benzene, which was separated and washed with 1% sodium hydroxide until the alkaline extracts were nearly colorless. After washing with water, drying over sodium sulfate and decolorization with Norite, the benzene was removed and the residue dried at 100° (12 mm.). In this way tetra-acetyl-y-ethylfructoside was obtained as a colorless, mobile sirup, the yield from 65 g. of fructose ranging from *33* to 47 g. As the preparation yielded a mixture of ***a***- and β-forms, the specific rotation varied slightly in different preparations, the extremes being $[\alpha]_{\mathrm{D}}$ $+39.0^\circ$ and $+47.9^\circ$ in chloroform solution $(c = 5)$; n_{D} varied from 1.4528 to 1.4542.

Anal. Calcd. for $C_{16}H_{24}O_{10}$: C, 51.06; H, 6.38; OC_2H_5, 11.9; CH_3CO, 45.7. Found: C, 51.09, 50.75, 50.84; H, 6.36, 6.51, 6.42; OC_2H_5, 11.1, 11.8; CH_3CO, 46.3, 47.5.

For the purpose of confirming that the compound was actually a derivative of fructose, it was converted under quantitative conditions into the parent monosaccharide, a weighed quantity of the acetate being dissolved in methyl alcohol and boiled for fifteen minutes with more than the calculated amount of normal sodium hydroxide. Thereafter the alkali was neutralized and sufficient hydrochloric acid added to make the total acid concentration $N/10$. The solution was then boiled under a condenser in the presence of a small quantity of Norite and after thirty-five minutes the value $[\alpha]_{\mathrm{D}}$ -84.1° was recorded, the concentration being calculated on the basis of complete conversion into fructose. In a control experiment in which pure fructose was boiled with the same concentration of aqueous acid the value $[\alpha]_{\mathrm{D}}$ −85.8" was obtained in the same time. Similarly, a sample of tetra-acetyl-y-ethylfructoside when subjected to consecutive alkaline and acid hydrolysis gave 99% of the weight of glucose phenylosazone obtained in a control experiment carried out with the equivalent amount of pure fructose.

Stage **III. Hydroxylation** of **Tetra-acetyl-γ-ethylfructoside.**—A 10% solution of tetra-acetyl-y-ethylfructoside in acetyl chloride was saturated with dry hydrogen chloride and allowed to stand at room temperature for eighteen hours. When the reaction was complete, as indicated by the attainment of a constant rotation, the solvent was removed under diminished pressure at a temperature not exceeding 45°. The residue was dried, weighed, dissolved in benzene and an amount of silver oxide equal in weight to that of the sirup added together with a small quantity of water. The mixture was then shaken until a sample of the liquid gave no precipitate when diluted with alcohol and boiled with an alcoholic solution of silver nitrate. Water was removed by means of sodium sulfate, the solids were filtered and washed with benzene, the total filtrate being shaken with water until the extracts gave only a slight reduction with Fehling's solution. Thereafter the united aqueous extracts were shaken repeatedly with chloroform, which was separated and dried over sodium sulfate. Care had to be taken to carry out this extraction with chloroform promptly as otherwise the yields were seriously impaired. On removal of the solvent an almost colorless sirup remained which was dried at 100° (12 mm.) and consisted of tetra-acetylfructose.

Anal. Calcd. for $C_{14}H_{20}O_{10}$: C, 48.27; H, 5.74; CH_3CO, 49.4. Found: C, 48.18, 48.10; H, 5.90, 5.79; CH_3CO, 50.8; $[\alpha]_D$ in chloroform, $+31.5°$ for $c = 1.808$, and in benzene, $+38.7°$ for $c = 5.379$; $n_D = 1.4645$.

Preparation of Tetra-acetyl-y-fructose from Inulin.—Inulin is a convenient source of tetra-acetyl-y-fructose but the product is not so pure as when made from ethylfructoside and the process cannot be so accurately described in view of the variations shown by specimens of triacetylinulin prepared by different methods. A 10% solution of triacetylinulin in acetyl chloride was saturated with hydrogen chloride, polarimetric readings of the solution being taken at intervals. Using triacetate prepared by Pringsheim's method the specific rotation increased in four days to a value between +60° and +70°. The further procedure was exactly as described in Stage III of the preceding preparation although it proved necessary to repeat the successive treatment with benzene and with chloroform in order to obtain a colorless product. In a typical experiment 42 g. of inulin triacetate gave 32.8 g. of tetra-acetyl-y-fructose together with 3.4 g. of a crystalline triacetyl anhydro-fructose.[12]

Anal. Calcd. for $C_{14}H_{20}O_{10}$: C, 48.27; H, 5.74; CH_3CO, 49.4. Found: C, 47.87, 47.94; H, 6.05, 5.95; CH_3CO, 49.6; $[\alpha]_D$ in chloroform, $+37.8°$ for $c = 1.838$; $n_D = 1.4662$.

Tetra-acetyl-y-fructose shows a wide range of solubility in organic solvents and differs from the form described by Pictet in rotation and in being soluble in dry ether.

Tetra-acetyl-y-fructose.—It is evident that by both the methods described above a form of tetra-acetylfructose is obtained isomeric with the crystalline tetra-acetylfructose of the stable type. In order to show that both preparations were derivatives of fructose, weighed amounts of each were dissolved in water containing ice and a measured excess of 2 N sodium hydroxide was added. The acetyl groups were completely removed when the solution was allowed to stand immersed in ice water for twenty minutes

---

[12] This crystalline derivative of fructose, hitherto undescribed, was first encountered in the course of a separate research conducted in this Laboratory, the results of which will shortly be published. The compound remains behind when the benzene extract of tetra-acetylfructose is evaporated to dryness and can be obtained crystalline from the alcohol extract of the sirup.

and the excess of alkali was then estimated. Thereafter the solution was diluted to a known volume and the rotation determined. In a control experiment crystalline tetra-acetylfructose of the stable type was similarly treated, the results being:

		Acetyl content	$[\alpha]_D$
Crystalline tetra-acetylfructose		51.1	−92.4"
Tetra-acetyl-γ-fructose	From ethylfructoside	50.8	−89.8
	From inulin	49.6 (calcd. 49.4)	−89.4

As, moreover, the three compounds specified above gave yields of glucose phenylosazone comparable with that given by the equivalent weight of fructose, there can be no doubt that they are derived from this monosaccharide.

Evidence that the Dextrorotatory Tetra-acetylfructose is Derived from γ-Fructose.—Tetra-acetylfructose prepared from inulin was methylated by the action of methyl iodide and silver oxide until the reaction on Fehling's solution disappeared. The tetra-acetylmethylfructoside thus produced was then de-acetylated by the action of sodium methylate and the alkylation completed in the usual manner. In this way tetramethylmethylfructoside was formed in nearly quantitative amount and on hydrolysis by means of *N*/100 hydrochloric acid was converted into tetramethylfructose. Analysis of a distilled sample gave: C, 50.72; H, 8.59; OCH_3, 51.2. Calcd. for $C_{10}H_{20}O_6$: C, 50.84; H, 8.47; OCH_3, 52.5.

Comparison of the product with a sample of tetramethyl-γ-fructose obtained from methylated sucrose showed that the compounds displayed so close a similarity that they may be regarded as identical. The refractive indices (n_D = 1.4533) were the same and the specific rotations in water for $c = 5$ although not identical were dextro and of the same order.

	Tetramethylfructose from tetra-acetylfructose	Tetramethylfructose from octamethylsucrose
Initial $[\alpha]_D$	+26.4°	+31.8°
After 3 days	+30.1	+34.1
After 5 days	+30.1	+34.1

Taking into consideration the possibility that coincidence or similarity of optical rotations determined on liquid compounds may be fortuitous, the comparison of the two specimens of tetramethylfructose was further extended. Sodium derivatives of each were prepared by the method of Freudenberg[13] and the products showed the characteristic optical inversion, in each case the value of $[\alpha]_D$ being of the order −45°. In addition, the behavior of the two sugars when condensed with methyl alcohol was compared and likewise the rate of hydrolysis of the two specimens of tetramethylmethylfructoside thus produced. Two series of experiments were made. In one of them, 5% solutions of the two tetramethylfructoses in

---

[13] Freudenberg, Ber., 56, 1119 (1923).

methyl alcohol containing 0.1% of hydrogen chloride were preserved at 15° and polarimetric records taken, initially at intervals of a few minutes and afterwards at hourly periods. The curves obtained on plotting the optical values against time were parallel (Fig. 1), although the specimen of methylated fructose prepared from sucrose showed throughout a higher dextro specific rotation of four degrees. A similar result was obtained in a second experiment in which the acid concentration was increased to 0.25% and the characteristic fall and rise of dextrorotation in the early stages of the reaction was observed in each case. In addition, the polarimetric curves representing the condensation were strictly parallel, as shown in Fig. 2.

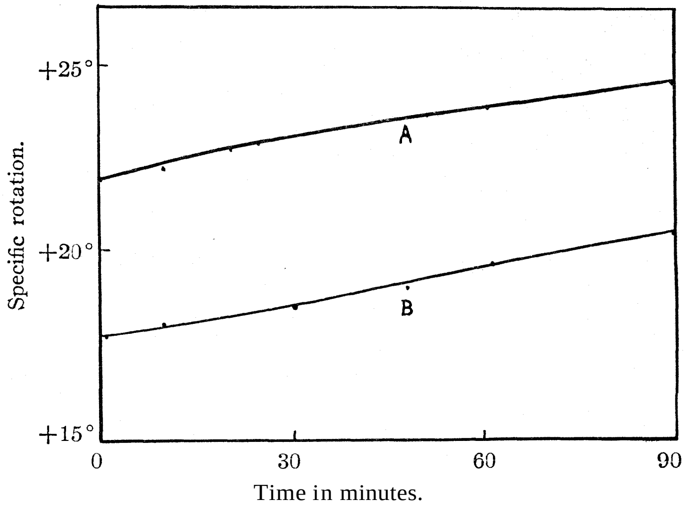


Fig. 1.—Condensation of tetraniethylfructose with methyl alcohol. Acid concentration = 0.1%. T = 15°. A. Sugar obtained from sucrose. B. Sugar obtained from tetra-acetylfructose.

The specimens of tetramethylmethylfructoside produced in the reaction were isolated in the usual manner and distilled in a high vacuum, the refractive index and methoxyl content showing that the compounds were pure. Thereafter in parallel experiments the methylated fructosides were hydrolyzed by the action of *N*/100 hydrochloric acid at 85°. The polarimetric records of the hydrolysis were identical, as shown in Fig. **3,** thus affording substantial evidence that the tetra-acetylfructose now under consideration is a y-form.

Preparation of Tetra-acetylchloro-y-fructose.—Although tetra-acetylchloro-y-fructose may be obtained by the action of acetyl chloride on tetra-acetyl-y-ethylfructoside, tetra-acetyl-7-fructose is a more convenient starting-material. A 9% solution of this compound in acetyl chloride was saturated with dry hydrogen chloride and polarimetric observations were taken at short intervals. The specific rotation, which was initially +47.7°, increased rapidly, the maximum value of +56.5° being attained in about thirty minutes. At this stage the solvent was removed under diminished pressure at a temperature which must not exceed 45° and a mobile sirup remained which was dissolved in benzene. The solution was allowed to stand over potassium carbonate and on removal of the solvent a sirup remained which was essentially tetra-acetylchloro-?-fructose. Owing to the instability of the compound no further purification was possible. On the basis of analysis the mixture contained 87% of the chloro derivative and this was confirmed by conversion of the compound by standard methods into tetra-acetyl-y-fructose and tetra-acetyl-γ-ethylfructoside, respectively.

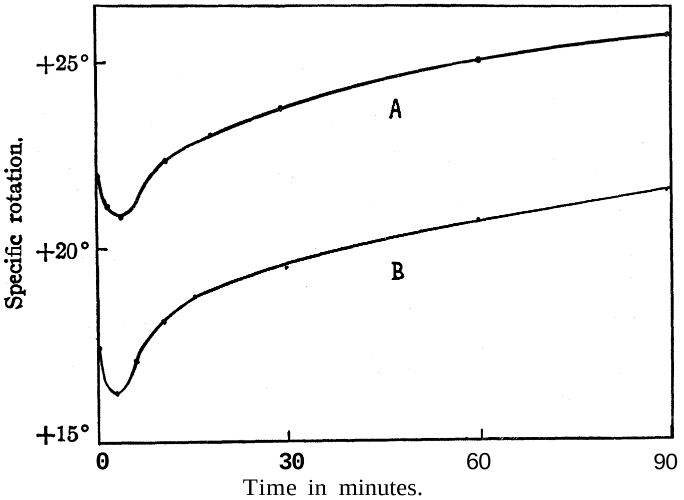

Fig. 2.—Condensation of tetramethylfructose with methyl alcohol. Acidconcentration = **0.25%.** T = 15°. A. Sugar obtained from sucrose. B. Sugar **obtained** from tetra-acetylfructose.

Preparation of **Tetra-acetylglucose.**—The method described by Fischer[14] was slightly modified. Tetra-acetylbromoglucose was dissolved in acetone and as much water added as was possible without causing precipitation. The solution was then shaken under thorough cooling with excess of silver oxide until a test portion showed that all bromine had been eliminated. The bulk of the acetone was removed under diminished pressure, excess of cold water was added and the solution extracted twice with benzene which in turn was extracted with water. The united aqueous solution and washings was shaken with chloroform, a good yield of glucose tetra-acetate being isolated from the extract in the usual way. The prod-

---

[14] Fischer, Ber., 42,2778 (1909).

uct crystallized on mixing with dry ether, the soluble sirupy variety which was used in the condensation experiments thereby passing into solution.

Condensation of Tetra-acetyl-γ-fructose with Tetra-acetylglucose.—This reaction was carried out under varying conditions, the union of the glucose and fructose residues being conducted in benzene solution by the agency of phosphoric anhydride. As the crystalline variety of tetra-acetylglucose is very sparingly soluble in benzene the non-crystalline tetra-acetyl glucose was employed. Equal weights of the glucose and fructose acetates were dissolved in benzene to give a total concentration of solids not exceeding 10%. Excess of phosphoric anhydride was added and the liquid thoroughly shaken, care being taken to ensure that the phosphoric anhydride did not settle to the bottom of the vessel. In no case did the reducing action upon Fehling's solution entirely disappear and the optimum time at which to arrest the reaction could be ascertained only by experience, but as a rule it was necessary to continue shaking for at least fifteen hours. The benzene solution was decanted and exhaustively extracted with water until the washings no longer reduced Fehling's solution. This treatment removed unchanged glucose and fructose tetraacetates, which were recovered by extracting the water with chloroform.

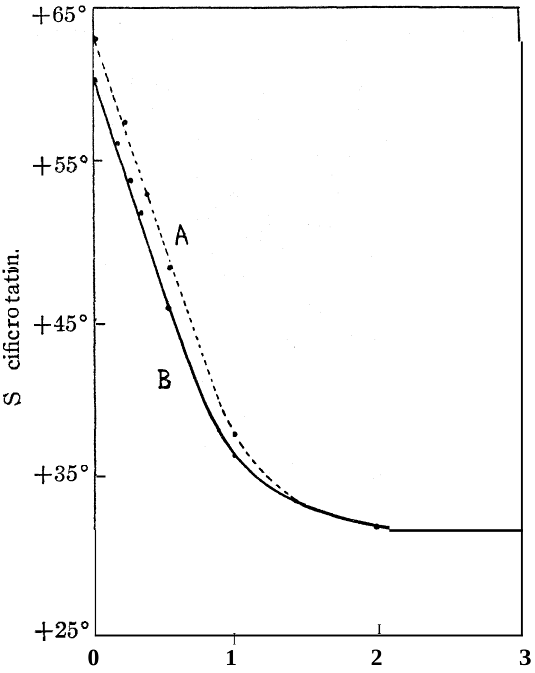

Fig. %.—Hydrolysis of tetramethylmethylfructoside. Acid concentration = 0.36%. T = 85°. A. From sucrose. B. From tetra-acetylfructose.

The benzene was again washed, first with 1% sodium hydroxide and then with water, dried over sodium sulfate and taken to dryness under diminished pressure at a temperature not exceeding 60°. On stirring the residue with dry ether, crystals separated which were filtered, washed with ether and recrystallized from absolute alcohol. The compound, which proved to be an octa-acetyl-iso-sucrose, melted at 131–132°. Although this octa-acetyl-iso-sucrose was the only crystalline gluco-fructose derivative which was isolated, it was ascertained that iso-trehalose was formed simultaneously. Moreover, the yields of disaccharide derivatives were invariably small, the bulk of the materials originally employed remaining uncondensed. This is shown by the following table.

Tetra-acetylfructose and -glucose, g.........	46	34.9	22.0	16.0	85.0	56.0
Acetylated monosacch. recov. unchanged, g....	34.9	22.0	16.0	4.9	56.0	..
Acetylated disaccharides, g................	7.7	4.3	4.0	7.2	10.0	9.0
Octa-acetyl-iso-sucrose (m. p. 131–132°), g....	(.......1.7......)			2.0	1.0	1.5

The investigation of the acetylated disaccharides other than *iso*-sucrose octa-acetate is being continued.

Condensation of Tetra-acetylchloro-γ-fructose with **Tetra-acetylglucose.**—To a solution of 27 g. of the chloro compound and 30 g. of sirupy tetra-acetylglucose in 135 cc. of dry chloroform were added sodium sulfate and excess of silver carbonate. The liquid was shaken until no chlorine remained in solution and after filtration the solvent was removed. On dissolving the residue in benzene and extracting repeatedly with water, reducing sugars were eliminated for the most part, while the condensation products, together with penta-acetylglucose, remained dissolved in the benzene. The solvent was evaporated, the residue dissolved in alcoholic dimethylamine and heated at 100° for three hours, reducing sugars being destroyed by the action of the base while disaccharides remained unaffected. On removal of the solvent the discolored sirup was extracted successively with ether, acetone and chloroform, most of the coloring matter thereby passing into solution. The residue was then acetylated to convert any non-reducing disaccharide into octa-acetate.

Examination of the Mixture of Disaccharide Octa-acetates.—A sample of the sirupy product, 'before the separation of the octa-acetate of *iso*-sucrose referred to below, was hydrolyzed under standard conditions by the successive action of alkali and acid. After removal of the acetyl groups the specific rotation was $+65.9°$, a value which is practically identical with that of sucrose. Moreover, on heating subsequently at 100° with *N*/10 hydrochloric acid the end-point $[\alpha]_D$ -16.4" was obtained while a control experiment carried out on sucrose gave under identical conditions $[\alpha]_D$ $-19.1°$. This result proves that the disaccharide acetates under examination were convertible into "invert sugar" but the mixture, on crystallization from ether, yielded one-third of. its weight of the crystalline *iso*-sucrose octa-acetate (m. p. 131–132°) already described. As the *iso*-sucrose corresponding with this acetate shows, when liberated under the same conditions, $[\alpha]_D$ $+31.2°$, it follows that the identity of the activity of the total product with that of sucrose must be fortuitous. Further, even if sucrose be formed in the condensation under discussion, a third isomeric gluco-fructose showing a specific rotation substantially higher than $+65.9°$ must also be present.

Octa-acetyl-iso-sucrose.—This compound prepared by either of the methods described above is the only crystalline derivative of a non-reducing gluco-fructose isolated by us. It dissolves readily in hot ethyl or methyl alcohols, chloroform or acetone, is sparingly soluble in benzene or ether and is insoluble in water. When recrystallized from hot alcohol it separates in prisms.

Anal. Calcd. for $C_{28}H_{38}O_{19}$: C, 49.55; H, 5.60; CH_3CO, 50.7; mol. wt., 678. Found: C, 49.41; H, 5.61; CH_3CO, 53.0; mol. wt. in chloroform by boiling-point method, 687.

The fact that the sugar suffers slight decomposition in the presence of alkali accounts for the high acetyl value.

Solvent	Chloroform	Acetone	Benzene
c	3.762	4.072	3.918
$[\alpha]_D$	+19.9°	+20.0°	−2.0°

Iso-sucrose.—A 20% solution of crystalline octa-acetyl-iso-sucrose in absolute ethyl alcohol containing 30% of dimethylamine was heated for 150 minutes at 100° in a sealed tube. After removal of the solvent, the residue was dried at 100° (12 mm.). On dissolving this residue in the minimum amount of methyl alcohol and adding a small quantity of ethyl alcohol, a dense crop of crystals separated. These were recrystallized from the same medium, normally in the form of needles, occasionally as prisms which sintered at 152°, and decomposed sharply at 194° (uncorrected). When the sirup present in the united mother liquors was isolated, dissolved in ethyl alcohol and precipitated with ether, the total yield of de-acetylated sugar was almost quantitative.

Anal. Calcd. for $C_{12}H_{22}O_{11}$: C, 42.10; H, 6.43. Found: C, 42.09; H, 6.51.

In solubility and in crystalline form this variety of iso-sucrose displays a very close similarity to sucrose the difference between the two disaccharides being shown by the melting point and by the fact that this particular isomeride of sucrose is slowly decomposed on prolonged boiling with alkali and gives a small yield of glucose phenylosazone under standard conditions. The specific rotation is also markedly different from that of sucrose.

Solvent	*c*	$[\alpha]_D$
Methyl alcohol	2.130	+50.0° without mutarotation
Water	5.264	+34.2° without mutarotation

Inversion of the Iso-sucrose.—Although the form of iso-sucrose was devoid of action upon Fehling's solution for a normal period of boiling, prolonged heating occasioned a slight reduction. This indicates a greater instability toward hydrolysis than in the case of sucrose, a view which was supported by the behavior of the compound on acid hydrolysis. When heated at 100° with $N/1000$ hydrochloric acid, inversion took place, the specific rotation rapidly altering to levo and attaining the constant value

—19.2'. Under parallel conditions sucrose was hydrolyzed much more slowly, as shown from the figures quoted below:

Time, min.	Iso-sucrose	Sucrose
Initial	+32.8°	+66.3°
30	−16.0	+ 4.4
60	−18.2'	− 7.2
90	−19.2" (constant)	.....
100	− 19.8	−13.4
135	− 19.6	-15.5^a
165	.....	-17.2^a
195	.....	−19.2

c =2.038; acid, N/1000 HCl; T = 100".

[a] $[\alpha]_D$ recalculated for change of concentration.

The end-point is thus the same as that given by sucrose and the hydrolysis solution behaved exactly as a solution of "invert sugar" in that the optical activity vanished on heating to 80°. The yield of glucose phenylosazone from the hydrolysis liquid was also the same as that obtainable from invert sugar in equal concentration.

The thanks of the authors are due to the Carnegie Trust for Research Fellowships which enabled two of the collaborators to take part ~~in the~~ investigation.

Summary

1. For the purposes of the research, pure tetra-acetyl-y-fructose and tetra-acetylchloro-y-fructose have been prepared for the first time, and their relationship to y-fructose established by the methylation method.

2. In attempts to synthesize sucrose from these reagents the following reactions have been carried out: *(a)* condensation of tetra-acetylchloro-γ-fructose with tetra-acetylglucose in the presence of a base, (b) condensation of tetra-acetyl-y-fructose with tetraacetylglucose in the presence of a dehydrating agent.

3. In each case the only crystalline product isolated was an *iso*-sucrose octa-acetate (m. p. 131–132'; $[\alpha]_D$ +20.3° in chloroform). No sucrose octa-acetate was detected, although evidence was obtained that acetylated gluco-fructoses other than *iso*-sucrose octa-acetate and also diglucoses were formed.

4. The mixed products obtained in the above condensations gave a specific rotation practically identical with that of sucrose and are convertible quantitatively into "invert sugar." This result is, however, fortuitous.

5. Iso-sucrose has been isolated as needles decomposing at 194° and showing $[\alpha]_D$ $34.2' in water. The compound is hydrolyzed more readily than sucrose and is then converted into "invert sugar."

6. No union of glucose and fructose residues takes place when tetra-acetylbromoglucose is shaken in solution with tetra-acetyl-y-fructose.

7. The collective results lead to the conclusion that sucrose is β-glucosido-α-(γ)-fructose and that the iso-sucrose now described is β-glucosido-β-(γ)-fructose.

NATURAL AND SYNTHETIC RUBBER. II.
REDUCTION OF ISOPRENE BY $Na-NH_3$

BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

RECEIVED DECEMBER 7, 1928 PUBLISHED APRIL 5, 1929

The reduction of isoprene by sodium in liquid ammonia was attempted to determine: (1) whether reduction would take place in preference to polymerization and **(2)** the location of the added hydrogen.

Isoprene was added to sodium dissolved in liquid ammonia and a 60% yield of 2-methyl-2-butene resulted. No other volatile hydrocarbon was found. High molecular weight hydrocarbons were formed but were not investigated. It is thus shown: (1) that the predominant reaction proceeds in accordance with the equation $C_5H_8 + 2Na + 2NH_3 = C_5H_{10} + 2NaNH_2$ and (2) that hydrogen adds to isoprene in the 1,4-position, in agreement with Thiele's theory.

The hydrogen addition is similar to the bromination of isoprene at low temperature.[1] If properly conducted the latter reaction stops after 2 atoms of bromine have been added to 1 molecule of isoprene; the resulting compound, 1,4-dibromo-2-methyl-2-butene, is characterized by the inactivity of its double bond toward bromine. Similarly, 2-methyl-2-butene obtained by reduction of isoprene is not reduced to isopentane by an excess of $Na-NH_3$ reagent.

Procedure.—750 cc. of liquid ammonia are placed in a one-liter round-bottomed flask (Pyrex) and 46 g. of sodium is dissolved in it. The flask is equipped with a rubber stopper carrying a separatory funnel and an abduction tube. One mole of isoprene is slowly dripped into the liquid; the stem of the separatory funnel should nearly reach the surface of the ammonia in order to prevent abduction of isoprene by the escaping ammonia vapors. When the isoprene drops strike the ammonia, a clear sound is heard which can be used to regulate the delivery. The ammonia vapors carry the reduced hydrocarbon, together with a small quantity of unchanged isoprene, through an empty safety bottle to a cylinder filled with cracked ice. Ammonia dissolves immediately, the ice melts and the water flows into a large separatory funnel; the hydrocarbon, which condenses on the ice, is carried with the water and collects as an upper

---

[1] Staudinger, *Helv. Chim. Acta*, 5, 756–767 (1922).

layer in the separatory funnel. By rerunning, the hydrocarbon can be completely freed of isoprene.

NATURAL AND SYNTHETIC RUBBER. III. DIMETHYLOCTADIENE

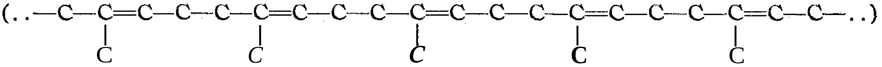
BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

RECEIVED DECEMBER 7, 1928 PUBLISHED APRIL 5, 1929

The polymerization of isoprene to synthetic rubber has long been known. The mechanism of this reaction has, however, so far escaped detection. To throw light upon this question, it was decided to polymerize isoprene in the presence of active hydrogen, with the hope that polymerization might be stopped at the dimer stage. This was accomplished in the following manner.

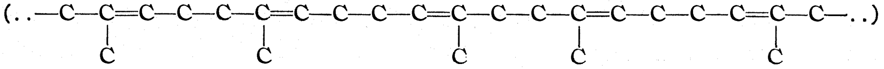
Well-purified isoprene, active toward polymerization, was placed in contact with metallic potassium chips and ethyl alcohol slowly added at a rate just sufficient to give a moderate evolution of hydrogen at the surface of the potassium. A good yield of a light yellow oil resulted, which upon analysis proved to be a mixture of 2,6-, 2,7- and 3,6-dimethyl-2,G-octadienes. These isomers are the dihydro dimers of isoprene resulting from a junction at the 1,4-, the 4,4- or the 1,1-carbon atoms, respectively, and the addition of hydrogen to the 1,8-positions of the dimer. No trace of a compound of cyclic nature could be detected.

These results suggest that the polymer of isoprene produced by contact with alkali metals and called "sodium rubber" (the commonest of the synthetic rubbers) is a long chain formed of isoprene units linked together by means of their 1 and 4 carbon atoms. This chain very closely resembles the long-chain structural formula of natural rubber proposed by Staudiiger[1] and his associates, except that the recurring methyl groups may be placed at either side of the double bond, thus



$$(..\text{—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—}..)$$

Section of the natural rubber molecule (Staudinger)



$$(..\text{—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—C=}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{—C—C—}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{=C—C—C—C=}\underset{\overset{|}{\mathrm{C}}}{\mathrm{C}}\text{—C—}..)$$

Section of the synthetic rubber molecule

It should be noted that in the natural product the groups attached to each double bond may be expected to present always the same *cis-* or trans-configuration, whilst such uniformity can hardly be hoped for in the synthetic product.

---

[1] **Staudinger, *Helv. Chim. Acta*, 5, 785–805 (1922), and later papers.**

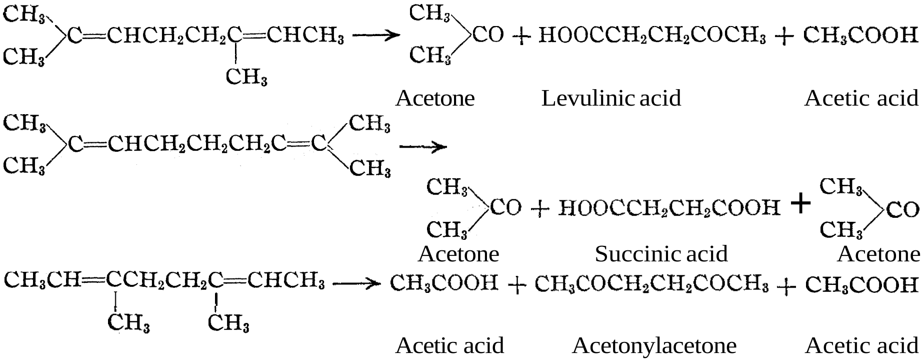
The products of the side reactions appear to be high polymers; their constitution is being studied at the present time. It is thought that a small amount of 2-methyl-2-butene was formed during the reaction but it was lost with the escaping hydrogen excess.

Procedure.—The apparatus comprises a 500-cc. round-bottomed flask equipped with a reflux condenser and a separatory funnel. The top of the condenser is connected to a glass tube whose end dips into a test-tube containing a little alcohol, thus making it possible to judge the rate at which hydrogen escapes.

Two-gram molecules of isoprene were placed in the flask, 4-g. atoms of potassium shavings quickly added and the flask connected to the condenser and separatory funnel; alcohol was dripped in at such a rate that a hydrogen excess escaped slowly from the apparatus. During the reaction the potassiuin remained shiny; when it was completely used, the potassium ethylate formed during the reaction was decomposed by adding water slowly through the separatory funnel. The reaction product was decanted, washed, dried and distilled. The mixture of dimethyloctadienes had the following constants: b. p., 163–167°; d_{20}^{20}, 0.769; n_D^{20}, 1.4457; mol. wt., 136.8 (138, theoretical). The bromination number determined with a $KBrO_3$–KBr mixture gives 2 double bonds per $C_{10}H_{18}$. Combustion checks the previous formula. Hydrogenation requires 2 moles of hydrogen and yields 2,6-, 2,7- and 3,6-dimethyloctanes.

Analysis of the **Dimethyloctadienes.**—The hydrocarbon was oxidized by means of a solution of CrO_3 in acetic acid. After removal of the bulk of Cr_2O_3 as $Cr_2(SO_4)_3$, insoluble in H_2SO_4, the following products were detected: acetone, 2,5-hexanedione, levulinic acid and succinic acid. These compounds are all very easily characterized: acetone by means of its mercury compounds, acetonylacetone by its dioxime and its unusually strong reaction with bromine, levulinic acid by its reaction with sodium nitroprusside and succinic acid by the pyrrole–pine shaving reaction.

The following diagram compares the oxidation products with the hydrocarbons from which they are formed.



$$\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!C{=}CHCH_2CH_2\underset{\underset{CH_3}{|}}{C}{=}CHCH_3 \longrightarrow \begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!CO + HOOCCH_2CH_2COCH_3 + CH_3COOH$$

$$\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!C{=}CHCH_2CH_2CH_2C{=}C\!\!<\!\begin{matrix}CH_3\\CH_3\end{matrix} \longrightarrow \begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!CO + HOOCCH_2CH_2COOH + \begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!CO$$

$$CH_3CH{=}\underset{\underset{CH_3}{|}}{C}CH_2CH_2\underset{\underset{CH_3}{|}}{C}{=}CHCH_3 \longrightarrow CH_3COOH + CH_3COCH_2CH_2COCH_3 + CH_3COOH$$

Although one of the oxidation products probably was acetic acid, it is obvious that it could not be detected, since the oxidation was carried out in an acetic acid solution. It is nevertheless evident that the hydrocarbon obtained by polymerization and simultaneous reduction of isoprene is a mixture of 2,6-, 2,7- and 3,6-dimethyl-2,6-octadienes.

Summary

The dimer of isoprene formed under conditions which normally produce "sodium rubber" has been stabilized by the addition of hydrogen. This partially hydrogenated dimer is a mixture of three isomeric dimethyloctadienes; its formation indicates that the mechanism of the polymerization of isoprene to synthetic rubber is the joining of many isoprene molecules by linkage of the 1,1-, the 1,4- or the 4,4-carbon atoms to produce a long-chain molecule.

ITHACA, NEW YORK

NEW BOOKS

Annual Survey of American Chemistry. Vol. III, July 1,1927, to July 1, 1928. Edited by CLARENCE J. WEST. Prepared under the auspices of the Division of Chemistry and Chemical Technology, National Research Council. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York, 1928. 395 pp. 13.5 × 21.5 cm. Price $3.00.

This volume of the Survey contains forty-six chapters which deal with the more actively studied fields in chemistry. A change in policy by the editorial board is announced in the foreword. This consists in "varying the subjects treated from year to year, which will mean that certain less active fields will be covered only every second or third year. Different authors also will be asked to write the reviews, thus distributing the effort of preparing the chapters among the authorities in the fields involved, and giving the readers more than one man's point of view on a particular subject."

The last volume of the Survey is well up to the standard of the former ones. The book is invaluable to one who wishes to keep in touch with the remarkable advance in research in chemistry in this country.

JAMES F. NORRIS

Gmelins Handbuch der anorganischen **Chemie.** (**Gmelin's** Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition, completely rewritten. Sodium. System No. 21. Issued by the Deutsche Chemische Gesellschaft. Verlag **Chemie,** G. m. b. H., Corneliusstrasse 3, Berlin, W 10, Germany; 1928. 18 + 33 + 992 pp. 75 figs. 17 × 25 cm. Price, to subscribers, M. 118; singly, M. 150 (postage included).

This is the largest volume so far published in this encyclopedia of inorganic chemistry. It contains almost a thousand pages, exclusive of the extensive table of contents. In accordance with the scheme of treatment followed throughout the encyclopedia, it first discusses sodium itself and then all of the compounds of sodium with elements bearing a lower number in the arbitrary numerical series that has been adopted.

The text is replete with many hundreds of tables of numerical data and with many skilfully executed diagrams. One cannot but be impressed first with the tremendous amount of human effort that has been devoted to the investigation of even this limited corner of the universe, and second with the industry, patience and understanding which the succinct recapitulation of all this information has required.

Particular features are the forty page account of the occurrence of sodium compounds; the eighty-five page account of the physico-chemical properties of the element and the sixty page account of sodium chloride. The literature has been covered up to January 1, 1928.

We cannot but he grateful to the editor and to the numerous staff of collaborators who have been responsible for this excellent and valuable volume.

ARTHUR B. LAMB

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition, revised. Radium and its Isotopes. System No. 31. By OTTO ERBACHER. Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany; 1928. xxii + 80 pp. 4 figs. 17 X 25 cm. Price, to subscribers, M. 12; singly, M. 15.

This volume is the smallest of the series so far. At first blush this small size appears surprising when one recalls the immense amount of study which has been devoted to radium. On further thought, one realizes that partly because of the short time that has elapsed since its discovery and more because of its great rarity, little actual study of the chemical behavior of radium or of the properties of its compounds has been made. Moreover, its radioactive properties are of such transcendently greater interest that the investigation of the ordinary chemistry of radium has doubtless seemed hardly worth while. Indeed, an inspection of this book shows that only about a score of radium compounds have so far been made.

The literature has been covered up to January 1, 1928.

ARTHUR B. LAMB

Symbols and Formulae in Chemistry. By R. M. CAVEN, D.Sc., F.I.C., Professor of Inorganic Chemistry in the Royal Technical College, Glasgow, and J. A. CRANSTON, D.Sc., A.I.C., Lecturer in Physical Chemistry in the Royal Technical College, Glasgow. Blackie and Son, Ltd., London and Glasgow, England, 1928. ix + 220 pp. 15 X 22.5 cm. Price, 15s., net.

According to the title page this book is an historical study of symbols and formulas in chemistry. In reality the growth of the ideas represented by the symbols and formulas is illuminatingly traced; this is, of course, as it should be, and the book is really a history of the growth of chemical ideas.

For example, the rise and fall of the dualistic theory of Berzelius is sympathetically and fully discussed, even though there were but few symbols specifically applied to this theory. The tenacious adherence of Berzelius to what he was convinced was the truth, and what really embodied the truth in a vague sort of way, is vividly set forth; also his inability to support his theory against the unitary view of Dumas just because he could not grasp a clear conception of a relation between matter and electricity. It needed but the recognition of the adding or subtracting of discrete charges of electricity later to bring the dualistic theory into its own again; in fact, the modern study of the electron in chemistry is but the culmination of Berzelius' ideas of dualism.

The various modern ideas concerning the function of the electron in chemical structure and valence are briefly but adequately and impartially presented and the great confusion arising from the contradictory meanings with which modern theorists use old symbols in fashioning their formulas is noted. The idea suggests itself to the reader that perhaps the modern theories are suffering, just as did Berzelius' theory, from a failure to grasp some elusive but probably very simple and clarifying conception.

ARTHUR A. BLANCHARD

Problbmes et calculs de chimie générale, recueil destine aux élèves des grandes écoles et aux étudiants en chimie. (Problems and Calculations of General Chemistry, a Compilation for Students in Advanced Schools and Students of Chemistry.) By R. HOCART, Licencié in the Physical Sciences. Preface by H. Copaux. Gauthier-Villars et Cie., 55 Quai des Grands-Augustins, Paris, France, 1928. x + 181 pp. 14 figs. 14 × 22.5 cm. Price, 30 fr.

The problems here set forth were first presented in a series of lectures by M. Hocart. Each chapter begins with a brief presentation of the fundamental principles and follows with a large number of carefully selected problems. As a collection of problems the volume is unique in that a complete solution is given for every problem presented, together with a reference to the literature in many cases. The large variety in the subject matter of the problems makes the volume not only informative and valuable in the understanding of the fundamental principles but also useful in the solution of industrial problems. Nearly a hundred problems are presented in the following chapters: (1) Thermo-chemistry; (2) Dissociation of Gases, Law of Mass Action, Equilibrium and Temperature, Free Energy; (3) Electrolytic Dissociation, Solubility Product, Distribution Coefficient, Hydrolysis; (4) Reversible Cells, Gibbs-Helmholtz Equation, Free Energy and Temperature; *(5)* Speed of Reactions.

STUDIES IN IODIMETRY. III. COPPER AS A STANDARD IN IODIMETRY

BY STEPHEN POPOFF, MARGARET JONES, CARL TUCKER AND W. W. BECKER

RECEIVED JANUARY 3, 1928 PUBLISHED MAY 6, 1929

The standardization of solutions in iodimetry has been studied extensively by many investigators. It has been shown by Popoff and Whitman[1] that potassium permanganate, potassium dichromate and potassium bromate can be used as independent standards for sodium thiosulfate solutions and that they all give practically the same value (within 0.05%) as that obtained when iodine is used as a standard.

It is usually considered that copper cannot serve as an independent standard for sodium thiosulfate solutions and therefore it is generally recommended that thiosulfate solutions be standardized against metallic copper under identically the same conditions that are to be used subsequently. It has been possible, however, to find conditions which give the same value (within 0.05%) when using copper and iodine as standards for sodium thiosulfate solutions. The foregoing was made possible by the use of an unquestionable, reliable and easily reproducible preliminary standard (iodine), by controlling the factors which influence the reactions so that variations were kept within 0.05%, and finally by the exclusive use of electrometric methods of determining the end-points.

The use of copper as a standard in iodimetry was first mentioned by de Haen[2] in 1854. Since 1854 many investigators have made a study of the causes of variations in the results obtained by standardizing the sodium thiosulfate solution against copper and against pure iodine. The larger deviations have been attributed to various causes.

The object of the present investigation was to determine the factors which influence the reaction between copper solutions and potassium iodide and thus to enable us to place copper as an independent standard in iodimetry.

Materials

Iodine.—Best quality iodine was resublimed once from potassium iodide and twice alone.

Sodium Thiosulfate.—C. P. quality sodium thiosulfate crystals were placed in a large bottle, through the stopper of which a glass tube was connected to the condenser of an all-glass water still and redistilled water was distilled over into the bottle until the solution was approximately 0.1 N. The normality of this solution did not change for over three weeks.

Copper Sulfate.—Analyzed C. P. cupric sulfate was twice recrystallized and a 0.1 N solution was prepared using redistilled water.

Copper.—Pure electrolytic copper was employed. This metal was prepared by the method given on p. 1305.

Potassium Iodide.—A solution of Mallinckrodt's reagent quality potassium iodide was employed which gave no color to phenolphthalein and which contained no iodate.

Water.—The ordinary laboratory distilled water was redistilled in the presence of potassium permanganate in an all-glass apparatus.

Experimental Procedure

The easiest approach to the solution of the problem at hand consisted in the study of the various factors which determine the reaction between a copper sulfate solution and potassium iodide. If these were determined beforehand, it would be an easy matter to decide whether or not copper can serve as an independent standard for sodium thiosulfate solutions.

The factors which may determine the extent and kind of reaction are: (1) concentration of potassium iodide, (2) kind and concentration of acid, (3) cuprous iodide, (4) order of addition of reagents, (5) time of standing and (6) the presence of salts.

In order to study the foregoing factors, approximately 0.1 N solutions of copper sulfate and sodium thiosulfate were prepared and kept in bottles which were painted with black auto enamel. The reagents were added very slowly (about 15 cc. per minute) and with constant stirring whenever reactions were taking place. The end-point was determined electrometrically. The end-point was calculated by the simple process of interpolation described formerly.

Practically all of the determinations were made by using weight burets. The concentrations of all the solutions are expressed in the final volume, which was 160 cc. in all cases. The total time of each titration was about fifteen minutes. The copper sulfate was added from an especially made weight pipet. In all cases the volumes of the copper sulfate and the sodium thiosulfate solutions employed were about 35 to 38 cc. The numerical values given represent the averages of at least two determinations which did not differ by more than 0.05 of a per cent. Unless otherwise stated the copper sulfate solution was added to the potassium iodide solution.

1. Effect of the Concentration of Potassium Iodide.—The concentration of potassium iodide was varied from 2 to 24%. These concentrations do not allow for the iodide ion used up in the reaction. Table I shows the influence of the concentration of potassium iodide in the reaction between copper sulfate and potassium iodide in neutral solution. In all cases the iodide was added to the copper solution. The ratios are weight ratios of sodium thiosulfate solution to copper sulfate solution.

TABLE I

THE EFFECT OF CONCENTRATION OF POTASSIUM IODIDE

Concn. of KI, %	2	4	6	8	12
Weight ratios	1.0926	1.0935	1.0932	1.0928	1.0936

Up to 12% of potassium iodide the effect of increasing the concentration of potassium iodide is negligible. The lowest result obtained when 2% potassium iodide was used is no doubt due to loss of iodine, as in the final volume there was not 2% of potassium iodide present. When sufficient potassium iodide was present to dissolve the cuprous iodide completely, the weight ratio was increased by about 0.2%. The latter may be due to the oxidation of the cuprous ion to cupric by the air with the subsequent liberation of more iodine. It is possible, however, that Bray and MacKay's[3] suggestion that cuprous iodide adsorbs iodine is correct.

2. Effect of Kind and Concentration of Acid.—In order to determine the effect of acid on the reaction, the concentration of potassium iodide was kept constant at 4% and the reactions were made in neutral, 0.1 M sulfuric acid and 0.4 M acetic acid solutions. The reactions were carried out in the dark in order to prevent oxidation of the iodide ion by the air. The results obtained are recorded in Table II.

TABLE II

KIND AND CONCENTRATION OF ACID

Acid	Neutral	0.1 M sulfuric	0.4 M acetic
Ratios	1.0934	1.0959	1.0942

Evidently acid increases the amount of iodine set free. This may be due either to the oxidation of the iodide ion by the air, or to the oxidation of the cuprous ion to cupric (by the air) with the subsequent reaction with the iodide ion to form iodine. The presence of acid will no doubt increase the above oxidation. Since, however, it has been shown in previous investigations that the former does not take place in diffused light, the increase of the iodine set free may be due entirely to the oxidation of the cuprous ion to the cupric. Cuprous salts, especially the chloride and bromide, are well-known oxygen carriers in acid solutions.

Evidently the hydrogen-ion concentration is a decided factor, as the iodine set free is greater with sulfuric acid than with acetic acid. It is advisable, therefore, to keep the actual acidity as low as possible. The results obtained appear to differ from those reported by others. Bray and MacKay[3] find sulfuric acid objectionable but not acetic acid. Peters[4] finds that a small concentration of sulfuric acid or a large concentration of acetic acid can be employed without any effect.

3. The Effect of Cuprous Iodide.—In order to determine the effect

---

[3] Bray and MacKay, THIS JOURNAL, 32, 1199 (1910).

[4] Peters, *ibid.*, 34, 422 (1912).

of cuprous iodide, it was found necessary to prepare cuprous iodide and observe its effect upon the sodium thiosulfate–iodine reaction. The cuprous iodide was prepared by the addition of copper sulfate solution to potassium iodide solution. The cuprous iodide was washed with dilute potassium iodide solution (making use of the centrifuge) until practically free from iodine. The amount of iodine that remained in the cuprous iodide was determined by electrometric titration with sodium thiosulfate and the volume of thiosulfate required was subtracted from the total volume of thiosulfate in the subsequent titrations. Experiments were performed in which the effect of cuprous iodide on the thiosulfate–iodine reaction in the presence of 4% potassium iodide in neutral and in acid solution was determined. The results are given in Table III.

TABLE III

EFFECT OF CUPROUS IODIDE ON THIOSULFATE–IODINE REACTION

	Neutral, no CuI	Neutral + CuI	0.1 M H_2SO_4 + CuI	0.4 *M* HAc + CuI
Series I	0.9916	0.9917	....	....
Series II	.9905	....	0.9945	0.9930

From the foregoing results it may be concluded that cuprous iodide has no effect on the thiosulfate–iodine reaction in neutral solutions containing 4% of potassium iodide. In acid solutions, however, the effect is appreciable. It is advisable, therefore, to keep the solutions in titrations involving cupric salts and iodide ions as nearly neutral as possible. The effect of acetic acid seems to be much greater than that shown in Table II. This may be due to the fact that it was almost physically impossible to duplicate the experimental conditions.

4. Order of Addition of **Reagents.**—It was found that the order of addition of the reagents (when using 4% potassium iodide) made practically no difference, as the values obtained were 1.0935 and 1.0933.

5. **Time** of Standing.—In the dichromate-ion–iodine-ion–hydrogen-ion reaction it is necessary to let the reaction proceed for ten minutes before sodium thiosulfate is added. The effect of time of standing with the cupric-ion–iodide-ion reaction was determined using 4% potassium iodide. Table IV gives the results obtained.

TABLE IV

EFFECT OF TIME OF STANDING

	Weight ratio
Titrated immediately	1.0935
Standing for 10 min. before beginning titration	1.0934
Standing for 10 min. just before the end-point	1.0935

Evidently, under the conditions employed, the reaction between copper sulfate and potassium iodide goes to completion immediately and no time of standing is necessary.

6. The Presence of Salts.—The effect of the presence of salts was not determined. According to former investigators, potassium sulfate or salts in general decrease the amount of liberated iodine. It was deemed advisable, therefore, to keep the concentration of salts as small as possible in the standardization of the sodium thiosulfate solution by metallic copper.

The Determination of the Concentration of the Copper Sulfate Solution

From the study of the effect of the various factors in the copper sulfate–potassium iodide reaction, it was found necessary to perform the reaction in a solution which was as nearly neutral as possible and in the absence of salts. In order that these conditions might be rigidly maintained, a 0.1 *N* solution of copper sulfate was prepared and its concentration determined accurately by electrolysis. Former studies on the electrolytic determination of copper in this Laboratory by Tucker[5] were of special value.

The Electrolytic Determination of Copper.—A rotating platinum anode and copper gauze cathode served as the electrodes. A current of 1.5 amperes was used. The electrolysis was made to proceed until no positive test was obtained by haemotoxylin. The use of haemotoxylin as a test for copper was first introduced by Bradley;[6] however, no specific directions are given by former investigators. The test as finally employed was as follows.

About 2 cc. of the solution (after electrolysis had proceeded for about forty minutes) was placed in a small porcelain crucible. Two or three drops of the haemotoxylin indicator were added and then enough solid sodium carbonate to produce a red color. Finally, a saturated solution of sodium bisulfite was added dropwise until the red color disappeared. If copper were present, a blue color remained. A decided positive test for copper was obtained from a solution which contained 0.06 mg. of copper in 200 cc. of solution. If 0.06 mg. of copper still remained in solution the error would be about 6 parts in 30,000 or 0.02%. In this connection it may be of interest to state that the potassium ferrocyanide spot-plate test, as ordinarily used, is hardly sensitive enough as there can be as much as one mg. of copper without detection. Again, the method7 of adding more water to the electrolysis solution and observing whether or not any copper is deposited on the freshly exposed platinum surface of the cathode, cannot be considered a sensitive test for copper as we have not been able to observe any deposit of copper when there was 0.5 mg. of copper in 200 cc. of solution. Again, the method employed by Quisumbing and Thomas[7] of withdrawing the cathode is open to very serious objections, as is shown by the following experiments.

Solutions containing varying concentration of acids per 200 cc. were prepared. These were placed in the electrolysis apparatus and the weight of the cathode before and after withdrawal was determined. The current was left on and the cathode was quickly withdrawn and plunged into distilled water. This method will be called the "short cut" in order to contrast it with the "siphon" method, in which the electrolysis solution was continually being siphoned off and distilled water added so as to keep the solution over the cathode. The latter process is continued until the ammeter showed very little or no current (this required about 2 liters of water). Table V gives the results obtained.

---

[7] Quisumbing and Thomas, This Journal, 43, 1503 (1921).

TABLE V

LOSS OF COPPER USING THE "SHORT CUT" AND "SIPHON" METHODS OF WITHDRAWING THE CATHODE

Vol. of concd. acids, cc.	2, nitric	0.3, nitric	2, sulfuric	0.3, sulfuric
"Short cut" loss, mg.	1.3	0.3	1.8	0.8
"Siphon" loss, mg.	0	0	0	0

It can be seen readily that even at a concentration of 0.3 cc. of concd. nitric acid there is a loss of 0.3 mg. by the "short cut" method, as compared with no loss by the "siphon" method even when 2 cc. of concd. sulfuric acid were employed.

Strangely enough no one except Fales[8] has considered the solubility of the platinum anode in the electrolytic determination of copper. The solubility of platinum serving as the anode is not negligible and amounts to about 0.2 mg. when 2 cc. of concd. sulfuric acid and 1 cc. of concd. nitric acid per 200 cc. are employed. It must be stated, however, that Fales' suggestion of weighing the cathode after the deposition (not before) is complete, dissolving the cathode deposit and weighing the platinum electrode will hardly allow for the solvent action of the platinum anode. Certainly no platinum is present in the solution just as electrolysis is started. Any platinum that dissolves during the electrolysis will be deposited over the copper and it will be removed on dissolving the copper. It was ascertained that a mixture of nitric and sulfuric acids present to the extent of 0.15 cc. of each or 0.3 cc. of sulfuric acid only, will not exert solvent action on the platinum anode. In subsequent determinations these concentrations of acids were employed.

Although the haemotoxylin test for copper was negative, nevertheless it was deemed necessary to make absolutely certain that no appreciable amount of copper was left in the two liters of the "wash" solution There-fore the entire solution was evaporated to dryness. A few drops of nitric acid was added, the solution neutralized with ammonium hydroxide and then acidified with sulfuric acid. At the same time about two liters of water were evaporated and the residue (if any) treated in similar fashion. Potassium iodide was added to these solutions. Both solutions required only one drop of sodium thiosulfate to pass the electrometric end-point. It is believed that the foregoing tests show conclusively that the deposition of copper, as performed, is practically complete, especially since haemotoxylin gave no test for copper after the "wash" solution was evaporated to about two cubic centimeters.

Table VI gives the results obtained for the concentration of copper in the copper sulfate solution which was employed for the standardization of the sodium thiosulfate solution.

THE CONCENTRATION OF THE COPPER SULFATE SOLUTION

Series I. 0.15 cc. of HNO_3 + 0.15 cc. of H_2SO_4

	1	2	3	4
Wt. of $CuSO_4$ soln., g.	54.486	52.417	53.158	49.893
Wt. of Cu deposited, g.	0.3365	0.3235	0.3281	0.3052
Cu per g. of $CuSO_4$ soln., g.	0.006174	0.006171	0 006172	0.006177

Series II. 0.30 cc. of H_2SO_4

	5	6	7
Wt. of $CuSO_4$ soln., g.	50.892	50.655	50.603
Wt. of Cu deposited, g.	0.3141	0.3127	0.3125
Cu per g. of $CuSO_4$ soln., g.	0.006172	0.006173	0.006175

Average of Series I (excluding No. 4) = 0.006172
Average of Series II = 0.006173
Average of all values = 0.006173

The Standardization of Sodium Thiosulfate

Since pure elementary iodine is considered to be the best standard for sodium thiosulfate solutions, the sodium thiosulfate was standardized against pure iodine according to the method of Popoff and Whitman[1] and the results were compared with the values obtained when using the standard copper sulfate solutions and pure copper.

The Iodine Method.—The special apparatus described by Popoff and Whitman was employed. The final volume was 160 cc. and 4% of potassium iodide was used.

The Copper Sulfate Method.—The copper sulfate solution was added to a potassium iodide solution containing 4% of potassium iodide in the final volume of 160 cc.

The Copper Method.—Pure electrolytic copper was prepared and used in this determination. To prepare the pure copper, copper sulfate was recrystallized several times and an acidified solution of this salt was used in the electrolysis. A copper foil was employed as the cathode for the preparation of the electrolytic copper. It was a comparatively easy matter to remove the copper from the copper foil. The attempt to use aluminum foil failed as the electrolytic copper seemed to be contaminated with aluminum.

About 0.24 g. of copper was dissolved in 8 cc. of 6 M nitric acid. The solution was evaporated on the steam-bath until on cooling it would completely solidify. The residue was dissolved in about 20 cc. of water and dilute sodium hydroxide solution added until a permanent precipitate was just formed. Now 8 M acetic acid was introduced until the precipitate completely dissolved and then about four drops in excess. The solution was diluted to about 100 cc. with water and enough potassium iodide was added so that in the final volume of 160 cc. there would be 4% potassium iodide. If a sufficient amount of acetic acid was added to make the solution 0.4 M as directed by Fales, the error was increased by about 0.1%.

In all of the experimental work the potassium iodide was a 50% solution (by volume) and it was added very slowly with constant stirring (by an electric motor).

The copper sulfate solution, as well as the sodium thiosulfate solution, was weighed and the results given in Table VII are calculated on the basis of 1000 g. of sodium thiosulfate solution.

TABLE VII

THE NORMALITY OF THE SODIUM THIOSULFATE SOLUTION

Standard	Series	Normality	Diff. comp. to I_2, %	Series	Normality	Diff. comp. to I_2, %
Iodine	I	0.08880	..	I	0.00880	..
$CuSO_4$	I	0.08881	0.01	II	0.08883	0.03
Cu	I	0.08881	0.01	II	0.08881	0.01

No attempt will be made at this time to explain why previous workers were not able to make the standardization of a thiosulfate solution by copper check with other standards, because an explanation is not possible when all the factors are not known. One may venture stating that the standards and probably the conditions employed by former investigators were not ideal.

Summary

1. (a) From the study of the reaction between copper sulfate and potassium iodide, it was found that a change of concentration of the latter from 4 to 12% in neutral solutions had no effect on the thiosulfate–copper sulfate ratio.

(b) In the presence of 0.1 M sulfuric acid and 4% potassium iodide the thiosulfate–copper sulfate ratio is increased by about 0.2% and in the presence of 0.4 M acetic acid by 0.08%.

(c) The order of addition of the reagents makes no difference in neutral solutions when 4% potassium iodide is used.

(d) Time of standing (ten minutes) has no effect in the presence of 4% potassium iodide.

2. Cuprous iodide has no effect on the thiosulfate–iodine ratio in the presence of 4% potassium iodide and in neutral solutions. In acid solutions it causes an increase in the ratio.

3. Some glaring errors are pointed out in the electrolytic determination of copper. It is recommended that the concentration of acid be kept low and that practically all of the acid be removed before the copper cathode is taken from the solution. A very sensitive test for copper is used.

4. It is now possible to use either copper sulfate solution or pure copper as an independent standard in iodimetry provided the salt and the acid concentration are kept very small.

STUDIES IN IODIMETRY. IV. POTASSIUM PERMANGANATE AS A STANDARD IN IODIMETRY

BY STEPHEN POPOFF AND ADOLF H. KUNZ

RECEIVED JANUARY 6, 1928 PUBLISHED MAY 6, 1929

Although in a former article[1] it has been shown that potassium permanganate can be used as an independent standard in iodimetry, there were a number of factors which necessitated further study, especially in view of some helpful suggestions by Dr. W. C. Bray. In the former investigation volume burets were employed and it seemed that differences of 0.05% could well be attributed to experimental errors. Weight burets were used in the present investigation in order to reduce errors to a minimum.

Winther[2] has shown that in acid solution the rate at which oxygen reacts with iodide ion in the dark increases as iodine is liberated and that it proceeds much more rapidly in the light. It is true that the thiosulfate–permanganate ratio in **0.1** *M* sulfuric acid is larger when 6% iodide is used than with 2%. However, when iodine solution is titrated under the same conditions no difference in the thiosulfate–iodine ratio is obtained.[3] This indicates that the difference must be due to some other factors.

Effect of Salts.—Since in the titration of the iodine set free by permanganate there are manganous and potassium salts present, the influence of these salts on the thiosulfate–iodine reaction was studied. Table I shows that manganous sulfate and potassium sulfate in 6% potassium iodide and 0.1 M sulfuric acid solution and with ten minutes' standing before titration have no effect on the thiosulfate–iodine reaction. The amount of these salts added was that equivalent to 40 cc. of **0.1** *N* potassium permanganate.

TABLE I

EFFECT OF POTASSIUM AND MANGANOUS SALTS

	Wt. ratio		Wt. ratio
No salts present	1.0701	Salts present	1.0704
No salts present	1.0702	Salts present	1.0702

Effect of Concentration of Iodide, Acid and Light.—It seemed desirable to show that in the thiosulfate–iodine reaction up to 6% potassium iodide and **0.1** M sulfuric acid can be used together with ten minutes standing without producing any appreciable change in the thiosulfate–iodine weight ratio, provided, of course, the titrations are carried out in the dark. Table II bears out this statement. In this and subsequent tables the concentrations given are at the end of the titrations. Where

[2] Winther, *Z. physik.* Chem., 108, 236 (1924); 113, 274 (1924).

[3] See ref. 1, p. 2270.

duplicate results are not given, the values were obtained from two or more determinations in which the maximum variation was 0.05%.

TABLE II

EFFECT OF CONCENTRATION OF IODIDE, ACID AND LIGHT

Potassium iodide, %	2	2	6	
Acid	None	None	0.1 M sulfuric	
Time of standing	None	None	Ten minutes	
Wt. ratio in light	1.0688	1.0686	1.0701	1.0702
Wt. ratio in dark	1.0689	1.0693	1.0690	1.0691

The light used in the experiments with 6% potassium iodide was artificial light from four 100-watt bulbs in a room 18' X 15' × 13'. Evidently light from such an electric source cannot be substituted for diffused light. In subsequent experiments red light furnished the necessary illumination.

Winther[2] showed that in the light oxidation of iodide by blowing air through the solution requires a thirty-minute induction period and that the speed of the reaction is increased by the presence of a very small amount of iodine. In our experiments air is not blown through the solutions, there are about 40 cc. of 0.1 N iodine solution present, the time of titration is at most twenty-five minutes and the experiments are performed in the dark. Therefore, the conditions under which Winther performed his experiments are widely different and no appreciable oxidation of the iodide ion takes place under the conditions recommended in our work in iodimetry.

Effect of Rate and Method of Introducing Permanganate.—A study was made of the effect on the thiosulfate–permanganate ratio of introducing the permanganate above and below the surface of the acidified solution of potassium iodide, the acid concentration being 0.1 M sulfuric acid. The stirring during the addition of the permanganate was not done by means of an electric motor as in the experiments (open vessel) given in Table V. The diierence between the results given in Tables III and V emphasizes

TABLE III

EFFECT OF RATE AND METHOD OF INTRODUCING PERMANGANATE

% KI	Time of standing	Rate of addition	Method of addition	Thiosul.-perman. wt. ratio
6	None	5 minutes	Above	1.0836
6	None	5 minutes	Above	1.0838
6	10 minutes	5 minutes	Above	1.0836
6	10 minutes	5 minutes	Above	1.0832
6	10 minutes	5 minutes	Below	1.0836
6	10 minutes	5 minutes	Below	1.0838
6	10 minutes	1 minute	Above	1.0836
6	10 minutes	5 minutes	Above	1.0832
2	None	1 minute	Below	1.0817
2	None	1 minute	Below	1.0818
2	None	1 minute	Above	1.0798
2	None	1 minute	Above	1.0800

the necessity of using 6% rather than 2% potassium iodide. The results are given in Table III.

These results show that neither the rate nor mode of addition (within certain limits) of the permanganate has any effect when 6% potassium iodide is used. When 2% iodide is used the weight ratio is greater when the permanganate is added below the surface. Evidently 6% potassium iodide is to be preferred.

In the former paper we quoted incorrectly that Bray and MacKay[4] claimed that the reaction between the permanganate and iodide is slow, hence the necessity of using 6% potassium iodide and ten minutes' standing. This contention, however, must be abandoned in view of the more precise data given in Table III. The former results may be attributed to the failure to exclude light from artificial source (see Table II).

Effect of Alkali.—While it is generally known that the potassium iodide used in most work in iodimetry must be practically free from alkali, yet labels of many analyzed "c. p." samples of potassium iodide do not specify the alkalinity. It is very likely that some of the workers who have recommended the use of acid solutions, when standardizing thiosulfate solutions with iodine, had used slightly alkaline iodide without being aware of the presence of the alkali. Table IV shows the effect of using a "c. p." potassium iodide (analysis of which showed alkali) compared to another not containing alkali.

TABLE IV

EFFECT OF ALKALI IN POTASSIUM IODIDE

% KI	Acid	Thiosulfate–iodine weight ratio Alk. iodide	Non-alk. iodide
2	0.1 *M* H_2SO_4	1.0695	0.9522
2	0.1 M H_2SO_4	1.0695	.9524
2	No acid	1.0672	.9523
2	No acid	1.0669	.9524

It is recommended that the specifications for potassium iodide given by the Committee on Guaranteed Reagents[6] be followed rigidly.

Effect of Concentration of Potassium Iodide in Closed and Open Vessels.—It was further deemed advisable to study whether or not the large difference in the thiosulfate–permanganate ratios, when using 2 and 6% potassium iodide, is due to the fact that iodine is set free rapidly and that unless 6% iodide is employed iodine is lost by volatilization. In order to determine this, a special apparatus was constructed in which the formation and titration of practically all the iodine were performed in a closed vessel similar to the one previously used for weighing iodine.[6] The endpoint was then determined in a beaker. Not more than six drops was re-

quired to obtain the electrometric end-point. Table V gives the data obtained.

TABLE V

EFFECT OF CONCENTRATION OF POTASSIUM IODIDE IN CLOSED AND OPEN VESSELS

Potassium iodide, %	2	2	6	6
Vessel	Closed	Open	Closed	Open
Thiosul.-perman. wt. ratio	1.2155	1.2148	1.2173	1.2164

It can readily be seen that the difference between using 2 and 6% potassium iodide in the permanganate–iodide reaction is not due to loss of iodine in the former by volatilization. It must probably be attributed to the "loss of oxygen" by the permanganate while in the process of reduction. It is significant to note that the loss of iodine in 2 and 6% potassium iodide (when results in closed and open vessels are compared) is about the same.

The Weight Normality of Potassium Permanganate Solution.—In order to show that 6% potassium iodide must be employed in the permanganate method and no time of standing is necessary, the data of Table VI are presented. The standardization of potassium permanganate with sodium oxalate was carried out as recommended by McBride[7] (except that the end-point was determined electrometrically). In the standardization of the sodium thiosulfate by iodine, 2% potassium iodide was employed, while by potassium permanganate 6% of potassium iodide and 0.1 M sulfuric acid. All concentrations are referred to a final volume of 160 cc. About 40 cc. of solution was used and about 20 cc. of water was employed for washing the sides of the vessel just before the end-point.

TABLE VI

THE WEIGHT NORMALITY OF POTASSIUM PERMANGANATE SOLUTION[a]

Normality by sodium oxalate	1.0484
Normality by iodine and wt. ratio of thiosul.-permanganate	1.0483

[a] In all the experiments at least two duplicate determinations were made with a maximum variation of 0.05%.

Summary

1. It has been shown by using weight burets that in the thiosulfate–iodine reaction there is no appreciable oxidation of the iodide ion by the oxygen of the air in a solution containing 6% potassium iodide and 0.1 M sulfuric acid, even after standing for ten minutes, provided titrations are made in the dark.

2. Manganous and potassium sulfates in concentrations corresponding to 40 cc. of 0.1 N potassium permanganate have no effect under the conditions specified in 1.

3. Potassium iodide used in iodimetry must meet the specifications of the committee on guaranteed reagents in respect to alkalinity.

---

[7] McBride, THIS JOURNAL, 34,393 (1912).

4. Six per cent. potassium iodide must be employed when sodium thiosulfate solutions are standardized with potassium permanganate. Standing is not necessary. The acid concentration may be 0.1 M sulfuric.

ZIRCONIUM. IV. PRECIPITATION OF ZIRCONIUM BY PHOSPHATES

BY RUFUS D. REED AND JAMES R. WITHROW

RECEIVED JULY 16, 1928 PUBLISHED MAY 6, 1929

This paper is devoted to a study of the completeness of precipitation of zirconium by other phosphates. In testing for completeness of precipitation of potassium by zirconium sulfate it was found that this reagent also gave a precipitate with sodium cobaltic nitrite. Therefore, it became necessary to remove the zirconium before testing for potassium. As phosphates have been used for quantitatively determining zirconium and as Noyes and Bray[1] have shown that phosphates do not interfere with the detection of potassium by sodium cobaltic nitrite, the completeness of removal of zirconium by phosphates prior to testing for potassium was investigated.

The results indicated that a five-fold excess of ammonium phosphate, phosphoric acid or microcosmic salt in the presence of 0.344 molal sulfuric acid were all efficient in removing zirconium but that sodium phosphate was inefficient except when used in forty-fold excess. The presence of added acid was necessary.

Literature

Phosphates.—Sodium phosphate,[2] ammonium phosphate,[3] microcosmic salt[4] and phosphoric acid[5] have been used to determine zirconium quantitatively in the presence of sulfuric acid. Biltz and Mecklenburg[6] recommend the qualitative detection of zirconium by sodium phosphate in the presence of hydrochloric or nitric acid, as sulfuric acid slowed up the reaction.

Conditions for the Precipitation of Zirconium Phosphate.—Marden and Rich[2] recommend "a slight excess of sodium phosphate" in the presence of 10% sulfuric acid. Lundell and Knowles[3] recommend an excess of 10 to 100 times the calculated amount of ammonium phosphate in

the presence of 2 to 20% tepid sulfuric acid. Less than 0.5% sulfuric acid caused the formation of basic zirconium phosphate. Noyes, Bray and Spear[7] found that an excess of sodium phosphate was needed to remove practically all of the zirconium from solution. Steiger[4] stated that the zirconium was completely removed by microcosmic salt except when the acidity was from 5 to 10% sulfuric acid. Marden and Rich investigated the yield of zirconium phosphate by precipitation with various phosphates and concluded[5] "that $(NH_4)_2HPO_4$, Na_2HPO_4 or H_3PO_4 gave equally good results." If one chooses results from their determinations given in the table, agreeing results are secured, but the average of their determinations of zirconium by sodium phosphate is less than the average of either the ammonium phosphate or phosphoric acid results.

While zirconium has been determined quantitatively by all four phosphates, their efficiency in removing zirconium completely in the presence of hydrochloric, nitric and sulfuric acids of varying concentrations was still subject to question. It was decided, therefore, to investigate the completeness of removal of zirconium by these phosphates.

Experimental

Reagents.—The zirconium sulfate solution contained **0.1134** g. of zirconium sulfate per cc. The approximate strengths of the acids were determined by specific gravity. The phosphates were analyzed for phosphate by the magnesium pyrophosphate method according to Treadwell and Hall.[8]

General Procedure.—To 1-cc. portions of zirconium sulfate solution in the presence of no added acid and also hydrochloric, nitric or sulfuric acid, a solution of either phosphoric acid, sodium phosphate, microcosmic salt or ammonium phosphate was added. After standing for two hours or overnight the solutions were filtered through closest grained filter paper and washed four times with cold water. Early experiments showed that if medium texture paper was used the zirconium phosphate would pass through the paper. To make any precipitate more noticeable, the filtrate and washings were concentrated upon a sand-bath to **10** or **20** cc. Then concentrated ammonium hydroxide was added to neutralize the acid. If the solution gave no deposit, it was warmed and allowed to stsnd to see if a tardy precipitate would form.

Sodium phosphate as a reagent for precipitation of zirconium was investigated more minutely than the others as it would not interfere with the detection of potassium after zirconium was removed. The efficiency of all four reagents is shown in the table.

Discussion

In Expts. 1 to 4 where no acid was added the precipitate settled slowly and filtered with difficulty. In Expts. 5 to 25 where acid was added the precipitate settled readily and filtered much more rapidly than where no acid was added. Evidently acid must be added to secure a proper

[a] The amount of ammonium phosphate used in Expt. 20 was not 0.5696 g. of P_2O_5 as in the other three cases but 0.5405 g. of P_2O_5. All other conditions were the same.

physical condition of the precipitate. In Expts. 18 to 25, where sulfuric acid was present, the precipitate formed only after standing for a few seconds, while in all other cases, Expts. 1 to 17, where either none or hydrochloric or nitric acid was present, it formed as soon as any precipitant was added. This agreed with the observation of Biltz and Mecklenburg.[6]

In Expt. 5 the zirconium was precipitated from hot solution while in Expt. 6 the precipitation was made from solution at room temperature, all other conditions being equal. The bulk of precipitate was greater in the filtrate from 5 than from 6, possibly indicating that zirconium was more completely removed when precipitation was made at room temperature than from hot solution. All other precipitations were made at room temperature.

Effect of Added Acid.—In Expts. 5 to 12 where hydrochloric acid was present, only one condition—Expt. 12, 0.204 N hydrochloric acid—succeeded in removing all of the zirconium. An excess of 50 times the calculated amount of phosphoric acid was needed for this. Expts. 13–17, where 0.269 N nitric acid was present, indicated that in Expt. 17, 20 times the calculated needed amount of phosphoric acid, microcosmic salt or ammonium phosphate would remove all of the zirconium from solution. Expts. 18–25, in which sulfuric acid was present, indicated that either phosphoric acid, microcosmic salt or ammonium phosphate—Expts. 20, 21, 23—when used in excess of 5 to 10 times the calculated needed amount would remove all of the zirconium from solution in the presence of 0.817 g. (0.168 molal or 0.334 normal) to 1.634 g. (0.334 molal or 0.668 normal) of sulfuric acid per 50 cc. of solution. Expt. 25 showed that as much as 8.17 g. of sulfuric acid per 50 cc. of solution did not prevent the complete removal of zirconium by 10 times the calculated amount of ammonium phosphate. These results indicated that the presence of sulfuric acid, while retarding the appearance of a precipitate, was more beneficial than either hydrochloric or nitric acid in aiding the removal of zirconium by phosphates.

Efficiency of Various Phosphates.—Sodium phosphate—Expts. 19 to 23—was less efficient than phosphoric acid, microcosmic salt or ammonium phosphate in removing zirconium from solution. However, the amount of zirconium left in solution by sodium phosphate was very small and the precipitate of zirconium phosphate formed only after standing. The bulk of the deposits, in the ammonium phosphate column, marked "slight if any" amounted to but a few flakes which would be unweighable on ignition and might have been shreds of filter paper.

Summary

1. The efficiency of sodium phosphate, phosphoric acid, ammonium phosphate and microcosmic salt as precipitants for zirconium has been investigated and the last three were found to be equally efficient and more efficient than sodium phosphate. Even sodium phosphate removed practically all of the zirconium.

2. The phosphates were found most efficient in the presence of 0.344 to 0.668 N sulfuric acid and less efficient in the presence of 0.269 N nitric acid or 0.204 N hydrochloric acid.

3. Although record was found in the literature of the formation of

basic zirconium phosphate in the absence of added acid, no record was found indicating incompleteness of precipitation of zirconium under these conditions. Investigation showed that phosphates are not efficient in removing zirconium in the absence of added acid.

THE SINGLE POTENTIAL OF THE COPPER ELECTRODE

BY EDGAR NEWBERY

RECEIVED JULY 20, 1928 PUBLISHED MAY 6, 1929

The determination of the normal single potential of a copper electrode has been attempted by many investigators with very discordant results and at the present time its value is not known with certainty within a possible error of 40 millivolts. This work was undertaken, therefore, with the object first of finding the reasons for the variation in the results obtained, and, second, if possible, of removing or circumventing the disturbing factors and determining the true value.

Possible sources of error or of variability of results are: (1) impurities in the electrode, (2) impurities in the electrolyte, (3) variations in the nature of the electrode surface, (4) changes in constitution of electrolyte during measurement, (5) chemical action between electrode and electrolyte producing any or all of the conditions (1) to (4).

1. Most investigators have exercised great care to ensure that the copper electrodes used were free from traces of other metals. Unfortunately one of the most dangerous impurities, hydrogen, which is very frequently present and has a profound potential-disturbing capacity, has been ignored. If two copper plates cut from the same sheet be immersed in dilute acid and a current passed for a few seconds, a potential difference of several millivolts is produced which may persist for several hours. By introducing a third electrode cut from the same sheet at the same time it may be shown that this potential change is mainly due to the cathode.

This cannot be due to deposition of copper on the cathode since the effect is quite unchanged if the three electrodes are placed in separate compartments connected only by narrow tubes.

Lewis and Lacey[1] used electrolytic copper sponge for the determination of the single potential of copper and this was undoubtedly contaminated with hydrogen.

Their attempt to show that occluded hydrogen was not taking part in the electrode process was very unconvincing. They found that the presence of 0.0005 M sulfuric acid in the solution had no effect upon the e.m.f.

---

[1] Lewis and Lacey, THIS JOURNAL, 36, 804 (1914).

If the hydrogen in the copper exists as unsaturated solid solution, as is probably the case, such a solution will show a single potential intermediate between that of pure copper and of a hydrogen electrode. The effect of change of H-ion concentration will, therefore, be much less than in the case of a hydrogen electrode. Also, the extremely small quantity of acid added by Lewis and Lacey, the buffer action of the salt present and the natural acidity of the copper sulfate solution due to hydrolysis (copper hydroxide being a weak base) all indicate that the change of H-ion concentration due to the addition of the acid must have been very small.

If more concentrated acid is used (say 0.05 M), the tendency for the copper to go into solution becomes marked and a considerable fall of potential is observed (5 or 6 millivolts) whether the electrode contains hydrogen or not. With an electrode containing hydrogen in very dilute acid, the two effects tend to balance each other.

Lewis and Lacey's experiment, therefore, fails to prove that the original single potential of the copper was not affected by the presence of hydrogen.

2. The precautions taken by most investigators with regard to the purity of the copper salts and the water used preclude the possibility of any serious errors from this source. Further, preliminary experiments showed that quite appreciable quantities of certain impurities—acid, iron salts, etc.—had very little effect upon the measured potentials.

3. It is remarkable that nearly all workers have been unanimous in ascribing the variations in measured single potentials of copper to variations in the nature of the surface.

Preliminary experiments were carried out in order to examine this effect. Various specimens of copper wire, sheet, ingot, etc., were subjected to the most drastic treatment—heating to near the melting point and cooling in ice water or very slowly in an electric furnace, drawing wire through dies, hammering out to thin plates, cleaning with several grades of emery or glass paper, polishing, burnishing, etc., but the results were entirely negative. In no case could any change of potential be definitely ascribed to mechanical conditions. It is evident, therefore, that this effect has been greatly overestimated.

Getman[2] investigated this effect and came to a similar conclusion. Unfortunately, however, he rendered his results of doubtful value by polishing his samples with emery cloth after each treatment, thus destroying to some extent the surface he had been preparing. In the above work all cleaning was done before other treatment, the formation of oxide films during heating being avoided by carrying this out in a vacuum, except in the case where sudden cooling was required. In the latter case the oxide film was removed by scraping with a steel knife and is thus open to criticism, but the remaining cases are sufficient to indicate that the theory of surface strains is

---

[2] Getman, *Trans. Am. Electrochem. Soc.*, **26,** 67(1914).

inadequate to explain the large changes of single potential observed when copper is placed in a solution of one of its salts or when different forms of copper (massive, sponge, powder, amalgam, etc.) are used.

On the other hand, the nature of the surface certainly affects the speed of the reaction which occurs between electrode and electrolyte (see under 5). If, therefore, thirty minutes be allowed in each case (as was done by Getman) for this reaction to proceed, differences of potential may well be observed, but these are not true normal potentials.

The maximum potential differences found by Method C, described later, between dead, soft and hard hammered copper and between brightly polished and very rough surfaces were of the order of one millivolt, whereas the values found by Getman vary by 30 millivolts in 0.01 M solution and by 200 millivolts in 0.001 *M* solution.

4. The stability of copper sulfate solutions is open to question. It is frequently observed that a bottle of the solution standing for some months in the laboratory deposits a pale blue precipitate. O'Sullivan[3] observed a marked drift of the potential of a quinhydrone electrode in neutral copper sulfate solution amounting to over 20 millivolts in seven days, but accounted for this by the reducing action of the quinhydrone on the copper sulfate. He found that no change was observable in copper sulfate solution which had been kept for a month. From experiments carried out in connection with the present work, it appears probable that if he had used a solution three to six months old, a change would have been observed.

A sample of 0.5 M copper sulfate which had been kept in a stoppered measuring flask for three months was compared with a fresh solution by measuring the single potential of a clean copper rod against a mercurous sulfate electrode first in the old solution and then in the new. The rod was cleaned before each immersion and rotated during measurements and a definite difference of potential of 2 to 4 millivolts was observed as a result of about 24 measurements. This would appear to involve a change of the order of 17 to 37% in the concentration of the copper ions in solution. A similar sample of solution which had been kept in a partly filled stoppered bottle for nearly a year and which showed a visible precipitate, gave a value of the single potential of copper 20 millivolts lower than that in a fresh solution. This would imply a reduction of the copper-ion concentration to one-fifth of that in a fresh solution—a very improbable effect. It is possible that crystalline copper sulfate may consist largely of a complex cupri-sulfuric acid and that the real concentration of copper ions in solution is very small and easily disturbed without producing any marked visible effect in the solution as a whole. Possibly also the solution may tend to decompose with the formation of cuprous salt which remains in colloidal solution, and alkali dissolved from the glass container may affect

---

[3] O'Sullivan, *Trans. Faraday Soc.*, **23**, 52 (1927).

either of these conditions. In any case, the action under ordinary conditions is a very slow one and cannot account for the rapid changes of 2 millivolts in two minutes frequently observed when a clean copper electrode is placed in old or fresh solution.

5. In order to ascertain whether the electrolyte reacted with the electrode, small copper rods or strips of foil were prepared in various ways and placed in solutions of cupric sulfate, chloride, nitrate and acetate. In every case visible chemical action occurred and the electrodes were coated with basic salts. In some cases, notably with rough electrodes in chloride solutions, the effect was visible after a few seconds' immersion, in other cases it was much slower. A highly polished strip of foil completely covered with a half molar solution of pure copper sulfate and enclosed in a weighing bottle containing only a small quantity of air was not visibly affected during the first twenty-four hours. After four weeks a fairly thick, hard-red deposit was formed on the copper near the surface of the liquid and along minute scratches left by the polishing, but most of the surface was still bright and untarnished. The admission of air materially hastened the formation of further deposit.

In some solutions, crusts a millimeter thick containing visible faces of dark green crystals were formed in less than a week.

Since an invisible film of no more than molecular thickness may profoundly affect the single potential of the metal, it is evident that this action is the main source of all the difficulties experienced in determining the single potential of copper.

The following experiments were carried out, therefore, with a view to eliminate the effect of this film.

Experimental

(A) The first method of attack consisted in an attempt to determine the single potential of the copper immediately after the passage of a very small current either depositing or dissolving copper from an electrode in a half molar solution of the sulfate. For this purpose the rotating commutator apparatus previously used for overvoltage measurements was employed.[4] A Tinsley vernier potentiometer reading to five significant figures with no slide wire and a galvanometer reading to 10^{-9} amp. were used. The subsidiary electrode was a sheet of pure copper and the standard electrode was mercurous sulfate in half molar sulfuric acid.

When the experimental electrode is made the cathode, pure copper is deposited on it and the single potential of this was measured at such a short interval after interrupting the current that the objectionable film of basic salt has no time to form. The deposited copper, however, always contains hydrogen and the single potential will, therefore, always be too low (negative).

On the other hand, when the experimental electrode is the anode, small quantities of metal will be removed continuously from the surface, thus hindering the formation of a basic film but at the same time oxygen or some oxidizing agent is formed on the surface and the measured single potential will be too high (positive).

---

[4] Newbery, *J. Chem. Soc.*, **105,** 2420 **(1914).**

It was hoped that an extrapolation to zero current would eliminate **both** of these errors. At the same time errors due to local changes of concentration were eliminated by stirring the liquid by means of a small spiral glass stirrer revolving rapidly in front of the electrode. At first currents of *a* few micro-amperes were tried, but the single potentials observed were very erratic and indefinite. When heavier currents up to 12 milliamperes per sq. cm. were applied, more consistent results were obtained and these are illustrated by the curve shown in Fig. 1, which gives the average values obtained in four complete series of observations. In this curve ordinates represent the single potential in volts (assuming that of the normal mercurous sulfate electrode to be 0.968 volt at 20°) and abscissas the current density in milliamperes per sq. cm.

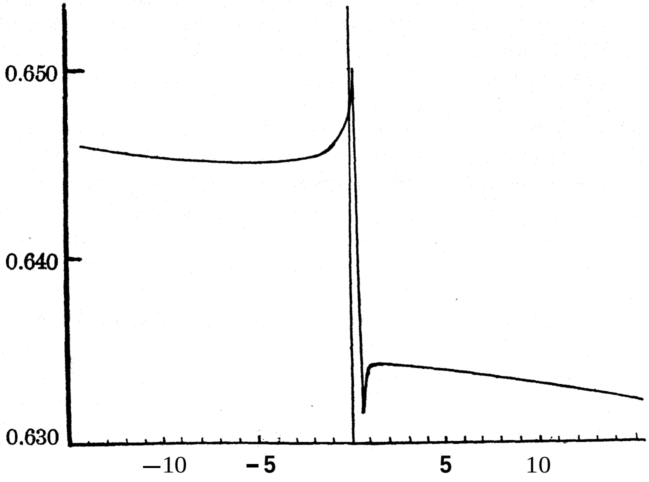

Fig. 1.

It is evident that extrapolation to zero current is quite out of the question with a curve such as this, where the two branches of the curve are pointing in opposite directions instead of approaching each other near the zero line as might have been expected. It is, however, of considerable interest as showing that the production of hydrides or other reducing bodies at the cathode and of oxides or other oxidizing bodies at the anode occurs even at extremely low current densities. In fact, the single potential of the electrode depends greatly upon its previous history for some time past. An attempt was next made to bring the two arms of this curve together by constructing a triple four-part commutator which gave the following cycle: (1) current applied, test electrode cathode; (2) current broken, test electrode connected to potentiometer; (3) current applied, test electrode anode; (4) current broken, test electrode connected to potentiometer. When the commutator gave about twenty complete cycles per second, steady readings were obtained on the potentiometer at all current densities and it was found that these readings were almost unaffected by changes of current density. Nevertheless, the original slow drift of potential again became evident, so it appeared that this treatment could not succeed in preventing formation of films of basic salt.

The addition of sulfuric acid up to a concentration equal to that of the copper salt was next tried with both of the preceding methods but no greater consistency was observed.

(B) The electrochemical methods outlined above having failed to prevent the formation of the basic film, purely chemical methods were next tried. When a strongly acid solution of cupric chloride is treated with metallic copper in excess, the remaining copper appears clean and fairly bright. An attempt was therefore made to prepare a cuprous chloride electrode after the style of the calomel electrode. The above solution was precipitated by the addition of air-free water and washed with normal potassium chloride solution. It was found that the pure white precipitate acquired a yellow stain as soon as the acidity fell below a certain limit even in complete absence of free oxygen, evidently due to hydrolysis of the cuprous chloride. The stain was very slight and the following cell was therefore made up: $Cu | CuCl_2 | M KCl | Hg_2Cl_2 | Hg$. An average value of 0.1385 volt at 20° was obtained, which was fairly constant for two hours, but this rose to over 0.14 volt in forty-eight hours. This change of potential cannot be due to oxidation of the cuprous chloride since that would have lowered the e.m.f. of the cell. Hence, it must be concluded that chemical action is proceeding between electrode and electrolyte. On dismantling the cell, the copper electrode was found to be coated with a dark brown substance. Other relatively insoluble copper salts were tried with similar results and this line of attack was therefore abandoned.

(C) Since chemical and electrochemical methods failed to produce the desired effect, purely mechanical methods were again resorted to. Very rapid stirring of the electrolyte and very rapid rotation of the electrode were found only to retard the rapid change of potential of copper in various solutions of cupric salts. Mechanical cleaning of the electrode while immersed in the electrolyte would be difficult and results obtained would be open to considerable doubts as to the effect of such cleaning on the equilibrium between electrode and its ions. The electrode was therefore arranged in a rotating holder so that it could be easily and rapidly cleaned, and immersed in the electrolyte immediately after. The glass tube leading from a mercurous sulfate electrode in half molar copper sulfate was arranged alongside the freshly cleaned and still rotating copper electrode and immersion of both effected by quickly raising a beaker containing half molar copper sulfate previously placed below the electrodes. Before this was done the electrodes were connected to the potentiometer, which was set as near as possible to the point expected. Raising the beaker then completed the potentiometer circuit and the first direction of movement of the galvanometer was noted. Continued repetition of this process, the electrode being washed, dried and cleaned each time, finally gave a limiting value which could be reproduced with different electrodes repeatedly within a few tenths of a millivolt. The electrodes were in the form of small circular rods or thick wires with flat ends, the upper portions being covered with hard sealing wax; the cleaning was effected with No. 000 emery paper or rouge paper. The final value obtained for the cell $Cu | 0.5\ M\ CuSO_4 | Hg_2SO_4 | Hg$ was 0.3630 ± 0.0005 volt at 20°.

Nielsen and Brown[6] have carried out a series of careful determinations using a two-phase copper amalgam as a standard copper electrode. It appeared of interest, therefore, to compare the above result with such an amalgam electrode. Three samples of copper amalgam were prepared by the electrolysis of acidified copper sulfate solution with a mercury cathode, and after thorough washing and heating to destroy any hydride and expel any adsorbed hydrogen present, were used in the above cell to replace the copper electrode. All three samples gave the value 0.3633 ± 0.0003 volt at 20°. We thus arrive at the conclusion that within the limits of experimental error the single potentials of pure copper and of two-phase copper amalgam are identical. Nielsen and Brown's claims for the two-phase

---

[6] Nielsen and Brown, THIS JOURNAL, 49, **2423** (1927).

amalgam as a standard form of copper are therefore justified in a wider sense than the authors appeared to expect. At first sight it seems remarkable that the presence of a large quantity of mercury should have absolutely no effect upon the single potential of copper but the case is not without parallel. In the case of the hydrogen electrode, the single potential of the base metal—platinum, palladium, etc.—is completely submerged and that of the dissolved and dissociated atomic hydrogen alone determines the observed values.

The action of the mercury in checking the influence of basic films on copper appears to be similar to its action on aluminum, where the softening of the underlying metal allows of easy fracture of the oxide film with consequent exposure of the metal. Formation of a film is not entirely prevented by the mercury in the case of copper amalgam, as may be shown by allowing an amalgam electrode to stand under pure copper sulfate for some hours. A steady drift of potential occurs similar to that in the case of pure copper but very much slower. After a few days a red crystalline deposit appears on the amalgam but the original single potential is restored by stirring the surface. This very slow change of potential of the amalgam is in marked contrast to that of pure copper, where the true single potential is not constant for more than half a second.

The Standard Potential of Copper.—The absolute values obtained in the previous work were not very reliable for two reasons. (1) No thermostat was used owing to mechanical difficulties involved and the room temperature varied ±1° from 20° during the experiments and (2) the mercurous sulfate electrode was not fresh and showed signs of variation. The main conclusion from this work namely, that the single potentials of pure copper and two-phase copper amalgam are identical, is not affected by the above errors; we are therefore justified in using the convenient amalgam for the determination of the standard potential of copper against a normal solution of cupric ions.

This has already been done by Nielsen and Brown with considerable care but one point in their work is open to criticism. They preserved their amalgam under an acid solution of copper sulfate and the presence of this acid may possibly give rise to the appearance of traces of hydrogen in the electrode—a very dangerous impurity. They are well aware of the fact that freshly prepared copper shows abnormally high reducing power but took no precautions to ensure the absence of hydrogen in their amalgam. Their experiments were therefore repeated in the single case of the cell $Cu{\cdot}Hg \mid CuSO_4 \mid 0.5\ M\ Hg_2SO_4 \mid Hg$, using a thermostat adjusted to 25 ± 0.02°. All of the materials used were prepared by methods similar to those used by Nielsen and Brown except that the amalgam before use was heated to near the boiling point of mercury. The value obtained for the above cell in this work was 0.3596 volt, whereas Nielsen and Brown obtained 0.3592 volt. The difference between the two results is so small that it is evident that the amalgam prepared by Nielsen and Brown was free from hydrogen and their results may therefore be accepted as standard values for the pure copper electrode with a considerable degree of confidence.

How far their calculations for the potential of the normal copper electrode are justified is open to doubt since the activity equations break down at such high concentrations. If their value of 0.3502 volt referred to the hydrogen electrode be accepted, then taking the absolute potential of the normal hydrogen electrode as 0.285 volt, the absolute potential of the normal copper electrode will be 0.635 volt as compared with the values 0.60 to 0.62 volt previously given in the literature.

In view of the success of the above work it should be possible to determine the absolute potentials of iron, nickel and cobalt electrodes in the same way. Discrepancies in the values assigned to these metals are far greater than in the case of copper. Work along these lines is already in progress.

Part of the preliminary work was carried out in 1926 at this University by Mr. R. C. MacGaffin, to whom the author tenders his thanks.

Summary

The variations in the single potential of a copper electrode have been traced to the formation of insoluble films of basic cuprous or cupric salts on the electrode surface. These films are produced by the chemical action of the electrolyte upon the metallic copper, more rapidly in the presence of air, and may attain a thickness of 1 millimeter in a few days.

A method is described whereby the single potential of the copper electrode is measured before the film has time to form.

The single potential of a two-phase copper amalgam is identical with that of pure copper but much easier to measure with accuracy. Reasons for this are given.

Nielsen and Brown's work on the two-phase copper amalgam may be accepted as standard for pure copper.

The absolute potential of the normal copper (cupric) electrode is 0.635 volt if that of the normal hydrogen electrode is 0.285 volt.

FERROUS NITROSO COMPOUNDS

BY H. I. SCHLESINGER AND H. B. VAN VALKENBURGH[1,2]

RECEIVED SEPTEMBER 1, 1928 PUBLISHED MAY 6, 1929

When nitric oxide is passed into solutions of ferrous sulfate, the compound $FeSO_4 \cdot NO$ is formed. The work of Manchot,[3] of Kohlschütter,[4] and more recently of Schlesinger and Salathe,[5] has shown that there are two substances, one brown and one red, which have this composition. Schlesinger and Salathe have demonstrated that the brown compound exists in solutions containing up to about 55% acid, and that the red compound exists in solutions of acid concentration greater than 65%.[6] Between these limits the two compounds are apparently in equilibrium with each other.

Manchot has proved that the aqueous or dilute sulfuric acid solutions contain a complex ion of nitric oxide and ferrous iron by demonstrating that this ion travels to the cathode. About the compound existing in concentrated acid solutions, several views have been expressed. Manchot believes that the nitric oxide in the compound is attached to the ferrous sulfate molecule as a whole. Raschig[7] holds that it is a derivative of the hypothetical nitrosi-sulfonic acid, H_2SNO_5, and makes use of this hypothesis in demonstrating his theory of the lead chamber process. Kohlschütter, finally, is of the opinion that the effect of the sulfuric acid is due in part to auto-complex formation and in part to the dehydrating action of the acid. The latter view receives decisive support from the investigation herein reported.

Kohlschütter has already shown that ferrous chloride in alcoholic solutions reacts with nitric oxide, and that the compound formed in the presence of water is brown, like the ferrous sulfate complex, while in the alcoholic solutions a green color is obtained, and that the two have dif-

[6] Manchot and Linckh, *Ber.*, 59, 406 (1926), apparently without knowledge of the earlier work of Schlesinger and Salathe, published data concerning the absorption spectra of various metal–nitroso compounds in different solvents and obtained results in close agreement with those found in this Laboratory. The question of the range of concentration in which the transition occurs was not studied by them.

[7] Raschig, *Z. angew. Chem.*, 18, 1281 (1905); *J. Soc. Chem. Ind.*, 30, 166 (1911).

ferent absorption spectra. The spectra obtained visually by Kohlschiitter are not accurate enough to be of use in deciding definitely whether they are of the same character as those of solutions of the ferrous sulfate–nitric oxide complex, or to determine at what concentration the transition from one compound to the other occurs. Photographs taken by us answer these questions more satisfactorily.

In Fig. 1 are shown the absorption spectra of the compound FeCl$_2$·NO when dissolved in water, in water alcohol mixtures and in absolute alcohol. An absorption band extending approximately from oscillation frequencies 1920 to 2320 is shown in 30, 70 and 90% alcohol. In the aqueous solution the band is somewhat narrower, but its right-hand margin and the region of maximum transmission are the same as for the alcohol–water mixtures. The slight difference observed may be accounted for by the fact that in solutions containing water the concentration of the complex is lower than in alcoholic solutions because its stability decreases as the concentration of alcohol decreases. Consequently at a given nitric oxide pressure (atmospheric in our experiments) less of the ferrous chloride is converted into the complex than in the solutions containing more alcohol. This fact also explains the greater depth of the band in alcoholic solutions. When absolute alcohol is used the band is definitely different from all of the others, showing with respect to them a displacement toward the red of both margins and of the region of maximum transmission.

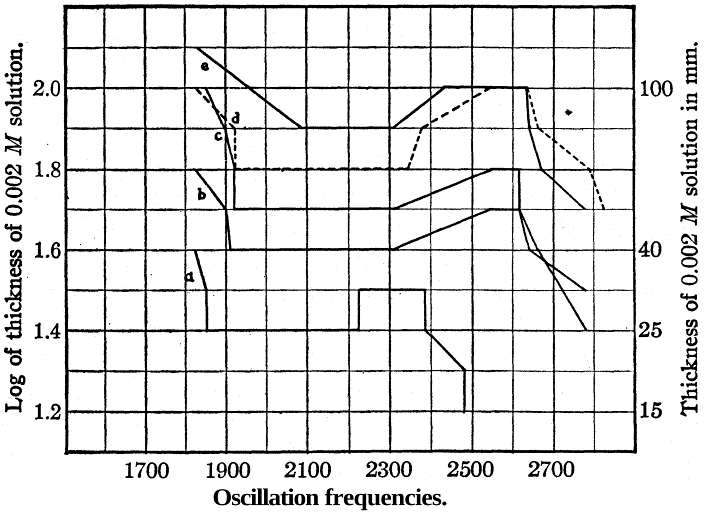

Fig. 1.--0.002 M FeCl$_2$·NO in alcohol of following concentrations: a = absolute, b = 90%, c = 70%, d = 30%, e = water solution.

Comparison of these spectra with those obtained by Schlesinger and Salathe[6] reveals several significant facts. As shown in Fig. 2, the spectra of the dilute alcoholic solutions of the complex $FeCl_2 \cdot NO$ are practically identical, so far as location of the band is concerned, with those of the less strongly acid solutions of the compound $FeSO_4 \cdot NO$. The slight differences which exist are unquestionably due in part to the difficulty of obtaining exact measurements of solutions so subject to contamination with actinic substances as are those under investigation, and in part to difference in the stability of the two solutions. The second point to be considered is

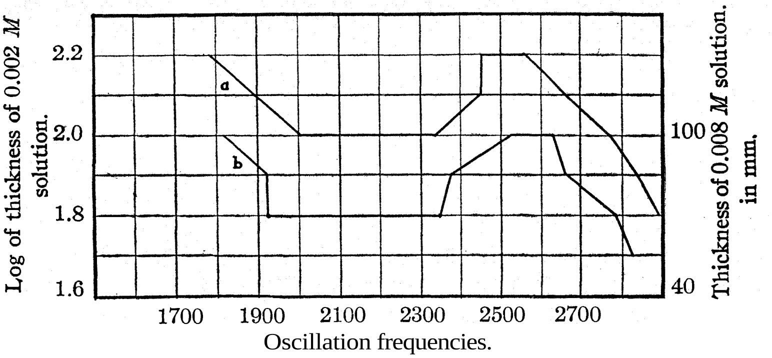

Fig. 2.—a = 0.0125 M $FeSO_4 \cdot NO$ in 45% H_2SO_4, after Schlesinger and Salathe; b = 0.002 *M* $FeCl_2 \cdot NO$ in 30% C_2H_5OH.

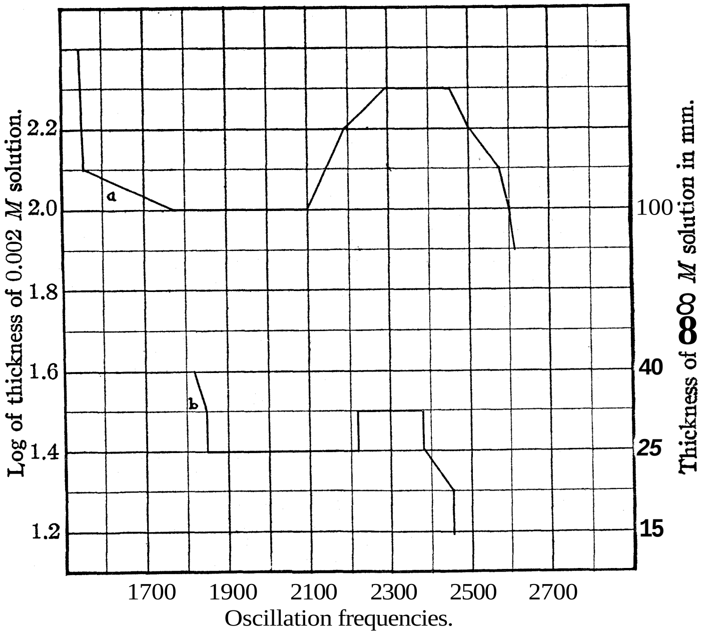

Fig. 3.—a = 0.0125 M $FeSO_4 \cdot NO$ in 93.1% H_2SO_4, after Schlesinger and Salathe; b = 0.002 M $FeCl_2 \cdot NO$ in absolute alcohol.

that both in the alcoholic solutions of $FeCl_2 \cdot NO$ and in the acid solution of $FeSO_4 \cdot NO$, decrease in the amount of water causes a similar shift in the absorption spectrum. It is true that the band in the concentrated sulfuric acid is not identical with that in absolute alcohol (See Fig. 3), a fact which will be discussed more fully below; but the spectra and their changes are sufficiently similar to point to the conclusion that the sulfate ion is not concerned in the reaction. They seem therefore to contradict the view of Raschig[7] that a salt of nitrosi-sulfonic acid is involved.

On account of the slight but definite differences between the spectra of $FeCl_2 \cdot NO$ in absolute alcohol and of $FeSO_4 \cdot NO$ in concentrated sulfuric acid, the results just described do not settle the problem definitely; hence we undertook a study of the behavior of the compound $FeHPO_4 \cdot NO$, the preparation of which has been described by Manchot.[8] In aqueous solutions it has the brown color characteristic of aqueous and slightly acid solutions of $FeSO_4 \cdot NO$. If phosphoric acid is added, the color changes and finally becomes cherry-red as the phosphoric acid becomes very concentrated. To show that this phenomenon is analogous to that with the sulfate, it is necessary to demonstrate that the change in color is not accompanied by a change in the ratio of ferrous salt to nitric oxide. For this purpose the procedure of Manchot was used; that is, as shown in Table I, the amount of nitric oxide absorbed per gram molecule of ferrous phosphate was determined, due allowance being made for the solubility of the gas in the concentrated acid used as solvent.

						Av.	22.2

The data in the sixth column of the table represent the total volume of nitric oxide absorbed by the solution at the temperature and pressure indicated. The data in Col. 7 give the volume of nitric oxide, referred to standard conditions, absorbed by the ferrous phosphate alone; allowance

---

[8] Manchot, *Ber.*, 47, 1601 (1914).

is made for the solubility of the gas in the acid on the assumption that this solubility is the same in the solution as it is in the pure solvent. The solubility of nitric oxide in concentrated phosphoric acid, referred to standard conditions, was found to be 16.9 cc. per 100 g. of acid.

The fact that 22.2 liters of nitric oxide, referred to standard conditions, are absorbed, on the average, per gram atom of iron shows that the formula of the red compound, like that of the brown one, is $FeHPO_4{\cdot}NO$, except for the possibility of hydration, which will be discussed below. The variation in the data of Col. 8 is due to experimental error, as shown by the fact that it is entirely unrelated to changes in concentration of the solutions. The experimental difficulty is a secondary reaction of the nitric oxide with the ferrous salt, for if nitric oxide is passed through the solution for some time, the color entirely disappears as a result of oxidation of ferrous to ferric salt. It is, therefore, difficult to be sure that the solution is neither unsaturated nor treated with an excess of the gas.

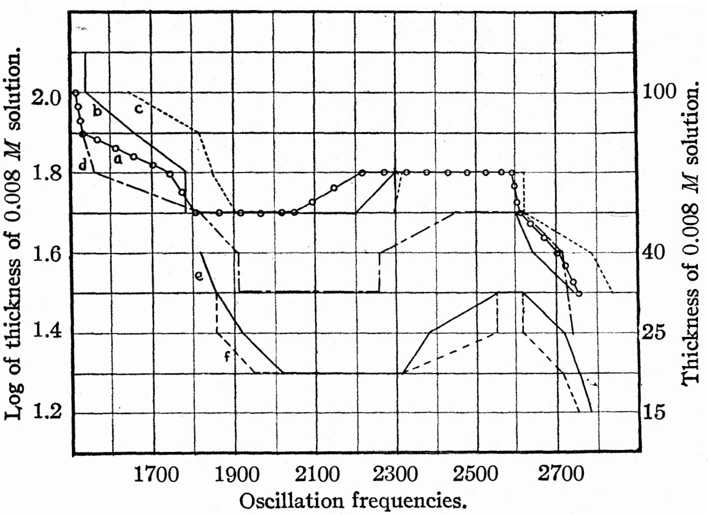

Fig. 4.—0.008 *M* $FeHPO_4{\cdot}NO$ in H_3PO_4 of following concentrations: a = 90%, b = 85%, c = 70%, d = 60%, e = 20%, f = 10%.

The absorption spectra of ferrous phosphate saturated with nitric oxide in solutions containing various amounts of phosphoric acid are shown in Fig. 4. The absorption band in solutions of 88 to 90% acid is almost identical in position with that of $FeSO_4{\cdot}NO$ in solutions of sulfuric acid stronger than 65%. As the phosphoric acid becomes more dilute the absorption band widens and shifts toward the violet end of the spectrum, as is the case when the concentration of sulfuric acid in solutions of $FeSO_4{\cdot}NO$ is decreased. In aqueous and dilute acid solutions the absorption spectra of the ferrous sulfate complex are again almost identical with those of the ferrous phosphate complex. For comparison Fig. 5 is reproduced from the work of Schlesinger and Salathe.

A study of the composition of the solvent in which the transition from one type of compound to the other occurs reveals a very significant relationship between the beginning and the completion of the shift of the absorption band and the aqueous tension of the solvent. The data for the latter could not all be found for the temperature at which our work was done. Consequently, the comparison for phosphoric and sulfuric acids is made at 0°, while the comparison of the sulfuric acid with the alcoholic solutions is made at 25°. There seems to be no reason to believe that the conclusions reached are, in any important way, affected by the discrepancy. In sulfuric acid the shift begins in 55% solution which has an aqueous tension at 0° of 1.04 mm., and is complete in 65% acid in which the aqueous tension is 0.36 mm. To have these same aqueous tensions phosphoric acid solutions must be, respectively, 68 and 88%, and it is exactly in this range that the transition occurs for the ferrous phosphate-nitric oxide complex. The solutions of sulfuric acid just mentioned have at 25° aqueous tensions of 6.5 mm. and 2.75 mm., respectively. These aqueous tensions are reproduced by 94 and 97% solutions of alcohol. Our observations show that the transition of the complex $FeCl_2 \cdot NO$ begins when the concentration of the alcohol is above 90% and is complete in absolute alcohol.[9]

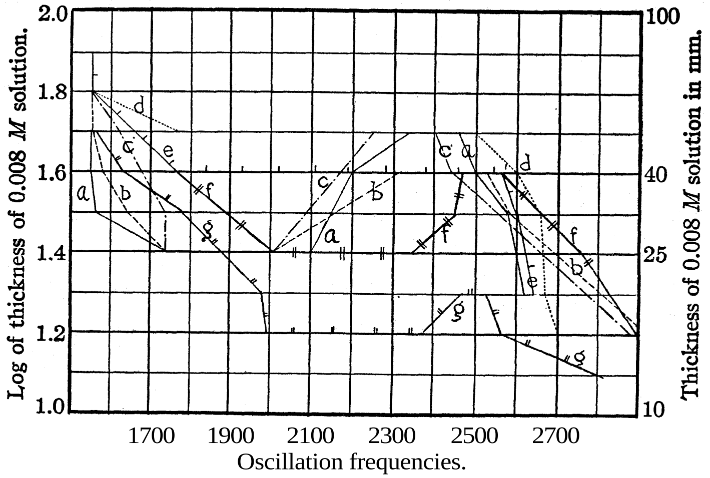

Fig. 5.—0.0125 M $FeSO_4 \cdot NO$ in H_2SO_4 of following concentrations: (taken from the work of Schlesinger and Salathe) a = 93.1%, b = 82.3%, c = 71.5%, d = 65.0%, e = 59.4%, f = 45.0%, g = 0%.

---

[9] The data for the aqueous tensions of the acid solutions are taken from Landolt-Börnstein, "Physikalisch-Chemische Tabellen," 5th ed., p. 1395, and those for the alcoholic solutions from Foote and Scholes, THIS JOURNAL, 33,1309 (1911).

The foregoing offers strong support for the conclusion that the transition in the three pairs of compounds having, respectively, the empirical formulas $FeSO_4 \cdot NO$, $FeHPO_4 \cdot NO$ and $FeCl_2 \cdot NO$, is in no way related to the nature of the negative ion but is determined by the activity of the water in the solution. The influence of the water is best explained by the assumption that in dilute aqueous solutions the positive ion in each case is $[Fe \cdot NO \cdot (H_2O)_x]^{++}$ and that the action of sulfuric acid, of phosphoric acid and of alcohol consists in removing all or part of the water in the complex ion. It is of interest to note that when Manchot attempted to prepare the solid brown compound $FeNOSO_4$ by precipitation with alcohol, he obtained a crystalline product containing ferrous sulfate and a much larger amount of water than that due to hydration of the ferrous sulfate present. Manchot also prepared the solid complex of nitric oxide and ferrous phosphate but the analytical data given by him refer only to the ratio NO:Fe and cannot be used to determine whether the salt is hydrated. On the other hand, Manchot and Linckh[10] found that the solid brown complex of ferrous selenate and nitric oxide, when precipitated from solutions containing water, alcohol and acetone, has the formula $FeSeO_4 \cdot NO \cdot 4H_2O$. These facts confirm the idea that in aqueous solutions hydrated complex ions are present; they cannot, however, be accepted as guides to judge of the formula of the complex.

That this is not the only factor involved in the alcoholic solutions of the ferrous chloride–nitric oxide complex is shown by the fact that the absorption spectrum of this substance in absolute alcohol is not quite identical with that of the solutions of complexes with the phosphate and the sulfate in the concentrated acids. According to Kohlschiitter the nitric oxide in alcoholic solutions of $FeCl_2$ is at least in part attached to a negative ion which also contains iron. He has therefore assumed that ferrous chloride is associated into $FeFeCl_4$ in these solutions, and that the nitric oxide reacts with the ion $FeCl_4$.[11] Our work does not bear on this phase of the problem. It does, however, emphasize the fact that dehydration of the aquo ion precedes formation of the chloro ion. This agrees with what is known to happen in the formation of the $CuCl_4$-ion from the hydrated cupric ion. The great similarity in the absorption spectra of $FeSO_4 \cdot NO$ in concentrated sulfuric acid and of $FeHPO_4 \cdot NO$ in concentrated phosphoric acid seems to indicate that the dehydrating action is the only function of the acids in these cases and that no complex ion containing iron, nitric oxide and the simple negative ion is formed. This

[10] Manchot and Linckh, *Z. anorg. allgem. Chem.*, **140,** 37 (1924).

[11] Our results explain why, in transference experiments, nitric oxide in alcoholic ferrous chloride solution is transported both to the anode and to the cathode. Since the transition from one type of compound to the other is not complete except in nearly 100% alcohol, the presence of water from the layer of diluted alcohol used causes a partial formation of the hydrated complex ion.

conclusion is supported by the fact that Kohlschiitter observed no transport of nitric oxide toward the anode in concentrated sulfuric acid solutions of $FeSO_4 \cdot NO$.[12]

An investigation was made to determine whether similar phenomena could be observed with other salts. Accordingly, the spectra of the following solutions were photographed before and after saturation with nitric oxide: nickel, cobalt and cadmium sulfates in water and sulfuric acid; cadmium chloride in water and in hydrochloric acid; nickel and cobalt chlorides in absolute alcohol. Cadmium chloride was studied because of its great tendency to form complexes, and cobalt and nickel sulfates because of the reports in the literature[13] that they dissolve appreciable quantities of nitric oxide. The spectrograms, however, failed to reveal even traces of complex ions in the solutions.

Experimental

It is not necessary to discuss in detail the experimental procedures because, in general, the methods and apparatus described by Schlesinger and Salathe were employed. The data obtained with the quartz spectrograph were in some instances supplemented by visual observations in the spectral region, for which the quartz instrument has small dispersion. Ferrous chloride was prepared by passing dry hydrogen chloride over hot iron wire in the absence of oxygen and was purified by sublimation. The product dissolves more slowly in concentrated than in dilute and very slowly in absolute alcohol, but no difficulty was encountered in finally obtaining solutions of the desired concentration. For the preparation of ferrous phosphate the method of Evans[14] was first tried but the analysis showed that only 79% of the iron in the product was in the ferrous condition, and the method was abandoned in favor of that of Debray.[15] Phosphoric acid of the desired concentration was obtained either by diluting the 85% acid with water or by heating it for several hours at 110–115° to obtain the stronger solutions. Weighed amounts of pure iron wire were then dissolved in the acid while a stream of oxygen-free hydrogen was passing through the solution. Thus were obtained solutions of ferrous salt free from ferric compounds and of the desired concentration. The solutions were then forced into the Baly tubes by a stream of hydrogen. The precautions mentioned by Schlesinger and Salathe for preventing access of oxygen to the tubes during the observations were taken.

Summary

Absorption spectra of the complexes formed by ferrous phosphate with nitric oxide in solutions of phosphoric acid of various concentrations, and by ferrous chloride with nitric oxide in alcohol solutions of various concentrations, have been photographed and found to be almost identical with those of the ferrous sulfate–nitric oxide complex in sulfuric acid.

---

[12] Too great stress, however, must not be placed on the transference experiments in concentrated sulfuric acid. In these solutions the conductance of the solvent is so high that only a small fraction of the current is carried by the solute, which is present in relatively small amounts.

[13] Hiifner, *Z. physik.* Chem., 59,416 (1907); Usher, *ibid.*, **62,022** (1908).

[14] Evans, ***Pharm.* J.**, [4] 4,141 (1897).

[15] Debray, *Ann. chim.*, **[3]** 61,437 (1861).

The shift of the absorption band toward the violet end of the spectrum, which occurs with increasing dilution of sulfuric acid solutions of ferrous sulfate saturated with nitric oxide, also occurs on diluting phosphoric acid solutions of ferrous phosphate, and alcohol solutions of ferrous chloride saturated with nitric oxide. This shift of the absorption band indicates a transition of one compound into another. The transition of the three pairs of compounds having, respectively, the empirical formulas $FeSO_4 \cdot NO$, $FeHPO_4 \cdot NO$, $FeCl_2 \cdot NO$ is probably determined in each case by the activity of the water in the solutions, that is, the transition occurs when the aqueous tensions of the solutions reach the same numerical value. This condition obtains when the concentrations of the three solvents H_2SO_4, H_3PO_4 and C_2H_5OH are, respectively, about 65, 88 and 97%.

The function of the concentrated acids and alcohol is probably largely that of dehydrating the complex ion which exists in dilute solutions.

TEMPERATURE–CONDUCTANCE CURVES OF SOLID SALTS. II. HALIDES OF POTASSIUM AND THALLIUM

BY T. E. PHIPPS AND E. G. PARTRIDGE[1]

RECEIVED SEPTEMBER 6, 1928 PUBLISHED MAY 6, 1929

In a recent investigation[2] of temperature–conductance curves of the solid halides of sodium, the data in most cases showed two distinct slopes when plotted to the axes log k (logarithm of specific conductance) against $1/T$ (reciprocal of the absolute temperature). In the discussion of these data it was assumed that the conductance of the solid is proportional only to the number of ions in its lattice which have an energy greater than a certain threshold value and, further, that the mobility of these ions is nearly independent of the temperature. With these assumptions it was shown that the slope of the log k–$1/T$ curve may measure the threshold energy (designated as heat of liberation) which the conducting ion or ions must acquire in order to participate in the conduction process. To explain the existence at higher temperatures of a second slope, which was within experimental error double the slope at lower temperatures it was assumed[3] that at higher temperatures both ions take part in the conduction

---

[1] This paper is an abstract of a thesis submitted by E. G. Partridge in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[2] Phipps, Lansing and Cooke, THIS JOURNAL, 48, 112 (1926).

[3] A subsequent investigation by Phipps and Leslie [*ibid.*, 50, 2412 (1928)] of transference numbers in solid sodium chloride at high temperatures gives definite evidence that both ions conduct at high temperatures.

process. At low temperatures experimental evidence has already been adduced in the case of sodium chloride that only the sodium ion conducts.[4]

In continuing this work it seemed desirable first to test the adequacy of the log k–$1/T$ relation to represent experimental data for uni-univalent salts of widely different polarity, and thus to determine whether or not the concept of heat of liberation of the conducting ion is a fundamental one. Second, if heat of liberation appears to be a fundamental lattice property, it is of interest to discover its possible relation to other lattice quantities such as the natural quantum of the lattice, the lattice energy and the property vaguely designated as polarity.

We may state briefly the principal results of this investigation. The log $k-1/T$ relation is judged to be adequate to represent the conductance data of both potassium and thallous halides. The two-slope behavior found previously for sodium halides also characterizes the conductance curves of potassium halides. Thallous halides show a single slope only. The heat of liberation of the potassium ion decreases in the series chloride to iodide, as in the sodium series. The heat of liberation of the potassium ion is distinctly greater than that for the sodium ion in the corresponding halide. An approximately linear relation exists in the sodium and potassium series between heat of liberation and melting point.

Experimental

Apparatus.—The conductivity apparatus was similar to that used previously except that the base was made from a large nickel disk about 6.5 cm. in diameter and 3.0 cm. in thickness, recessed to a depth of 1.5 cm. The diameter of the recessed hole was about 3.6 cm. This large mass of nickel served to smooth out temperature fluctuations of the furnace more effectively than had been the case with the old apparatus. An alternating current Wheatstone bridge method was used for resistances up to one megohm. For greater resistances the d. c. bridge method employed in the previous investigation was unsatisfactory due to the large polarization which it produced in the crystals. Accordingly a d. c. deflection method was adopted in which a variable e.m.f. and a high sensitivity galvanometer (figure of merit 7.76×10^{-10}, resistance 500 ohms, critical damping resistance 10,800 ohms) and a reversing switch were put in series with the crystal, the e.m.f. being so regulated that the amount of current flowing in the circuit was of the order of 10^{-8} amps. For resistances between 10^5 megohms and 50 megohms, voltages from 100 to 2 volts were obtained from radio "B" batteries, and for resistances between 50 and 10 megohms the variable e.m.f. in the circuit was replaced by a potentiometer source. At resistances greater than 30 megohms, reversal of the current through the crystal usually gave equal deflections in opposite directions. Between 30 and 10 megohms the deflections were often unsymmetrical and erratic, so that the d. c. points in this range are not considered reliable. This erratic behavior is due largely to polarization, and perhaps in part to the fact that unavoidable thermal e.m.f.'s became appreciable in this range in comparison with the applied e.m.f.

A platinum–platinum-rhodium thermocouple and Weston Universal potentiometer were substituted for the two-junction chromel–alumel couple and extended Student Type potentiometer used in the previous investigation. The temperature could be

---

[4] V. Seelen, Z. *Physik*, 29, 125 (1924).

kept constant to about 0.1°. Calibration of the noble metal couple on three occasions during the investigation, at the steam point, sulfur point and melting points of potassium chloride and potassium sulfate, showed a maximum variation of 0.7° at the fixed points and an average variation of 0.3°.

Materials.—The thallous halides were prepared from an old stock of Kahlbaum's thallous acetate by precipitation with the appropriate halogen acid. The work was carried out in a dark room as the thallous halides are sensitive to light. The acids were distilled in an all-pyrex apparatus and the middle fraction was used for the precipitation. The precipitates were washed thoroughly with conductivity water, dried, fused and poured into a clean iron die. The plunger was quickly inserted into the die after the pouring, and given a light tap with a hammer to form the pellet. Very satisfactory homogeneous pellets resulted. These were kept in dark glass bottles.

The potassium salts were "reagent quality" or "C. P." stock, recrystallized in all cases twice or thrice from conductivity water.

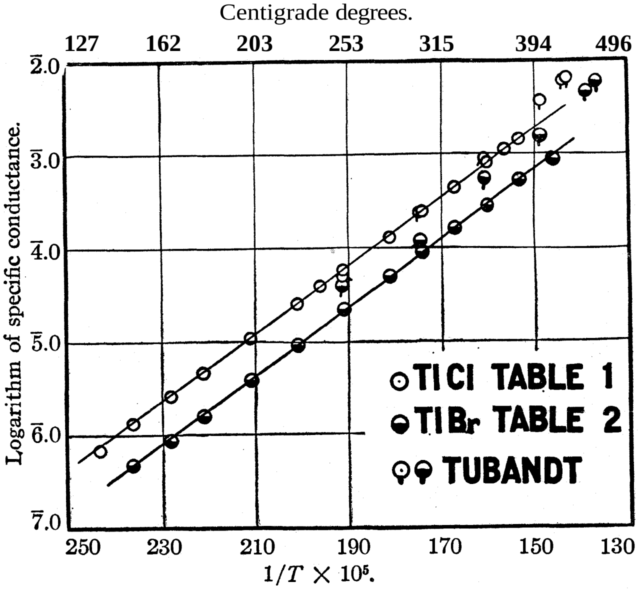

Fig. 1.—Conductance of thallous chloride and thallous bromide.

Preparation of Crystals and Pellets.—Crystals of potassium chloride and potassium bromide were grown by the method of Tammann and Veszi.[5] Visually perfect crystals from 0.5 to 1.0 cm. on edge, and 0.3 to 0.5 cm. thick were obtained. Attempts to grow crystals of potassium iodide were unsuccessful. Pellets of all the halides of potassium were made in a die with a specially hardened steel plunger at pressures of 230,000 lb. per sq. in. (16,200 kg. per sq. cm.). These pressures were somewhat higher than those applied in the case of sodium halides previously, since it was hoped that higher pressures would produce bodies which in their conduction process would approach more nearly to single crystal lattices. All three[6] halides gave translucent pellets. The bromide was more nearly transparent than the others.

---

[5] Tammann and Veszi, Z. *anorg. allgem. Chem.*, *150,* 355 (1926).

[6] On account of the hygroscopic character of potassium fluoride it could not be handled satisfactorily in the present apparatus and no data for it appear here.

Experimental Results

Thallous Halides.—In Figs. 1 and 2 are plotted the data for one run on each of the halides of thallium. These curves indicate the adequacy of the log *k*–1/*T* relation to represent the experimental data in these cases. For all the thallous halides the conductivity readings were very distinct and reproducible. This high degree of reproducibility is a matter of interest. It seems to indicate that polarization may depend upon lattice rigidity and may vary in degree on passing from the brittle polar salts, where restoring forces are strong, to the waxy salts where these forces are relatively weak. The change in crystal form in thallous iodide is strikingly shown in Fig. 2.

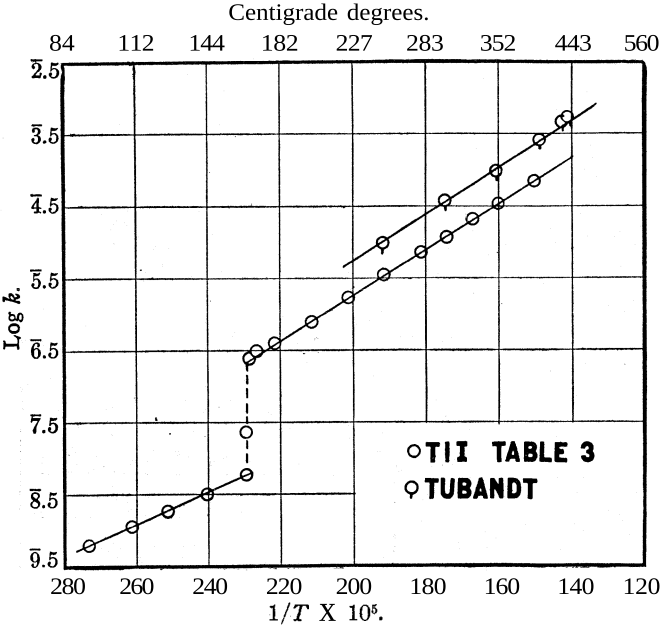

Fig. 2.—Conductance of thallous iodide.

Table I

Thallous Chloride

1/*T* × 10^5	153	156	160	167	174	181	191
Log k	$\bar{3}.152$	$\bar{3}.045$	3.910	$\bar{4}.643$	$\bar{4}.391$	$\bar{4}.110$	$\bar{5}.762$
1/*T* X 10^5	196	201	211	221	228	236	243
Log *k*	$\bar{5}.585$	$\bar{5}.405$	$\bar{5}.033$	$\bar{6}.662$	$\bar{6}.408$	$\bar{6}.120$	$\bar{7}.833$

The heat of liberation calculated from the above data was 11.57 × 10^{-13} ergs per ion. Two other independent runs under identical conditions gave the values 11.50 and 11.38 X 10^{-13}. The average for the three runs was 11.48 X 10^{-13}.

TABLE II

THALLOUS BROMIDE

$1/T \times 10^5$	146	153	160	167	174	181

			(a.c.)	(d.c.)					

The heat of liberation from the above data for the upper slope was 10.2 X 10^{-13} ergs per ion and for the lower slope 6.6 X 10^{-13}. Two other runs under identical conditions gave for the upper slope 10.2 and 9.7 × 10^{-13}. The average of three runs gave for the upper slope 10.0 X 10^{-13}.

Potassium Halides. A. C. Values in the Transition Range.—In Fig. 3 it will be noted that the a. c. points veer off at a temperature of about 550° from the straight line upon which the high temperature points lie, and that the a. c. curve becomes almost horizontal at about 350". Tammann and Veszi's points for potassium chloride crystal show a similar behavior. However, these investigators did not follow the curve lower than a temperature of 520°, and it is below this temperature that the anomalous behavior of the a. c. conductance values becomes most striking. A similar example of the a. c. anomaly may be seen in Fig. 5, in the case of potassium bromide crystals. A complete explanation of this behavior is lacking. It was thought at first that large high-frequency currents might be carried by a capacity effect in the crystal. However, calculation showed that the fraction of the total current which could be carried by the capacity effect (even with an assumed dielectric for the salt as great as 20) is negligibly small when 1000-cycle current is used as in the present case. The suggestion has been made that these abnormally high a. c. conductances may be explained as due to a carrying of high-frequency overtones of the alternating current by oscillation of the ions of the lattice. As lending slight experimental support to this suggestion, it may be seen that the a. c. anomaly in the transition range is less marked in the case of conglomerates (pellets) (see Figs. 4, 6 and 7) than in the case of crystals (Figs. 3 and 5). Oscillation currents would be expected to be greater in the more perfect lattice of the crystal than in the conglomerate. It is significant that the anomalous a. c. values occur in the temperature interval where we have evidence from transference numbers that the conduction process is changing from uni-ionic to bi-ionic conduction. It is possible that the impressed a. c. affects the transition from one type of conduction to the other. The conclusion of Tammann and Veszi that the log k–T relation represents the course of the conductance curve in the high temperature range better than the log k–1/T relation will perhaps need to be modified if due account is taken of the a. c. anomaly.

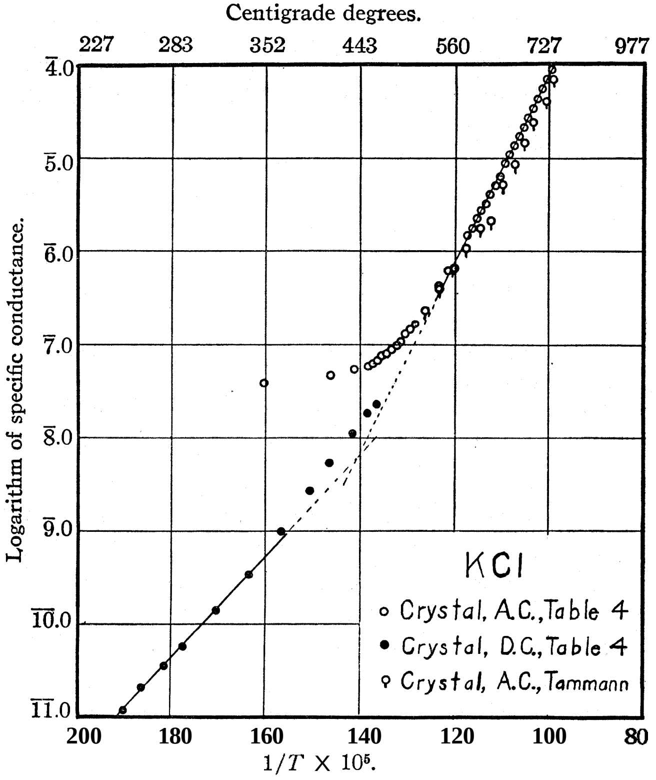

Fig. 3.—Showing (1) anomalous a. c. behavior; (2) the one-half relation between the lower and upper slopes; (3) Tammann and Veszi's crystal data.

100	$\bar{5}.861$	136	$\bar{7}.536$	181	$\bar{9}.348$
103	$\bar{5}.550$	141	$\bar{7}.346$	177	$\bar{9}.523$
106	$\bar{5}.270$	146	$\bar{7}.168$	172	$\bar{9}.751$
108	$\bar{5}.097$	206	$\overline{10}.218$	167	$\bar{9}.973$
111	$\bar{6}.860$	201	$\overline{10}.441$	162	$\bar{8}.191$
116	6.524	196	$\overline{10}.679$	156	$\bar{8}.446$
121	6.226	191	$\overline{10}.901$	150	8.699
126	$\bar{7}.971$				

The heat of liberation from the above data for the upper slope was 30.5 and for the lower slope 14.2 × 10^{-13} ergs per ion. Three other runs under identical conditions gave for the upper slope 30.0, 30.3 and 30.3 X 10^{-13}, and another run gave for the lower slope 15.2 X 10^{-13}. The average of four values for the upper slope was 30.3 × 10^{-13}, and the average of two runs for the lower slope was 14.7 × 10^{-13}.

D. C. Values in the Transition Range.[7]—It will be noted in Pig. 3 that at the lowest temperatures (250–350°) the d. c. points lie upon a straight line, but between 350 and 450° they diverge considerably in the direction of conductance greater than the expected. In this transition region of temperature, namely, 350 to 500° for potassium chloride and 300–450° for potassium bromide (Fig. 5), there is probably a profound change in the conduction process. The polarization e.m.f. is no longer negligible com-

[7] Since this account was written the treatment by Joffe [Joffe, "The Physics of Crystals," McGraw-Hill Book Co., New York, 1928, p. 75 ff.] of the polarization e.m.f. in crystals has come to the attention of the writer. Adequate data are not at hand for correcting our transition range values according to his methods. Below the transition range the polarization is undoubtedly negligible compared with the applied potential.

pared with the applied e.m.f., and the course of the curve is very uncertain throughout this range.

TABLE VI

POTASSIUM BROMIDE CRYSTAL

193	$\bar{9}.461$	109	$\bar{5}.344$	150	$\bar{7}.540$

The heat of liberation from the above data for the upper slope was 29.4 X 10^{-13} ergs per ion and for the lower slope 14.7 × 10^{-13}. Another run under identical conditions gave for the upper slope 29.0 and for the lower slope, 14.1 X 10^{-13}. The average of the two runs for the upper slope was 29.2 and for the lower slope 14.4 X 10^{-13}.

Differences between Conduction in Crystals and Pellets.—Figures 4 and 6 show the difference in conductance between pellets and crystals. The discrepancy is seen to be greater at lower temperatures, the pellet tending to have a slightly lesser slope. It will be noted in all of these cases that the uncertainty of the d. c. points in the transition range is less for the pellets than for the crystals. It seems to be generally true that polarization is less in the conglomerate than in the crystal. This is readily seen by comparing pellets of potassium chloride (Fig. 4) with crystals of potassium chloride (Fig. 3). In the case of the pellet the d. c. points fall regularly on a straight line to conductances greater than 10^{-8}, while in the case of the crystal there is a marked deviation even at conductances less than 10^{-9} reciprocal ohms. A second striking difference between the behavior of crystal and pellet is that the change in slope (and presumably the change in the conduction process also) occurs at a much higher temperature for the pellet than for the crystal. For example, in Fig. 3 for the crystal the intersection of the two slopes (produced) is at approximately 440°. On the other hand, in Fig. 4 for the pellet the corresponding intersection comes at a temperature of approximately 570°. Similarly for the potassium bromide crystal in Fig. 5 the intersection comes at

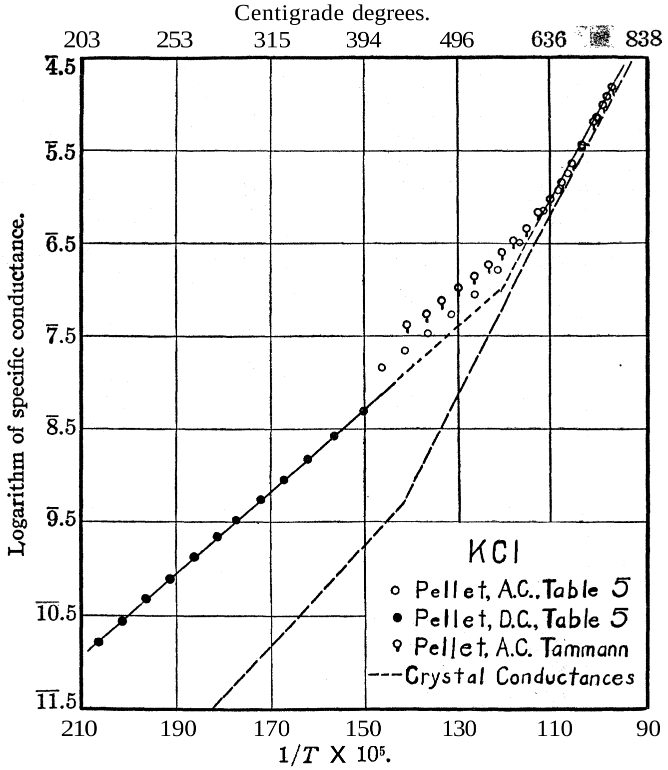

Fig. 4.—Showing (1) the higher conductance and lesser slope of pellets as compared with crystals at lower temperatures; (2) the merging of pellet and crystal data at higher temperatures; (3) Tammann and Veszi's pellet data.

approximately 370 and for the potassium bromide pellet in Fig. 6 it comes at about 600°. A third point of difference between pellet and crystal is that the heat of liberation is slightly less for the pellet than for the crystal. This is shown in Table IX. Potassium chloride crystals, for example, show values of 15.7 and 32.1 × 10^{-13} ergs/ion, calculated from the lower and upper slopes, respectively. The corresponding values for potassium chloride pellets are 14.7 and 30.3 × 10^{-13} ergs/ion.

143	$\bar{7}.358$	107	$\bar{5}.994$	146	$\bar{7}.483$
144	$\bar{7}.311$	108	$\bar{5}.903$		

The heat of liberation from the data of Pellet No. 1 for the upper slope was 24.0 and for the lower slope, 12.5 × 10^{-13} ergs per ion. For Pellet No. 2 the upper slope gave 25.6 and the lower slope 13.0 X 10^{-13}. Another run under identical conditions gave for the upper slope 27.5 and for the lower slope 15.0. The average of the three runs gave for the upper slope 25.7 and for the lower slope 13.5 × 10^{-13}.

Discussion of Results

The Conduction Process.—Two slopes were found for all the halides of sodium and potassium investigated, with the exception of sodium fluoride.[8] Single slopes only were found for thallous chloride and bromide.

---

[8] The anomalous behavior of sodium iodide and sodium fluoride in the neighborhood of the melting point, reported in the previous paper, is now thought to be due to impurities. Extremely pure sodium iodide and potassium iodide failed to show the sudden rise in conductance reported for sodium iodide.

Two slopes were found for thallous iodide, but in this case it is well known that the change in slope arises from a change in crystal form. In the case of all of the halides of sodium and potassium which exhibit two slopes, the upper slope is approximately double the lower slope. That the conduction at lower temperatures is due to the alkali metal ion only is shown by the transference experiment of v. Seelen[4] upon sodium chloride at 400°, and by the transference experiments of Phipps and Leslie[5] upon sodium chloride between 410 and 510°. Indirect evidence pointing to the same conclusion is seen in the work of Schmidt,[9] who found at lower temperatures that one ion only (usually the positive ion) was emitted from solid salts. At higher temperatures Schmidt found that both ions were emitted from solid salts in nearly all cases. In agreement with this, transference data now available[3] for sodium chloride between the temperatures of 558 and 655° indicate that both ions take part in the conduction process over this range of temperature.

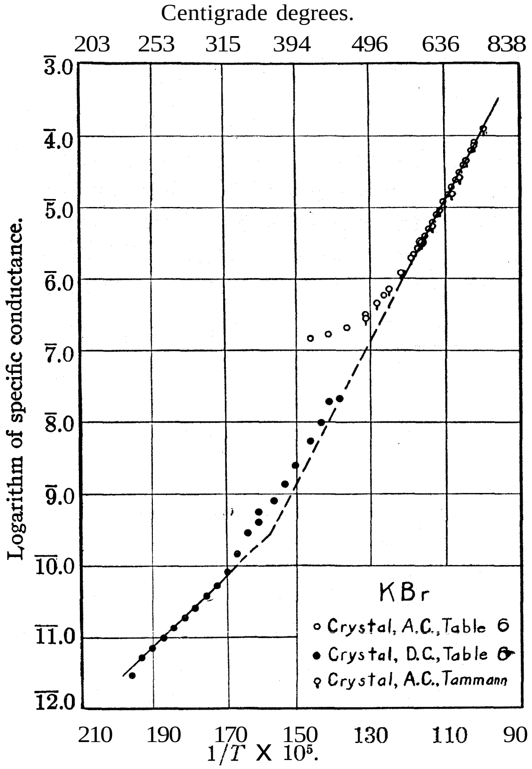

Fig. 5.—Showing (1)the one-half relation between lower and upper slopes; (2) deviation of both a. c. and d. c. points at intermediate temperatures; (3) Tammann and Veszi's crystal data.

Change from uni-ionic to bi-ionic conduction is exhibited by the chlorides, bromides and iodides of both sodium and potassium. This phenomenon appears to be characteristic of, and perhaps limited to, high-melting polar salts, since it is not shown by the halides of silver, thallium or lead.

The Adequacy of the Log *k*-1/*T* Relation.—The log k–1/T relation fits the data admirably in the case of the thallous halides over a range of temperature from 150° to temperatures within 30" of their melting points. In the case of the potassium halides we have already pointed out the need for caution in accepting the results of either an a.-c. or an uncorrected

TABLE IX

ILLUSTRATING DIFFERENCES BETWEEN HEATS OF LIBERATION IN CRYSTALS AND IN PELLETS

		$\epsilon \times 10^{13}$ ergs/ion	
Salt	Form	Lower slope	Upper slope
KCl	Crystal	15.7	32.1
	Pellet	14.7	30.3
KBr	Crystal	15.4	31.3
	Pellet	14.4	29.2
KI	Crystal	..	..
	Pellet	13.6	25.7

d.-c. method in the transition range where the conduction process is changing, and where polarization effects are greatest. If greater weight is given to the points in the two regions where reproducibility of measurement is the greatest, namely, to those a.-c. points which are well above

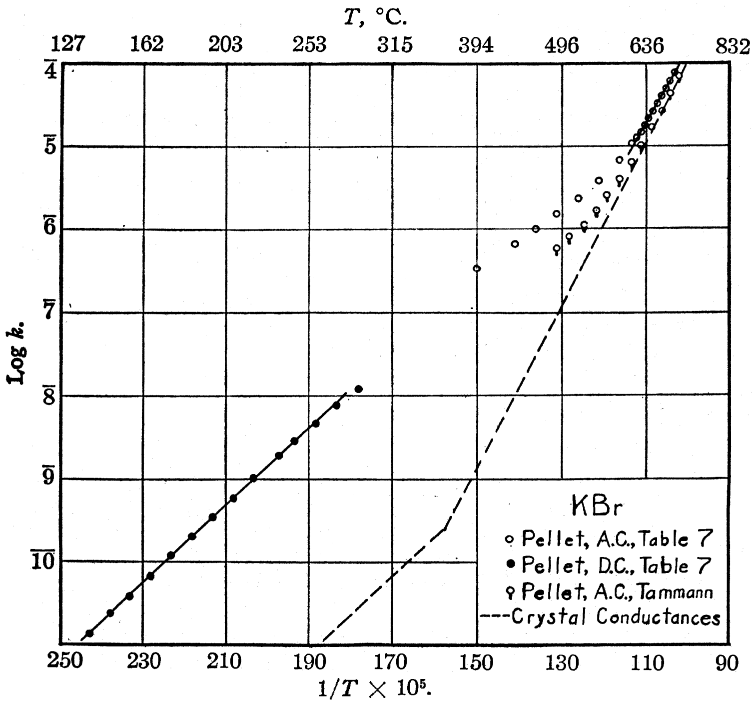

Fig. 6.—Showing (1) the one-half relation between lower and upper slopes; (2) higher conductance of pellet as compared with crystal; (3) Tammann and Veszi's pellet data.

the transition range, and to those d.-c. points which are well below it, the log k–$1/T$ relation is entirely adequate. The remarkable success of the log k-$1/T$ relation in the thallous series where polarization is a minimum and the conduction process uniform, gives us considerable confidence in its application to the less regular data of the polar salts where marked polarization accompanying the change in the conduction process has hitherto caused doubt in the choice between the log $k-1/T$ and the log k–T relation.

Heats of Liberation.—In Table X are summarized values for the heats of liberation of the halides of sodium, potassium and thallium. We may

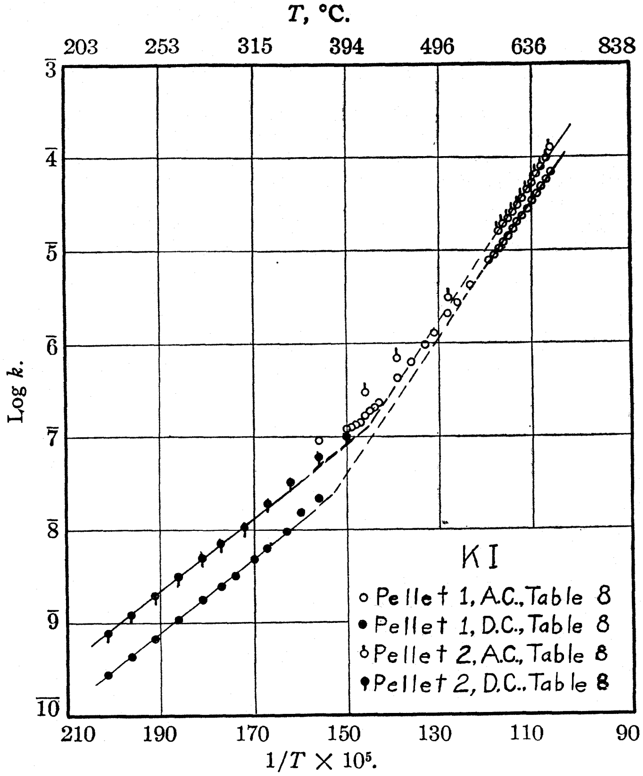

Fig. 7.—Showing (1) the one-half relation between the lower and upper slopes; (2) agreement in slope of two runs upon different pellets.

say provisionally that the values in Col. 3 are the heats of liberation of the positive ion, and the values in Col. 4 the heats of liberation of both positive **and** negative ions of the lattice in each case. On comparing Cols. 3 and 4 it is evident that in six cases the heat of liberation calculated from the upper slope is within experimental error double that from the lower slope. In the upper temperature range the lattice is "loosened," and whenever a positive ion of exceptional energy takes part in the conduction process it appears that a negative ion also receives the activating energy.

TABLE X

SUMMARY OF HEATS OF LIBERATION

Salt	M. p., °K.	AH, cal./g.-ion (lower slope)	AH, cal./g.-mole (upper slope)
NaCl	1077	20200	39800
NaBr	1028	18400	38400
NaI	924	13800	28300
KC1	1043"	22800	46600
KBr	1006"	22400	45400
KI	952"	19600	37200
T1C1	702"	16700	....
TlBr	732"	17000	....
TlI	713	14600	(9600)[b]

[a] Redetermined for the salts used in this investigation.

[b] Change in crystal form accounts for the existence of an upper slope in this case.

It will be noticed that the potassium ion has a larger heat of liberation than has the sodium ion in the same halide lattice, corresponding to the common conception of the potassium halides as more polar than the sodium halides. The heat of liberation in the thallous series is less than in the sodium or potassium series. Furthermore, the decrease in the heat of liberation (just as the decrease in melting point) is less in the sequence thallous chloride to iodide than the corresponding decreases in the other series. In the sodium and potassium series, heats of liberation (Col. 4) are approximately proportional to the absolute temperature of the melting point (Col. 2), within each series. In the thallous series the iodide, which changes crystal form, shows a departure from this rule.

In the study of the sodium series[2] it was shown that the ratio, heat of liberation per ion divided by the natural lattice quantum (as calculated from specific heat data), was roughly constant and had a value of about 40. A similar calculation from meager specific heat data for the potassium series gave values as follows: for potassium chloride, 51; for potassium bromide, 62; for potassium iodide, 60; average, 58. Further data are necessary before any conclusions can be drawn as to a possible relation between heat of liberation and natural quantum of the lattice.

The lattice energy of potassium chloride as calculated by Born is 163,000 cal. per gram-mole. The heat of liberation per gram-mole of potassium chloride (Col. 4, Table X) is about 47,000 cal.

Thus it appears that two oppositely charged ions which attain the threshold conduction energy in a potassium chloride lattice have less than one-third of the energy necessary to remove them completely from the lattice.

Summary

Temperature–conductance curves for the solid halides of potassium and thallium have been determined over wide temperature ranges. As in the case of the sodium halides two distinct slopes were observed for the potassium salts when the data were plotted to the axes log k (specific conductance) *versus* $1/T$. Only one slope was observed for thallous halides except in the case of thallous iodide, which undergoes a change of crystal form. In the light of recent high-temperature transference experiments, it is concluded that in the polar lattices only the positive ion conducts at lower temperatures, but that both ions conduct at higher temperatures. Change from uni-ionic to bi-ionic conduction seems to be characteristic of, and limited to, high-melting polar salts. Heats of liberation of the conducting ions in the various lattices have been calculated from the corresponding slopes. Within the sodium and potassium series heats of liberation are proportional to the melting points.

A STUDY OF THE CALCIUM AMALGAM ELECTRODE IN DILUTE AQUEOUS SOLUTIONS[1]

BY RUSSEL JOHN FOSBINDER

RECEIVED SEPTEMBER 10, 1928 PUBLISHED MAY 6, 1929

The determination of the calcium-ion activities in dilute solutions of calcium salts by the measurement of the electromotive force of a cell of the proper type is interesting for two reasons. First, the electrochemical behavior of calcium amalgams against aqueous solutions of calcium salts apparently discloses many peculiarities not exhibited by other amalgam electrodes. Second, calcium-ion concentration is a matter of considerable importance in physiological chemistry.

Byers[2] attempted to determine equilibrium conditions in a system of calcium hydroxide and sodium carbonate by means of the electromotive-force method. Neuhausen and Marshall[3] studied the electrolyte equilibrium in the blood by the use of amalgam electrodes. Lucasse[4] measured the potentials of cells with and without liquid junctions to determine transference numbers and activity coefficients of the alkaline earth chlorides. Drucker and Luft[5] made a careful and critical study of the calcium electrode in solutions of calcium. Kirk and Schmidt[6] attempted to measure the calcium-ion activities in solutions of certain protein salts but stated that their technique was entirely inadequate.

[6] Kirk and Schmidt, *J. Biol. Chem.*, *76*, 115 (1928).

The purpose of this investigation was to develop an apparatus and a technique suitable for the accurate determination of the effective calcium-ion concentration in dilute solutions, and also to study the possibility of applying the electrode in determining the state of calcium in solutions of physiological importance.

The Determination of Activity Coefficients of Calcium Chloride.—The activity coefficients of calcium chloride were determined from 0.01–**3.3** M in order to become familiar with the technique involved in the operation of the calcium electrode. The apparatus used and the method of procedure for the cells were, in general, similar to those described by Lucasse.[4] The calcium amalgam was prepared electrolytically according to the method prescribed by Neuhausen.[7] In making the determinations one cell was always filled with 0.0099 M calcium chloride, while the concentration of the solution in the other cell was varied at will. It was found that it was not necessary to have the solutions flowing, provided the readings were taken immediately after the amalgam flow was started. By such a procedure steady, reproducible potentials were obtained.

In Table I are given the results, where m is the number of moles of salt dissolved in 1000 **g.** of solvent, E is the electromotive force generated in the cell and γ is the activity coefficient.

TABLE I

DATA OBTAINED FOR CELLS OF THE TYPE Ag | AgCl | $CaCl_2$ (m) | Ca_xHg | $CaCl_2$ (m = 0.0099) | AgCl | Ag

m	E	γ	m	E	7
0.0099	0.00000	(0.716)	0.3069	0.11735	0.481
.0435	.04870	.572	.7158	.15605	.577
.0628	.06070	.550	1.2081	.18289	.689
.0781	,06885	.534	1.5378	.20232	.871
.0897	.06685	.494	1.9833	.21702	.974
.1411	.08940	.499	3.2702	27665	2.820

For a concentration cell without liquid junction containing a bi-univalent salt, the electromotive force, activity coefficient and concentration are related according to the equation

$$E = \frac{RT}{NF}\ln\left(\frac{\gamma_1\ 2^{2/3}m_1}{\gamma_2\ 2^{2/3}m_2}\right)^3 = \frac{3RT}{2F}\ln\frac{\gamma_1\ m_1}{\gamma_2\ m_2}$$

In calculating the values of the activity coefficient, it was assumed, as Lucasse assumed, that γ is 0.716 at 25° for the 0.0099 M $CaCl_2$ solution. Introducing the numerical values, the equation finally takes the form

$$\log \gamma_1 = 11.27E + (7.84695 - 10) - \log m_1$$

Taking the activity coefficients at round molal concentrations and comparing the values obtained with those of Lucasse, it is seen that they are in excellent agreement up to 1 M.

The Determination of Activity Coefficients of Calcium Ions.—The problem of determining individual *ionic* activities by electromotive-force measurements involves the determination of liquid junction potentials, and although these potentials can be reduced to small values, they are not known with certainty. While individual ionic activities are of less value from the thermodynamic point of view than the activities of the ionized salts, they are of great importance in many biological and chemical fields where specific ion effects are considered.

There also exists the problem of determining a reference activity, since in working with amalgam electrodes it is difficult to extend the dilution sufficiently in order to take a_1 to be very small. However, in the concentration range studied (0.001–0.01 M) one can calculate the value of a reference activity by employing the equation developed by Debye and Hückel. The limiting expression for the activity coefficient of an ion in aqueous solution at 25° is $-\log_{10} \gamma = 0.505z^2\sqrt{\mu}$, where γ is the activity coefficient, z the valence of the ion, and μ the ionic strength. Experiments have shown that this equation applies at least approximately up to an ionic strength of 0.01. The ion activity, a, may be obtained from the relation $a = \gamma c$, where c is the stoichiometrical concentration. In this investigation these equations have been employed in calculating the value of the reference activity.

Drucker and Luft[5] attempted to determine the ionic activity of calcium in solutions of calcium sulfate but they stated that the limited solubility of the salt made accurate measurements impossible. As yet no one has attempted to work with amalgam electrodes in dilute solutions, possibly because of the fact that such measurements have been considered to be unreliable. The work of Allmand and Polack[8] on the sodium electrode has been criticized by Michaelis and Kawai[9] who claim that in dilute solutions the electrode functions as a mixed hydrogen and sodium electrode. Allmand and Polack made but very few determinations with dilute solutions, the most dilute being 0.01 molal.

In the course of developing an electrode suitable for use with dilute solutions, preliminary studies indicated the following facts. (1) A single electrode is preferable because double dropping electrodes are very difficult

---

[8] Allmand and Polack, J. Chem. Soc., 115, 1020 (1919).

[9] Michaelis and Kawai, *Biochem. Z.*, 163, 1 (1925).

to adjust properly. (2) There is an optimum amalgam concentration for a definite range of solution concentration. **(3)** The effect of electrode surface area is to be considered. (4) The solutions must be air free. (5) Small particles must be kept from depositing on the electrode surface, as they cause the rapid decomposition of the amalgam.

Experimental Procedure

A high grade of calcium sulfate was repeatedly shaken with conductivity water and filtered. The resulting paste was then used in making up the saturated solution.

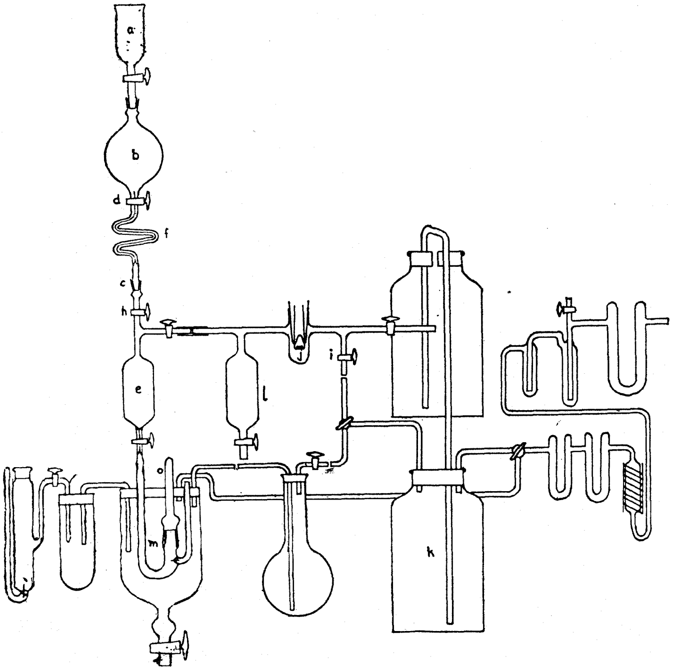

Fig. 1.—Apparatus for calcium electrode,

Other calcium salts used were listed as chemically pure and free from heavy metals. The solutions were made up accurately by weight on the molal basis.

In this part of the investigation the thermostat was discarded in order to facilitate manipulation of the apparatus. The temperature of the room was fairly constant, varying from 23.5–25°, and the errors from temperature fluctuations were less than other errors of measurement.

Commercial hydrogen from a tank was purified by passing it through solid potassium hydroxide, neutral permariganate solution, platinized asbestos at 300°, calcium chloride and phosphorus peatoxide.

The saturated calomel electrode was prepared using pure mercury, mercurous chloride and recrystallized potassium chloride. The bridge was made of saturated potassium chloride in agar-agar.

The apparatus employed is shown in Fig. 1. The entire system was first evacuated, then hydrogen from k was allowed to enter the system. Next a weighed quantity of metallic calcium was introduced into b and the apparatus again evacuated, and a weighed amount of mercury was allowed to flow into b from a. That part of the system which was above the ground-glass joint c was removed and the calcium was shaken with mercury to effect amalgamation. The apparatus was then reassembled and the system below the stopcock d was repeatedly evacuated and flushed out with hydrogen and finally evacuated. The stopcock d was opened and the amalgam allowed to flow from b into the reservoir e through the capillary filter f, which removed any oxide impurities. The stopcock h was then closed and pure hydrogen from k allowed to enter the system through i, which was then closed. The compartment j contained phosphorus pentoxide and a platinum glower to remove residual oxygen and water. The leveling bulb l was used to keep a pressure of hydrogen over the amalgam. The electrode m was fitted with a close-fitting cap o which was removed after the solution was introduced into the cell. With this type of apparatus the amalgam concentration and the electrode surface area were studied. For a solution concentration range of 0.02–0.001 M an amalgam concentration of 0.005–0.015% by weight was found to be satisfactory,

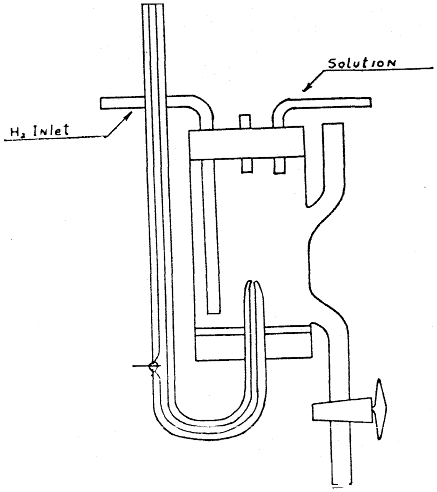

Fig. 2.—Final form of dropping electrode for calcium amalgam.

The first electrode studied was 15 mm. in diameter. In an attempt to measure the potential of an amalgam against a saturated solution of calcium sulfate, large voltage fluctuations were observed due to the decomposition of the amalgam at the surface. The second electrode was 9 mm. in diameter and was equipped with a rotating stirrer which not only agitated the solution but constantly scraped the surface of the amalgam. It was hoped that with this apparatus the solid particles of calcium hydroxide would be removed and the decomposition retarded, but the results were still erratic. Considerably better results were obtained with an electrode 4 mm. in diameter.

The final electrode is shown in Fig. 2. It was of the capillary type with a 1-mm. opening and was used in the experiments recorded in the tables. The stopper in the bottom of the cell was thickly coated with paraffin and inserted at such an angle as to insure the complete removal of the amalgam as it dropped off the tip of the capillary. Before a series of determinations was begun the tip of the capillary was filled with paraffin oil. This procedure was quite necessary as in the absence of the oil the electrode tip very soon became clogged on account of the accumulation of solid calcium hydroxide, necessitating the cleaning of the apparatus. The hydrogen inlet tube served to keep an atmosphere of hydrogen above the solution in the cell and also to agitate the solution during the operation of the electrode.

An inspection of the following tables shows that fairly accurate values of the activity coefficients may be obtained if the electrode surface area is small so that catalytic decomposition of the amalgam by particles of calcium hydroxide is minimized.

For a concentration cell with liquid junction the electromotive force and activity are related according to the following equation

$$E = E_1 - E_2 = \frac{RT}{NF} \ln \frac{a_1}{a_2}$$

or, substituting numerical values

$$E_1 - E_2 = 0.0295(\log \gamma_1 c_1 - \log \gamma_2 c_2)$$

The value of γ_1 is obtained from the Debye–Hückel equation. To illustrate the method of obtaining $-\log \gamma_2$, a calculation is carried out below using data from Table V.

$c_1 = 0.0015$ $c_2 = 0.0031$

$E_1 = 2.2335$ $E_2 = 2.2267$

$\log \gamma_1 = -0.158$ $\log \gamma_1 c_1 = -2.980$

Substituting these values in the above equation, $-\log \gamma_2 = 0.240$.

Results

All of the results have been calculated for the hypothetical cells Ca_xHg | c_1Ca^{++} | Satd. KCl in agar-agar | c_2Ca^{++} | Ca_xHg.

The amalgam contained 0.012% of calcium in all cases except in Tables V and VIII, where it contained 0.015%.

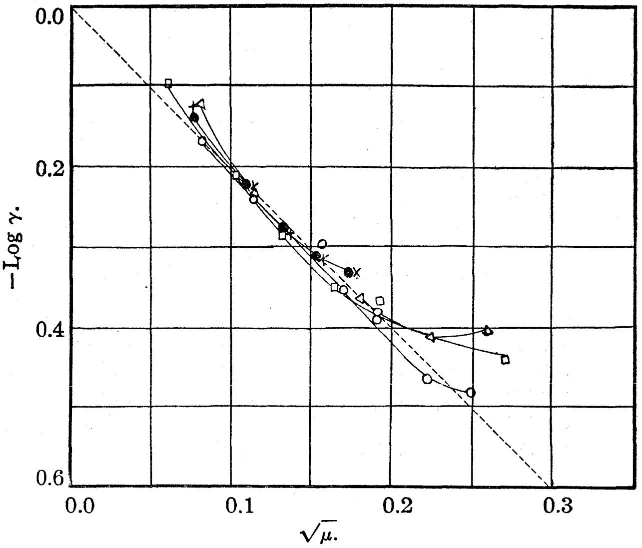
In the preceding tables the value of the reference voltage was taken as the average of several determinations, and the results of duplicate experiments are given in the last two columns. In most cases the reference electrode was taken as the next to the most dilute solution rather than the most dilute solution because the experimental errors in the latter are larger.

The Debye–Huckel equation gives a straight line if $-\log \gamma$ is plotted as ordinates and the $\sqrt{\mu}$ as abscissas, as shown by the dotted line of Fig. **3.** Fig. **3** also contains the experimental data for the five different calcium compounds.



○, Calcium sulfate; △, calcium hydroxide; □, calcium chloride; ●, calcium lactate; X, calcium acetate.

Fig. 3.—Graph showing the relation between the activity coefficient of calcium ions and the ionic strength.

While the equation is a limiting expression and valid only up to the region of an ionic strength of 0.01 (or $\sqrt{\mu} = 0.1$) it may be employed as a first approximation in the region of the concentration studied. The curves obtained for the calcium salts deviate from the theoretical line, the deviations being larger at the higher ionic strength due to the failure of the simple theoretical equation in this region. No attempt is made here to test the validity of the Debye–Hückel expression but it is employed merely as a first approximation to which the experimental data may be compared. The exact curves are probably not significant because the experimental errors are large, but it is seen that they fall fairly close to the Debye–Huckel line. The deviations in the case of the most dilute solutions **may** probably be attributed to experimental difficulties in this region.

The Effect of Cations on the Potential of the Calcium Electrode.—Electromotive-force determinations of aqueous solutions of calcium salts against calcium amalgam have shown that the electrode is reliable in a concentration of calcium ions comparable to that contained in most physiological systems. The possible application of the calcium electrode to biological problems is at once suggested providing that the potential of the electrode is not seriously disturbed by other electrolytes or proteins present in such solutions.

Neuhausen[10] studied the effect of gelatin and various electrolytes on the reliability of the sodium electrode. From the results of a series of experiments he concluded that the addition of other electrolytes, in general, did not affect the potential of the electrode. To test this point in regard to the calcium electrode a small amount of another electrolyte was added to a solution of calcium sulfate and the effect on the potential was observed. The results of such a series of experiments are contained in Table X.

TABLE X

THE INFLUENCE OF ADDED ELECTROLYTES ON THE POTENTIAL OF A CALCIUM AMALGAM ELECTRODE

.0074	None	2.2185	.0000

In every case the potential of the electrode was lowered, probably on account of the formation of a mixed amalgam electrode. In the case of iron and copper ions it is likely that the amalgam decomposed rather rapidly. The potassium and sodium ions entered the amalgam and replaced calcium to a certain extent. This replacement is opposed to the normal positions in the electromotive-force series, but the difference between the potential of the sodium or potassium electrode and the calcium electrode is so small that a high concentration of sodium or potassium ions can replace a small number of calcium atoms.[11]

In order to determine if a similar effect can be observed in the case of a physiological solution containing other cations in addition to calcium

---

[10] Neuhausen, THIS JOURNAL, 44, 1445 (1922).

ions, a series of samples of fresh dog's blood was prepared. In the following table are contained the results of the determination of the electromotive force of a calcium amalgam against the blood samples. The author is indebted to Professor W. J. Meek of this University for help in these experiments.

TABLE XI

POTENTIALS OF A CALCIUM AMALGAM ELECTRODE IN BLOOD

$t = 25°$

Sample	Treatment	E
0.0153 M $CaSO_4$	....	1.9543
Blood	Hirudin added	1.7834
Blood	Oxalated	1.8095
Blood	Whipped	1.8112
Plasma	Centrifuged	1.7660
Blood	Whipped	1.8134
0.0153 M $CaSO_4$	....	1.9537

While the absolute values of the electromotive force are not exact, the data show conclusively the impossibility of applying the calcium electrode in this way to the determination of the calcium-ion concentration in blood or any solution containing cations other than calcium. The lower potentials with blood correspond to an impossibly high concentration of calcium.

It had been hoped that a relation would be found between the effect of various materials on the coagulation of blood and on the calcium-ion activity, but no conclusion can be drawn on account of the complication of other ions.

The Effect of Proteins on the Potential of the Calcium Electrode.—Neuhausen[10] reported that the addition of isoelectric gelatin to solutions containing sodium ions produced no observable effect on the reliability of the sodium electrode. For this reason it was thought that the calcium electrode might be applied in studying calcium proteinate systems.

One hundred grams of 8% isoelectric gelatin was covered with 600 cc. of air-free, saturated calcium hydroxide solution. The system was then immersed in ice water and allowed to stand for one hundred hours. The liquid outside the gelatin was poured off and the gelatin washed with ice water.

Approximately ten g. of Merck's soluble crystallized egg albumin was added to 400 cc. of an air-free saturated calcium hydroxide solution. The mixture was placed in a shaking machine and the shaking continued for a period of seven hours. During this time a slow stream of pure hydrogen was allowed to bubble through the solution. Solutions of calcium caseinate were prepared in a similar manner. The results of electromotive-force determinations of calcium amalgam against solutions of calcium proteinate are given in the following tables.

TABLE XII
INFLUENCE OF GELATIN

Solution	E	$a_{Ca^{++}}$
$Ca(OH)_2$, 0.0074 M	2.2215	0.0046
$Ca(OH)_2$, 0.0074 M	2.2214	.0046

1 cc. Ca caseinate + 49 cc. $Ca(OH)_2$	.0223	2.2120	.0086
$Ca(OH)_2$	.0219	2.2206	.0000

The data clearly show that in a solution containing 0.02% or even a smaller amount of protein the reliability of the electrode is destroyed, for the values of "a" and ΔE correspond to an impossibly high concentration of calcium ions.

The alteration in the potential must be due to a change which takes place at the surface of the electrode. To account for this effect the following explanation is advanced. Because of a tendency of the protein to form a film on a metallic surface a coating is formed on the surface of the electrode. This film prevents the ordinary electrode equilibrium from taking place and results in the building up of a large ionic concentration inside the film. Experiments conducted with other metallic electrodes in protein solutions indicated the plausibility of this hypothesis. The results also suggest the reason for the failure of other investigators to develop a technique applicable to the study of calcium solutions containing protein.

The author desires to acknowledge the help given by Professor Farrington Daniels, under whose direction this investigation has been carried out.

Summary

1. Values of the activity coefficients of calcium chloride are given from **0.01–3.3** molal. The values up to a concentration of 1.0 molal agree very well with those obtained by Lucasse.

2. A technique and an apparatus suitable for the determination of the activity coefficients of calcium ions have been developed.

3. Values of the activity coefficients of calcium ions in aqueous solution for five calcium salts have been determined from 0.01-0.001 molal.

4. The investigation has revealed apparently insurmountable difficulties in using the calcium electrode for the determination of calcium-ion activities in physiological solutions. The potential is lowered by the presence of cations, either above or below calcium in the electromotive-force series. The potential is lowered also by the presence of protein.

MICRO-POTENTIOMETRIC DETERMINATION OF REDUCING CARBOHYDRATES

BY JOSEPH B. NIEDERL AND RALPH H. MÜLLER

RECEIVED SEPTEMBER 24, 1928 PUBLISHED MAY 6, 1929

Introduction

Of the various types of methods in existence for the micro-determination of reducing sugars, the copper reduction method with its various modifications is used most extensively.[1]

It has been shown by Daggett, Campbell and Whitman[2] that reducing sugars can be determined potentiometrically. The purpose of this communication is to show that micro-analytical determination can be made by this method and that the method may be simplified by the use of a more convenient electrode than the calomel electrode employed by these authors. The more important carbohydrates have been studied and their reduction values ascertained. One method (semi-micro) permits the determination of 3 to 5 mg. with an accuracy of about ±1%, while the other (micro) permits a quantitative determination of as little as 0.05 mg. of reducing carbohydrates.

[2] Daggett, Campbell and Whitman, THIS JOURNAL, 45, 1043 (1923).

Apparatus.—The apparatus consisted of two vessels filled with Fehling's solution of the same concentrations. Platinum electrodes were immersed in each vessel, the two vessels being connected by an agar agar–potassium chloride bridge. One vessel was heated and the sugar solution added slowly from a buret. The difference in the potential of the electrodes was followed by means of a Leeds and Northrup Type K potentiometer. The Hildebrand[3] arrangement was also used successfully.

Figure 1 illustrates this arrangement as employed in the micro-determination. The vessels in this case were small pyrex tubes. The bridge consisted of a capillary tube of 1 mm. outside diameter, filled with agar agar–potassium chloride gel.

Experimental Part

Three to 5 mg. of the substance is weighed accurately on a micro-analytical balance down to 0.001 mg. (Kuhlmann balance; Becker's micro-analytical balance might also be used) and dissolved in distilled water, one cc. for each mg. The solution is put in the micro-buret. To each of the two vessels 1 cc. of Fehling's solution containing one mg. of copper per cc. is added. **A** reading is now taken on the potentiometer. Then the Fehling's solution in container **A** is heated to boiling and a reading taken again.

A preliminary titration is first carried out as follows: 0.1 cc. of the solution containing the carbohydrate is added from the buret, the mixture boiled and a reading taken again. These additions are continued until 1.2 cc. has been used.

In the region of the end-point the increase in potential is very rapid. The maximum value of millivolts per 0.01 cc. marks the end-point.

The Fehling's solution used was prepared as follows: 3.95 g. of $CuSO_4 \cdot 5H_2O$ in 500 cc. of water, and 19.75 g. of sodium potassium tartrate and 7.40 g. of sodium hydroxide in 500 cc. of water.

The actual determination is carried out in the same way as the previous one, using larger amounts until the end-point is approached. From this point small amounts, not exceeding 0.02 cc., are added and after boiling readings are taken. This is continued over the range ascertained in the first trial.

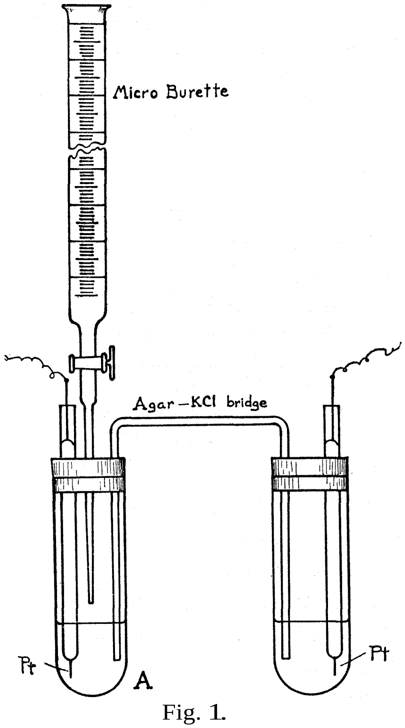

Fig. 1.

The change in potential in the vicinity of the end-point was always very large, enabling one to determine it without difficulty. The actual values of the potentials, however, were not as highly reproducible, owing to the fact that the reaction was

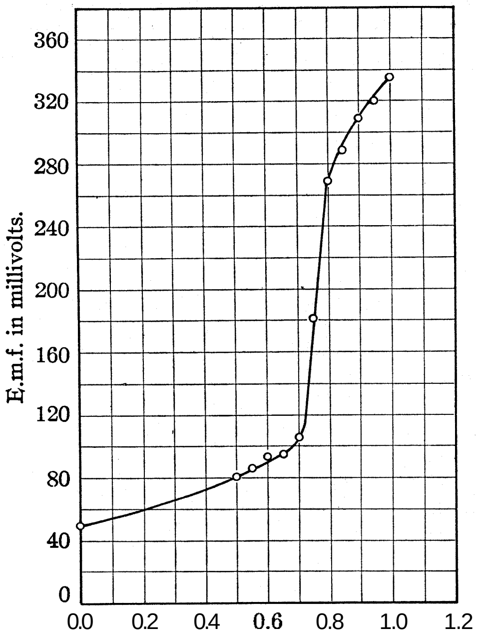
---

[3] Hildebrand, This Journal, 35, 847 (1913).

carried out in an alkaline medium and no particular precautions were taken for constant temperature. A typical titration curve is reproduced in Fig. 2.

For those cases in which less than four mg. is available, the material is weighed out according to **Pregl**,[4] and placed directly in the titrating vessel. Then Fehling's solution is added as before, boiled and readings are taken on the potentiometer.

The titration itself, however, is completed with standard glucose solution (1 mg. in 1 cc.) in the manner given. The difference in the volume necessary for the end-point gives the amount of carbohydrate present. Naturally a solution (1 cc.) free from other reducing substances might also be used instead of the solids.



Sugar solution (concn., 1 mg. in 1 cc.), cc.

Fig. 2.

Discussion of Results

Under the experimental conditions outlined above, the following empirical standard values were obtained.

1 Mg. of Copper

Sugar	Mg.
d-Glucose	0.635
d-Mannose	.638
d-Galactose	.770
d-Fructose	.679
Maltose	1.019
Lactose	.884
Sucrose (inverted)	.657

1 Mg. of Sugar

	Cu, mg.
d-Glucose	1.575
d-Mannose	1.567
d-Galactose	1.298
d-Fructose	1.472
Maltose	0.981
Lactose	.884
Sucrose (inverted)	1.522

Each of these empirical standard values represents the average of at least six determinations.

Some of the results as obtained by this method by various individuals are given below. The Fehling's solution contained 1 mg. of copper in 1 cc. All the sugar solutions used also contained 1 mg. of reducing carbohydrate in 1 cc. The materials used were "Kahlbaum" chemicals of highest purity.

Since the reducing power of the various carbohydrates changes with the reaction conditions, such as concentration, temperature and oxidizing reagent, the foregoing values do not check absolutely with the figures given in the literature and obtained under different conditions, although

1 Mg. sample	Cu, mg.	Average	1 Mg. sample	Cu, mg.	Average
d-Glucose	0.630–0 660	0.645	d-Fructose	0 675–0.700	0.687
Standard value,	.630– .640	.635	Standard value,	.650– .680	.665
0.635	.630	.630	0 679	.675– .700	.687
	.630	.630	Maltose	1.050–1.100	1.075
	.630	.630	Standard value,	1.000–i.050	1 025
	.620– .640	.630	1.019	1.000–1.025	1.013
	,630–.650	.640		1.000–1.030	1.015
	.625– .650	.638		1.000–1.050	1 025
d-Mannose	0.625–0.650	0.638	Lactose	0.850–0.900	0.875
Standard value,	.625– 650	.638	Standard value,	.850– .900	875
0.638	.625– .650	.638	0.884	.880– .900	.890
	.600– .700	.650		.880– .900	.890
	625– .650	.638		.880– .900	.890
d-Galactose	0.750–0.800	0.775	Sucrose (inverted)	0.650–0.675	0 663
Standard value,	,770– 800	.785	Standard value,	.650	.650
0.770	,750–.780	.765	0.657	.650– .675	,663
	.750– .780	.765			
	.750– 775	.760			

they correspond in the order of the reducing power with those obtained by related methods. The comparison is as follows.

Order of red. power	Potent. titr.	E. Wein	Lewis Benedict	Folin–Wu	Fehling	Knapp	Sachsse
1	Glucose	Glucose	Glucose	Glucose	Glucose	Fructose	Fructose
2	Sucrose	Sucrose			Sucrose	Sucrose	Sucrose
3	Mannose		Mannose	Fructose			
4	Fructose		Fructose	Galactose	Galactose	Glucose	Glucose
5	Galactose		Galactose	Mannose	Fructose	Galactose	Galactose
6	Lactose	Lactose	Lactose	Lactose	Lactose	Lactose	Lactose
7	Maltose	Maltose	Maltose	Maltose	Maltose	Maltose	Maltose

In carrying out numerous titrations by the method set forth herein where the Fehling's solution is just brought to boiling after each addition of the carbohydrate solution, no appreciable differences in the results were noted, whether the solution was boiled up 5, 6, 7 or 8 consecutive times. Perhaps in such diluted solutions the time factor no longer is of marked influence.

Since the various sugars have different standard values, it is evident that in a pure sample also the qualitative nature of the carbohydrate may be ascertained by comparing the titration curve obtained with the standards. For example, if a pure sample weighing 1 mg. consumes **0.981** mg. of copper it can only be maltose, etc.

The authors desire also to thank Mr. Nathan Ambinder for carrying out a large number of titrations.

Summary

Micro-potentiometric methods for the quantitative determination of reducing carbohydrates have been described.

CRITICAL TEMPERATURE MEASUREMENTS ON CARBON DIOXIDE IN SMALL CAPILLARIES[1]

BY HARVEY THOMAS KENNEDY

RECEIVED OCTOBER 10, 1928 PUBLISHED MAY 6, 1929

Patrick and McGavack[2] have established the relation between the quantity of gas adsorbed by silica gel and the equilibrium pressure, as follows

$$V = K\left(\frac{\sigma P}{P_0}\right)^{1/n}$$

where V is the volume of liquefied gas at the prevailing temperature and pressure, σ the corresponding surface tension, P is the equilibrium pressure, P_0 is the ordinary saturation pressure and K and n are constants. This equation has been used to correlate measurements of adsorption in silica gel with the vapor pressures of sulfur dioxide and ammonia by Patrick and Davidheiser,[3] of butane by Patrick and Long[4] and of nitrous oxide and carbon dioxide by Patrick, Preston and Owens.[5] The latter writers made measurements of adsorption both above and below the critical temperature and concluded that liquid exists in the pores of the adsorbant above the critical temperature, as ordinarily measured in large tubes. Thus they believe that liquid carbon dioxide exists in the pores of silica gel at 40°, about 9° higher than the previously reported critical temperature.

While it is perhaps impossible to test this hypothesis directly, that is, by actual observation of a liquid phase within the fine pores of an adsorbent, it was thought that if the hypothesis were in accord with the facts, some increase in critical temperature should be observed in very fine glass capillaries, even though the diameters of the capillaries were many times those of the finest pores in silica gel. The work here described was undertaken largely to determine what relation, if any, exists between the diameter of small capillaries and the critical temperature of material measured in them.

Carbon dioxide was chosen for this work because its critical point is conveniently near to room temperature and because it is easily obtained in a state of high purity.

The first attempt to determine the effect which diameter of capillary had on the critical temperature consisted in the construction of the apparatus shown in Fig. 1 which contains carbon dioxide adjusted to critical volume. When the temperature is raised slowly from slightly below the

critical to slightly above, it was expected, if the diminishing diameter had the effect of raising the critical temperature, that the meniscus would appear in the tube D and slowly move from the upper and larger end to the lower and smaller end. Conversely, as the temperature is lowered, the opposite motion should be observed.

As impurities in the carbon dioxide might give the same effect as described above, without the diameter itself having any effect, the greatest care was exercised in preparation and purification.[6]

Figure 2 shows diagrammatically the apparatus by which the carbon dioxide was further purified and conducted into the tube shown in Fig. 1 by multiple sublimation.

Before the purification was completed, no measurable pressure was indicated on the McLeod gage when liquid air was placed under either I or J, and the sublimation into it completed, the stopcock O being closed.

The behavior of the meniscus was then observed by placing the tube D before a microscope, the optical axis of which was horizontal, and which was so arranged that it could be moved up and down, thus allowing the tube to be viewed throughout its length. A mercury thermometer graduated in 0.01° was placed at the side of the tube D, and the room temperature was varied very slowly and regularly by means of a large fan and gas flames placed a considerable distance from the apparatus.

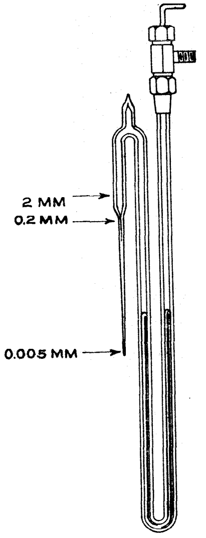

Fig. 1.

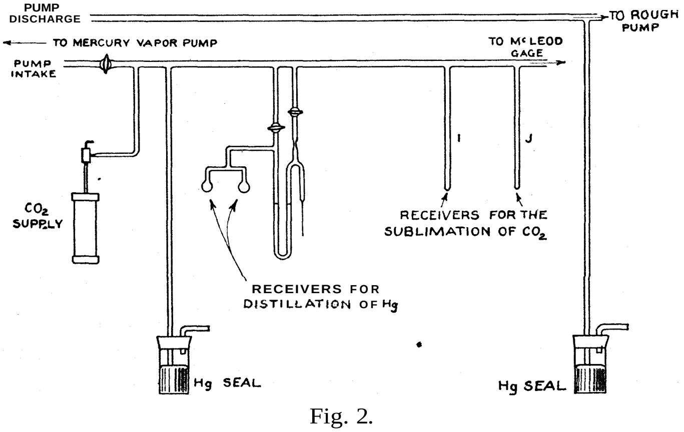

Fig. 2.

The result predicted by the hypothesis explained at the beginning of this paper, namely, that the meniscus should move downward in the tube D as

---

[6] For a detailed description of the generation and purification of the carbon dioxide used in this investigation, see Meyers and Van Dusen, *Refrigerating Eng.*, 13, 180 (1926).

the temperature was raised, and vice versa, was not observed since no meniscus was observed in the small tube D at any time, although the temperature was raised above the critical and lowered many times, and various schemes of illumination tried.

It was then decided that the negative result obtained was not entirely conclusive. The meniscus, if present in the very fine tube would be difficult to see, and great delicacy in temperature control might be necessary to hold it at any point in the tube for a long time. It was, therefore, decided to make determinations of the critical temperature of carbon dioxide in very fine capillaries of different diameters and to compare these values with those obtained in larger tubes.

To make and fill these tubes, essentially the same apparatus was used as is shown in Fig. 2, the fine tubes being made by heating the ends of tubes I and J, drawing out to the required internal diameter and, after filling, collapsing until adjusted to critical volume.

These small tubes were drawn as described for two reasons: first, the ratio of surface to volume in them was very great as compared to tubes in which critical temperatures have previously been determined, and small quantities of adsorbed gases on the glass walls would have a much greater effect; second, previous work has shown that the action of water on soft glass essentially changes its surface, and irregularities thus caused might interfere with observations of critical temperature. It is believed that with freshly drawn tubing, which has never been in contact with any gas except carbon dioxide of high purity, both of these difficulties are overcome.

The apparatus for the determination of the critical temperatures of carbon dioxide in the small tubes is shown in Fig. 3.

Temperature regulation was secured by the 40-watt lamp I, which was connected to a line the voltage of which could be varied in 11-volt steps. External resistance in series with the lamp was also provided so that fairly rapid or very slow rates of heating could be obtained. The lamp was surrounded with a section of a cone, made of black paper, with a disk of the same material on its top so perforated that the direct radiation from the lamp did not fall upon the contents of the Dewar tube.

Illumination was secured by a 200-watt tungsten lamp set beyond the Dewar tube at an angle of about 30° with the optical axis of the microscope. Between the Dewar tube and the lamp was placed a large bottle of water so as to shield the water in the Dewar from the heat from this source. It was found that the very small tube could best be observed by moving the microscope objective somewhat further away from the tube than the position corresponding to sharp focus and observing a greatly enlarged pattern formed only when an angle of approximately 30" existed between the optical axis of the microscope and the line from the lamp to the Dewar tube. In this pattern liquid and vapor were differentiated as light and dark bands, and could be clearly distinguished, especially when moving, in tubes so small that the two sides could be resolved only with difficulty with the magnifying power available.

A number 4 objective was used, the limitation imposed by the thickness of the wall of the Dewar preventing the use of one of higher magnifying power.

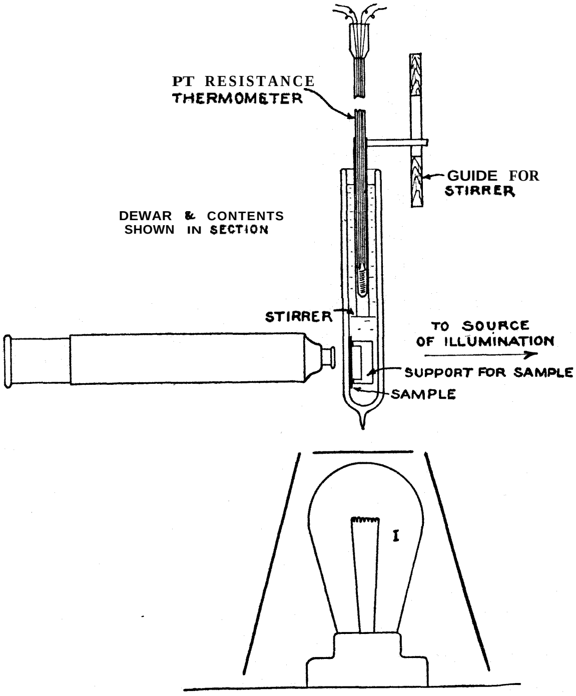

Fig. 3.

Determinations of critical temperatures were made on samples contained in two small capillary tubes whose internal diameters midway between the two ends were 0.004 and 0.060 mm., respectively, as measured microscopically and corrected for the magnifying power of the glass. Several determinations were also made on the 2-mm. tube shown in Fig. 1 and

TABLE I

RESULTS OF EXPERIMENTS

	Tube no.		
	1	2	3
Internal diameter, mm.	0.004	0.060	2.0
Approximate length, mm.	15	15	80
Meniscus appeared	30.96 30.95	30.96	30.96
	30.985 30.94	30.96	30.96
Average	30.96	30.96	30.96
Meniscus disappeared	30.95 30.94	30.95 30.95	30.96
	30.98 30.93	30.96 30.96	
Average	30.95	30.955	30.96

these values are tabulated here for comparison. Temperatures are recorded at which the meniscus first appeared as the temperature was falling, and at the highest temperature at which a meniscus was seen as the tubes were slowly heated.

It will be observed that while the reproducibility of results on tube No. 1 leaves much to be desired, the average of the temperatures at which the meniscus appears is the same for all the tubes, that is, 30.96". Similarly the meniscus disappears between 30.95 and 30.96°, taking average figures, for all of the tubes, regardless of size. Runs in which the temperatures changed more than 0.02° per minute are not tabulated above.

The temperature 30.96 * 0.01" as the critical point of carbon dioxide, measured as here described, appears to be the most probable result, independent of the diameter of the tube in which it is measured. Whether the independence of capillary diameter and critical temperature holds in tubes whose diameter is of the same order of magnitude as the finest pores in charcoal or other adsorbing material, is of course conjectural. What is here proved is that there is no effect exceeding 0.03" for tubes as small as 4 microns in diameter.

The above figure is also suggested as an accurate value for the critical temperature of carbon dioxide, and the method here described as one of unexcelled precision, although more laborious than methods previously described. The greatest precision is probably attained in tubes the internal diameter of which is about 60 microns. The precision attainable in small tubes illuminated as described arises from the fact that up to the critical temperatures a sharp meniscus is observed. As the critical point is reached, violent motion is observed, and within a few thousandths of a degree, the meniscus, still moving, disappears. No bands or fog, such as are observed in large tubes with the naked eye, are visible.

Comparing the value here reported with critical temperatures determined by the more recent investigators, it will be noted that the present value is, in general, low. Thus, Meyers and Van Dusen[6] set 31.1° as the best figure. Hein[7] obtained 30.97"; Cardoso and Bell,[8] 31.00"; Dorsman,[9] 31.10"; Bradley, Brown and Hale,[10] 31.26°; Onnes and Fabius,[11] 30.985°; Brinkmann,[12] 31.12°; Keesom[13] 30.98°, and von Wesendonck[14] considered

[14] Von Wesendonck, *Verh. deutsch. phys. Ges.*, *5,* 238 (1903).

the critical temperature indefinite within the range 30.95 to 31.7°. Among the results obtained previous to 1900, Andrews' value[15] of 30.92° is the lowest, all other temperatures recorded being 31.0" or higher.

The critical temperature, as used in this work, is the highest temperature at which a meniscus of sufficient sharpness to be seen in the field of a microscope when the material is examined by transmitted light can be observed. As the same results were obtained with an ordinary reading glass as with the microscope previously described, it is believed that this definition need not be amplified as regards magnification. It is suggested that the variation in critical temperatures as measured by the more modern workers in this field is due largely to the different criteria employed to define the critical point. Thus, when the 3-mm. tube used by Meyers and Van Dusen was examined by the author using transmitted light of high intensity[16] no meniscus that was entirely sharp was observed above 30.97". By reflected light, however, a wide band was observed up to 31.1°, and fog at temperatures above 31.11". Similarly, when the tube shown in Fig. 1 was observed by reflected light, a wide band was observed up to 31.04'. Observations on the band could not be repeated with satisfactory precision.

The selection of any one of the various physical phenomena which occur at the critical temperature as a means of defining this temperature precisely is necessarily somewhat arbitrary. Of the two phenomena described in this paper, namely, the appearance or disappearance of a band and the appearance or disappearance of the meniscus, the latter seems to be better adapted for practical definition of the critical temperature. It has been pointed out by Mr. C. H. Meyers,[17] however, that, due to the extreme compressibility of a substance in the critical region, a pressure gradient such as that due to gravity may cause a region of rapidly changing refractive index in a single-phase system, giving the appearance of a band which becomes sharper the nearer the temperature approaches the critical, as here defined.

This opportunity is taken to acknowledge with gratitude the encouragement and advice received from Dr. J. C. W. Frazer and Dr. W. A. Patrick, of the Department of Chemistry, Johns Hopkins University, whose guidance has made this work possible.

The kindness of Dr. H. C. Dickinson, Chief of the Heat and Power Division, Bureau of Standards, in making available to the writer much of the apparatus and materials used in this work, is gratefully acknowledged.

---

[15] Andrews, *Trans.* Roy. *Soc. London,* II, **159,** *575* (1869).

[16] The tube used by Meyers and Van Dusen was mounted on a solid backed board and could not be illuminated from directly behind. The meniscus was observed by so placing a 200-watt tungsten lamp that the line between the lamp and the observer's eye was nearly parallel to the board.

[17] Private communication.

To Mr. C. H. Meyers of the Bureau of Standards, especial credit is due for placing at the writer's disposal his specialized knowledge of critical temperature determinations, and for assistance freely given in cases where two observers were required.

Summary

The critical temperature of carbon dioxide has been measured in glass tubes ranging from 2 mm. to **0.004** mm. in diameter. The critical temperature was found to be independent of the size of the tube and 30.96° was taken as the most probable value. Large differences in critical point were found for different methods of illumination and depending on whether a sharp meniscus or diffuse band is taken as a criterion.

VOLUMETRIC DETERMINATION OF VANADIUM BY MEANS OF POTASSIUM IODATE

BY ERNEST H. SWIFT AND RAYMOND W. HOEPPEL

RECEIVED NOVEMBER 13, 1928 PUBLISHED MAY 6, 1929

Introduction

The advantages of the iodate method of volumetric analysis have been pointed out by Andrews[1] and Jamieson,[2] and more recently reviewed by Heisig.[3] Among these advantages are the ease with which a standard solution of potassium iodate is prepared and the stability of its solution. Not only can substances which reduce iodate in hydrochloric acid solution be titrated, but it has been shown by Andrews[1] that oxidizing agents, such as chromates and chlorates, which oxidize iodide and are not re-oxidized by iodine monochloride, can be determined by adding an excess of a standard solution of potassium iodide and then converting the iodine liberated and the excess of iodide to iodine monochloride by titration with iodate solution. It was to be expected that a similar determination of vanadium as vanadate could be made, provided a sufficiently high concentration of hydrochloric acid could be maintained during the titration with the iodate to prevent re-oxidation of the quadrivalent vanadium formed. The chemical reactions involved in such a process can be represented as follows

$$H_3VO_4 + HI + 2HCl = VOCl_2 + \tfrac{1}{2}I_2 + 3H_2O$$
$$2I_2 + HIO_3 + 5HCl = 5ICl + 3H_2O \text{ and}$$
$$2HI + HIO_3 + 3HCl = 3ICl + 3H_2O$$

---

[1] Andrews, *Z. anorg. Chem.*, 36, 83 (1903); THIS JOURNAL, 25, 756 (1903).

[2] Jamieson, "Volumetric Iodate Methods," Chemical Catalog Co., New York, 1926, p. 9.

[3] Heisig, THIS JOURNAL, 50, 1687 (1928).

Such a method would offer the advantages of not requiring a previous reduction of the vanadate, which is the most commonly occurring form of vanadium, and of determining vanadium in the presence of iron, arsenic and phosphate, substances commonly occurring with vanadium in its natural sources.

Preliminary determinations which gave promising results were carried out by Mr. T. G. Bernhardi in this Laboratory. A more detailed study of the method was then undertaken by the authors.

Substances and Solutions.—All chemicals used were of "analytical chemical" grade.

Ammonium metavanadate was used as the source of the vanadium. The solution was prepared by weighing out the solid, dissolving it in an equivalent amount of sodium carbonate solution and expelling the ammonia by boiling. The vanadate solution was then standardized by the iodimetric method, using the procedure recommended by Ramsey.[4] Three determinations gave the values 0.05215, 0.05217 and 0.05215 for the molal concentration of the solution.

The potassium iodate was tested for iodide with negative results. The solutions were prepared by weighing out the dried salt and dissolving it in the proper volume of water to make the resulting solutions 0.025 molal.

The potassium iodide solution was prepared from the same grade of salt and proved to be iodate-free. The salt was weighed out and dissolved, and the concentration was determined by titration with the iodate solution under the conditions of the method being used.

The Method of Analysis.—The general procedure was to pipet the vanadate solution into a 200-ml. or 400-ml. conical flask with a ground-glass stopper and then to add slowly to this, while cooling the flask with tap water, the volume of 12 molal hydrochloric acid necessary to give the final concentration of the acid which was desired. The hydrochloric acid used in most cases had previously had a slow current of carbon dioxide passed through it for fifteen to twenty minutes in order to remove most of the dissolved oxygen. Through the flask containing the acid and the vanadate was then passed over the solution for two to three minutes a vigorous current of carbon dioxide. Then 3 to 5 ml. of carbon tetrachloride and a measured excess of the standard potassium iodide solution were added, the flask was closed and allowed to stand for one to two minutes; the solution was titrated as rapidly as possible with the iodate solution until no more iodine color could be detected in the carbon tetrachloride.

Test Analyses: Effect of Acid Concentration and Presence of Air.—In Table I are shown the results obtained in titrating known quantities of vanadium in the presence of hydrochloric acid at different concentrations and under certain other variations of the conditions.

In each case 25 ml. of the standard potassium iodide solution was added, except in Expt. 18, where 50 ml. was taken. Two standard solutions of potassium iodide were used in the experiments, one solution being 0.05414 molal and the other 0.05404 molal. The volume of potassium iodate used in the titrations varied from 13.46 ml. in Expt. 1 to 28.08 ml. in Expt. 18.

It will be seen that when the final concentration of the hydrochloric acid is 6 molal or 7 molal the results are satisfactory. The average of the fifteen

[b] The flask was not swept out with carbon dioxide.

[c] Carbon dioxide was passed through the flask with vanadate before adding hydrochloric acid.

analyses at 6.0 M (excluding Expts. 26–29 for the reasons given below) is 0.08% low, and the greatest deviation from the correct value is 0.43%.

When the hydrochloric acid is 5 molal the results are not so good; they are low where the air is excluded and high when it is present, the latter probably being due to slight re-oxidation of the quadrivalent vanadium. It will be noted that a difference of about 1% is caused by not excluding the oxygen of the air. This effect (of not excluding the air) is apparently larger than with the 6 molal acid. It seems remarkable that this effect is not greater, considering the larger deviation obtained by Ramsey[4] when he allowed vanadate and iodine to react without excluding the oxygen of the air at much lower concentration of acid than was present in these experiments, but the smaller excess of iodide here present probably decreases the oxygen error.

At the lowest concentration of the hydrochloric acid the results show still more variability. This may be attributed to two factors: partial re-oxidation of the vanadium to vanadate and insufficient concentration of the hydrochloric acid to prevent hydrolysis of the iodine monochloride; this concentration is at the minimum of 12% which Jamieson[2] states is necessary in order to eliminate this hydrolysis.

It may be mentioned that the acid concentration during the vanadate–iodide reaction varies from 7 to 10 molal, and that under these conditions the vanadium may be reduced below the quadrivalent state; but, so long as oxygen is excluded, this causes no error, since it is immediately re-oxidized upon addition of the iodate.

In Expts. 26–29 the solution of the vanadate was 10 molal in hydrochloric acid while being swept with carbon dioxide; subsequent tests above the surface of the solution with paper strips moistened with a solution of starch and potassium iodide showed that a slight amount of chlorine was formed even in a cold solution, thus accounting for the low results obtained. Under the same conditions when the hydrochloric acid was added after sweeping out the flask with carbon dioxide and the iodide was immediately added, the error was eliminated. The results with 7 molal hydrochloric acid are consistent, but, owing to the large amounts of acid required, it is desirable to work at the lowest possible concentration. In Expt. 34 only half of the hydrochloric acid was added before adding the potassium iodide, making the hydrochloric acid slightly less than 6 molal during the vanadate–iodide reaction. The remainder of the acid was added when the titration was half finished.

Test Analyses: Effect of Presence of Other Constituents.—–In Table II are shown the results obtained when vanadium was present with various other substances. Here the final concentration of the hydrochloric acid was always approximately 6 molal. The amount of vanadium taken was 66.4 mg. in all cases (except in Expts. 6 and 9), and in every case 25 ml. of potassium iodide of the concentration shown in the table was used.

TABLE II

TITRATION OF VANADIUM WITH IODATE IN THE PRESENCE OF OTHER SUBSTANCES

[a] 26.58 mg. of vanadium taken.

[b] WO_3 was dissolved in the H_3PO_4.

[c] WO_3 was partly dissolved in the H_3PO_4.

Experiments 1, 6, 10 and 11 in Table II show that even a large excess of phosphoric acid has very little effect on the determination. This shows that any phosphate–vanadate complex molecule that is formed is not so stable as to prevent reduction of the vanadate. The presence of ferric ion, even in very large quantities, seems to cause only a slight, though apparently definite, decrease in the amount of vanadium found. The reason for this is not clear. The ferric chloride used was proved to contain no appreciable quantity of ferrous salt; moreover, the work of Heisig[3] shows the tendency of ferrous chloride solutions to oxidize rapidly in the presence of air under the conditions of this procedure; this would cause an effect opposite to that observed. Expts. 8 and 9 show that although arsenic acid oxidizes iodide, it is re-oxidized by iodine monochloride when titrated with iodate and does not interfere with this determination of vanadium. Expts. 10 and 11 show that tungstic acid can be held in solution with phosphoric acid and the titration made in its presence.

Final Analytical Procedure.—Upon the basis of the above experiments the following procedure is suggested. Bring the vanadium as vanadate into as small a volume of solution as possible, preferably not over 25 ml., in order to avoid the use of an excessive quantity of hydrochloric acid. Transfer the solution to a 200–400-ml. conical flask with a ground-glass stopper and pass for two to three minutes a rapid current of carbon dioxide into the flask, but not through the solution. Gently swirl the solution in the flask during this time. Add through a funnel to the solution in the flask such a volume of 12 molal hydrochloric acid as will make the solution 6–8 molal in acid during the vanadate–iodide reaction. Cool the flask with tap water during the addition of the acid. Add to the solution from a pipet or buret an excess (as small as practicable) of standard potassium iodide solution. Mix the solutions, let the flask stand for one to two minutes, add to it 5 ml. of carbon tetrachloride and then titrate with standard iodate solution, adding 12 molal hydrochloric acid as needed so that its concentration may never fall below 6 molal in the solution being titrated. Where the approximate amount of vanadium present is known, the calculated volume of hydrochloric acid can be added before the titration. When approaching the end-point shake the solution vigorously so that equilibrium of the iodine between the carbon tetrachloride and water layers is attained. Cool the solution with tap water during this shaking to prevent drops of the solution from blowing out around the stopper when the flask is opened.

As a direct test of this procedure some ammonium metavanadate from the same source as that used in preparing the vanadate solution was recrystallized, then ignited to the oxide at 400–500°. This product was moistened with nitric acid and again heated at the same temperature. Of this 1.4174 g. was weighed out, dissolved in sodium carbonate solution, the solution diluted to 100 ml., four 10-ml. portions were pipetted out and treated by the above procedure. The results obtained are shown below. The iodide solution was 0.05404 molal.

TABLE III

TEST ANALYSES FOR FINAL PROCEDURE

No.	1	2	3	4
Iodine added, ml.	35	35	35	35
Iodate used, ml.	22.25	22.27	38.47	38.50
Vanadium found, mg.	79.40	79.29	79.34	79.19

The calculated weight of vanadium present was 79.41 milligrams.

In No. 1 half of the hydrochloric acid was added before adding the potassium iodide and the remainder during the titration. In No. 2 all of the acid was added before the iodide, while in Nos. 3 and 4 half of the acid was added before the iodide and half just before beginning the titration.

Summary

A method for the volumetric determination of vanadium by means of standard solutions of potassium iodide and potassium iodate has been developed. The method depends upon the reduction of vanadate by a known amount of iodide in hydrochloric acid solution and conversion of the iodine formed and of the excess of iodide into iodine monochloride by titration with iodate.

It is shown that when the concentration of the hydrochloric acid is 6 molal or more, quadrivalent vanadium is not oxidized by the iodine monochloride and the reactions are quantitative.

Tests analyses proved that vanadate can be determined by this method in the presence of phosphate, arsenate or ferric iron, and also in the presence of tungstic acid, which may be held in solution by adding phosphoric acid.

PASADENA, CALIFORNIA

THE ABSORPTION SPECTRUM AND DECOMPOSITION OF HYDROGEN PEROXIDE BY LIGHT

BY H. C. UREY, L. H. DAWSEY AND F. O. RICE

RECEIVED NOVEMBER 28, 1928 PUBLISHED MAY 6, 1929

Very extensive studies have been made on hydrogen peroxide in dilute and concentrated solutions and recently in the pure liquid state.[1] These studies have dealt particularly with its thermal, photochemical and catalytic decomposition in solution.[2] No work has been done on its decomposition in the gaseous state other than that of Elder and Rideal,[3] showing that the thermal decomposition is predominantly a surface reaction.

The thermal, photochemical and catalytic decomposition is undoubtedly a very complicated one and in view of the work of Rice and Reiff[4] and of Rice and Kilpatrick[5] on the effect of ultramicroscopic particles on the thermal and photochemical decomposition it seems that much of the previous work cannot be regarded as conclusive.

The absorption spectrum of hydrogen peroxide solutions has been photographed by Henri and Wurmser,[6] who found that it was continuous, but no studies have been made on its absorption spectrum in the gaseous state and no determinations of the coefficient of absorption at different wave lengths, either in solution or as a gas. It was the purpose of this research to investigate these two subjects to see what light they might throw on the photochemical decomposition.

Preparation of the Hydrogen Peroxide.—We have used the methods of Maass and Hatcher[1] and of Rice, Reiff and Kilpatrick[7] in the preparation of the hydrogen peroxide. For the study of the dilute solutions, a 30% solution of the trade substance, Superoxol, was diluted down to the required concentration and in order to get more concentrated solution the water was evaporated off in a vacuum desiccator over sulfuric acid to a concentration of 88 to 90%. From this point pure hydrogen peroxide was made by repeated crystallizations. The strength of the hydrogen peroxide was determined by titration with potassium permanganate, The concentration of the liquid used in the study of light absorption of the vapor was always greater than 95%.

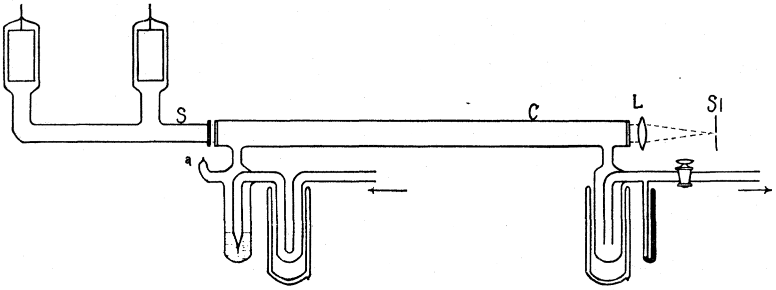

Fig. 1.

Apparatus for Determining the Absorption Spectrum.—In Fig. 1 is given a sketch of the apparatus, which remained essentially the same throughout the various experiments on absorption, though different types of absorption cells were used at different times. A hydrogen vacuum discharge tube, similar to that used by Tingey and Gerke[8] in their study of the absorption spectra of the hydrogen halides, was used as a source of continuous light and is shown in the figure at S. Electrolytic hydrogen was sealed off into the pyrex tube after degassing by passing a strong discharge through the tube, which raised it to a temperature of about 300°. A quartz window was sealed to the end with de Khotinsky cement to allow the passage of the ultraviolet light. We found

that at the high pressures of hydrogen within the tube necessary for the production of the hydrogen continuous (about 3 mm. of mercury) it was not satisfactory to cool the tube, with water directly, due to puncture of the glass by the high potential required to produce the discharge but we had to immerse it in transformer oil through which water circulated in a copper coil. The tube gave a dense continuous emission extending from the sensitivity of our plates in the green down inta the Schumann region. The maximum of the intensity of the continuous emission appeared to be about 3500 Å., though due to the greater dispersion in the ultraviolet is undoubtedly further to the violet. The first three lines of the Balmer series appeared; the green line was intense, and **the** blue line weak, being lost in the continuous. The color of the discharge was light blue with a tinge of pink. The current was supplied to the tube from a separate 110-volt, 60-cycle generator and stepped up to about 5000 volts across the tube. The current in the primary of the transformer was kept at 25 amperes and thus the emission intensity of the discharge tube remained quite constant. This tube has been used through the course of a year without renewing the hydrogen. The light from this source was passed through the absorption cell, C, of which several kinds were used. The light passing through the cell is approximately parallel due to the fact that the light from the luminous portion of the discharge tube passed through about 10 cm. of tubing before passing the quartz window. **A** lense at **I**, focused the light on the slit of the spectrograph at S1.

Two Hilger quartz spectrographs were used in our measurements, the larger, E-3, being used for the absorption curve, and the small one, E-37, to investigate the region 1850 to 2350 Å. and the fluorescence. **A** Hilger rotating sector photometer was used to vary the times of exposure in the comparison photometry to estimate the coefficient of absorption.

In the first experiment a quartz cell was constructed of 67.5 cm. length and **3** cm. diameter, and it was so arranged that the temperature of the cell and containing bulb could be raised to any desired temperature between 25 and 100° by means of an electrical heating coil surrounding both cell and containing bulb. The absorption spectrum of the vapor photographed through this cell held at different temperatures showed that the spectrum is continuous throughout the range from 2000 to **3100** Å. No absorption could be detected on our plates for wave lengths longer than about 3000 or 3100 Å., but the absorption extends further to the violet with no indication of a maximum in this region. It was impossible to duplicate the intensities of blackening for the same wave length in different experiments at temperatures above 25°, probably due to poor temperature control and thermal decomposition of the vapor. For this reason experiments at higher than room temperature were discontinued.

By using a cell 183.5 cm. in length and **3** cm. in diameter, it was possible to get the product of concentration and the length sufficiently great to determine the coefficient of absorption at 2750 **Å.** and shorter wave lengths with a vapor pressure of about 1.5 mm., corresponding to 20°. This long cell was constructed of a pyrex tube with quartz windows sealed on with de Khotinsky cement. The hydrogen peroxide vapor at room temperatures did not attack the de Khotinsky cement appreciably, though such action is to be expected. No difference in the absorption could be detected when this cell was used and when other shorter cells not having the de Khotinsky cement were used.

Method for Determining the Coefficient of Absorption.—The coefficient of absorption per molecule is defined by the formula

$$I = I_0 e^{-acd} \text{ or } a = 1/cd \ln I/I_0 \qquad (1)$$

where c is the concentration in molecules per cc., d the length of the column of gas and I and I_0 are the intensities after passing through the filled and empty cells, respectively. Assuming that

$$I/I_0 = t_0/t \tag{2}$$

where t_0 and t are the times required for the plate to be blackened to the same extent at a particular wave length by the light passing through the empty cell and the filled cell, respectively, we have

$$a = 1/cd \ln t_0/t \tag{3}$$

In our experiments it was necessary to use rather wide absorption cells because of the great length of absorbing vapor at low pressures required to secure absorption and this made it impossible to use two parallel identical cells, one empty and the other filled, as is usually done. We therefore adopted the following procedure. Exposures of the continuous spectrum through the empty cell for different values of $\ln t_0$ were taken, leaving alternate spaces on the photographic plate unexposed; then with the cell filled with the absorbing vapor exposures were made at these intermediate positions, using different values of $\ln t$. In this way we cannot compare the intensities of two spectra lying right side by side. We therefore matched the limit of the observable blackening of the plate. Taking two spectra, one through the empty cell and one through the filled cell having the same limit of blackening, the coefficient of absorption for this wave length is secured by substituting the values of $\ln t$ and $\ln t_0$ for these two spectra in (3) and it was found by trial that this limit was very reproducible. This method differs from the more usual one only in that we match the blackening on the plate for the point of zero blackening instead of at a finite intensity of blackening. We believe the errors of observation by this method are at least not much greater than in the more usual method.[10] Variation in the intensity of illumination was avoided by maintaining the current in the primary of the transformer constant during the experiments. We believe that this variation is small even over several hours, since the tube has been in use for months and therefore should not change with time, and, since it is well cooled, there should be no variation due to temperature. In practice we found it best to plot curves of $\ln t$ and $\ln t_0$ against wave length for the limits of blackening for the light passing through the filled cell and empty cell, respectively, and take the difference in $\ln t$ and $\ln t_0$ for a particular wave length from these curves.

Method of Experimental Procedure.—Into the bulb, a, a quantity of 97–100% hydrogen peroxide was introduced and air was bubbled through the liquid after first passing through the U-tube cooled in liquid air to remove all moisture. The dry air was admitted through a capillary tube and bubbled slowly through the liquid hydrogen peroxide to insure saturation with the vapor at the temperature of the bulb. Thus a constant current of vapor at a constant partial pressure streamed through the absorption cell while the absorption was being measured. This method of distilling the vapor partly eliminated the decomposition effect of the hydrogen peroxide due to the ultraviolet light. The total pressure maintained during a measurement was about 300 mm. of air and hydrogen peroxide. The hydrogen peroxide and any water produced were caught at the right end of the absorption cell in another liquid-air trap, beyond which were the mercury manometer and the oil pump.

---

[9] Schwarzschild first wrote this equation in the form $I/I_0 = (t_0/t)^n$ where n is slightly less than unity. Recent work by Gibson, McNicolas, Tyndall and Frehafer (Scientific Papers of the Bureau of Standards, No. 440, June, 1922) and by Baly, Morton and Riding, Proc. Roy. *Soc.* London, **113A**, 709 (1927), shows, however, that the exponent may be taken as unity with an error of not over a few per cent.

[10] Henri, "Études de Photochimie," Gauthier-Villars et Cie, Paris, 1919.

The bulb was held at a temperature of about 20° so that the vapor pressure according to Maass and Hatcher[10] is 1.5 mm. The value of *cd* is therefore $cd = 2.702 \times 10^{19} \times 273/293 \times 1.5/760 \times 183.5 = 0.88 \times 10^{20}$. We believe that this value is correct within about 10 to 20%. The possible sources of error are the rapid change of the vapor pressure with temperature, the incomplete saturation of the air passing through the liquid and any decomposition of the hydrogen peroxide due to the light and hear.

The coefficients of absorption of the aqueous solutions were determined by using a cell 5 cm. in length and varying the concentration in order to get suitable blackening at different wave lengths. Absorption begins between 3700 and 3800 Å.; the absorption coefficient increases slightly to 3000 Å., after which it increases rapidly with decreasing wave length. These *cd* values were correct to within 1 or 2% because of the more precise method for determining the concentration.

Table I is a summary of our measurements and Pig. 2 shows them in graphical form. The circles represent values of a calculated from two plates for the solution and show the magnitude of deviation from the mean value. The crosses represent the absorption coefficients for the vapor. These cannot be regarded as very precise because of the uncertainty of the cd, but within this estimated uncertainty the curves for the vapor and solution coincide.

TABLE I

SUMMARY OF MEASUREMENTS

Wave length	Mean a	Number of plates	Wave length	Mean a	Number of plates
3800	0	2	2700	4.1	6
3700	0.1	2	2650	5.4	7
3600	0.2	2	2600	6.9	7
3500	0.2	2	2550	8.3	4
3400	0.3	2	2500	10.2	4
3300	0.4	2	2450	12.2	3
3200	0.5	3	2400	14.7	3
3100	0.7	3	2350	17.9	3
3000	1.0	4	2300	22.0	3
2900	1.5	5	2250	25.6	3
2800	2.4	5	2200	28.9	3
2750	3.1	5	2150	31.5	3

Value of *cd* for the vapor $= 0.882 \times 10^{20}$; values for the liquid $cd = 1.148, 0.579, 0.289, 0.114, 0.0723, 0.0362 \times 10^{20}$.

Discussion of the Absorption Experiments.—Since the spectrum is continuous, with no structure of any kind, we must conclude that the elementary process of the absorption of light is to dissociate the molecule into two or more fragments in accordance with Franck's[11] interpretation of continuous absorption spectra of the hydrogen halides and halogens. The conservation of energy requires that the energy of the quantum absorbed shall be

$$h\nu = E_1' + E_2' + \ldots\ldots + D + {}^1/_2M_1v_1^2 + {}^1/_2M_2v_2^2\ldots\ldots \qquad (4_2)$$

---

[11] For the theory of the dissociation process see Franck, *Trans. Faraday Soc.*, 21, 536 (1925); Condon, *Phys. Rev.*, 28,1182 (1926).

where E'_1, E'_2...... are the energies of excitation of the resulting molecules, D is the energy of dissociation and $^1/_2M_1v_1^2$, $^1/_2M_2v_2^2$.... are the kinetic energies of the resulting molecules relative to the center of mass of the system. Since these resulting molecules can have unquantized kinetic energy of translation, the continuous absorption spectrum will lie on the violet side of the wave length for which

$$h\nu = E'_1 + E'_2 + \ldots\ldots + D \qquad (5_2)$$

and any discontinuous spectrum on the long wave length side. It may happen that the main intensity of absorption may occur considerably toward the violet side of this limit and thus only a continuous spectrum will be observed. This appears to be true of hydrogen peroxide. In the case of the alkali halides and hydrogen halides[12] only such continuous absorption spectra are observed, while in the case of the halogens the discontinuous and continuous absorption spectra are both known and meet at the frequency defined by (5). These considerations are repeated here because they have a direct bearing on the interpretation of this continuous spectrum.

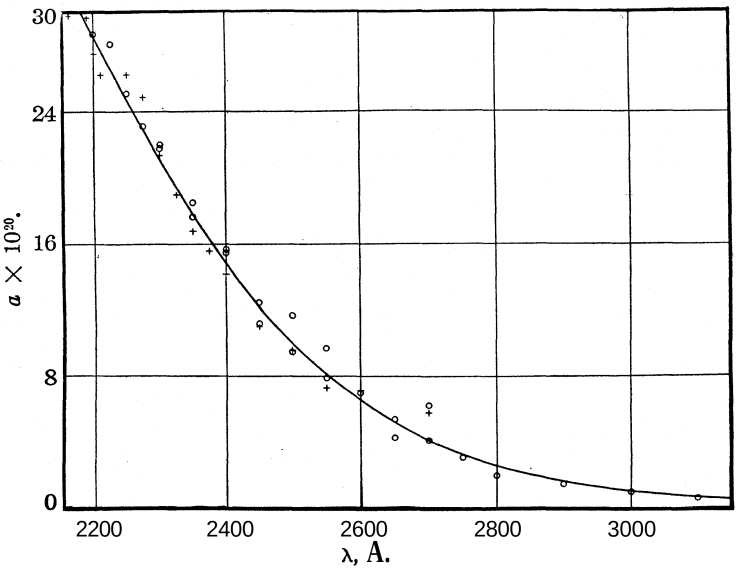

Fig. 2.

Henri has found that such continuous spectra are observed for associated vapors and there is a possibility that the absorption in the vapor state is due to the presence of a small percentage of $(H_2O_2)_n$. The absorption of light by such a molecule might result in its dissociation into

---

[12] Franck, Kuhn and Rollefson, *Z. Physik*, 43, 155 (1927); Franck and Kuhn, *ibid.*, 43, 164 (1927); 44, 607 (1927); Franck and Hogness, *ibid.*, 44, 26 (1927).

one excited and one unexcited molecule and thus even if the molecule is not dissociated into atoms or unstable molecules such as OH, the spectrum might be continuous. Most of our work has been done at very low pressures, however, and under these conditions we expect that any such association would be very small. Elder and Rideal[3] find no evidence of association of hydrogen peroxide at 85 mm. and 85°. Kendall[13] has considered the question of association of water vapor and concludes that over a considerable range of pressures and temperatures there is no evidence for association. Because of the great similarity of physical properties of hydrogen peroxide and water, this makes it probable that such association of hydrogen peroxide must be small. Even if a continuous absorption of a very small fraction of polymerized molecules were present, one would expect a band spectrum of greater intensity superimposed on it. The absence of such a band spectrum indicates that the normal unassociated molecule must also have a continuous absorption spectrum. The question could be definitely decided by studying the absorption of the vapor at high and low pressures with the same value of cd, for the absorption should be greater at the higher pressures if polymerized molecules are responsible for the absorption and it should be the same if the unpolymerized molecules are responsible for the absorption. This would be very difficult with hydrogen peroxide because of its low vapor pressure at temperatures where thermal dissociation is slow. Thus to compare the absorption by two columns of vapor, one at 1.5 mm. pressure and say 183 cm. long, and another at 0.15 mm. pressure and some 18 meters long, would be impossible.

Hydrogen peroxide may be considered to be a pseudo-halogen. The normal states of the halogen atoms are inverted ^2P states with inner quantum numbers 3/2 and 1/2, the 3/2 state being the one with lower energy. Similarly, the OH molecule has the same number of electrons as the fluorine atom and also its normal state is an inverted ^2P state according to Mulliken.[14] We may make the postulate that the hydrogen peroxide molecule is formed of two OH molecules in a way similar to the formation of the halogen molecules from the individual atoms. Our experiments on the absorption of light described above support such an assumption. It is true, of course, that in chemical and physical properties there is very little similarity between hydrogen peroxide and the halogens, but the curves for the coefficients of absorption for I_2, Br_2 and Cl_2 show a progressive change which would lead us to expect that this curve for hydrogen peroxide would lie as it does. According to Ribaud and Kuhn,[15] the maxima for the absorption by I_2, Br_2 and Cl_2 lie 400,

900 and 1400 Å., respectively, to the violet side of the critical wave lengths required for dissociation into a normal and excited atom, respectively. These critical wave lengths are 4995, 5107 and 4785 Å. and thus the three maxima lie at 4595, 4207 and 3385 Å., respectively. The absorption spectrum of fluorine is unknown, but it would probably have a maximum absorption at a considerably shorter wave length than that of chlorine, and if the action of light on the hydrogen peroxide molecule is similar, the maximum should also lie to the violet side of that for chlorine, as it does. The continuous absorption by I_2, Br_2 and Cl_2 is due to molecules in the lowest vibrational state; in the case of Cl_2 absorption by molecules in the lowest vibrational state occurs only in the continuous region, and its band spectrum is due to absorption by molecules in the first or second vibrational state. In the case of hydrogen peroxide it appears that molecules in all the vibrational states present in appreciable number at 20° absorb only in the continuous region, and that this continuous region is far to the violet side of the critical wave length for dissociation. We shall now consider in detail the known energy relations for the various conceivable ways that the molecule could dissociate.

Assuming hydrogen peroxide to have the structural formula H–O–O–H, it appears that primary dissociation might occur in three ways, namely, to produce two OH molecules in their normal states, or to break off one H atom leaving the HOO molecule; the removal of an oxygen atom from the middle of the molecule, thus leaving a water molecule, appears less probable. We wish to calculate the energy change for these three reactions from known data. In the thermochemical equations which follow, we employ the usual convention in regard to sign of the energy change, namely, the energy of the products minus that of the reactants. The energy of dissociation into H_2O and O can be exactly calculated as follows

$$\begin{array}{lll}
\text{(a)} & \mathrm{HOOH = HOH + {}^1/_2O_2} & -25.2\ \text{cal.}^{16} \\
\text{(b)} & \mathrm{{}^1/_2O_2 \;\;= O} & 81.0\ \text{cal.}^{17} \\
\hline
\textit{(c)} & \mathrm{HOOH = HOH + O} & 55.8\ \text{cal.}
\end{array}$$

The energy change for dissociation into two OH molecules cannot be exactly calculated, but can be approximated from the following equations

$$\begin{array}{lll}
\text{(a)} & \mathrm{HOOH = HOH + {}^1/_2O_2} & -25.2\ \text{cal.} \\
\text{(d)} & \mathrm{2HOH = 2H + 2OH} & 224.0\ \text{cal.}^{18} \\
\text{(e)} & \mathrm{2H \;+ = He} & -102\ \text{cal.}^{19} \\
\text{(f)} & \mathrm{H_2O + {}^1/_2O_2 = HOH} & -57.8\ \text{cal.}^{16} \\
\hline
\text{(g)} & \mathrm{HOOH = 2OH} & 39\ \text{cal.}
\end{array}$$

[17] Birge and Sponer, *Phys. Rev.*, N. S., 28,259 (1926).

[18] Taylor and Bates, *Proc. Nat. Acad. Sci.*, 12, 714 (1926); THIS JOURNAL, 49, 2438 (1927).

[19] Witmer, *Phys. Rev.*, 28, 1223 (1926); Dieke and Hopfield, *Z. Physik*, 40, 299 (1926).

The uncertainty in this figure is in the energy required to remove one hydrogen atom from water and this is less than 112 cal., since Taylor and Bates were able to dissociate water vapor with mercury atoms excited to the $^3P_1$ state. The energy change for dissociation into HOO and H cannot be calculated. The energy change for the reaction $HOOH = 2H + O_2$ can be calculated from the following equations

(h) $HOOH = H_2 + O_2$ 32.6 cal.[16]
(e) $H_2 = 2H$ 102.0 cal.[19]

(i) $HOOH = 2H + O_2$ 134.6 cal.

and assuming that the change for the removal of the two hydrogen atoms, successively, is the same, we have

(j) $HOOH = HOO + H$ 67.3 cal.
(k) $HOO = H + O_2$ 67.3 cal.

In the case of water the removal of the first hydrogen requires less energy than the second, for from the equations given for the dissociation of O_2 and H_2 and the energy of formation of water, (b), (e) and (f), we have

(m) $HOH = 2H + O$ 240.8 cal.

and thus using (d)

(n) $OH = O + H$ 128.8 cal.

From analogy, the energy change for (j) may be less than 67.3 cal. and that for (k) greater than 67.3 cal., though this is not necessarily true.

The longer wave-length limit of absorption of the liquid is about 3750 Å., which is equivalent to 76.2 cal., and the longest wave length for the observed absorption of the vapor is about 3000 Å., corresponding to 95 cal. Over the range from 2250 to 2750 Å., where we found it possible to determine the coefficients of absorption for the solution and the gas, these coefficients agree within the limits of our measurements. It was impossible to determine the absorption coefficient for the gas at longer wave lengths because of the impossibility of getting a larger value of *cd* without increasing the temperature. It may be that the vapor would also absorb out to 3750 Å., if a sufficiently thick layer could be secured. It is evident in any case that there is sufficient energy even at 3750 Å. to cause any of the three reactions postulated to take place, and give considerable kinetic energy of translation or internal vibrational or rotational energy to the products. We cannot on this basis alone exclude any of them.

Effect of an Electric Discharge on Hydrogen Peroxide.—It is well known that the so-called water bands due to the OH molecule and the atomic spectrum of hydrogen appear with great intensity when water vapor is excited by an electric discharge at low pressures. The atomic oxygen spectrum appears only with comparatively low intensity. With a condensed discharge, or, if the discharge tube is allowed to become hot, the oxygen spectrum appears. We interpret this to mean that the comparatively low velocity electrons of the uncondensed discharge cause a disruption of water molecules into excited or unexcited OH molecules and H-atoms. The faintness of the O and H_2 spectra indicates that these are not primary products of bombardment of water in the uncondensed discharge.

An uncondensed electric discharge in hydrogen peroxide gives quite a different spectrum from that of water, if the hydrogen peroxide is streamed rapidly through the discharge tube, and the tube is kept well cooled. In these experiments hydrogen peroxide of nearly 100% purity was passed through a quartz tube 1 cm. in diameter by evaporating liquid hydrogen peroxide from a side arm of the tube and condensing it and any water formed in a liquid-air trap and pumping off the gases. Under these conditions the hydrogen peroxide must have been in this discharge only 0.1 to 0.01 second. As long as the tube was cool and the evaporation of hydrogen peroxide was rapid, the tube had a dull blue color in contrast to the characteristic red color of the discharge in water. By using a spectroscope we found that both atomic and molecular spectra of hydrogen were almost entirely absent. The faint blue color of the tube is due to a faint continuous spectrum. A photograph of the spectrum with the quartz spectrograph shows that the water bands are very intense and also that the continuous in the ultraviolet is faint. We are unable as yet to decide whether the continuous spectrum is identical with that of hydrogen or not.

The absence of the molecular and atomic spectra of hydrogen under these conditions leads us to believe that the comparatively slow electron bombardment causes the dissociation of hydrogen peroxide into two normal OH molecules and their subsequent excitation, or into one excited and one unexcited OH molecule, or into two excited OH molecules, so that the predominant spectrum is that of the water bands. The dissociation in such a way that oxygen or hydrogen atoms appear is at least much less probable. Since inelastic collisions of electrons with atoms and molecules are more probable, if the transition is one permitted by the selection rules for the emission and absorption of light, this experiment favors the postulate that light also dissociates hydrogen peroxide into normal or excited OH molecules.[20]

Experiments on the Fluorescence of Hydrogen Peroxide.—Our calculations on the energy changes thus far have considered only the dissociation into molecules in their lowest energy states. If the dissociation of hydrogen peroxide by light is similar to that of the halogens, the one OH molecule should be left in a $^2P_{1/2}$ state and the other in a $^2P_{3/2}$ state. However, since the energy difference of these two states is only 140.25 wave numbers according to Kemble,[21] which is equivalent to only 0.4 cal., and of the

---

[20] See Franck and Jordan, "Handbuch der Physik," Julius Springer, 1926, Vol. 23, p. 721.

[21] Kemble, Phys. *Rev.*, N. S. 30,387 (1927).

order of the rotation energy of the molecule, it is too small to be of importance in our thermochemical calculations. The next higher state is probably the ^2S state, which is the excited state for the emission of the water bands. Five of these bands are well known; their wave lengths and the initial and final values of the vibration quantums, n', and n'', are: 3064 (0,0); 2811, (1,0); 2875 (2,1); 2608 (2,0); and 3428 (0,1).[22] The wave numbers of the 3064, 2811 and 2608 bands give directly the energies required to excite the OH molecule to the ^2S state with vibrational quantum numbers 0, 1 and 2, respectively. These wave numbers are 32,637, 35,575 and 38,343, respectively. If then hydrogen peroxide is illuminated with light of sufficiently high wave number to dissociate the molecule into a normal OH molecule and an excited OH molecule in a ^2S state and one of these vibrational states, and if the dissociation in this way is a possible one, it should be possible to observe the OH bands in fluorescence under proper conditions. The essential experimental requirements are *intense illumination of the vapor at low pressure* so that the fluorescence is not quenched by collisions with other hydrogen peroxide molecules or water molecules. Since the vapor pressure of water at 20° is 17.4 mm. of mercury, while that of hydrogen peroxide is only 1.5 mm., it is necessary to use very pure hydrogen peroxide.

The energy required to dissociate hydrogen peroxide into two normal OH molecules is less than 39 cal. (Eq. g), which is equivalent to 13,660 wave numbers. The wave number, $\tilde{\nu}$, and wave lengths of the light required to dissociate the molecule and excite the one OH molecule to the ^2S state with different amounts of vibrational energy are

		$\tilde{\nu}$	λ
(g)	$HOOH = \mathrm{OH}(^2P) + \mathrm{OH}(^2P)$	13660 cm.$^{-1}$	7320 Å.
(o)	$HOOH = \mathrm{OH}(^2P) + \mathrm{OH}(^2S, n' = 0)$	46350 cm.$^{-1}$	2160 Å.
(p)	$HOOH = \mathrm{OH}(^2P) + \mathrm{OH}(^2S, n' = 1)$	49020 cm.$^{-1}$	2040 Å.
(q)	$HOOH = \mathrm{OH}(^2P) + \mathrm{OH}(^2S, n' = 2)$	52050 cm.$^{-1}$	1920 Å.

Hydrogen peroxide vapor at a pressure of about 1 mm. of mercury was illuminated with the 2025, 2060, 2087, 2100 and 2138 Å. lines of the zinc spark, and the presence of the 3064 Å. water band was detected in fluorescence. The light from a zinc spark was passed through an acetone filter, which absorbed all the light from 2138 to 3075 Å., and transmitted longer wave lengths and shorter wave lengths to about 2025 Å., so that this zinc line is faint. The longer wave lengths are only slightly absorbed by hydrogen peroxide and are therefore of no importance. The zinc

Fortrat J. *Phys.*, 5, *20 (1924)*; W. *W.* Watson, *Astrophys.* **J.**, 60, *145 (1924)*; *G. H.* Dieke, *Proc. Acad. Sci. Amsterdam*, 28, *174 (1925)*; *R. T.* Birge, Chapter LV, Part **5**, National Research Council Report on Molecular Spectra in Gases; D. Jack, *Proc. Roy. Soc. London*, **115A**, *373 (1927)*; **118A**, *647 (1928)*; *E.* C. Kemble, *Phys. Rev.*, 30,337 *(1927)*.

spark has only the five strong lines between 2138 Å. and 2025 Å. Thus these five intense lines and less intense ones are the only ones effective in producing fluorescence. After passing the acetone filter the light passed through a long cell of hydrogen peroxide vapor. The spectrograph was placed in the direct line of this incident light. The photographic plate showed these incident wave lengths strongly so that the entire tube must have been excited to fluorescence. The fluorescent water bands fall in the region of absorption of acetone so that the presence of the incident light on the plate did not prevent the detection of the fluorescent light. The head of the 3064 Å. water band falls about 11 Å. to the short wave-length side of the 3075 Å. line of the zinc spark and appears as a faint sharp edge just in this position. No other water bands were detected, probably because of their lower intensities or because the light used may not be of sufficiently short wave length to excite the higher vibration levels.

This experiment shows definitely that the reaction (o) is one possible way in which light dissociates the molecule.[23]

One of us (L. H. D.) is continuing this phase of the work with better methods for exciting this fluorescence expecting to secure the other water bands and determine, if possible, the energy change of (g) more accurately by this method. Furthermore, the recent work of Kondratjew and Leipunsky[24] on the recombination spectra of the halogens and that of Bates and Urey[25] on the continuous spectra emitted by flames containing hydrogen and the halogens and interpreted by them as the recombination spectra of halogen atoms, suggest that further study of the continuous emission spectrum of hydrogen peroxide may give more information

---

[23] Since the writing of this paper an article has appeared [Bonhoeffer and Haber, *Z. physik. Chem.*, 137, **263 (1928)**] in which the heat of dissociation of the OH molecule has been taken as **123** cal. and the energy of dissociation of the first H atom from the water molecule as **115** cal. The energy of dissociation of hydrogen peroxide into gaseous hydrogen and oxygen is taken as **38** cal. by a different method of calculation. However, the value of **32.8** cal. for the energy of formation of hydrogen peroxide as calculated by Lewis and Randall[16] seems to us a better value than that calculated by Wartenberg and Sieg [*Ber.*, 53, **2192** (1920)] and the energy of formation of water from the atoms is **240.8** according to our calculations. These values have not been calculated to absolute zero and are therefore not very accurate. If the value of 54 Cal. for Equation (g) is correct, we should not have been able to secure the **3064 Å.** water band in fluorescence and in fact the energy change in this reaction cannot be much greater than **39** cal. if the **3064** Å. band is to be excited by the wave lengths we have used. The photochemical experiments of Bates and Taylor[18] and Senftleben and Rehren [Z. *Physik*, 37, **529** (1926)] and also Bonhoeffer and Reichardt [Z. *Elektrochem.*, 34, **652** (1928)] on the equilibrium $2H_2O = H_2 + 2OH$ at high temperatures indicate that **115** cal. is too large. If we use **115** cal. instead of **112** cal. and leave the remaining values in our calculations the same, the water band should not appear in our experiments.

[24] Kondratjew and Leipunsky, *Z. Physik*, 50, **366 (1928).**

[25] Bates and Urey, *Phys. Rev.*, N. S., article to appear soon.

in regard to the processes taking place in the discharge; this will be studied further.

Summary

1. The absorption spectrum of hydrogen peroxide vapor in the ultra-violet has been found to be continuous with no indication of any structure beginning at about 3000–3100 Å. and extended toward the ultra-violet.

2. The coefficients of absorption of hydrogen peroxide in solution have been determined for wave lengths from 3750 to 2150 Å. and those of its vapor for wave lengths 2150 to 2750 Å. Over this latter range and within the limits of experimental error the two absorption curves are the same.

3. The possible photochemical processes are discussed and it is found that the quantum of energy of the longest wave lengths absorbed would be more than sufficient to cause any of the following three reactions to take place

$$H_2O_2 + h\nu \longrightarrow 2OH \qquad H_2O_2 + h\nu \longrightarrow HO_2 \qquad H_2O_2 + h\nu \longrightarrow H_2O + O$$

4. The emission spectrum of hydrogen peroxide when streamed rapidly through a cool discharge tube is predominantly that of the water bands (due to OH). This favors the first of these three reactions as the one occurring in the photochemical process.

5. Illumination with the zinc spark lines from 2025 to 2138 Å. caused the water bands to appear in fluorescence. This shows that the following reaction takes place under these conditions

$$H_2O_2 + h\nu = OH(^2P) + OH(^2S)$$

6. The analogy of hydrogen peroxide to the halogens with respect to structure is pointed out and the evidence, though not conclusive, favors the following reaction as the one occurring when it is illuminated with wave lengths from about 2200 to 3000 Å.

$$H_2O_2 + h\nu = OH(^2P_{1/2}) + OH(^2P_{3/2})$$

This would be similar to the primary process occurring when the halogens absorb light in the continuous region of their spectra.

THE NEAR INFRA-RED ABSORPTION SPECTRA OF SOME ALDEHYDES, KETONES, ESTERS AND ETHERS

BY JOSEPH W. ELLIS

RECEIVED DECEMBER 11, 1928 PUBLISHED MAY 6, 1929

The infra-red absorption spectra of a group of aldehydes, ketones and esters have been obtained in the wave length region shorter than 2.5 μ with the primary purpose of ascertaining whether there are any features in such spectra assignable to the carbonyl group. The spectra of ethyl sulfate, pentane and three ethers have also been recorded for comparison purposes. The technique adopted was similar to that followed in some previous investigations by the author.[1] A few changes in the procedure of securing these absorption records are perhaps worthy of mention.

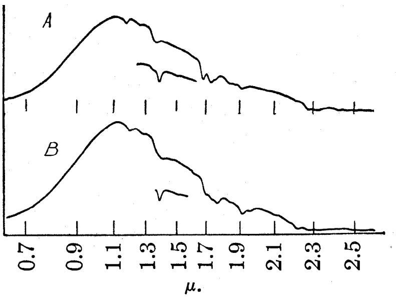

Fig. 1.—A, Acetaldehyde; B, propionaldehyde.

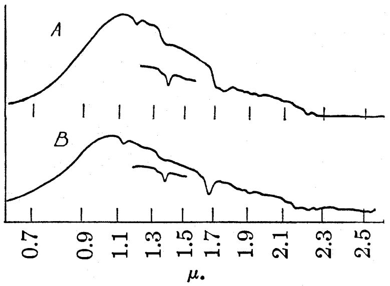

Fig. 2.—A, Butyraldehyde; B, benzaldehyde.

The tungsten lamp, rated at 7.5 amperes, was operated on much higher currents during this investigation. This permitted the use of narrower slits in the spectrograph. In obtaining the first set of records, Figs. 1–13, the initial slit and the one in front of the thermopile had a width of 0.152 mm. A slit of this width covers a spectral region of about 0.007 μ in the vicinity of 1.8 μ. The cell thickness, with two exceptions to be mentioned later, was 1 mm. The lamp source was operated on 9 amperes. The second set of records, Figs. 14–23, was for a cell thickness of 40 mm. The current was increased to 10 amperes and the slits narrowed to 0.127 mm., which is equivalent to about 0.006 μ at 1.8 μ.

With slits as narrow as this it was found impractical to adopt the previous method of using a visible emission spectrum line for a standard of reference. Consequently, it was decided to use the relatively sharp 1.39 μ absorption band of a 2-mm. cell of chloroform. To see whether it would be permissible to rack the plate-holder back to the vicinity of 1.4 μ

---

[1] (a) Ellis, THIS JOURNAL, 49,347 (1927); (b) 50,685 (1928).

after an absorption record had been taken, for the purpose of tracing the chloroform band, several records of absorption curves were retraced on their original plates. The almost exact superposition of these records indicated that it would be practicable to rely upon this method of superposing a standard baod upon the plate. This reference band is found in Figs. 1–13.

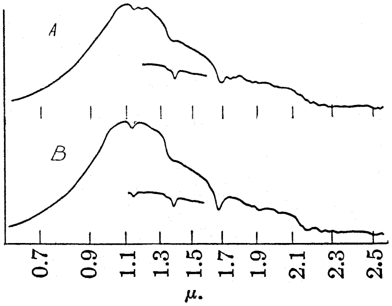

Fig. 3.—A, p-Tolualdehyde; B, cinnamaldehyde.

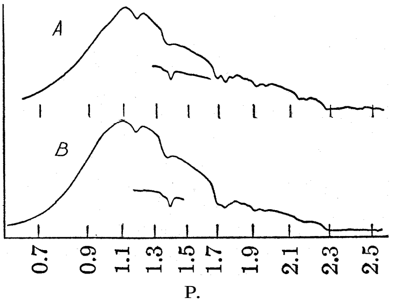

Fig. 4.—A, Acetone; B, methyl-n-propyl ketone.

It was discovered during the investigation, however, that there was an occasional record in which the 1.39 μ band was apparently shifted with respect to the spectrum recorded. This shift was ascertained from the following two observations. (1) As a result of a study of a considerable number of organic compounds, it becomes possible to predict fairly accurately the wave length positions of certain recurring bands. (2) A considerable increase in resolving power resulting from a narrowing of the slits revealed the identity of the so-called P, Q and R branches of the 1.87 μ atmospheric water-vapor band. The sharp Q branch is observable not only in the intensity distribution curve of Fig. 13A but also in all of the absorption records of Figs. 1–13. This band, therefore, was chosen as the reference line in these measurements. In obtaining the records of Figs. 14–23 the 40-mm. cell was removed near 1.5 μ although the record

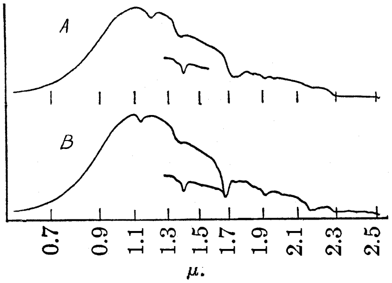

Fig. 5.—A, Methyl-n-amyl ketone; B, acetophenone.

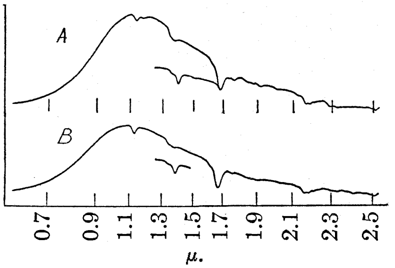

Fig. 6.—A, Propiophenone; B, benzophenone.

was continued to include the 1.87 μ water-vapor band. This reference band, however, has not been included in the figures.

Of the twenty-five compounds whose absorption curves are here presented eighteen contain a single carbonyl group, $=C=O$, while two others contain two such groups. Pentane and ethyl sulfate were included to show the behavior of a typical hydrocarbon and a typical alkyl radical, respectively. The three ethers were studied to see if any features appear which are characteristic of the oxygen atom in the chain.

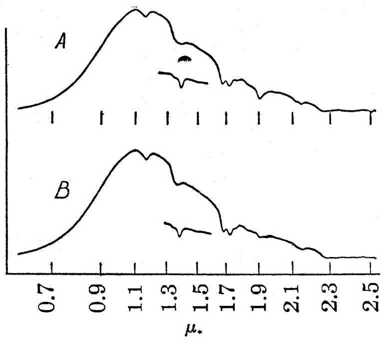

Fig. **7.—A,** Methyl acetate; B, ethyl acetate.

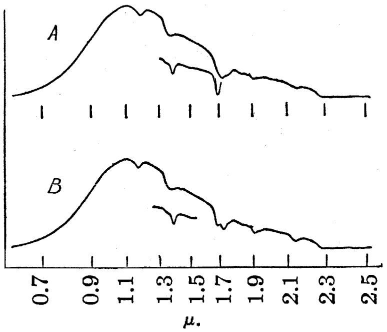

Fig. **8.—A,** ***n*-Butyl** acetate; B, ethyl **malonate.**

All of the compounds are liquids at room temperature except quinone and benzophenone, which are solids. These latter two substances were therefore examined in carbon tetrachloride solution. A 40-mm. cell of the solution containing an amount of the solid equivalent to a 1-mm. thickness of the material in its crystalline state was used. Their spectra have been included with the 1-mm. cell records of the liquid compounds. All of the materials whose absorption spectra are here presented were purchased from the Eastman Kodak Company.

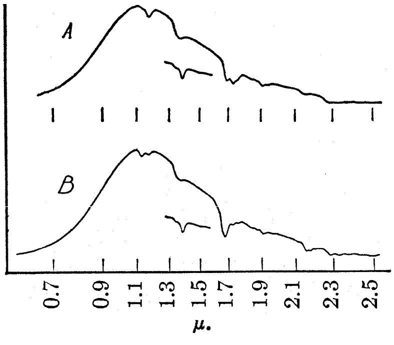

Fig. **9.—A,** Ethyl propionate; B, ethyl benzoate.

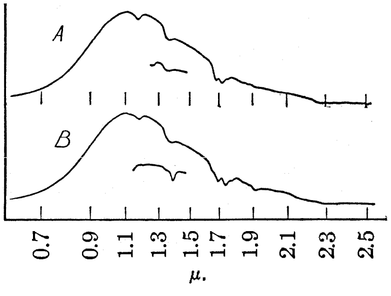

Fig. **10.—A,** Ethyl sulfate; B, acetylacetone.

Several investigations, mainly in the infra-red, already described in the literature, have some bearing upon the present study. Smith and Boord[2] in an investigation apparently undertaken to test the present author's previous conclusion that there is a C–H series of absorption bands characteristic of carbon–hydrogen compounds, included in their group of substances several of which contain the carbonyl group. Their investigation did not extend beyond 2.5 μ. The resolution of bands which they secured was good in spite of the fact that they used a spectroscope equipped with a single 60° rock-salt prism. The region covered by them was the same as that covered in this investigation. However, the quartz prisms used here gave a dispersion and a resolution many times that secured by Smith and Boord. This is shown by a comparison of absorption curves of the three substances common to both investigations.

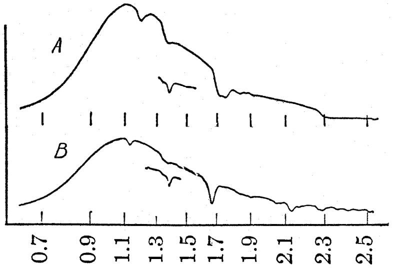

Fig. 12.—A, n-Butyl ether; B, quinone.

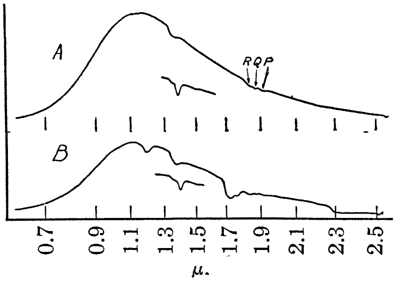

Fig. 13.—A, Intensity distribution; B, pentane.

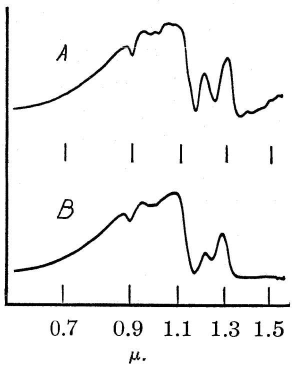

Fig. 14.—A, Acetaldehyde; B, propionaldehyde.

Several investigations made in the region beyond 2.5 μ include molecules

---

[2] Smith and Boord, This Journal, 48, 1512 (1926).

containing the carbonyl group. The extensive study made by Coblentz[3] includes several of these molecules. His records show in each case a strong band near 5.8 μ which he apparently refrains from definitely associating with the $=C=O$ pair because the paraffin hydrocarbons also show a weaker band at this position.

Marsh[4] pointed out that in an investigation made by Spence[5] upon a number of alkaloids the presence or absence of a strong 5.8 μ band marks a distinguishing feature between those molecules containing the carbonyl group and those which do not contain it.

Henri[6] concluded from his study of several aldehydes, ketones and acids that three bands at 8.2–8.5, 5.7–5.85 and 4.9 μ are produced by the $=C=O$ pair.

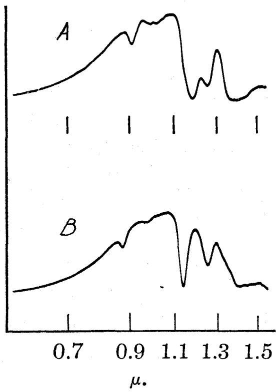

Fig. 15.—A, Butyraldehyde; B, benzaldehyde.

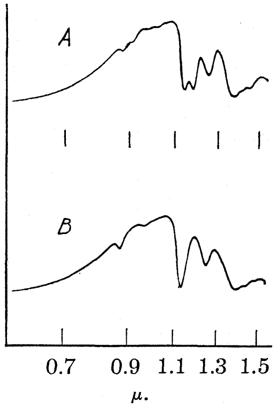

Fig. 16.—A, p-Tolualdehyde: B, cinnamaldehyde.

Bonino's[7] investigation of four homologous ketones was limited to the C–H band at 3.4 μ.

From the results of a study of twenty-five aldehydes and ketones Lecomte[8] concluded that a band occurring between 5.90 and 6.03 μ characterizes the $=C=O$ group, while a weaker one at 2.90–3.05 μ is its first overtone. (Lecomte's values are obviously consistently too high, as is evidenced by a comparison of the values in this and others of his papers with numerous determinations by various investigators.)

In his visible Tesla emission spectra of some aldehydes and ketones, Marsh[9]

found certain "blue bands" which showed a constant frequency separation of 172 mm.^{-1}. This frequency he associated with a molecular vibration which also gives rise under the proper conditions to the 5.8 μ infra-red absorption bands of these substances.

A conclusion by Bell[10] derived from his examination of the infra-red absorption of several tropine alkaloids is of interest. He is unwilling to conclude that the 5.8 μ band which he observed in those compounds containing the =C=O groups is a unique characteristic of this group inasmuch as the simple chain hydrocarbons also show absorption in the same region. Bell[11] still retains this attitude in his recent interpretation of the appearance of a strong 5.75 μ band in his spectra of seven organic carbonates.

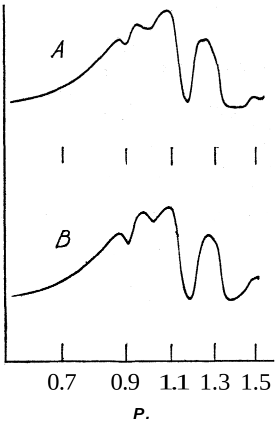

Fig. 17.—A, Acetone; B, methyl-n-propyl ketone.

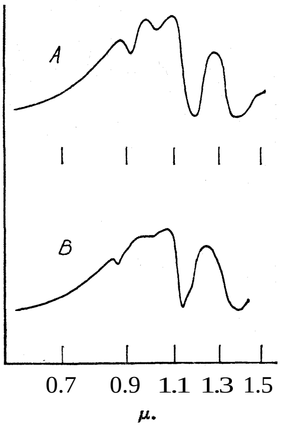

Fig. 18.—A, Methyl-n-amyl ketone; B, Acetophenone.

Bennett and Daniels[12] have recorded the absorption of acetic acid, mono-, di- and trichloro-acetic acids, methyl acetate and acetic anhydride in the regions 2–6 μ and 7–8 μ. They observed a strong band at 5.9 μ for acetic acid which progressively shifts to 5.75 μ upon successive substitutions of chlorine atoms. Their conclusion that this absorption maximum arises from the hydroxyl pair of the carboxyl group is not supported by the appearance of equally intense bands at 5.8 μ and 5.6 μ in their spectra of methyl acetate and acetic anhydride, respectively. It seems more probable that the bands in all six substances arise from the =C=O pair.

On the assumption that the 5.8 μ absorption maximum which is commonly observed is a fundamental band originating in a change of vibration

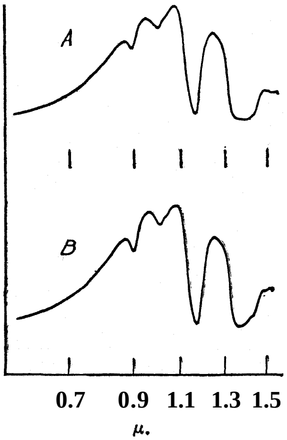
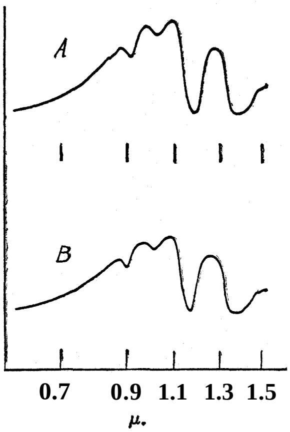
[12] Bennett and Daniels, *ibid.*, **49**, 50 (1927).

of the $=C=O$ atoms and that the 2.9 μ band found by Lecomte is its first overtone, it might be reasonably anticipated that higher overtones could be found below 2.5 μ provided cells of sufficient thickness were used. Now in the records of the absorption by the 1-mm. layers of the compounds containing the carbonyl group, Figs. 1–13, eighteen out of twenty of these substances show definite absorption at 1.9–2.0 μ, which is not characteristic of ordinary hydrocarbons. The other two examples, *p*-tolualdehyde and benzophenone, are doubtful. If the bands do occur in their records they are weak. The uncertainty in these two instances is increased by the fact that the band in question falls upon the P branch of the 1.87 μ water-vapor band. The weakness of the band in benzophenone, assuming that it really is present, could possibly be explained by the fact that the molecular weight of this molecule is relatively high, thus reducing the number of $=C=O$ absorbing centers per cubic centimeter; and also perhaps by the fact that this substance was one of the two examined in carbon tetrachloride solution. Its weakness, or absence, in p-tolualdehyde is not so easy to understand.



Pig. 19.—A, Methyl acetate; B, ethyl acetate.



Pig. 20.—A, Butyl acetate; B, ethyl malonate.

The region 1.9–2.0 μ is the one in which a second overtone band of the 5.8 μ band would be sought. Because of the variation in the location of this longer wave length band as recorded by different observers, it is a little difficult to decide whether there is an exact integer relationship between it and the 1.9 μ band. A slight deviation from an exact one-to-three ratio between their frequencies would be anticipated as a result of numerous observations made upon infra-red absorption series. Thus the wave length of this possible harmonic band should be slightly greater than one-third of the wave length of the fundamental. A deviation comparable to the 1.5% variation from a 1:3 relationship found by Schaefer and Thomas[13] and calculated by Birge[14] between the fundamental carbon monoxide band at 4.67 μ and its second overtone at 1.57 μ mould be expected. The much larger variation, 4%, found by the writer[15] for infrared absorption bands produced by C–H anti N–H groups is doubtless due to the greater amplitudes of vibration resulting from the lightness of the hydrogen atom.

The inability to ascertain the exact nature of the overtone relationship existing between the 5.8 μ and the 1.9 μ bands is increased by the fact that the latter band appears double in a majority of the spectra. Whether this doubling has any bearing upon a similar phenomenon in many hydrocarbon bands[15] cannot be decided at this time.

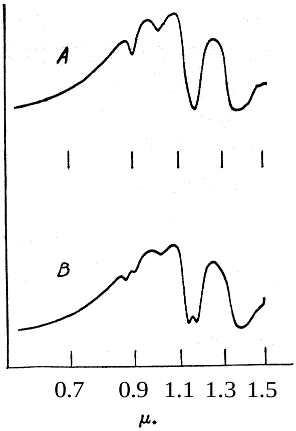


Fig. 21.—A, Ethyl propionate; B, ethyl benzoate.

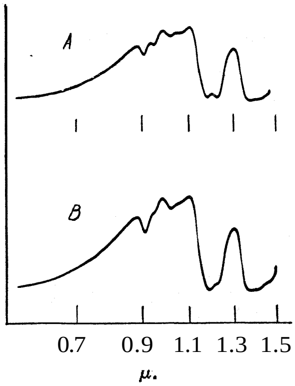

Fig. 22.—A, Ethyl ether; B, propyl ether.

As an example of the uncertainty which arises we may consider the spectrum of acetone, Fig. 4A. It shows prominent bands at 1.91 and 1.97 μ. Now the long wave length absorption maximum has been located by Coblentz[3] at 5.75 μ and by Henri[6] at 5.7 μ. Thus an exactly harmonic band would be expected between 1.90 and 1.92 μ. The question remains whether this overtone band is to be sought in the observed 1.91 μ or the 1.97 μ band or in their weighted mean. The writer inclines toward the latter point of view.

A third overtone of the 5.8 μ band would occur near 1.45 μ. The records of the 40-mm. cells, Figs. 14–23, show absorption at this point, indications of doubling appearing in several instances. Again, uncertainty

[14] Birge, *Phys. Rev.*, 28, 1157 (1926).

[15] Ellis, *ibid.*, **33,** 27 (1929).

is introduced because of the proximity of the complicated 1.4 μ band characteristic of hydrocarbons.

A fourth overtone, if present, should occur near 1.16 μ. This again falls upon or near a C–H band. The asymmetry of the deep 1.14–1.20 μ absorption band in many instances indicates the possible presence of such an overtone.

A fifth overtone would be found near 0.97 μ. Such a band does appear in the records of the aldehydes. If it is present in many of the other curves it is either very weak or has shifted to merge with the 1.0 μ hydrocarbon band.

Absorption near 0.9, 1.0, 1.18, 1.4, 1.7 and 2.18 μ (benzene and phenyl radical), 2.3 μ (paraffins and alkyl radicals) is characteristic of hydrocarbons. In addition to these bands and those mentioned above as probably belonging to the carbonyl pair, there are other special features of these records which seem to be introduced by the presence of the carbonyl pair. Thus in the six aldehyde curves, Figs. 14–16, there appears a strong band at 1.25 μ. Again, in the records of most of the substances, excluding the three ethers, there is absorption near 2.15 p, in many instances the band being noticeably double. If there are other fundamental absorption bands assignable to the $=C=O$ group, as claimed by Henri, then combination bands obtained from these and the 5.8 μ band and its overtones might be expected in this shorter wave length region. Thus if we add the frequency of Henri's 8.3 μ band to the frequency of the 2.9 μ overtone of Lecomte we obtain a frequency of a band at 2.15 μ. Again, a combination of the 8.3 μ and our 1.45 μ band yields a value of 1.23 μ. These values are in good agreement with those mentioned above.

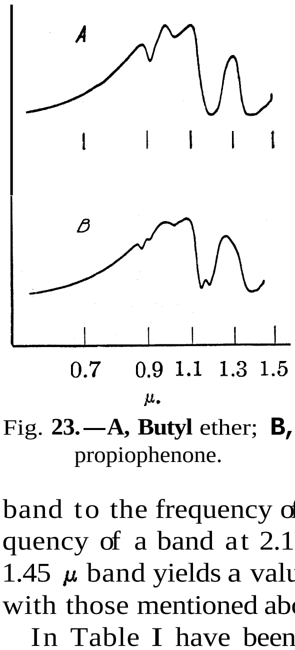

Fig. **23.—A, Butyl** ether; **B,** propiophenone.

In Table I have been assembled the values for the absorption bands which are here assumed to arise from the carbonyl group. Determinations by other investigators have been included also.

There are features of these spectra other than those apparently originating in the $=C=O$ pair which are of interest. Most of the remaining prominent absorption maxima are characteristic of hydrocarbons. The bands near 1.7, 1.2 and 0.9 μ can now fairly certainly be identified[15] as the first, second and third overtones, respectively, of a 3.3–3.4 μ band, all of which arise from oscillations of the carbon–hydrogen atom pair. They may be referred to as C–H bands. Bands near 1.0, 1.4 and 2.3 μ (or 2.18 μ) also always appear in the spectra of hydrocarbons and may be

referred to as hydrocarbon bands. Their origins are probably more complicated than those giving rise to the 3.4 μ fundamental and its harmonics. A possible interpretation of their origins, which further study may show to be only partially correct, has already been suggested by the writer.[1b]

The author[15] has already commented upon the doubleness of the C–H bands of certain compounds, suggesting that this doubleness may arise from two types of C–H linkages. Such an hypothesis is supported by the conclusions of Mrs. Lonsdale[16] in her critical study of the physical evidences pointing toward an anisotropy of the carbon atom. She has concluded that carbon will in general exhibit two each of two types of valency. This doubleness is evident in the 1.75 μ band of many of the alkyl compounds. It always appears when a methyl or ethyl group is present and sometimes when a propyl radical occurs. The breadth of the band when higher radicals are used, for example butyl, suggests that the doubleness is still there but that it is partially obscured. The 1.68 μ band, which appears clearly separated from the 1.75 μ doublet in the spectra of alkyl derivatives in which the radical is relatively light, but which merges into this latter band when the alkyl radical is heavy, seems to be a characteristic feature of paraffins and alkyl radicals. Its exact nature is not understood.

[16] Lonsdale, *Phil.* Mag., **6,433** (1928).

The two molecules benzophenone and quinone, containing aryl groups without alkyl groups, show a single band at 1.68 μ corresponding to the alkyl doublet at 1.75 μ. Those compounds containing both types of radical show the alkyl doublet and single aryl band clearly separated.

The resolving power of the instrument is probably insufficient to reveal a doubling of the 1.2 μ and the 0.9 μ alkyl C–H bands if it exists. A distinct separation in these bands, however, is found between the alkyl and aryl components.

An unexpected and widely separated doubling of the 1.2 μ and the 0.9 μ bands occurs in the spectra of the three ethers. Since the changes in the intensity ratio of the two components are similar as one goes from ethyl ether to n-butyl ether, it seems that both members are C–H bands. The only explanation which the author can offer for this doubling is a possible weakening of the C–H bonds in the cases of carbon atoms adjoining the oxygen atom.

The increased resolving power obtained in these records has revealed the fact that the 2.18 μ hydrocarbon band of the phenyl radical is double. A new record taken of benzene, not reproduced in this paper, shows a corresponding doubling.

The writer wishes to acknowledge the assistance of Mr. Charles Shaw in a portion of this investigation.

Summary

1. The infra-red absorption spectra below 2.5 μ have been recorded for a group of aldehydes, ketones, esters and ethers.

2. An absorption band, often double, between 1.9 and 2 μ is interpreted as a second overtone of a prominent 5.8 μ band previously recorded by many observers. Both are assigned to the carbonyl group.

3. Evidence pointing toward the existence of third, fourth and fifth overtones of the 5.8 μ band is found near 1.45, 1.16 and 0.97 μ in the spectra of some of the compounds.

4. Features characterizing hydrocarbons and their derivatives are found in these spectra at positions where they were anticipated.

BUDDE EFFECT IN BROMINE AND CHLORINE

BY GEORGE B. KISTIAKOWSKY

RECEIVED JANUARY 2, 1929 PUBLISHED MAY 6, 1929

Some time ago[1] the writer described experiments intended to show that extensive drying produces neither appreciable fluorescence in chlorine on illumination, nor a change in its absorption spectrum. That the absorption spectrum remains unchanged on drying was found, independently and simultaneously, by Miss Kornfeld and Steiner.[2] The existing literature,' on the other hand, seemed to indicate that the Budde effect, or the heat expansion of halogens on illumination, decreases when the halogens are subjected to a more or less thorough drying. These divergent observations are difficult to reconcile and it was tentatively suggested that, while the primary photochemical process in halogens is a dissociation into atoms in the way suggested by Franck, the secondary process, a homogeneous recombination of atoms, which contributes mainly to the heating of the gas, requires the presence of water vapor, being otherwise slow. In this case the halogen atoms in highly dried gases will have time to diffuse to the walls before recombining; they will be cleaned up there and will recombine in a wall reaction, the heat liberated being conducted away by glass and little heating of the gas being produced. The present experiments were intended to test this suggestion but, first of all, to investigate generally the observations obtained elsewhere on the influence of water vapor on Budde effect. While these experiments were being conducted, Brown and Chapman[3] published their observations showing that in a mixture of bromine vapor and air very extensive drying by phosphorus pentoxide lasting over a period of several months does not produce any change in the magnitude of the Budde effect. These experiments are quite conclusive by themselves, but they do not touch on the problem of whether the Budde effect in bromine from which all impurities, particularly such as oxygen, have been removed, might not still show a dependence on the presence of water vapor. To settle this last problem, for chlorine as well as for bromine, is the object of the investigations reported here.

Experimental Details

To study the Budde effect, a cylindrical Pyrex tube 23 × 3.5 cm. with polished sealed-on end-plates was used. It was connected to an all-glass manometer, a thin caved-in glass bulb with a long pointer being used. The movements of the pointer were observed in a microscope, the sensitivity of the system being *ca.* 10 divisions on the ocular scale per 1 mm. of mercury. Since such devices usually do not withstand large pressure differences, the whole manometer was sealed in a glass enclosure, which com-

municated, through a by-pass, with the illumination vessel. The whole was evacuated, baked out and filled with the halogen vapor. The outside of the manometer, however, could be disconnected, before the illumination experiments, by heating and collapsing a constriction in the by-pass. Inside the illumination vessel along its axis and at a distance of a few mm. from the side wall was suspended a loop of an almost hair-fine glass capillary through which a platinum wire was drawn. The wire acted as a resistance thermometer, its leads being carried to the outside of the vessel. The construction was such that the halogen vapors came in contact with glass only, no metal parts being exposed. **A** short tubing connected with the illumination vessel an inner, magnetically operated, seal which opened to a space of about 1-cc. volume filled with water vapor of atmospheric pressure.

The drying of bromine was carried out with the aid of phosphorus pentoxide. This latter was purified by a double distillation in a stream of pure oxygen and afterward by a double distillation in high vacuum. It was then distributed, by a careful sublimation in vacuum, over the walls of two wide U-tubes and their connecting tube. Bromine of C. P. grade was further purified and moderately dried by the standard chemical methods. It was then distilled twice in vacuum, the middle sections only being retained and finally was admitted to the phosphorus pentoxide tubes by breaking an inner seal. The quantity of bromine thus introduced was relatively small and it wetted only a fraction of the P_2O_5-covered surface. By cooling different parts of this surface bromine was distilled back and forth, this operation being continued for forty-eight hours. Later, an inner seal separating the illumination vessel and manometer system from the phosphorus pentoxide tubes was broken and bromine vapor admitted into the former. This inner seal was on the opposite end of the P_2O_5-tubes from that at which the undried bromine originally entered. The illumination vessel and manometer system, as well as the P_2O_5-tubes, prior to filling were baked out in vacuum for about twenty hours. The temperature was raised first to 500° for two hours and maintained at 350" the rest of the time.

Chlorine taken from a half empty tank was dried by repeaied distillation in vacuum from a bath of melting ethyl bromide (—119"). In the first of the series of three experiments an attempt was made to remove traces of oxygen present by an initial prolonged bubbling of pure hydrogen through liquid chlorine at —80°. In the other two experiments a larger quantity of chlorine was condensed from the tank, about four-fifths of it was boiled away under reduced pressure and only the first half of the remaining fraction was used for the succeeding vacuum distillations. The distilling train, allowing four distillations, was divided by an inner seal into two sections with separate pumping aggregates. Inner seals separated the train from the vessel into which chlorine was originally condensed and from the illumination vessel aggregate.

It was intended to test the dryness of chlorine by the sensitivity of the hydrogen–chlorine mixture to light and the apparatus contained, therefore, besides the parts described, four small cylindrical tubes sealed in parallel which also could be filled with dry chlorine. These tubes were separated by an inner seal from the hydrogen-drying section of the apparatus. The drying of purified hydrogen was carried out by allowing it to pass through a long spiral (4-mm. tubing, 50 cm. long) immersed in liquid air. The rate of flowof hydrogen through the spiral was adjusted by a capillary and amounted to **250** cc. in twenty hours. Dried hydrogen entered in the first experiment a half-liter flask which was evacuated together with the rest of the apparatus. In the second experiment the flask was replaced by a wide glass tubing forming a closed circle. The lower part of it was immersed in liquid air and one side was gently heated (to *ca.* 100°) so that hydrogen entering from the spiral was circulated continuously over liquid air. In the third experiment the flask was replaced by a vessel of a cylindrical shape which **was** completely immersed in liquid air for forty-eight hours.

On filling the four reaction tubes with chlorine at *ca.* **0.3** atmosphere pressure, they were sealed off from the chlorine side of the apparatus and were connected, by breaking an inner seal, to the hydrogen section which contained gas at about **0.5** atm. pressure. Chlorine was then frozen out by liquid air in each of the vessels and they were finally completely sealed from the apparatus.

The baking out of the whole apparatus was done in an electric furnace, the temperature, as in the case of bromine, being raised first to 500° and maintained later at **350".** The baking was continued for twenty-four hours in the first experiment and was extended to ten days in the last one. Here the heating was interrupted on the fifth day and all constrictions, to be sealed off afterward, were heated to the softening point and allowed to collapse almost completely; the baking was then resumed. The degassing was rather thorough in this experiment, as is shown by the fact that on the tenth day the McLeod gage, sensitive to less than 10^{-5} mm. of mercury, showed no measurable pressure after the apparatus was shut off from the pump overnight, while being heated to **350°.**

For the study of the Budde effect a carbon arc burning on **20** amp. and a system of lenses and diaphragms was used by means of which a parallel beam of light of about **2** cm. diameter was separated. In front of the illumination vessel, which was rigidly fastened to the optical bench supporting the arc and the lenses, was arranged a shutter to make possible a rapid succession of illumination and darkening of the vessel.

Experimental Results

With the apparatus described three samples of bromine and three of chlorine were prepared and tested. The general procedure was to take a simultaneous series of the glass manometer and of the platinum resistance readings with the shutter alternately closed and opened, then to break the inner seal separating the water vapor compartment and take a new series of readings. Under no circumstances could even the slightest difference exceeding the experimental error be observed between the two series of readings. In the third experiment on bromine a second inner seal was attached to the illumination vessel. It separated a small evacuated volume filled with phosphorus pentoxide prepared in the same manner as the materials used in the initial drying of bromine. After the first series of readings with this bromine, the seal separating the phosphorus pentoxide was broken and the latter transferred, by shaking, into the illumination vessel. It was left there for ten days, occasional readings being taken. Then the seal separating the water vapor was broken and readings were taken immediately after and on the next day. As an example of the nature of readings bbtained these series with bromine No. **3** are reproduced in Table I.

Under "glass-manometer" are given the deflections of the pointer in scale divisions of the microscope scale as caused by sudden changes from dark to light and back; under "Pt-resistance thermometer" the deflections in scale divisions of the galvanometer, which, together with a Mueller type bridge, was used to measure the resistance of the platinum wire. The temperature change and the expansion of the gas on illumination, as measured here by the two devices, agree fairly well. Ten divisions on

TABLE I

BUDDE EFFECT IN BROMINE

	Dry bromine	P_2O_5 admitted	10 days later	H_2O admitted	1 day later
Glass-manometer	+11, −10; +10, −10; $11, − 9; $10, − 9; +10, − 9; + 9, − 9; $11, − 9; +10, − 9; av. 9.7	av. 9.3	av. 10.1	av. 9.9	av. 9.3
Pt-resistance thermometer	+24, −22; +21, −20; +21, −20; +22, −20; +20, −20; +19, −20; +23, −20; +20, −21; av. 20.8	av. 21.1	av. 21.7	av. 22.0	av. 20.6

the microscope scale corresponded very nearly to 1 mm. of mercury or to approximately one degree temperature change of bromine vapor which was used at 300 mm. pressure. The thermometer had a resistance of 5.9 ohms and the galvanometer sensitivity was 18 scale divisions for 0.01 ohm. The deflection of 21 scale divisions thus corresponds roughly to 0.7° temperature change. The difference is well accounted for by the facts that only about nine-tenths of the total length of the wire in the thin capillary could be rapidly heated by the gas and that the whole wire, being outside of the actual path of the light beam, was in a somewhat cooler part of the gas.

Table I, which is quite typical of the results obtained, shows quite definitely that the Budde effect in bromine is left entirely unchanged by drying or moistening of the halogen. Thus, the experiments of Lewis and Rideal,[1] who claimed that a proportionality exists between the concentration of the water vapor and the magnitude of the Budde effect, must be incorrect. It might be suggested, of course, that a "more thorough" drying would reveal an influence of water vapor. However, the experiments of Brown and Chapman[s] are against such suggestion. Moreover, it should be pointed out here that the drying now employed must have been quite efficient. With a magnifying glass, one could see a slight trace of moisture on the first grains of the drying agent where bromine first entered the phosphorus pentoxide tubes. The moisture, which could be noticed only in this location, indicates that the phosphorus pentoxide employed was active and had extracted the main fraction of the water vapor present already within the short time of contact with bromine vapor when this was being distilled under low pressure into the phosphorus pentoxide tubes.

The experiments with chlorine yielded the same result as those with bromine: no change in Budde effect could be observed on drying. Comparing the relative care taken in drying and purifying chlorine by Coehn and Jung[1] and in the present experiments, one might conclude that the halogen was in about the same state of dryness in both sets of experiments.

However, the first of the experiments described here yielded chlorine–hydrogen mixtures which all reacted very rapidly in visible light. The experiment, therefore, was repeated twice more, each time new precautions being taken, of which a part have been mentioned before. Still, the result was the same; the photochemical reactivity of the gases was not diminished by drying. On the other hand, a critical analysis of the drying method employed fails to indicate any systematic sources of moisture in chlorine. Another explanation of the failure to prepare dry chlorine–hydrogen mixtures seems to be very likely therefore. As has been pointed out to the writer by Dr. R. N. Pease of this Laboratory, according to his experience, hydrogen reduces Pyrex glass quite readily at the temperature of its softening point. Since the last sealing of the reaction tubes in our experiments has to be undertaken with an atmosphere of hydrogen inside, it is more than likely that a sufficient quantity of water vapor is produced to cause photochemical reactivity of the gases. The quantity of water vapor required for this can be estimated, on the basis of experiments of Coehn and Jung,[1] to be of the order of 10^{-10} g. for the 10-cc. tubes employed. An action of chlorine on Pyrex glass, also followed by evolution of water, is very unlikely and it can be claimed, therefore, that the chlorine here prepared—so long as it was not mixed with hydrogen—was of the same degree of dryness as that prepared by Coehn and Jung. The latter evidently avoided our difficulties with hydrogen–chlorine mixtures by the use of soft glass.

Summary

1. No change in Budde effect could be observed on purifying and carefully drying bromine and chlorine.
2. It is pointed out that dry mixtures of hydrogen and chlorine cannot be prepared in Pyrex glass, since the latter is reduced at its softening point by hydrogen with formation of water.

CYCLOHEXANOL AND THE THIRD LAW OF THERMODYNAMICS[1]

BY KENNETH K. KELLEY[2]

RECEIVED JANUARY 2, 1929 PUBLISHED MAY 6, 1929

All statements of the third law of thermodynamics with the exception of that of Eastman[3] agree that the entropies of two crystalline forms of the same substance may both be taken as zero at the absolute zero of temperature. The only test of this statement which has been made with sufficient accuracy to warrant consideration is for the two crystalline modifications of tin. Lange[4] has measured the specific heat of white tin down to 9.6°K. and of gray tin to 15.5°K. and Bronsted[5] has calorimetrically determined the heat of transition. The entropy of transition at 292°K. from Lange's data and the third law is 1.77 E. U. while Bronsted's measurement gives 1.83 E. U., a very good agreement. However, the gray tin which is transformed into the white on cooling goes back to the gray modification, thus making it necessary to use a sample of white tin in the specific heat measurements in a different physical state from that obtained by carrying the gray tin through the transition point. This probably causes only a very slight error. For a more complete discussion of the tin transition the reader is referred to that of Simon.[6]

The present paper presents data on two crystalline forms of cyclohexanol. The heat capacity curves for both forms were obtained down to about 13.5°K. and the heat of transition calorimetrically determined using the same sample of material and the same apparatus throughout. The apparatus and methods used have been described previously.[7]

Purification of Material.—The cyclohexanol was an Eastman Kodak Company product. It was dried with anhydrous sodium carbonate, decanted off and fractionally distilled twice. Further purification was obtained by fractional crystallization. The portion used for the measurements (about 50 cc. in volume) had a boiling range of 160.9–161.0° (760 mm.) and density $d_4^{22.2} = 0.9459$. It was kept in a sealed bottle until placed in the calorimeter.

The Measurements.—The specific heats in 15" calories per mole are given in Table I and shown graphically in Fig. 1.

When cyclohexanol is cooled slowly it undergoes a transformation at

about 263.5°K. If cooled with sufficient rapidity the high temperature form is supercooled and may be taken down to the temperature of liquid hydrogen with no difficulty. The nature of the specific heat curves in the transition region may be seen better in Fig. 2.

On warming, the supercooled high temperature form exhibits regular specific heats up to about 135°K. Here there is a very sharp rise similar to that encountered for glasses which are also supercooled forms of matter. This rise is over at 150°K. At about 160°K. the supercooled form on warming changes spontaneously into the low temperature form, This change always occurs at very nearly the same temperature, which is again similar to the behavior of glasses. Between 160 and 210°K. no measurements could be made on the high temperature form for this reason.

The two measurements between 210 and 220°K. were made with the substance very slowly changing over into the low temperature form and for this reason these two results may be somewhat low. Above 230°K. the high temperature form had considerable apparent stability and no difficulty was found in making measurements from here up to the melting point. This was fortunate because it meant that results on this form could be obtained throughout the region in which the low temperature form was undergoing the transition to the high. It is interesting to note that in the case of white tin Lange found no such sharp rise as that occurring around 140° in the present work. However, he omitted two large temperature intervals, from 57 to 92°K. and from 101 to 286°K. It is in the latter interval that such a phenomenon might be expected.

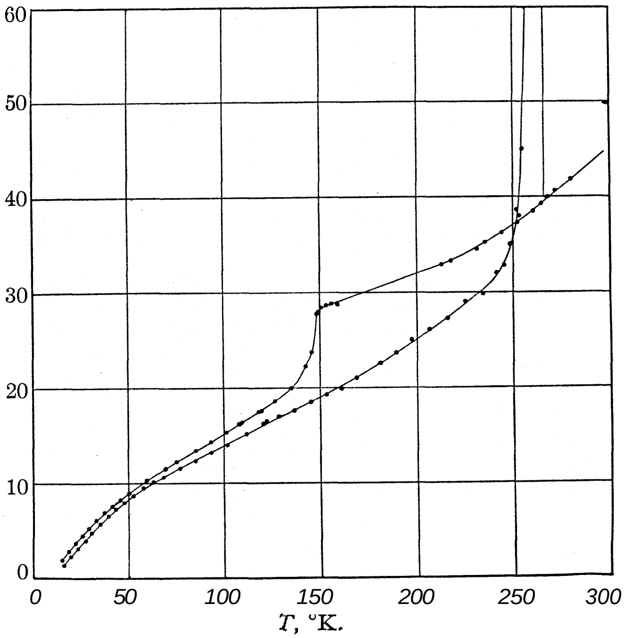

Fig. 1.—The specific heat of cyclohexanol in cal. per mole.

The low temperature form up to the transition region gave normal specific heats. The transition is apparently of the ammonium chloride type as is also the methyl alcohol transition." It is not possible to say just how great an effect the small amounts of impurities present have on the nature of the specific heat curve in this region.

The Temperature and Heat of Transition.—The mean temperature of the transition was found to be 263.5°K. and the heat of transition was also measured, the results obtained being given in Table II. By heat of transition here is meant the heat absorbed per mole in passing through the transition region in excess of the energy $\int_{T_1}^{T_2} C_p\mathrm{d}T$, under the "normal" heat-capacity curves extrapolated to 263.5°K. This is admittedly somewhat arbitrary but can cause no appreciable error in the entropy calculations to follow.

Table II

Heat of Transition in Cal. per Mole

T, °K. (average)	1st result	2nd result	Mean
263.5	1963	1957	1960

The Temperature and Heat of Fusion.—Richards and Shipley[8] have measured the temperature of fusion of a very pure sample of cyclohexanol as 297.0°K. Considerable difficulty was found in obtaining the temperature of fusion of this substance in the calorimeter because of its very low heat of fusion. The best value obtained was 0.2 or 0.3 of one degree lower than that obtained by Richards and Shipley. However, their value is undoubtedly the better since the substance absorbs water very readily and consequently in filling the calorimeter a slight amount of moisture may have been introduced. Therefore the heats of fusion given in Table III have been corrected to 297.0°K.

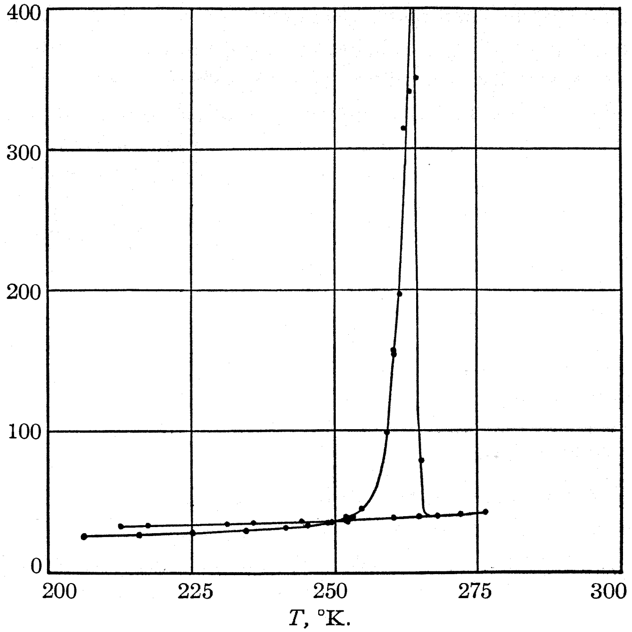

Fig. 2.—The specific heat of cyclohexanol in cal. per mole in the transition region.

---

[8] Richards and Shipley, This journal, 41, 2002 (1919).

TABLE III

HEAT OF FUSION IN CAL. PER MOLE

T, °K.	1st result	2nd result	Mean
297.0	408	404	406

The heat of fusion was recently obtained by Cauquil[9] by dissolving the crystalline and liquid forms at the same temperature. The value so obtained is 427 cal. per mole which, considering the method used, agrees as well as could be expected with the present value.

Accuracy of Measurement.—The specific heat measurements, except for those in the transition region between the low and high temperature forms which are not used in the entropy calculations, are considered to be in error on the average by not more than 0.5%. A more detailed discussion of the accuracy of measurement given before[7] will also apply here. The heat of transition also is not considered to be in error by more than 0.5%. The heat of fusion may easily be in error by 1%.

Entropy Calculations.—The entropy changes were calculated in the usual manner. Extrapolation below 13.5°K. was made by means of Debye functions with $\Theta = 112$ for the low temperature form and $\Theta = 84$ for the high. The extrapolated values, 0.27 and 0.58 E. U., respectively, are small and cannot be greatly in error. This may be readily seen from a comparison of these results with limiting values obtained by other means and given in Table IV.

TABLE IV

VALUES OF $S_{13.5}$ (EXTRAPOLATED)

Low temperature form	0.25	0.27	0.38
Method	aT^3	Debye	aT^b
High temperature form	0.49	0.58	0.80

The T^3 law applied below 13.5°K. must certainly give results which are too low since neither form has a low enough specific heat at 13.5°K. for this law to apply. The T^3 law, however, should apply at lower temperatures theoretically and has been found to do so experimentally for one organic substance, glycerin.[10] Fitting the lower end of each curve by an equation, $C_p = aT^b$, and using this as a basis of extrapolation should give too high results since $b = 2.38$ for the low temperature form and 1.89 for the high in the neighborhood of 13.5°K.

In Table V are given the results of the entropy calculations. Under I are given the entropy changes in passing from 0°K. to 298.1°K. starting with the low temperature form, transforming to the high temperature form at 263.5°K. and to the liquid at 297.0°K. Under II are given the corresponding values starting at 0°K. with the high temperature form which is carried up to the melting point and changed to liquid.

Discussion

If the entropies of the two crystalline forms at 0°K. are the same, then it follows that the entropy change corresponding to the warming of the substance from 0°K. to any temperature above the transition is the same for both possible paths. In making the calculations for Table V it was convenient to obtain the total heat of transition and assign it to a "mean" temperature for the purpose of calculating the entropy of transition. Since this has been done it is now convenient to compare the entropies at this point, 263.5°K., also. The values for the two paths are, respectively, 41.26 and 40.90 E. U., a difference of 0.36 E. U. Each of these values may be in error by ±0.25 E. U., so that this difference is within the upper limit of the experimental error and consequently in this case, as in the case of tin, the only conclusion which can be drawn is that both crystalline forms have the same entropy at 0°K. in agreement with the third law of thermodynamics.

The Free Energy.—The free energy of formation from the elements may be calculated by means of the equation $\Delta F = \Delta H - T\Delta S$.

The heat of combustion of solid cyclohexanol at 291°K. has been measured by Richards and Davis.[11] Their value when corrected to 15° calories gives 889,700 cal. per mole at constant pressure. From this value the heat of combustion of liquid cyclohexanol at 298.1°K. may be calculated by means of the specific heats of the substances involved and the heat of fusion of cyclohexanol. It so happens that the effect due to differences in the specific heats almost exactly counterbalances the heat of fusion and we have, therefore, 889,700 cal. per mole for the heat of combustion of liquid cyclohexanol at 298.1°K.

Making use of the values for the heats of combustion of graphitic carbon and of hydrogen previously adopted,[7] $\Delta H_{298.1}$ is found to be −85,840 cal. per mole.

Using 47.7 E. U. as $S_{298.1}$ for liquid cyclohexanol and the entropies of the elements,[7] $\Delta S_{298.1}$ is −162.2 E. U.

Therefore, $\Delta F_{298.1} = -37{,}500$ cal. per mole.

---

[11] Richards and Davis, THIS JOURNAL, 42, 1599 (1920).

Summary

1. The specific heats of two crystalline forms of cyclohexanol were measured down to about 13.5°K.
2. The "mean" temperature and heat of transition between the two crystalline modifications were obtained.
3. The heat of fusion of cyclohexanol was measured.
4. The entropy calculations show that both crystalline forms have the same entropy at 0°K. within the limits of experimental error.
5. The entropy and free energy of liquid cyclohexanol at 298.1°K. have been calculated.

THE PREPARATION OF PHOSPHENYL CHLORIDE

BY J. A. C. BOWLES AND C. JAMES

RECEIVED JANUARY 4, 1929 PUBLISHED MAY 6, 1929

Since derivatives of phosphenyl chloride have been desired from time to time during rare metal research, it was decided to investigate certain methods involved in the preparation of this substance with the hope of finding some suitable and convenient procedure.

The cheapest method appeared to be that of passing vapors of benzene and phosphorus trichloride repeatedly through a red-hot tube. The equipment required was very similar to that employed in the earlier method for the preparation of diphenyl. After giving this method a thorough trial it was discarded owing to the fact that such a long time was required to produce a small quantity of the product. It appeared to the workers that without doubt a considerable amount of the phosphenyl chloride was decomposed owing to the long heating as it passed through a considerable length of the red-hot quartz tube. It therefore seemed desirable to use an apparatus similar to that described in the preparation of diphenyl,[1] in which a glowing ribbon of nichrome was suspended in an atmosphere of benzene vapors. In this case the difficulty was to find a suitable ribbon or filament which would withstand the action of the vapors. The only material which resisted attack and fusion was a large carbon filament which was very carefully removed from a large and antiquated electric light bulb. Unfortunately in this case the filament kept gradually increasing in diameter due to the deposition of carbon, thereby requiring a gradual increase in current throughout the run. It was noticed, however, that much better yields were obtained than by the previous method.

---

[1] Lowe and James, THIS JOURNAL, 45, 2666 (1923).

The writers found that equipment which was transparent and which allowed the product to be quickly removed from the hot surface gave the best yields since the process could be more easily controlled by observation. The next change made in the diphenyl equipment was the substitution of the ribbon by a heating unit which was unattacked by the vapors in the reaction chamber. The heater which was tried out consisted of a winding of nichrome protected by a quartz tube. This type of heating unit required a different kind of reaction chamber, of a form not unlike that of a common condenser jacket. A study of the accompanying figure will give a better idea of the apparatus. The mixture of benzene and phosphorus trichloride was placed in flask A which is connected to the reaction chamber B by means of a rubber stopper. The upper outlet of the reaction chamber was connected to a reflux condenser. This connection should either be sealed or else a ground joint, since rubber tubing must be changed after every run. The heating element is placed in the interior central portion of the quartz Tube CC which is made tight by alundum cement over a few turns of asbestos rope. Carbon dioxide was admitted to the reaction chamber through the small Tube D. The reaction chamber, dimensions 60 cm. X 15 cm., was made of Pyrex glass.

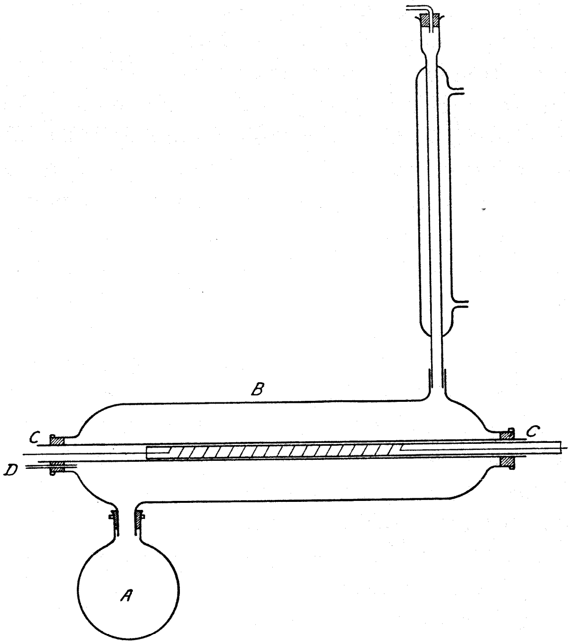

Fig. 1.

In commencing the operation, the liquid in A was heated until all the air in the reaction chamber had been displaced by vapor. At this point the heating current was turned on and the temperature of the quartz tube raised to a good red heat, care being taken to keep the temperature below carbonization. Under the right conditions the phosphenyl chloride could be observed flowing back to the flask along the bottom of the reaction chamber, the temperature of the latter being too high to allow much of the benzene and phosphorus trichloride vapors to condense. While no attempt was made to determine the maximum yield for an eight-hour run, it appeared that under the best conditions at least one kilo should be obtained *without any carbonization* with an equipment of this capacity.

This reaction chamber may be applied to other reactions where the vapor is heated to some definite temperature and where the reacting substances have similar boiling points. An interesting test was made in the case of the production of acetamide from acetic acid. The latter was just saturated with dry ammonia gas at the boiling point. This crude ammonium acetate was placed in the flask A and boiled while the temperature of the quartz tube was raised to 245° on the inside. As soon as the odor of acetic acid appeared at the top of the air condenser attached to the upper outlet of the reaction chamber, ammonia gas was slowly admitted through the small Tube D. When the speed of the ammonia gas was correctly adjusted practically nothing but steam was given off at the top of the condenser. The temperature of the escaping vapors was maintained at about 101°. At the end of a three hours' run it was found that the contents of the flask solidified to a mass of crystals on cooling. Fractional distillation showed that the product consisted almost entirely of acetamide. Under these conditions practically the theoretical amount of acetic acid was converted into acetamide.

In conclusion, it may be said that plans are being made to try out certain other reactions, involving this heating and cooling effect, and also the use of catalysts under such conditions.

THE POTENTIAL OF INERT ELECTRODES IN SOLUTIONS OF SULFUROUS ACID AND ITS BEHAVIOR AS AN OXIDIZING AND REDUCING AGENT

BY ARTHUR A. NOYES AND HAROLD H. STEINOUR

RECEIVED JANUARY 8, 1929 PUBLISHED MAY 6, 1929

I. Introduction

Certain reducing substances such as sulfurous acid, formic acid or oxalic acid show in their chemical behavior a much smaller reducing power than that calculated from the free-energy changes attending their conversion into their ordinary oxidation products (sulfuric acid or carbon dioxide and water). This is especially well known in the case of sulfurous acid, whose chemical reducing power is much less than corresponds to the potential (—0.14 volt) calculated for the conversion of SO_2(1 atm.) to SO_4^{--} (1 m.) in the presence of H^+ (1 m.).

The probable nature of the electrode process in a sulfite cell had been considered by Carter and James.[1] In view of the obvious discrepancy with the calculated sulfite–sulfate potential they attributed the observed potential to the tendency of the sulfur dioxide to be reduced rather than oxidized. The reduction product might be sulfur, but since their experiments showed that the addition of sulfur to the electrode vessel did not improve the constancy or reproducibility of the potential (which varied over 0.05 volt), they concluded that an intermediate reduction product of sulfurous acid was concerned. This product they considered to be probably dithionous acid,[2] $H_2S_2O_4$, since their experiments showed that this acid was produced by the cathodic reduction of sulfurous acid in acid solution.

---

[1] Carter and James, *J. Chem. Soc.*, 125, 2231–2240 (1924).

[2] This acid of formula $H_2S_2O_4$ is called by many authors hydrosulfurous acid, and by many others hyposulfurous acid. The first of these names is conventional and without theoretical significance; the second, although recommended by the Nomenclature Committee of the American and London Chemical Societies (see Crane and Patterson "Literature of Chemistry," p. 180), is distinctly irrational, since logically the name hyposulfurous acid should be applied (as it sometimes is) to the acid H_2SO_2 (of which derivatives only have been prepared). This last acid is, however, commonly called sulfoxylic acid. The confusion could be avoided and a rational system of nomenclature for these sulfur acids introduced by giving the acid H_2SO_2 its logical name, hyposulfurous acid, and giving the disulfur acid $H_2S_2O_4$ the new name dithionous acid, which would indicate that it stands in the same relation to sulfurous acid (and hyposulfurous acid) as dithionic acid stands to sulfuric acid (and sulfurous acid). These series of sulfur acids would then be: H_2SO_2, hyposulfurous; $H_2S_2O_4$, dithionous; H_2SO_3, sulfurous; $H_2S_2O_6$, dithionic; H_2SO_4, sulfuric. In the interest of the introduction of this rational nomenclature, the names "dithionous acid" and "dithionite" are used throughout this article.

This paper is a further contribution to the interpretation of this potential of sulfur dioxide, and of its behavior as an oxidizing and reducing agent. The experiments refer chiefly to the potentials exhibited at a platinized platinum electrode by a half-cell with various concentrations of sulfite and hydrogen ion in the presence of various other substances, and under different conditions of agitation and temperature. This half-cell was measured in combination with a hydrogen half-cell in which nearly the same hydrogen-ion concentration prevailed.

This investigation was assisted financially by a grant from the Carnegie Institution of Washington.

II. Hypotheses as to the Electrode Process in the Sulfite Half-Cell and the Thermodynamic Relations Involved

In order to facilitate the appreciation of the somewhat complex effects to be described in the following sections of this article, there may be presented in advance the following hypotheses, of whose adequacy to explain the phenomena the reader can judge as these are described. To the chemical equations numerical values are appended which show the free-energy decreases[3] attending the reactions at 25° when all the ions involved have a concentration of 1 molal.

1. The potential produced when a platinum electrode is placed in a solution of sulfurous acid arises from the tendency of this acid to reduce to a lower oxidation state, not from its tendency to oxidize to sulfuric acid in accordance with the electrode reactions

$$HSO_3^- + H20 = SO_4^{--} + 3H^+ + 2E- - 4245 \text{ cal. or} \qquad (1)$$
$$SO_2(g) + 2H_2O = SO_4^{--} + 4H^+ + 2E- - 6545 \text{ cal.} \qquad (2)$$

If the potential were determined by these reactions, the expressions for it would be

$$E = -0.092 - 0.0296 \log \frac{(SO_4^{--})(H^+)^3}{(HSO_3^-)} = -0.142 - 0.0296 \log \frac{(SO_4^{--})(H^+)^4}{p_{SO_2}} \qquad (3)$$

2. The sulfurous acid undergoes slight spontaneous decomposition into

---

[3] These free-energy decreases were calculated from the following data: $1H_2O$ (1), −56,560 cal.; $1HSO_3^-$ (1m.), −123,920 cal.; $1SO_2$ (1 atm.), −69,660 cal.; $1SO_4^{--}$ (1m.), −176,235 cal.; $1S_2O_3^{--}$ (1 m.), −121,345 cal.; $1S_2O_4^{--}$ (1 m.), −134,305 cal. The first three values are those given by Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, p. 607. That for $1SO_4^{--}$ was obtained by Sherrill and Noyes, THIS JOURNAL, 48, 1871 (1926), through revision of the value computed by Lewis and Randall. The free energy of $1S_2O_3^{--}$ at 25" was computed from that of $1HSO_3^{--}$ and from the equilibrium constant 0.013 at 11° determined by Foerster and Vogel, *Z anorg. allgem. Chem.*, 155, 189 (1926), for the reaction $HSO_3^- + S(s) = H^+ + S_2O_3^{--}$, neglecting the difference in temperature. That for $1S_2O_4^{--}$ was derived from the reduction potential (+0.009 volt) which was determined electrometrically by Jellinek, *Z. Electrochem.*, 17, 163 (1911), for the electrode reaction $S_2O_4^{--} + 2H_2O = 2HSO_3^- + 2H^+ + 2E-$, assuming the acid $H_2S_2O_4$ to be completely ionized, as the other disulfur acids $H_2S_2O_3$ and $H_2S_2O_6$ appear to be.

sulfuric acid and a lower reduction product, namely, dithionous acid $H_2S_2O_4$, in accordance with the reaction

$$3HSO_3^- = SO_4^{--} + S_2O_4^{--} + H^{\cdot} + H_2O - 4660 \text{ cal.} \qquad (4)$$

3. The sulfurous acid and the so produced dithionous acid are (as concluded by Carter and James) the electromotively active substances to which the electrode quickly responds and of which the concentrations determine its potential, so that the actual electrode reaction is

$$S_2O_4^{--} + 2H_2O = 2H^{\cdot} + 2HSO_3^- + 2E^- + 415 \text{ cal. or} \qquad (5)$$

$$S_2O_4^{--} = 2SO_2(g) + 2E^- + 5015 \text{ cal.} \qquad (6)$$

The corresponding expression for the electrode potential is

$$E = +0.009 - 0.0296 \log \frac{(HSO_3^-)^2(H^+)^2}{(S_2O_4^{--})} = +0.109 - 0.0296 \log \frac{(p_{SO_2})^2}{(S_2O_4^{--})} \qquad (7)$$

4. The dithionous acid itself gradually decomposes in solutions of large hydrogen-ion concentration according to the equation

$$2S_2O_4^{--} + H^{\cdot} + H_2O = S(s) + 3HSO_3^- + 46{,}590 \text{ cal.} \qquad (8)$$

or, more strictly, since sulfur rapidly unites with sulfurous acid to form thiosulfuric acid until this attains a considerable concentration, the dithionous acid decomposes in accordance with the equation

$$2S_2O_4^{--} + H_2O = S_2O_3^{--} + 2HSO_3^- + 44{,}015 \text{ cal.} \qquad (9)$$

5. The above-given free-energy values show that Reactions 4, 8 and 9 tend to take place in the direction in which they are written (when the other ion concentrations are 1 molal) in case the $S_2O_4^{--}$ concentration has the following values

Reaction 4, when it is less than 0.0004 molal.
Reaction 8, when it is greater than 10^{-17} molal.
Reaction 9, when it is greater than 10^{-16} molal.

These conditions are probably fulfilled under the actual conditions, as shown at the end of Section VII.

6. A fairly definite concentration of dithionite ion and a fairly definite potential establish themselves as a result of a steady state in which the quantity of this ion being produced by Reaction 4 is equal to that being destroyed by Reaction 9. Certain plausible mechanisms can be formulated from which a steady state would result, but they are so hypothetical that they will not be reproduced here.

7. The possibility should also be considered that sulfur, not dithionous acid, is the reduction product which in association with sulfurous acid determines the electrode potential; for sulfur could be produced by the decomposition of sulfurous acid, as a result of the successive occurrence of Reactions 4 and 8, in accordance with the equation

$$3HSO_3^- = S(s) + 2SO_4^{--} + H^+ + H_2O + 37{,}270 \text{ cal.} \qquad (10)$$

Indeed, not only is this reaction thermodynamically possible, but spontaneous decomposition of solutions of sulfurous acid into sulfur and sulfate has been observed at 100–180° by many investigators.[4] The sulfur so produced would, however, be expected to determine the electrode potential in the case, and only in the case, that Reaction 8 takes place so rapidly that its equilibrium conditions are substantially maintained. In that case the electrode potential would have a definite value corresponding to the electrode reaction

$$S(s) + 3H_2O = HSO_3^- + 5H^+ + 4E^- - 45{,}760 \text{ cal. or} \quad (11)$$

$$S(s) + 2H_2O = SO_2(g) + 4H^+ + 4E^- - 43{,}460 \text{ cal.} \quad (12)$$

Hence

$$E = -0.496 - 0.0296 \log (HSO_3^-)^{1/2}(H^+)^{5/2} = -0.471 - 0.0296 \log (p_{SO_2})^{1/2}(H^+)^2 \quad (13)$$

It has, however, already been stated that James and Carter concluded that sulfur was not the active reduction product, and confirmation of this conclusion is afforded by the measurements presented in this paper.

III. Solutions, Apparatus and Experimental Procedure

In the earlier experiments the electrode vessel could not be conveniently agitated, and the sulfur dioxide was introduced in solution. This plan was employed only in the experiments with the half-cell containing sulfite and dithionate, and in those upon the effect of the initial condition of the electrode. In all the later work sulfur dioxide gas was introduced into the cell and maintained at the desired partial pressure by bubbling through the cell a known mixture of this gas with nitrogen or other diluent. This gave better control and furnished a convenient means of agitation.

In the earlier procedure air-free sulfurous acid solution was prepared by bubbling sulfur dioxide, generated by displacement from sodium bisulfite, through boiled distilled water kept under nitrogen. Dithionic acid was made from a solution of the pure barium salt (prepared for us by Mr. R. D. Pomeroy) by adding the equivalent amount of sulfuric acid and filtering off the precipitated barium sulfate. This solution was also kept under nitrogen. By a simple arrangement the solutions could be admitted to nitrogen-filled burets without exposing them to the air at any time. The burets were then used for analyzing the solutions and for filling the cell. This was done by extending the buret tips through the stopper of a nitrogen-filled mixing vessel into which the desired amounts of solution were run and mixed by shaking. The mixing vessel communicated with the electrode chamber, which had been swept out with nitrogen. Both acids were analyzed prior to use, but the sulfite concentration in the cell solution was always determined after taking down the cell, since an error might otherwise result due to the appreciable vapor pressure of the sulfur dioxide.

The potential measurements in all of the work were made by means of a Type K Leeds and Northrup potentiometer. The sulfite half-cell was joined through a stopcock with a hydrogen half-cell containing sulfuric or hydrochloric acid. It was especially important to keep the two solutions separated, for the presence of a small

amount of sulfite poisoned the hydrogen electrodes. Each half-cell was equipped with two platinum foil electrodes, one centimeter square, sealed into glass stoppers placed about one centimeter apart and completely immersed in the cell solution. All electrodes were platinized (unless otherwise stated), those in the sulfite half-cell being replatinized for each set-up. Fig. 1 is a diagram of the hydrogen half-cell as it was used in all experiments. This was of a type used in former investigations in this Laboratory.[5] The side vessel is a saturator which was filled with some of the cell solution. The entering gas bubbled up through the helix, entered the bottom of the electrode vessel and passed out through the side trap. The hydrogen electrodes were considered to be operating satisfactorily when the difference of potential between them was not more than 0.1 millivolt and was not fluctuating; but this difference was usually less than 0.02 millivolt. The sulfite half-cell equipped for gas bubbling, which was used in the later work, was a duplicate of the hydrogen half-cell. The cell was kept in an oil thermostat.

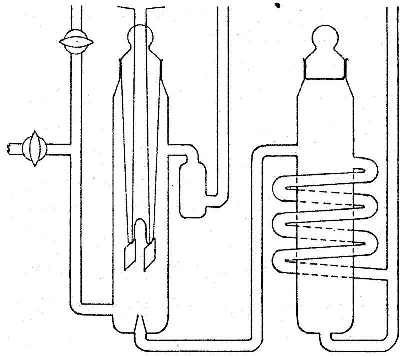

Fig. 1.—Hydrogen half-cell.

The apparatus for mixing the gases is shown diagrammatically in Fig. 2. Nitrogen was the diluent in most of the experiments. The gas from a cylinder was first purified from oxygen by bubbling it through two towers filled with copper turnings immersed in a mixture of equal volumes of concentrated ammonium hydroxide and saturated ammonium chloride solution. From these towers it passed through two wash bottles containing diluted and concentrated sulfuric acid to remove ammonia and water vapor. It passed through the capillary of a flow meter and was mixed with the current of sulfur dioxide. The sulfur dioxide was admitted from a gas cylinder, dried with concentrated sulfuric acid but not otherwise purified,[6] and passed through a flow meter. After the two streams joined, thorough mixing was insured by passing

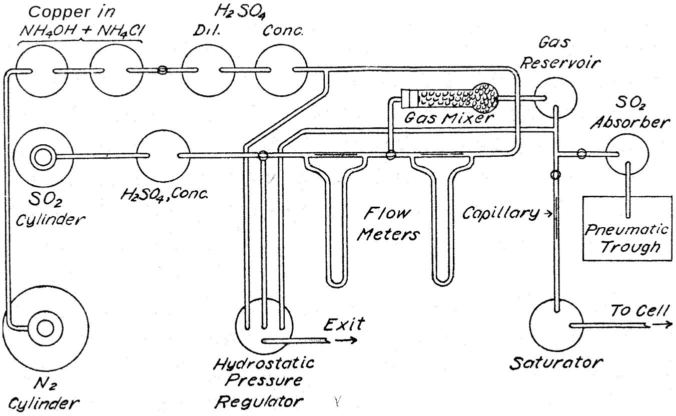

Fig. 2.—Apparatus for gas control.

the gas through a vessel filled with glass beads. The gas was then admitted to a small reservoir, passed thence to a saturator filled with the cell solution and finally led into the saturator which comprised part of the cell. The flow of gas was kept constant by means of by-passes to hydrostatic pressure exits arranged as shown in the figure and consisting of tubes whose depth of immersion in a well of transil oil could be varied. Gas was kept bubbling from them so that constant pressures were maintained. Nujol was used in the flow meters and their sensitivity was increased by inclining the gages. The various parts of the apparatus were joined with rubber tubing.

The gas mixtures corresponding to the gage settings adopted were analyzed by passing them slowly into an absorption vessel filled with standard iodine solution (to remove the sulfur dioxide) and then into a pneumatic trough, where the nitrogen was collected over water. The excess of iodine was titrated with thiosulfate solution. The agreement of the analyses is shown by the following data: for one gage setting the mixtures were found to contain 7.23, 7.29 and 7.32% of SO_2; for another setting, 23.8, 24.1 and 24.1% of SO_2.

IV. Behavior of a Platinum Electrode in Sulfurous Acid Solutions

When a half-cell that consists of a platinized electrode in an air-free solution of sulfurous acid containing also some stronger acid is allowed to stand at 25° for some hours without bubbling or other agitation, there is established a tolerably constant and reproducible potential, namely, one which as a rule changes by less than two centivolts during several days. This potential has a value of about -0.37 volt, referred to that of the molal hydrogen electrode as zero. If now a mixture of nitrogen and sulfur dioxide (at a partial pressure equal to its vapor pressure in the solution) is bubbled steadily through the solution, so as to mix the liquid surrounding the electrode with the rest of the solution, the potential immediately increases in negative value—an increase which in the course of half an hour usually amounts to two to four centivolts. It then reverts to less negative values, rapidly during the first two hours and then more slowly, attaining after some five or six hours a fairly constant value which may be one or two centivolts more negative than that exhibited before the solution was agitated. When the bubbling is stopped, the potential attains within twenty minutes substantially the value which it had previous to the agitation. If after standing for several hours the bubbling is resumed, the same sequence of phenomena is observed. Thus after a few hours of bubbling the same fairly constant value is obtained as before, usually differing from it by only two or three millivolts; and on quiet standing nearly the same final value results as before. The two duplicate electrodes in the cell then usually check within one or two millivolts, though occasionally they differ by as much as five or six millivolts. The constancy and reproducibility of the electrodes under quiet conditions are shown in detail by the data in Tables III and IV considered below.

The behavior just described is illustrated by Fig. 3, in which graphs for typical half-cells are drawn by plotting as ordinates the potential of the whole cell (with a hydrogen electrode in its other half-cell) and as abscissas the elapsed time in hours. Broken lines are used to indicate periods during which gas was bubbling through the cell; solid lines, periods when there was no agitation.

It will be seen from Fig. **3** and the above statements that four different effects are to be accounted for: (1) production under quiet conditions of a fairly reproducible potential of about **–0.37** volt; (2) production by short agitation of the solution of a much more negative potential varying much with the conditions, thus one of about **–0.410** and –0.393 in the cells considered; **(3)** production by long agitation of a potential steadily decreasing in negative value and slowly approaching a value not much larger than that in the quiet state; thus in the two cells after nine to thirteen hours' bubbling the values were **–0.370** and **–0.373**; **(4)** reestablishment of the original quiet-state value when the agitation is stopped, and reproduction of a much higher negative value when the stirring is resumed.

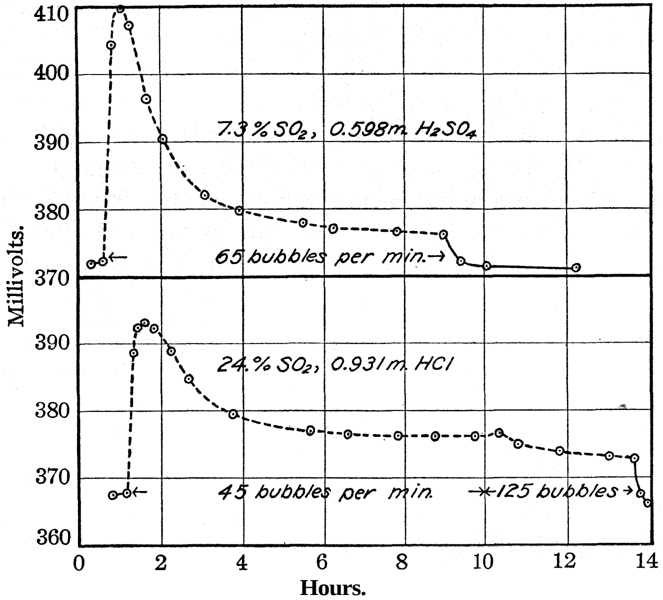

Fig. 3.—Effect of agitation of the sulfite solution upon the electromotive force.

We are not able to present evidence for specific explanations of these agitation phenomena, but they seem to be due to a combination of catalytic and adsorption effects at the electrode, which give rise at its surface to concentration changes that are distributed by stirring the solution.

V. Effect of Preliminary Treatments of the Sulfite Electrode

The following experiments were made in order to establish more fully the conclusion that the potential arises from sulfurous acid and a decomposition product and not from some accidental initial condition of the electrode. One series of experiments was made in which the electrode was treated in various ways before it was placed in the solution; another was made in which a small current was passed through the half-cell in one direction or the other, whereby the electrode would be charged with hydrogen or oxygen gas.

The first series was made with a half-cell with platinum electrodes in a mixture of 0.037–0.046 N sulfurous acid and 0.047 N dithionic acid, which will later be shown to have no specific effect on the potential, the other half-cell containing sulfuric acid (at 0.078–0.081 N) of about the same hydrogen-ion activity. The electromotive force of these cells after successive intervals of quiet standing is shown in Table I. In Expt. 1 platinized electrodes were used but in the other experiments the electrodes were deplatinized. In Expts. 1 and 2 the electrodes were charged with hydrogen by electrolysis in a sulfuric acid solution and then immediately put into the cell. In Expts. 3 and 4 they were allowed to stand overnight in concentrated sulfurous acid solution and in dithionic acid solution, respectively.

TABLE I

EFFECT OF VARIOUS INITIAL TREATMENTS OF THE ELECTRODE ON ITS POTENTIAL

Expt. no.	Electrode initially treated with	Electromotive force in millivolts after 10–20 min.	1 day	Several days
1	Hydrogen	...	415	447
2	Hydrogen	...	513	477
3	H_2SO_3	475	465	...
4	$H_2S_2O_6$	459	454	...

In a second series of experiments a current was passed through the cell, making the sulfite electrode in some cases the anode and in others the cathode. Somewhat similar experiments had already been made by Carter and James.' Our experiments were all made with a half-cell con-

TABLE II

ELECTROMOTIVE FORCE OF THE CELL AFTER POLARIZATION

Expt. no.	Sulfite electrode made	Applied potential Volts	Minutes	Before polarization	Electromotive force at various times after polarization 1–2 min.	5 min.	10 min.	20 min.	1 hr.	2 hrs.	1 day
5	Cathode	0[a]	5	434	304	340	400	435	439	434	...
6	Cathode	0"	5	427	314	344	389	432	441	433	429
7	Anode	1.6	3	427	484	465	455	449	438	...	427

9	Cathode	65[b]	20	460	220	...	275	305	327[c]	333	435[d]
10	Anode	65[b]	20	425	...	585	530	495	468	461	453

[a] In these cases the cell circuit was closed but no external voltage was applied.

[b] The resulting current was 0.01 ampere.

[c] Thirty minutes after polarization, when the electromotive force was about 340 mv., the cell was shaken; this stopped the rise of the electromotive force for a time.

[d] After two days.

taining platinized electrodes in a mixture containing sulfurous acid at 0.043 N (corresponding to a sulfur dioxide pressure of 0.014 atm.) and sulfuric acid at 0.068 *N;* the other half-cell with the hydrogen half-cell contained sulfuric acid at 0.081 *N*, which has about the same hydrogen-ion activity as the mixture of the two acids. The results are shown in Table II.

It will be seen that although the polarization produced great differences in the initial values of the electromotive force, all the final values are of about the same magnitude (430460 millivolts).

These two series of experiments clearly show that a platinum electrode in sulfurous acid solutions establishes a fairly reproducible potential which is independent of variations in the initial condition of the electrode.

VI. Sulfite Half-Cells with Dithionic Acid

It had been shown by previous investigators that the potential observed with solutions of sulfurous and sulfuric acids is not much affected by the concentration of sulfate ion, showing that this ion is not electromotively active. It was thought possible, however, that the intermediate oxidation product, dithionic acid ($H_2S_2O_6$), might establish with sulfurous acid a definite potential. Cells were, therefore, set up in which the electromotive force observed when sulfurous acid was present with dithionic acid could be compared with that produced when the latter acid was replaced by sulfuric acid. The results are shown in Table III. All potentials are expressed in millivolts.

Since it took several hours or more for the duplicate electrodes in the sulfite half-cell to come to such equilibrium as to check each other well, values were usually not recorded until the following day after starting a run; after this the duplicate electrodes almost always checked to within one or two millivolts.

Table III

Electromotive Force at 25° of Cells with Sulfurous, Sulfuric and Dithionic Acids

2	415	...	...	447	449	...	−370
3	479	474	470	470	466	459	−370

In calculating the potential of the sulfite half-cell no allowance was made for liquid potential; for the acid used in the hydrogen half-cell was of a strength calculated to have about the same hydrogen-ion activity as that of the mixture in the other half-cell. Hydrogen-ion activities were calculated with the aid of the data published by Sherrill and Noyes.[7] In estimating the ionic strength the dithionic acid was considered to be completely dissociated. Conductivity data show it to be a very strong acid.[8] Equilibrium pressures of sulfur dioxide were calculated by Henry's law, correction being made for the dissociation of the sulfurous acid.

It will be seen that the potential is not much different whether the acid present with the sulfurous acid is sulfuric or dithionic, showing that the electrode process which determines the potential does not directly involve either of these acids.

To establish completely the conclusion that the potential is not dependent upon these oxidation products of sulfurous acid, a series of cells was set up in which sulfur dioxide was the only sulfur compound added and the desired acidity was produced by hydrochloric acid. In this work sulfur dioxide gas diluted with nitrogen was bubbled through the cell, to establish a definite activity of sulfurous acid and to provide efficient stirring; the electromotive force was read, however, only after a long period of quiet standing. In order that the comparison might be direct, a similar series was made in which sulfuric acid was again used. The results which are presented later (in Table IV) show that, provided the hydrogen-ion concentration is nearly the same, hydrochloric acid and sulfuric acid produce (in association with sulfurous acid) substantially the same electromotive force.

VII. The Potential of Sulfite Half-Cells and the Effect upon it of the Concentration of Sulfurous Acid and of Hydrogen Ion

The series of comparative experiments with hydrochloric and sulfuric acids (referred to in Section VI), in which a definite concentration of sulfurous acid was attained by bubbling sulfur dioxide diluted with nitrogen through the cell and measuring the electromotive force after periods of quiet standing, also served to determine to what extent the potential depends upon the activity of sulfurous acid and upon that of hydrogen ion. A pair of comparative experiments at 25 and 50° was also made to determine the effect of temperature.

The results are presented in Table IV. The electromotive forces are those of cells of the type Pt + H_2 (1 atm.), HCl or H_2SO_4 (with H^+ at c_H), $\{SO_2$ (at p) + HCl or H_2SO_4 (with H^+ at $c_H)\}$, Pt. The electromotive forces and separate potentials are all expressed in millivolts. The recorded values

of the electromotive force of the cell are the daily averages of readings taken at intervals of one, two or three hours throughout the day during which the sulfur dioxide was not bubbling through. An asterisk indicates that after taking the reading the gas mixture was bubbled for several hours through the cell, which was then allowed to stand quietly overnight.[9]

[9] In cases where an experiment consisted merely in increasing the pressure of sulfur dioxide, the initial value recorded is that obtained on the first or second day after making such an increase, when it was believed that the equilibrium concentration had been established. In experiments which were the first of a series, where the air had to be displaced from the cell and the sulfurous acid concentration built up from an initial value of zero, the first recorded figures are in most cases those obtained after several days of gas bubbling, during which time the negative potential was decreasing from that corresponding roughly to an oxygen electrode; for although the electrodes were initially charged with hydrogen, the initial conditions in the cell were such as to establish a highly negative potential. Bubbling was not continued overnight, as it was not desirable to allow the gas to flow so long without observation. Prior to Expts. 1 and 4 the air in the cell was displaced with nitrogen before any sulfur dioxide was admitted. In the other independent experiments the gaseous mixture was started through at once. In Expt. 7 the third row of readings were those after 15, 16, 17, 18 and 19 days.

The hydrogen-ion activity of the hydrogen half-cell and its corresponding potential were calculated from the data given by Lewis and Randall[10] in the cases where hydrochloric acid was used, and from the data of Noyes and Stewart[11] where sulfuric acid was employed. The potential of the sulfite half-cell was obtained by subtracting the calculated value of that of the hydrogen half-cell from the "best value" of the electromotive force of the whole cell, no allowance being made for the liquid potential, which must have been small, since the hydrogen-ion concentrations had been made approximately equal.

Before considering the effects of concentration, it may be pointed out that the results confirm the previous statement that about the same electromotive force is produced with hydrochloric as with sulfuric acid, since the values of the potential obtained with the latter fit in with those obtained with hydrochloric acid both at higher and lower hydrogen-ion activities. There can therefore be no doubt that sulfuric acid is not electromotively active in establishing the potential.

Coming now to concentration effects, it is seen from Expts. 2 and 3 or from Expts. 4–6 that increasing 3.3-fold, or even 14-fold, the partial pressure of the sulfur dioxide has little, if any, effect upon the value of the potential.

It will also be seen that decrease in the hydrogen-ion activity produces a less negative value of the potential. Thus from Expts. 4 and 7 it is seen that a 5.6-fold decrease (from 0.955 to 0.170 molal) causes a decrease of 29 mv., while $^1/_2$ (H^+) per faraday would require a decrease of 22 mv. To express the observed results, the function of (H^+) which occurs in that electrode potential equation should therefore be $(H^+)^{4/3}$.

It is also important to note the absolute value of the potential of the sulfite half-cell. It will be seen that its mean value of 25° at a hydrogen-ion activity of 0.96 N is —366 mv., or —0.37 volt within the error of the measurements. The experimental values of the sulfite potential are therefore expressed by the empirical equation

$$E = -0.37 - 0.0296 \log(H^+)^{4/3} \qquad (14)$$

The effect of temperature is shown by Expts. 4 and 8, which were made at 25 and 50°, respectively. The best value of the potential is seen to be only 12 mv. less negative at 50 than at 25°. This shows that the same electrode process is involved at both temperatures, and confirms the conclusion that the potential is not an accidental one. The small change observed, based as it is on one experiment, should not be considered to indicate even the direction of the effect of temperature.

Regarding this —0.37 volt as a sulfite–dithionite potential, it shows,

[10] Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., New York, **1923,** p. **336.**

[11] Noyes and Stewart, THIS JOURNAL, 48, **1870** (1926).

when considered in relation to the molal potential +0.009 of that combination as expressed by Equation 7, that the $S_2O_4^{--}$ concentration in the assumed steady state, when (H^+) and (HSO_3^-) are 1 molal, is only $10^{-12.8}$ molal. Even this minute concentration is, however, about 20,000 times larger than the $S_2O_4^{--}$ concentration ($10^{-17.1}$ molal) that is shown by Equation 8 to be in equilibrium with solid sulfur and sulfurous acid when (H^+) and (HSO_3^-) are 1 molal.

VIII. Half-Cells with Sulfurous Acid and Sulfur

The experiments described in Sections VI and VII clearly showed that neither the usual oxidation product of sulfur dioxide, sulfuric acid, nor the intermediate oxidation product, dithionic acid, is electromotively active in association with sulfurous acid. Yet it has been seen that the potential set up in a solution of sulfurous acid is a characteristic, not an accidental, one. Attention must therefore be directed toward its reduction products.

A natural reduction product to consider is solid sulfur—a possibility which was suggested in Section II. If it were the electromotively active substance, the electrode potential established would be that corresponding to Equation.13 This requires an increase of 15 mv. in the negative value of the potential for a ten-fold increase in the pressure of the sulfur dioxide, and an increase of 59 mv. for a ten-fold increase in hydrogen-ion activity. The results of Table IV showed that in fact variation of the pressure of the sulfur dioxde has little or no effect, and that increase in hydrogen-ion activity has only about two-thirds of the required effect. Although these results with sulfur dioxide are not divergent enough to prove that sulfur is not the active substance involved in the electrode process, yet the absolute value of the molal electrode potential is hardly reconcilable with this assumption, for the observed value is only −370 mv., while that calculated from the free-energy data by Equation 13 is −471 mv. Thus there is a difference of 100 mv., which is about ten times as great as the variation in constancy and reproducibility shown by the data when the conditions are those of strong acidity and moderate pressure of sulfur dioxide. This shows that much more strongly reducing conditions prevail than would be caused by solid sulfur, and therefore that dithionite (or some other strongly reducing substance) is present at higher concentration than that which is in equilibrium with sulfur and sulfurous acid according to Equation 8.

Nevertheless, it seemed worth while to test further the possibility that sulfur is the active substance by depositing it in finely divided form on the electrode. The presence of this added sulfur should give a more constant and reproducible potential and one more nearly of the calculated magnitude if this substance is really electromotively active.

These experiments were first carried out at 50° with Cell 8 of Table IV after taking the readings there recorded. At 50° a cell of this composition should have an electromotive force of approximately 430 mv. if sulfur and sulfur dioxide are the electromotively active substances. The free-energy decrease that attends Reaction 12 at 50° is calculated from that at 25° and from the heat-content decrease at 37.5° (–67,400 cal.) to be —41,460 cal., and the corresponding electrode potential equation is

$$E = -0.449 - 0.0321 \log p_{SO_2}{}^{1/2}(H^+)^2 \qquad (15)$$

The two electrodes in the sulfite cell were removed and one of them was given a shaggy coating of free sulfur by electrolysis in a solution of sodium polysulfide. They were then soaked in hot water for a couple of hours, rinsed thoroughly and returned to the cell. The gas mixture was bubbled through the half-cell for several hours on the first and second days, after which the contents were no longer agitated. After standing overnight the electromotive force returned approximately to that (358 mv.) shown before the sulfur treatment, the two electrodes checking within 2 mv.; but during the next five days it gradually became more negative, after which it showed no consistent trend, though subject to daily fluctuations of 5–6 mv. It showed an average value of 412 mv. at the sulfur-treated electrode, and of 425 mv. at the other electrode.

The electrodes were again removed, cleaned and replatinized. One of them was coated with a thick, sirupy solution of sodium polysulfide and sulfur was precipitated from it by fuming it with concentrated hydrochloric acid overnight. The electrodes were then subjected to a very thorough washing and leaching with warm water; they were returned to the cell and gas was bubbled through it to replace any air. After standing quietly overnight the electromotive force of the cell was 396 mv. at the sulfur-treated electrode and 410 mv. at the other. The values rose over a period of six days, and then remained constant within 3 mv. for four days more at 444 mv. and 440 mv., respectively. These values are seen to be approximately equal to the calculated value (430 mv.), and indicate that at 50" the presence of sulfur on or near the electrode tends to establish the potential required by electrode Reaction 12 involving sulfur and sulfur dioxide.

In view of these results it seemed desirable to investigate the effect of the addition of sulfur at 25° also. The results so obtained are shown in Table V. One electrode was untreated but the other was coated with sulfur by the second method above described, and after the reading first recorded in the table some powdered rhombic sulfur was added to the sulfite half-cell.

It will be seen that the values obtained at 25° with the uncoated electrode are apparently not changed by adding solid sulfur to the solution,

[a] After this reading the gas mixture was bubbled for several hours through the cell, which then stood quietly overnight.

and even the values obtained at the sulfur-treated electrode differ from those at the untreated electrode by only 10 mv. in many cases, and show no tendency to deviate more than this.

These facts show that at 25° the additional sulfur does not determine the potential of the half-cell and that sulfur would have little effect even if it were formed on the electrode through decomposition of the sulfurous acid in cases where sulfur was not added. This presumably arises from the facts that it has much less electromotive activity than dithionite, and that the decomposition of the dithionite by Reaction 8 is not rapid enough, even though it may be catalyzed by solid sulfur, to reduce its concentration to that corresponding to the equilibrium conditions of Reaction 8. The result at 50° showing that the addition of sulfur causes the theoretical sulfur potential to be approximated is probably due to the fact that at this higher temperature the decomposition of the dithionite is rapid enough in the presence of sulfur to establish approximately the equilibrium conditions of Reaction 8.

IX. Sulfite Half-Cells in the Presence of Oxygen

An extensive investigation was carried out some years ago by Edgar, and reported later by Lewis, Randall and Bichowsky,[12] in which sulfur dioxide diluted with air was bubbled through a half-cell containing sulfuric acid solution and an iridized platinum electrode. The electrode potential of this half-cell was measured against a half-cell having a mercury–mercurous sulfate electrode and containing sulfuric acid at a concentration equal to that in the sulfite half-cell. Reproducibility to within about 1 mv. was obtained.

The electromotive forces directly observed by Edgar were calculated by us over to the molal hydrogen electrode with the aid of the values of Randall and Cushman[13] for the cell H_2 (1 atm.), H_2SO_4, $Hg_2SO_4(s) + Hg$, so as to obtain the electromotive forces of the cell H_2 (1 atm.), H_2SO_4 (c),

---

[13] Randall and Cushman, *ibid.*, 40, 393 (1918).

H_2SO_4 (c) + SO_2 (g). By subtracting from these the calculated values for the potential of the hydrogen half-cell, the potentials of the sulfite half-cell were obtained.

Table VI shows the results obtained by Edgar with the moderately concentrated solutions of sulfuric acid. The concentration of the sulfuric acid in the hydrogen half-cell was always the same as that in the sulfite half-cell. The potentials are as usual expressed in millivolts. The values in the last column were obtained from those in the preceding one by subtracting **0.0296** log p_{SO_2}. These values correspond to the assumption that the change in potential is determined by an electrode reaction including among the reduced substances $\frac{1}{2}SO_2$ per faraday. This fact was naturally interpreted by the earlier investigators as indicating that the observed quantity was a sulfite–sulfate potential established in accordance with Equation **3** of Section II.

TABLE VI

ELECTROMOTIVE FORCE AT 25° OF CELLS WITH SULFUR DIOXIDE AND AIR

(Calculated from Edgar's data)

Expt. no.	Sulfite half-cell Molality of H_2SO_4	 Pressure, SO_2 atm.	Hydrogen half-cell Activity H^+	 Potential calcd.	E.m.f. of cell	Sulfite half-cell Potential	 SO_2 at 1 atm.
1	0.5009	0.00689	0.497	18	458	−440	−376
2	.5009	.01328	.497	18	445	−427	−373
3	.5009	.02479	.497	18	437	−419	−372
4	.5009	.05080	.497	18	430	−412	−372
5	.5009	.1091	.497	18	422	−404	−376
6	.5125	.969	.508	17	371	−354	−354

The results shown by Table VI may be summed up as follows. When little or no oxygen is present, as in Expt. 6, the sulfite potential has the value −**354** mv., which corresponds closely to that (−358 mv.) required by our empirical Equation 14 of Section VII. But when, as in Expts. 1–5, oxygen is present and a considerable acid concentration prevails (this perhaps enabling the oxygen to cause oxidation) the potential is more negative (−**404** to −**440** mv.). This signifies that the reducing substance (the dithionite) involved in the steady state determining the potential is being destroyed not only by the spontaneous decomposition expressed by Equation **9** but also by oxidation by the air. Moreover, the negative value is increased by decreasing the concentration of the sulfite; that is to say, the potential becomes more oxidizing on diminishing the concentration of what is here regarded as the oxidizing substance. To explain this anomaly, one must assume that the concentration of the reducing substance (the dithionite) is decreased in still greater proportion when a lesser quantity of sulfurous acid is present from which it can be regenerated.

To study further the effect of oxygen, a series of experiments was made in which gas mixtures of air with sulfur dioxide were bubbled through a sulfite half-cell. The results are shown in Table VII.[14]

TABLE VII

ELECTROMOTIVE FORCE AT 25° OF CELLS WITH SULFUR DIOXIDE AND AIR

Expt. no.	Sulfite half-cell Molal. H_2SO_4	Sulfite half-cell SO_2 in gas, %	Hydrogen half-cell Activity of H^+	Hydrogen half-cell Potential, calcd.	Electromotive force of whole cell 1	2	3	4	8	6	7	Best value	Sulfite half-cell potential
1	0.590	1.5	0.594	13	512[a]	506[a]	491[a]	...	...	485[a]	491	489	-476

3	.590	7.3	.594	13	498[a]	486[a]	490[a]	487[a]	477[a]	481[a]	477	483	-470
4	.590	24.0	.594	13	459[a]	453	425[a]	440[a]	435[a]	422	...	430	-417
5	.590	24.0[b]	.594	13	466[a]	465[a]	...	460[a]	470	...	...	465	-452

[a] After this reading the gas mixture was bubbled for several hours through the cell, which then stood quietly overnight before the nest reading was made.

[b] In this experiment the SO_2 was diluted with oxygen, instead of air.

It will be seen that the experiments presented in Table VII do not show the constancy or agreement with one another exhibited by those of Edgar. It is evident that our conditions, probably especially those prevailing at the sulfite electrode, were not nearly as favorable as those in Edgar's experiments. Our results are cited here, not to cast doubt upon the previous ones, but only to show how capricious the potential may be when the electrode process is complicated by the presence of oxygen.

X. The Oxidizing and Reducing Properties of Sulfurous Acid

Finally, reference should be made to the chemical behavior of sulfurous acid in relation to its electrode potential. An extensive series of researches on the oxidizing and reducing action of this substance has recently been carried out by Wardlaw, Carter and their associates.[15]

---

[14] The method of recording the data is the same as that in Table IV. Immediately following Expt. 1 the electrodes were removed and resaturated with hydrogen before being replaced. This appeared to produce a permanent decrease in the electromotive force of the cell, as was shown by the character of the bubbling curve and by the non-bubbling value obtained the following morning (455 mv.). The sulfur dioxide pressure was then changed to 7.3% in Expt. 2. Expts. 3, 4 and 5 form a new series in which a fresh solution was taken.

The air used in these experiments was drawn from the laboratory compressed air lines and was passed through a solution of sodium hydroxide and then through concentrated sulfuric acid. Oxygen was drawn from a gas cylinder and passed through the same solutions. After taking down the cells the solution was analyzed by first titrating with thiosulfate for sulfite content and then with sodium hydroxide for total acidity. The increase in the molality of the sulfuric acid was calculated to be about 0.004 mole, although this cell was in operation for twenty days.

Soc.*, 117, 1093-1103 (1920); Wardlaw and Carter, *ibid.*, 1241-1247 (1920); Wardlaw and Pinkard, *ibid.*, 121, 210-221 (1922); Carter and Clews, *ibid.*, 125, 1880-1888 (1924); Carter and Lea, *ibid.*, 127, 499-510 (1925); Carter and Robinson, *ibid.*, 130, 1921-1923 (1927). For a summary of the results see Carter, *J. Soc. Chem. Ind.*, 45, 207-210 (1926); Wardlaw, *ibid.*, 45, 210-214 (1926).

These investigators have studied the effect at 95° or above of sulfurous acid, both as an oxidizing agent and as a reducing agent, on various combinations having a series of reduction potentials, namely, on different mixtures of ferrous and ferric chlorides, of ferrous and ferric phosphates, of cuprous and cupric chlorides, and of mercurous and mercuric chlorides, in the presence of the corresponding acid at widely varied concentrations. They have thus qualitatively determined the combinations which have near 95° such reduction potentials as cause them to be barely oxidized and such as cause them to be barely reduced by sulfurous acid at different acid concentrations. They have found in general: (1) that sulfurous acid, because of its tendency to undergo two entirely different reactions, behaves either as a reducing agent or an oxidizing agent depending on the nature of the combination acted upon and on the strength of the acid, (2) that at a given acid concentration the reduction potential of the combination acted upon need be varied by only a relatively small amount (say by 20 to 40 mv.) in order to change the action of sulfurous acid from a reducing one to an oxidizing one, and (3) that increase in acid concentration makes sulfurous acid a less powerful reducing agent, and also (to about the same extent) a more powerful oxidizing agent.

From a theoretical standpoint this chemical behavior of sulfurous acid may now be interpreted in the following way more quantitatively than was done by the English investigators.

Sulfur dioxide at 25° at 1 atm. in an aqueous solution containing hydrogen ion at 1 molal may be expected to behave toward other oxidation–reduction combinations of substances in three different ways according as the reduction potential of the latter (a) is more negative than -0.37 volt; (b) lies between -0.37 volt and -0.14 volt; (c) is more positive than -0.14 volt. (It may be recalled that the value -0.37 is the potential which sulfur dioxide has, under the specified conditions, with respect to its conversion into dithionite ion $S_2O_4^{--}$ as it exists in the steady reaction state, and that -0.14 is the potential which it has with respect to its conversion to sulfate ion, SO_4^{--}, at 1 molal.) For it is evident that sulfur dioxide may oxidize any combination with a reduction potential more reducing (less negative) than -0.37 volt, and that it may reduce any combination which has a potential more oxidizing (more negative) than -0.14 volt. Therefore it may either oxidize or reduce any combination with a potential between -0.37 and -0.14 volt, and which of these two possible effects actually occurs will depend on the relative rates of the oxidizing reaction and of the reducing reaction. For example, sulfur dioxide (at 25° and 1 atm. and with H^+ at 1 molal) can only reduce Fe^{++}(1 m.), Fe^{+++} (1 m.) for which E is -0.75 volt, or I^-(1 m.), I_2(s) for which E is -0.54 volt; and it can only oxidize Pb (s), Pb^{++} for which E is $+0.12$ volt, or H_2 (1 atm.), H^+ (1 m.), for which $E = \pm 0$. But it might either oxidize or reduce Hg (l) + Cl^-(1 m.), Hg_2Cl_2(s) for which E is —0.27 volt, or Cu(s), Cu^{++} (1m.) for which E is −0.34 volt. In fact, however, in such cases the oxidizing effect of sulfur dioxide (whereby it is converted to dithionite) seems to be more rapid than its reducing effect (whereby it is converted to sulfate), so that within the interval —0.37 to —0.14 volt it probably acts ordinarily as an oxidizing agent. If this is *the* case, the potential which a combination actually must have in order that it may be reduced by sulfur dioxide is —0.37, not —0.14, thus accounting for the condition mentioned in the Introduction that sulfur dioxide seems to be reducing through a narrower range than thermodynamic relations permit.

Increase of hydrogen-ion concentration, according to empirical Equation 14, extends the region (to more negative values than —0.37) within which sulfur dioxide can act oxidizing, and, according to theoretical Equation 3, it narrows the region (requiring more negative potentials than —0.14 in the combination acted upon) within which sulfur dioxide can act reducing. Thus increase of acidity should make sulfur dioxide more oxidizing, but less reducing, as the English investigators found.

XI. Summary

Experiments have been described in this article showing the electromotive force developed in various cells of the general type Pt, H_2SO_3 + HA at c_1, HA at c_2, H_2 + Pt, where c_1 and c_2 are so related that the hydrogen-ion concentration is nearly the same in the two solutions (thus largely eliminating the liquid potential), and where HA is sulfuric acid, dithionic acid or hydrochloric acid.

It is shown that fairly definite electromotive forces result when and only when the cells are allowed to stand quietly for many hours or for several days, since agitation immediately causes a large increase in the negative value of the electromotive force. This definite electromotive force is nearly independent of the concentration of the sulfurous acid and does not depend on whether the acid associated with it is sulfuric, dithionic or hydrochloric acid, thus proving that the anion of none of these acids determines the potential. At 25° the potential E of the sulfite half-cell (obtained by subtracting from the electromotive force the calculated potential of the hydrogen electrode) is approximately given by the empirical expression $E = -0.37 - 0.03 \log (H^+)^{4/3}$.

It is shown that the results are satisfactorily explained by the assumption, earlier made by Carter and James, that the sulfite potential arises from association with the sulfurous acid of one of its spontaneously produced reduction products, probably the acid $H_2S_2O_4$ (for which the rational name dithionous acid is proposed, in place of the conventional names hydrosulfurous or hyposulfurous acid used in the literature). It is suggested that the fairly definite potential is the result of a steady state in which the quantity of this acid produced per minute by the decomposition of sulfurous acid (into $H_2S_2O_4$ and H_2SO_4) becomes equal to the quantity of it destroyed per minute by its spontaneous decomposition (into H_2SO_3 and S or into $H_2S_2O_3$).

It is shown that the reduction product which determines the potential is not sulfur itself, for thermodynamic calculations require that the potential then be about 0.10 volt more negative than the observed value of —0.37 volt; moreover, experiments in which finely divided sulfur was added to the sulfite half-cell showed that it is not active enough to change the potential in the required direction. This is true at any rate at 25°, but there are indications that at higher temperatures, where the sulfur is more active and the rate of decomposition of the dithionous acid more rapid, sulfur may be the reduction product which determines the potential.

As an aid in the interpretation of the results the free energies and electrode potentials corresponding to all the sulfur reactions possibly involved have been derived from existing theremodynamic data and formulated (in Section II).

The existence of the definite steady-state potential (—0.37 volt at 25°) between sulfurous acid and its reduction product considered in connection with the thermodynamically known potential (—0.14 volt) of sulfite–sulfate, enables the behavior of this acid as an oxidizing agent and as a reducing agent to be predicted; namely, it is shown that a solution of sulfurous acid at 25° (when the corresponding pressure of sulfur dioxide is 1 atm. and the H^+ concentration is 1 molal) may oxidize any other oxidation–reduction combination which has a reduction potential more reducing (less negative) than —0.37 volt, and that it may reduce any combination which has a potential more oxidizing (more negative) than —0.14 volt. Therefore it may either oxidize or reduce any combination with a potential between —0.37 and —0.14 volt; which of these two possible effects actually occurs will depend on the relative rates of the oxidizing reaction and the reducing reaction.

THE SINGLE POTENTIAL OF THE NICKEL ELECTRODE

BY EDGAR NEWBERY

RECEIVED JANUARY 10, 1929 PUBLISHED MAY 6, 1929

The single potential of nickel has been the subject of numerous investigations during the past thirty-five years but so far no work has been done which has inspired sufficient confidence for the values obtained to be accepted as standard. Each investigator claims accurate reproducibility for his particular results and yet the variety of opinion is surprising. Some give positive values, some negative, and the range between extremes is of the order of one volt. The whole position is therefore highly unsatisfactory and the following work was undertaken with the view in the first place of investigating the reasons for these extraordinary variations and in the second place of deciding whether it is possible to assign any definite single potential to this metal.

Possible sources of variations in results are: (1) impurities in the electrode, (2) impurities in the electrolyte, (3) variations in nature of electrode surface, (4) changes in electrolyte during measurements, and (5) chemical action between electrode and electrolyte.

1. Pure nickel free from cobalt and iron has been used by most of the investigators. In the course of this work various samples from the purest available to markedly impure material containing iron, cobalt and up to 2% of copper were used, but no difference could be detected which could be ascribed definitely to these impurities. Extreme purity of nickel from other metals appears therefore to be of small importance for the purpose in hand.

Gaseous impurities, however, are in another category. Experiments were tried using the carefully cleaned metal in an atmosphere of nitrogen with air-free solutions. When air was admitted and even bubbled through the solution, no change could be detected. Oxygen is therefore an unimportant impurity, contrary to the opinion of certain investigators. On the other hand, hydrogen has a powerful effect. This gas is very appreciably soluble in metallic nickel and if present in any considerable quantity may transform the nickel into a hydrogen electrode. Freshly prepared electrolytic nickel contains large quantities of hydrogen and the single potential of such an electrode may differ by as much as 0.5 volt from that of a similar electrode free from the gas. Hydrogen is therefore a dangerous impurity and must be rigidly excluded. The values recently obtained by K. Murata[1] are invalidated for this reason.

2. Chemically pure nickel salts are available but preliminary experiments tried with crude commercial samples showed no variations which

---

[1] **Murata,** *Bull. Chem. Soc. Japan,* **3,** 57–69 **(1928).**

could be definitely ascribed to this source. Extreme purity of the electrolyte appears therefore to be a matter of little importance.

3. In the case of copper, recently investigated, it was found that variations in the nature of the electrode surface had little or no effect upon the single potential. In striking contrast to this, it has been found that the difference of potential between a highly polished and a very rough nickel surface is of the order of 0.4 volt and further that reproducible results at any stage between these limits could be obtained by choosing different grades of emery or glass paper for preparing the surface.

4. Nickel sulfate, the salt generally used for this purpose, is very stable in solution and there appears to be no reason for ascribing any appreciable influence to this factor.

5. Judging by the rapid changes of potential which occur when a nickel electrode is first placed in a solution of a nickel salt, there is no doubt that chemical action does occur between electrode and electrolyte. Such action is, however, extremely small though its effect upon the single potential is great. A highly-polished nickel rod immersed in a solution of nickel sulfate for several hours is unchanged in appearance even under the microscope, although its single potential may have changed by 0.3 volt during the period.

Experimental

The apparatus used was identical with that previously described for copper electrodes.

Especially pure nickel sulfate free from cobalt and iron was used for making up the solutions and the electrodes were made from Merck's A.R. nickel in the form of sheet 0.5 mm. thick or small rods 2 mm. thick. The electrodes were in most cases covered with hard white sealing wax leaving 1 sq. cm. exposed. This was done in order to avoid the possible interference of surface actions at the liquid–air boundary, but it is probable that this precaution is unnecessary.

It is essential that electrodes be kept in motion with respect to electrolyte during observations of single potential. An electrode which has been left at rest for some time in the electrolyte shows a sudden change of potential of the order of 0.2 volt when moved. This is most probably due to local concentration changes in the film of electrolyte in contact with the electrode and such changes can only be avoided by rapid relative motion between electrode and electrolyte. Where rods were used, they were rotated at speeds of about 500 r. p. m., and where plates were used a small spiral glass stirrer was rotated at the same speed close in front of the plate.

(a) In view of the success of Nielsen and Brown[2] in preparing a standard copper electrode by using a two-phase amalgam, this method was adopted for the first mode of attack. The amalgam was prepared by electrolyzing a solution of pure nickel chloride using a cathode of especially pure electrolytic mercury and an anode of pure sheet nickel. After washing, the amalgam was heated to the boiling point of mercury to expel any traces of hydrogen, and preserved under a half-molar solution of nickel sulfate.

The cell $\mathrm{NiHg} \mid \mathrm{NiSO_4}\ M/2 \mid \mathrm{Hg_2SO_4} \mid \mathrm{Hg}$ was then made up and immersed in a thermostat at 25°. This cell gave very erratic readings varying between 0.22 and 0.35

---

[2] Nielsen and Brown, THIS JOURNAL, 49, 2423 (1927).

volt when first made up and rising to nearly 0.7 volt after standing for two hours. A small spiral glass stirrer was then introduced to stir the amalgam surface during observations. The readings then obtained were much steadier but still varied between 0.4 and 0.55 volt. Similar experiments with more dilute amalgam gave similar results. With the use of twentieth molar nickel sulfate solution, still more erratic values were obtained.

A dropping electrode was then tried for the amalgam but the values given were extremely irregular, varying between 0.3 and 0.65 volt for no apparent reason. Further work with the amalgam was therefore abandoned.

(b) The method which proved successful with copper whereby the "instantaneous" potential of a rapidly rotating rod is measured during the actual process of immersion was now tried.

The cell used was Ni | $NiSO_4$ $M/2$ | Hg_2SO_4 | Hg, the mercury electrode being contained in a separate vessel communicating with the main vessel through 25 cm. of 1-mm. tubing, and the whole apparatus immersed in a thermostat at 25°.

The rotating electrode holder was attached to a stand fitted with rack and pinion for raising and lowering, and the main vessel was closed with a cork through which a glass tube passed, just wide enough to admit the rotating electrode. Other tubes allowed the vessel to be filled with air or nitrogen at will.

It was soon found that reproducible results could be obtained if the electrode was prepared in the same way, even with different samples of metal, some of which were certainly impure. If, however, the method of preparation of the surface was varied, the values obtained also varied widely. For each abrading or polishing material used, there appears to be a fairly definite limiting potential produced. With the finer polishing agents this limit is only obtained after long-continued and repeated application, whereas the coarser agents give a constant value at once. The values obtained with the various agents are given in the following table.

Polishing agent	E.m.f. of cell, volt	Polishing agent	E.m.f. of cell, volt
No. 1 emery cloth	0.63	Soft filter paper	0.45
No. 00 emery cloth	.59	Agate burnishers	.40
No. 000 emery paper	.56	Agate followed by selvyt cloth	.25

Since it was found that the value of 0.45 volt could be repeatedly obtained by using a certain sample of filter paper, various modifications were introduced while keeping to this polishing agent. (1) Previous heating of the electrode to redness in high vacuum had no effect. (2) Previous boiling of the solutions, cooling in an atmosphere of nitrogen and carrying out the measurements in an atmosphere of nitrogen had no effect. **(3)** Immersing the electrode in concentrated potassium hydroxide solution, washing and drying, lowered the e.m.f. of the cell from 0.45 to 0.40 volt. (4) On allowing the rotating electrode to remain in the solution, a fairly rapid rise to 0.53 volt occurs. (5) After (3) above, the electrode was abraded with No. 1 emery cloth, when the value 0.63 volt was again obtained. (6) Repeating (4) with the electrode after (5) treatment, a *fall* to 0.53 volt was observed.

From the above observations we conclude (1) that the presence of oxygen has no appreciable effect upon the single potential of nickel, (2) that immersion in alkali does not render nickel passive, since the single potential of passive nickel differs from that observed by about 1.2 volts and **(3)** that the value of 0.53 volt appears to be some kind of equilibrium value for the cell.

(c) The experimental electrode was now fitted up in a cell containing 0.5 M nickel sulfate together with a secondary nickel electrode and a standard mercurous sulfate electrode and connected to a commutator circuit for measuring back e.m.f., just as has been employed for measuring over-voltage.

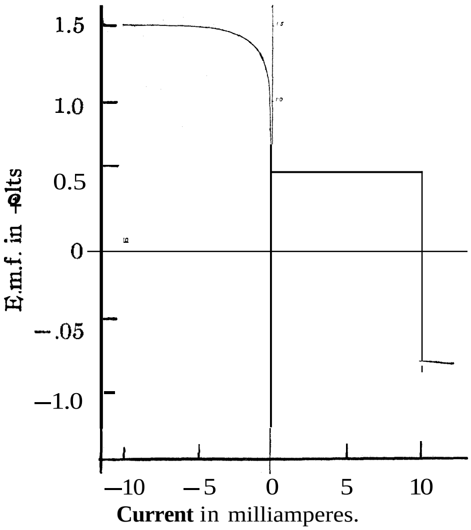

Fig. 1.

When the experimental electrode was made the cathode, the back e.m.f. of the cell rose very rapidly to over 1 volt with a current of 0.1 milliampere and hydrogen gas was liberated. When the same electrode was made the anode, the back e.m.f. fell slowly to 0.53 volt with a current of *2* milliamperes, then rose to 0.55 volt with a current of 4 milliamperes and retained this value up to a current of 10 milliamperes. At this stage after passing current for about one minute the back e.m.f. suddenly changed from 0.55 volt to -0.81 volt due to the electrode becoming passive. The accompanying curve illustrates these changes and should be compared with that obtained for copper in the same way.

These experiments show very clearly the dangerous nature of hydrogen as an impurity when measuring the single potential of nickel. A current of 10^{-5} ampere is sufficient to alter the value by 0.1 volt when the nickel is the cathode, whereas the value is nearly constant when the nickel is the anode until the current passing is one thousand times as great as this. It should be emphasized that no current is passing during the actual measurement of the above potentials. The constancy of the values under anodic treatment appears to be due to the slow continuous removal of the surface of the nickel leaving a clean surface always exposed to the electrolyte. Only under these conditions are the rapid fluctuations of single potential suppressed and constant reproducible values obtained.

Deductions from the Experimental Results.—The cell Ni | $NiSO_4$ $M/2$ | Hg_2SO_4 | Hg shows three distinct values under different conditions, two limiting values of approximately 0.26 and 0.65 volt and one somewhat persistent intermediate value of 0.53 volt at 25°.

Assuming the nickel salt to be 25% dissociated, the single potential of the mercury electrode is 0.96 volt referred to the normal calomel electrode as 0.56 volt. Hence the single potential of nickel in contact with a normal solution of nickel ions will be 0.73, 0.33 or 0.45 volt referred to normal calomel electrode=0.56 volt, and 0.45, 0.05 or 0.17 volt referred to normal hydrogen electrode=0.00 volt. In order to explain the existence of three values for one metal it is necessary first to note that the variability of the results obtained when nickel amalgam is used in a dropping electrode indicates that the variations are inherent in the nickel itself and are not due solely to interaction between electrode and electrolyte. Again, the extreme values are obtained at will by extreme polish or extreme roughness. It is well known that in polishing a metal the crystals are pressed down and the amorphous binding material is smoothed over the top of them. The obvious conclusion to draw, therefore, is that amorphous and crystalline nickel have different solution pressures and therefore different normal single potentials. These are 0.73 and 0.33 volt, respectively, whereas the intermediate value of 0.45 volt represents that of the equilibrium mixture normally present throughout the mass of the nickel. An objection to this theory may be made that in the amalgam it is not possible to have amorphous and crystalline nickel present at the same time. If, however, we call the two allotropes a-nickel and β-nickel, respectively, it is not necessary to postulate that these are identical with the amorphous and crystalline phases, but merely that the concentration of the a-nickel is higher in the amorphous phase and that of β-nickel in the crystalline. Both types may therefore retain their identity even when dissolved in mercury.

The extreme values found for the single potential will therefore still represent those of mixtures and not of pure a- and β-nickel. Since the experimental values are 0.45 and 0.05 volt, respectively, referred to the hydrogen electrode, we may safely put down the single potential of α-nickel as at least 0.5 volt and that of 0-nickel as approximately equal to that of hydrogen.

In the solution the existence of a-nickel is doubtful. If present at all it must be in very small proportions since no appreciable quantities of nickel are deposited in a nickel-plating cell until the applied e.m.f. greatly exceeds that theoretically needed for a metal with a single potential of 0.5 volt. β-Nickel and hydrogen are then deposited together; the hydrogen escapes and the β-nickel reverts to the equilibrium mixture of a- and β- by a comparatively slow change. These processes greatly hinder the formation of large crystals and thus produce a marked tendency to the production of smooth polished deposits. In addition, the escape of hydrogen, together with the rearrangement of the deposited metal, results in a contraction of the metal with consequent tendency to strip off the base metal, especially if the deposit is thick.

The suggestion that nickel contains two allotropic forms is not new. Others have used it in attempts to explain the passivity and the overvoltage of nickel and Glasstone[3] has used it to explain the retardation phenomena shown during electrolytic deposition of the iron group metals. If a current of about 0.02 amp. be passed between two nickel electrodes each of 1 sq. cm. surface in a neutral solution of nickel sulfate, hydrogen is liberated at one electrode, which then exhibits overvoltage, and oxygen at the other, which becomes passive. The back e.m.f. of this cell then exceeds 2.2 volts, the single potential of the cathode being at least 0.7 volt below that ascribed to β-nickel and that of the anode 1.0 volt above that ascribed to a-nickel. As an explanation of overvoltage or passivity, therefore, such a theory is untenable. As an explanation of the retardation phenomena along the lines suggested by Glasstone it is equally untenable. If β-nickel in solution requires the application of an e.m.f. similar to that needed for zinc to deposit it on a cathode, then in a solution containing zinc and nickel in equal proportions, a high current density should deposit the two metals in approximately equal quantity and the relative proportions should not vary greatly with change of current density. Such is far from being the case. It is found in practice that at the cathode of such a cell the proportion of nickel and of hydrogen relative to zinc becomes rapidly less as the current density increases and at a very high current density (200 to 600 amps. per sq. ft.) nearly pure zinc is deposited with high current efficiency. This shows that both nickel and hydrogen are subject to some powerful retarding force which increases with current density and which does not affect zinc. The hydrogen ion is almost certainly hydrated. When deposited on the cathode it must lose its water of hydration before it can form gaseous hydrogen—a process requiring time. If a part of the current is being carried by a non-hydrated ion at the same time, it is evident that at higher current densities a greater proportion of the current will be carried by the non-hydrated ion. Zinc appears to be such a non-hydrated ion, whereas nickel appears to be hydrated in a similar way to hydrogen.[4] The retardation phenomena observed with hydrogen and all the iron group metals are therefore to be explained on the basis of hydration of the ions. At higher temperatures the velocity of dehydration of the ions will increase and therefore the retarding forces will decrease, as has been observed by Glasstone.[3]

---

[3] Glasstone, J. Chem. *Soc.*, 129,2896 (1926).

[4] The term "hydration" here implies true chemical hydration and not mere surface adsorption. The hydration of the ions of the alkali metals, halogens, etc., which is assumed in order to explain anomalies in ionic velocities must be of an entirely different nature.

The variations of single potential of a nickel electrode in a solution of *a* nickel salt appear to be due to a variety of causes. If the surface is highly polished, the surface film contains excess of α-nickel and the potential first observed will be too high. This film is extremely thin and very slight attack by the electrolyte will be sufficient to expose the underlying @-nickel, with consequent fall of single potential. If the electrode is at rest, an interchange of ions with the solution occurs, but the ions received will be hydrated while those expelled will be non-hydrated. There will therefore be an accumulation of non-hydrated ions in the solution and an accumulation of water in contact with the electrode. At the same time a film of basic salt may form around the electrode and thus change the ionic concentration of the solution. Hence motion of the electrode with respect to the electrolyte may produce large changes of single potential, and the equilibrium potential of a stationary electrode will be very different from that of a rotating electrode.

Iwaśe and Miyazaki[5] have recently found that the single potential of an iron single crystal is much greater and more constant than that of polycrystalline iron. Hence the above theory will also apply to iron and probably to cobalt.

It appears probable that the true reversible single potential of a metal cannot be determined directly if that metal gives rise to hydrated ions.

Summary

The single potential of nickel in a solution of nickel sulfate has been measured by three distinct methods under very varied conditions. The values obtained vary greatly with the condition of the electrode surface, with time and with relative motion between electrode and electrolyte.

Constant and reproducible values are obtained when the nickel is treated anodically with a small current density insufficient to produce passivity, the potential being measured when the current is not passing. Whether these values represent true reversible potentials or not is open to question. Nickel amalgam is even more erratic than massive nickel when used for single potential measurements.

It is suggested that solid nickel contains two allotropes having normal single potentials of approximately + 0.5 and 0.0 volt, respectively, referred to the normal hydrogen electrode. The equilibrium mixture of the two allotropes normally present in massive nickel has a corresponding potential of 0.17 volt.

On the basis of the above theory, together with that of the hydration of nickel ions, an explanation is offered (1) of the observed variations of single potential, (2) of the retardation phenomena observed during elec-

AN ISOTOPE OF OXYGEN, MASS 18. INTERPRETATION OF THE ATMOSPHERIC ABSORPTION BANDS

BY W. F. GIAUQUE AND H. L. JOHNSTON

RECEIVED JANUARY 14, 1929 PUBLISHED MAY 6, 1929

In connection with our study of the entropies of gases we have recently considered the available spectroscopic data for oxygen. The atmospheric absorption bands of oxygen contain the necessary information concerning the rotation levels of the oxygen molecule but we found that no completely satisfactory interpretation of these bands has been given, although Mulliken[1] has recently arrived at a partial solution. However, he expresses the opinion that a revised interpretation will probably be necessary in order to include a weak band for which no explanation has been offered by any previous worker.

We can have little confidence in an entropy calculation based on uncertain interpretation since a misunderstood multiplicity would introduce a serious error in our result. We were thus led to a further study of the data.

We may say at once that, in view of our result, no revision of Mulliken's interpretation is necessary.

The most accurate data are those of Dieke and Babcock[2] so they alone have been considered.

The absorption bands are due to a 1.6-volt excitation from the various rotation levels of the normal oxygen molecule, to the various rotation levels of several vibration states of the 1.6-volt level. Only the alternate rotation levels are present, as would be expected for a non-polar molecule with two non-spinning nuclei. All of the lines of the bands, which are of the P and R types, appear as doublets and in addition a weak band is present, the "A' band," which appears to be an exact duplication of the A band except that the rotation lines have a different spacing.

Our principal problem was to decide whether the A and the A' bands originated from a common source or not. We tried many ways of combining the lines both within the strong A and the weak A' bands, respectively, and also combining weak with strong but could find no scheme that would account for the bands arising from a single molecular form. Mulliken considers that the normal oxygen molecule must be a triplet

[1] **Mulliken,** *Phys.* ***Rev.,*** **32,** *880* **(1928).**

[2] **Dieke and Babcock,** *Proc. Nat. Acad. Sci., 13, 670 (1927).*

S state and mentions the previous workers who have concluded this from the various spectroscopic observations and magnetic susceptibility data. The upper state of the atmospheric bands is a singlet S state. A triplet S state results from two unbalanced spinning electrons coupled together and having three possible orientations. One of these, called the F_1 state, has the spin momentum with the molecular rotation; in the F_3 state the spin is against the molecular rotation and the F_2 state has the spin approximately at right angles to the axis of the molecular rotation. With the above scheme Mulliken fully explains all of the observed lines of the A band and also the absence of the first line of the P_2 series. It is noteworthy that the energies accompanying the extremely loose couplings of the spin with the weak magnetic field, caused by the thermal rotation of the molecule, are of a reasonable amount, decreasing for F_1 states and increasing for F_3 states as the molecular rotation increases, as would be expected. This behavior is completely duplicated by the A' band except for the previously mentioned different spacing of the lines.

It occurred to us that the A' band might result from an isotope of oxygen and we have found that it is fully explained as originating from an oxygen molecule consisting of an atom of mass *16* combined with an atom of mass 18. Such an isotope has not previously been observed but its existence in small amount has certainly not been disproved. Since it is of practically the same mass as water, it might easily be misinterpreted in a mass spectrograph.

The necessary equations for this calculation have been given by Loomis.[3] The electron excitation is assumed to be identical, within the limit of error, for both the heavier and lighter molecules. Only the $^1/_2 \longrightarrow {}^1/_2$ vibration change was observed in the weak system. The vibrational isotope effect is given by the formula

$$\nu_2^{n={}^1/_2} - \nu_1^{n={}^1/_2} = (\rho - 1)\nu_1^{n={}^1/_2}$$

where $\rho = \sqrt{(M_1 + M_2)/2M_2}$ and M_1 and M_2 are the masses of the respective atoms. The rotational isotope effect is given by

$$\nu_2^m - \nu_1^m = (\rho^2 - 1)\nu_1^m$$

where m is the rotational quantum number. The symbol ν refers to the energy change divided by h for the various states concerned. The total isotope effect is the sum of the two.

Using the above formulas we obtain the following expressions for the isotopic doublets.

$$\Delta\nu_P = 2.12 + 0.0556\ [B''m^2 - \beta''m^4 - B'(m - 1)^2 + \beta'(m - 1)^4]$$
$$\Delta\nu_R = 2.12 + 0.0556\ [B''m^2 - \beta''m^4 - B'(m + 1)^2 + \beta'(m + 1)^4]$$
$$m = \frac{3}{2}, \frac{7}{2}, \frac{11}{2}, \ldots$$

---

[3] Loomis, *Bull. Nat. Res. Council,* 11, Chap. V (1926).

The constants as given by Dieke and Babcock are $B'' = 1.438$, $\beta'' = 6.31 \times 10^{-6}$, $B' = 1.390$ and $\beta' = 5.75 \times 10^{-6}$.

The rotation quantum number m is retained for convenience in using the equation of Dieke and Babcock instead of using the formulation in terms of j_k as indicated by wave mechanics. $m = j_k + {}^1/_2$, where j_k is the number of units of angular momentum due to the rotation of the molecule.

The first term, 2.12 cm.$^{-1}$, in the doublet formulas is the vibrational isotope effect for the zero point state of one-half unit of vibration. Its calculation makes use of the formula given by Birge[4] for the vibration of the normal oxygen molecule

$$\nu^n = 1565.37n - 11.37n^2$$

and of that given by Dieke and Babcock[2] for the 1.6-volt level

$$\nu^n = 1415.017n - 11.91n^2 - 0.3525n^3$$

where $n = 0, 1, 2, \ldots\ldots$

In accordance with wave mechanics both of these formulas should be transposed so that the state given as zero by the formulas corresponds to $n = {}^1/_2$.

Dieke and Babcock's j numbering of the lines is correct if it is taken **as** $j(= j_k)$ of the molecule in the upper state.

The calculated and observed values are given in Table I.

TABLE I

ROTATIONAL–VIBRATIONAL ISOTOPE DOUBLETS FOR OXYGEN

j_k, normal state	Calcd. separation in cm.$^{-1}$	$P_1' - P_1$	$P_2' - P_2$	j_k, normal state	Calcd. separation in cm.$^{-1}$	$R_1' - R_1$	$R_2' - R_2$
1	2.28	2.25	Excl. transition	1	1.82	..	..
				3	1.53	..	1.49
3	2.62	2.57	2.52	5	1.27	1.28	1.27
5	2.97	2.91	2.93	7	1.03	0.95	0.93
7	3.35	3.29	3.32	9	0.81	.75	.74
9	3.75	3.70	3.72	11	.61	.59	.55
11	4.17	4.10	4.13				
13	4.61	4.55	4.57				
15	5.07	5.01	5.01				
17	5.56	5.50	5.46				

The average deviation of observed minus calculated separations is -0.05 cm.$^{-1}$. The maximum deviation is -0.13 cm.$^{-1}$. This is well within the limit of accuracy of the data and is certainly better than we had expected in view of Dieke and Babcock's remarks about the accuracy.

We would obtain about the same p from a 17–17 molecule but calculation shows a poorer agreement with the data and the chance of formation of such molecules rather than 16–17 molecules seems definitely to eliminate it as a possibility. No other possibility would give even rough agree-

Birge, *Bull. Nat.* Res. *Council, 11,* Chap. *V (1926).*

ment. We are thus forced to conclude that an isotope of oxygen, mass 18, exists in the earth's atmosphere. From the relative intensities of the bands the amount must be very small and would thus be difficult to detect in a mass spectrograph. It seems possible that the 16–18 molecule might be a more efficient absorber of radiation than the 16–16 molecule due to the slight polarity introduced by the zero point vibration; thus relative intensities may be taken as an upper limit to the amount of 16–18 oxygen present.

Our conclusions are supported by the absence of the excluded line in the A' band which would correspond to the $j'' = 0 \rightarrow j' = 0$ transition, as was pointed out by Mulliken. It may also be noted that the vibrational and rotational isotope effects considered independently are in agreement. For example, $I_{18-16}/I_{16-16} = 1.059$ is the theoretical ratio of the two moments of inertia, while Dieke and Babcock's constants give 1.062 for the ratio in the normal state and 1.060 for the 1.6-volt level.

Addendum

Since the above paper was written, we have communicated with Mr. H. D. Babcock, of Mount Wilson Observatory, who has kindly placed some additional material in our hands. This consists of thirty-four weak lines and we have found that twenty-seven of these are due to the 16–18 oxygen molecule, being the alternate lines in the P_1', P_2', R_1' and R_2' series referred to above. This is in accordance with the predictions of wave mechanics since when the two ends of a molecule are different, all the rotation levels should be present. Since the lines corresponding to these new members of the above series do not occur in the 16–16 band, isotopic doublets are not observed in this case We have, therefore, made use of the equations given by Dieke and Babcock for the 16-16 molecule combined with the isotope effect to calculate the wave numbers to be expected for the new lines. In making this calculation we found that the equations of Dieke and Babcock did not reproduce their published data with sufficient accuracy for our purpose so we made use of a linear deviation plot in calculating the positions of the new lines.

The observed and calculated values are given below in Table II. The designations are in accordance with those used by Dieke and Babcock.[2]

The quantum number j refers to the rotation state in the upper electronic level. The symbol b indicates that an observed line has been used in two places and bb indicates use in three places. The symbol d is used where the line is known to be double. A number of the missing lines have undoubtedly been obscured by near coincidence with strong lines of the A band.

The seven unexplained lines which do not necessarily belong to oxygen are given in Table III.

[a] Close double used once in description of A' band.

Babcock has also estimated the relative intensities of A' and A lines as roughly 1% and that the odd and even members of the A' band are of about equal intensity. As we have pointed out in the above paper this probably cannot be taken as a measure of the relative amounts since the absorption coefficients may be quite different. Assuming that the two sorts of molecules did exist in the above proportions, the lighter isotope of oxygen would have an atomic weight of about 15.98. This is obtained due to the existence of twice as many levels in the 16–18 molecule, thus making the total absorption 2% of that due to 16–16 oxygen. The mass spectrograph results obtained by Aston in terms of the lighter isotope seem to fall too close to the atomic weight values based on other methods to permit a value of 15.98 for the light isotope of oxygen. The situation is complicated by the possibility of isotopes of all the light elements but the general agreement seems significant. Aston has pointed out that it is very difficult to prove the non-existence of other isotopes of oxygen with the mass spectrograph. However, this appears to be the most promising possibility for the estimation of the relative amount of O^{18}.

The presence of isotopes of oxygen will, of course, not affect chemical atomic weights except in the remote possibility of non-uniform distribution but before we can know the relationship between ordinary atomic weights and the results of the mass spectrograph, the amount of O^{18} must be known.

Another point of interest in connection with the new lines is as follows. If P, Q and R branches resulted from each of the triplet states of the oxygen molecule, we would have nine branches. Only four branches have been observed. This seems to indicate that the rotational momentum is required to change by an amount of plus or minus one that is, $\Delta j_k = *1$ in addition to the usual requirement $\Delta j = \pm 1$ or 0. Professor R. S. Mulliken of the University of Chicago has called our attention to the similarity of the above selection rule to that in the atomic case where for line spectra $\Delta l = \pm 1$ and $\Delta j = \pm 1$ or 0.

Summary

The weak band in the atmospheric absorption of oxygen has been explained and demonstrates the existence of an isotope of oxygen, mass 18, present in small amount.

THE HEAT CAPACITY OF HYDROGEN IODIDE FROM 15°K. TO ITS BOILING POINT AND ITS HEAT OF VAPORIZATION. THE ENTROPY FROM SPECTROSCOPIC DATA

BY W. F. GIAUQUE AND R. WIEBE

RECEIVED JANUARY 14, 1929 PUBLISHED MAY 6, 1929

We have previously shown[1] that for hydrogen chloride and for hydrogen bromide the entropies as calculated for the gaseous state with the assistance of spectroscopic data are in agreement with those obtained from our calorimetric measurements and the third law of thermodynamics. This paper contains similar calorimetric data for hydrogen iodide, again leading to agreement between the two methods of obtaining the entropy.

Preparation of Hydrogen Iodide.—Hydrogen iodide was prepared directly from the elements in a manner very similar to that used for the preparation of hydrogen bromide. Iodine was sublimed into a large tube which was attached to a reaction tube containing a platinum spiral wound on quartz. The whole apparatus was then immersed in a water-bath which was kept at the boiling point by electrical heating of the platinum

---

[1] Giauque and Wiebe, THIS JOURNAL, (a) 50, 101 (1928); (b) 50, 2193 (1928).

spiral to about 600°. Hydrogen was prepared by electrolysis and freed of oxygen by means of a nickel catalyst. Dry hydrogen was passed into the tube containing the iodine and became saturated at 100°. This left a large excess of hydrogen, which we considered desirable. The mixture passed over the hot platinum spiral and then through a trap surrounded by salt and ice to condense the considerable amount of unreacted iodine which was to be expected from the known equilibrium. The hydrogen iodide containing some iodine was finally condensed in a trap surrounded by liquid air, the hydrogen being allowed to escape. After a rough distillation had removed most of the iodine, the material was distilled into a bulb containing mercury which had been distilled onto the walls. This was very effectivein eliminating all trace of color, leaving an exceptionally clear liquid. The hydrogen iodide, which could at most have contained only a trace of water, was then distilled into a bulb containing a sufficiently large amount of phosphorus pentoxide to bring it into intimate contact with all of the liquid. The drying continued for about a week. It was kept cold with the assistance of a carbon dioxide and ether bath. This solidified the hydrogen iodide which was, however, frequently melted and kept melted over considerable periods. The material was then distilled several times, the end fractions being discarded. All of the above operations were carried out in a vacuum-tight system which was evacuated by means of a mercury diffusion pump.

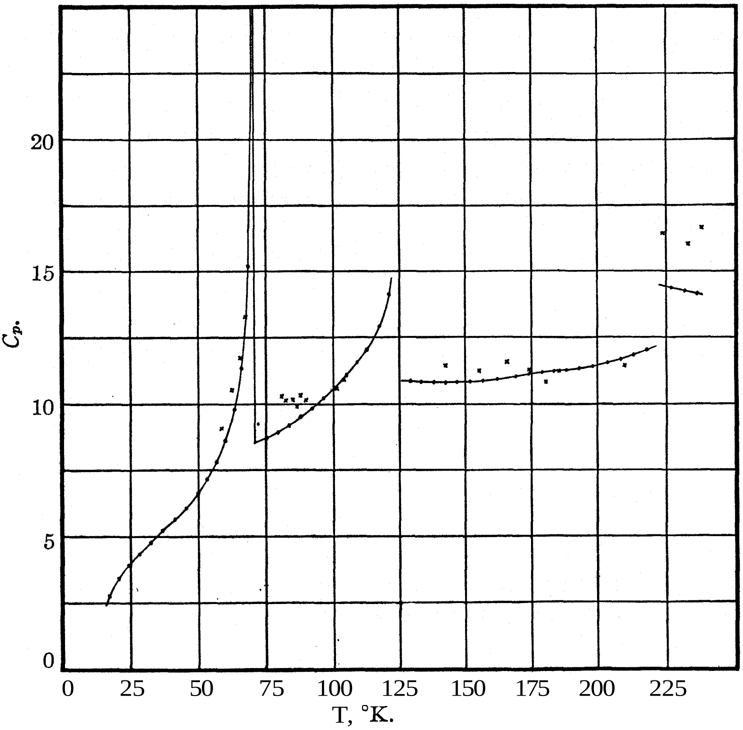
Heat Capacity Measurements.—The calorimetric measurements were all made with gold calorimeter II. The calorimeter and experimental method have been described in our previous paper.[1a] 1.9662 moles of hydrogen iodide were used for the measurements. The data are given in Table I.

The data are shown graphically in Fig. 1, which also includes the data of Eucken and Karwat,[2] who investigated this substance from 58°K. to its boiling point. Most of our data are accurate to two- or three-tenths of one per cent. Some points near 175°K. are probably off by about five-tenths of one per cent. due to small distillation heat effects. The measurement at 17.11°K. may be in error by one per cent.



×, Eucken and Karwat; ●, Giauque and Wiebe.

Fig. 1.—Heat capacity in calories per mole of hydrogen iodide.

The Transitions of Hydrogen Iodide.—Hydrogen iodide has two gradual transitions similar to those found for hydrogen bromide. In our previous discussion of the transitions of hydrogen bromide, we mentioned that lack of equilibrium was a factor, although we believed that the transitions would be gradual even with complete equilibrium. We have

---

[2] Eucken and Karwat, Z. *physik. Chem.*, 112, 467 (1924).

learned nothing from hydrogen iodide to change this opinion but some measurements on the transition occurring near 125°K. supply interesting information concerning the difficulty in obtaining true equilibrium and also show that a considerable amount of energy is absorbed within a very small temperature range if not at a definite temperature. Starting at a temperature of 122.99°K., 55.8 cal. per mole of substance was added over a period of ten minutes. At two minutes after energy input ceased, the temperature was 125.73°K., and this decreased at a gradually diminishing rate to 125.64°K. in seventy minutes, at which time the rate of decrease was 0.0004" per minute. The current was again passed through the heater adding 56.6 cal. per mole over a period of ten minutes. At two minutes after energy input ceased, the temperature was 125.88°K. and decreased to 125.64°K. in twenty minutes, at which time the rate of decrease was 0.004" per minute or ten times the previous rate at this temperature. At fifty minutes it had decreased to 125.60" and the rate of decrease was 0.0008" per minute. It is evident that as the transition approaches completion, equilibrium is obtained more readily. The results suggest the following possibility: the transition starts as a changing thermal equilibrium between energy states of the hydrogen iodide molecule, both in the same crystal lattice, but when a sufficient concentration of the higher energy state has been reached, the system becomes unstable and changes to a new crystalline form. This question could be investigated by X-ray measurements of crystal structure, although care might be necessary in cooling the hydrogen iodide slowly through the transition range if our conditions were to be duplicated. Simon and Simson[3] have found by X-ray analysis that the somewhat similar transition of ammonium chloride is not accompanied by a change in crystalline form and they conclude that it represents an equilibrium between molecular energy states.

It seems probable that many substances will have a change of phase induced by an increasing concentration of molecules with some degree of freedom excited in addition to the ordinary vibration.

The heat capacity measurements in the transition ranges were not used in obtaining the entropy, for which purpose separate determinations of total heat input over the whole range were obtained. The values are given in Table II.

TABLE II

HEAT ABSORBED IN TRANSITION REGIONS OF HYDROGEN IODIDE

Temp. interval, °K.	60.90–72.23	62.09–75.42	113.75–129.63	113.26–129.11
Heat absorbed, cal./mole	150.8	167.4	394.6	393.8

Heat of Fusion.—Two determinations of the heat of fusion gave 687.1 and 685.5 cal. per mole, respectively. The average is 686.3 ± 0.8

732, 688 (weighted mean, 726)	Eucken and Karwat[2] (1924)
687.1, 685.5 (mean, 686.3 ± 0.8)	Giauque and Wiebe (1929)

Melting- and Boiling-Point Temperatures of Hydrogen Iodide.—The melting point was observed with one-fourth, one-half and two-thirds of the material melted, respectively. The observations covered a period of six hours. The maximum deviation was 0.006" on the thermocouple and 0.004" on the resistance thermometer. The average deviation was 0.003" on the thermocouple and 0.002" on the resistance thermometer. The melting-point temperature was found to be 222.31 ± 0.05°K.

The boiling point was found to be 237.75 ± 0.05°K. This was obtained from measurements of pressure and temperature made in connection with the heat of vaporization determinations. The values obtained for the melting- and boiling-point temperatures by various observers are summarized in Table IV.

TABLE IV

MELTING- AND BOILING-POINT TEMPERATURES OF HYDROGEN IODIDE

Measurement of Amount of Hydrogen Iodide.—The amount of hydrogen iodide was measured by absorption in 30% sodium hydroxide after passing through a very small mercury trap, as was described for hydrogen chloride."' However, in this case we met a difficulty which was not encountered in the measurements on hydrogen chloride or hydrogen bromide. It was noticed that very small bubbles of gas rose slowly through the

sodium hydroxide to the surface and on testing the gas in the absorption bulb it proved to be hydrogen. The dissolved mercury was in the form of the very stable iodide complex which could not be precipitated by the addition of sulfide ion. Consequently the analysis was carried out by means of a zinc–copper couple. The effectiveness of this method was tested by duplicating the solutions except that known amounts of mercuric iodide complex were present. It was found that the method (in the rather rough manner in which we used it and for the amounts concerned) gave results 10% too low and the analyses were calculated on this basis. This was sufficiently accurate for our purpose since the total correction for hydrogen lost proved to be almost negligible. However, the evolution of hydrogen gave rise to another more serious difficulty, since during the initial weighing of the absorption bulb, the gas space was filled with air; while during the final weighing, it was nearly all hydrogen. The relative amounts of air and hydrogen in the gas space were determined and the correction was made. The total correction due to these two effects was about 0.2 of 1%.

Heat of Vaporization.—The heat of vaporization was measured by Method II, as described for the hydrogen chloride measurements.[10] The data are given in Table V.

[14] Cederberg, *Ber. chem. affin.*, Berlin, 1916.

logarithm of the absolute temperature. The method used for the two gradual transitions was the same as that previously described for hydrogen bromide. All energy above a value of 16 cal. per degree per mole was divided by the temperature selected as a center of gravity on a $(C_p - 16)$ against T plot. The temperatures selected are not to be confused with the transition temperature of ordinary "sharp transitions," nor are the heats to be taken as heats of transition, especially since the value of 16 cal. per degree subtracted over the range was purely arbitrary.

The extrapolation below 15.3°K. was carried out by means of a Debye curve with an $h\nu/k = 73$. The similarity of the heat capacity curve to those of hydrogen chloride and hydrogen bromide gives us considerable confidence in the extrapolation of the somewhat greater amount of entropy due to the lower characteristic frequency of this substance. A summary of the entropy calculation is given in Table VII.

TABLE VII

CALCULATION OF THE MOLAL ENTROPY OF HYDROGEN IODIDE GAS

Fusion, 686.3/222.31	3.087	
222.31-237.75°K., graphical	0.958	
Vaporization, 47241237.75	19.87	
Entropy at the boiling point.	47.8	± 0.1 E. U.

There are practically no data for use in making a correction for gas imperfection at the boiling point. We will, however, assume a very uncertain additive correction of 0.1 E. U., as was done in the case of hydrogen chloride and hydrogen bromide.

The Entropy of Hydrogen Iodide from Spectroscopic Data.—The only measurements on the rotational states of hydrogen iodide are those of Czerny,[15] who obtained only four lines of the pure rotation band. These are sufficient to determine the moment of inertia with some accuracy but are hardly enough to justify a calculation of the entropy from the individual energy states, as was possible with hydrogen chloride and hydrogen bromide, although Czerny gives a formula which could be used for extrapolation. However, for the case of a polar diamagnetic gas, we may use the approximate formula for rotational entropy obtained by Sackur and Tetrode, namely, $S_R = R + R$ In $8\pi^2IT/h^2$, where I represents the moment of inertia of the molecule and h is Planck's constant. This value added to the translational entropy obtained from the Sackur equation should give a theoretical value for the entropy which is sufficiently accurate for comparison with our calorimetric value.

---

[15] Czerny, (a) Z. *Physik*, 44, 235 (1927); (b)45, 476 (1927).

The value obtained for the entropy of ideal hydrogen iodide gas at the temperature of the boiling point and a pressure of one atmosphere is **47.8** or **47.5** cal. per degree per mole, corresponding, respectively, to the use of the Tetrode or Lewis constant for the Sackur equation. The results are given in Table VIII, which also summarizes the results for the other halogen acids.

TABLE VIII

COMPARISON OF SPECTROSCOPIC AND THIRD-LAW VALUES OF THE ENTROPY OF THE HYDROGEN HALIDES

		Spectroscopic		Third law	
	T, ° K.	Tetrode const.	Lewis const.	Actual gas	Corr. to ideal state
Hydrogen chloride	188.07	41.47	41.15	41.2 ± 0.1	41.3
	298.1	44.64	44.32	....	44.5
Hydrogen bromide	206.38	44.92	44.60	44.9 ± 0.1	45.0
	298.1	47.48	47.16	....	47.6
Hydrogen iodide	237.75	47.8	47.5	47.8 ± 0.1	47.9
	298.1	49.4	49.1	....	49.5

Table VIII contains two minor corrections to our previously published spectroscopic values. The value for hydrogen chloride at its boiling point has been increased by **0.03** E. U. The value for hydrogen bromide at 298.1°K. has been lowered by **0.05** E. U. Both these corrections are due to the detection of arithmetical errors in our previous calculations. The theoretical calculations should be accurate to **0.01** E. U.

In obtaining the third law value given for hydrogen iodide at **298.1**°K. (25°), it was assumed that $C_p = 7/2R$ between **237.75** and 298.1°K. This assumption is justified by the nearly complete absence of vibrational energy, as may be shown from the molecular vibrational frequency as estimated by Czerny.[15]

According to Redlich[16] the value of the chemical constant of hydrogen iodide obtained by Eucken, Karwat and Fried[17] leads to a value of **50.69** cal. per degree per mole for this substance. Eucken, Karwat and Fried had placed the error at ±0.7 E. U.

Our measurements support the Tetrode constant for the Sackur equation and also indicate that the third law of thermodynamics is, in fact, an exact law.

We express our thanks to Dr. H. L. Johnston for assistance in making the measurements on hydrogen iodide and to Prof. R. T. Birge for discussions of the spectroscopic data.

Summary

The heat capacity of solid and of liquid hydrogen iodide has been measured from **15.3**°K. to its boiling point.

---

[16] Redlich, "Thermodynamik und die freie Energie chemischer Substanzen," von Lewis und Randall, iibersetzt von Redlich, Julius Springer, Wien, 1927.

[17] Eucken, Karwat and Fried, Z. *Physik,* 29, **1 (1924).**

The melting point was found to be 222.31 ± 0.05°K.; the boiling point, 237.75 ± 0.05°K.

The heat of fusion is 686.3 ± 0.8 cal. per mole. The heat of vaporization at the boiling point is 4724 ± 5 cal. per mole.

Two regions of high heat capacity were found in the solid state which appear to be internal transitions of the molecule; however, one of these, in particular, after progressing over a considerable temperature range, seems to develop into the ordinary or sharp transition type.

The entropy has been calculated from the experimental data and the third law of thermodynamics.

The entropy has also been calculated from spectroscopic data. The two methods lead to the same value within the limit of our experimental error, thus supporting the validity of each method.

APPLICATIONS OF CERIC SULFATE IN VOLUMETRIC ANALYSIS. VI. OXIDATION OF HYDROGEN PEROXIDE BY CERIC SULFATE. INDIRECT DETERMINATION OF LEAD

BY N. HOWELL FURMAN AND JOHN H. WALLACE, JR.

RECEIVED JANUARY 21, 1929 PUBLISHED MAY 6, 1929

Introduction

Some of the uses of ceric sulfate in volumetric analysis have been described in other papers of this series[1] and in those of other investigators.[2] Von Knorre[3] made use of the reaction

$$2Ce(SO_4)_2 + H_2O_2 = Ce_2(SO_4)_3 + H_2SO_4 + O_2$$

in the determination of cerium. He added an excess of hydrogen peroxide (freshly standardized) to the ceric solution and determined the excess of the former with 0.1 N permanganate solution. Atanasiu and Stefanescu have published data for a single potentiometric titration of hydrogen peroxide with ceric sulfate in sulfuric acid solution. Our observations have been made with various acids and with a variety of different concentrations of acid.

Experimental

The apparatus was similar to that described in previous papers of this series; a bright platinum wire and a N calomel electrode made up the electrode system.

[3] V. Knorre, *Z. angew. Chem.*, 10, 685, 717 (1897); *Ber.*, 33, 1924 (1900).

The ceric sulfate solutions were prepared in two ways: (1) by dissolving commercial rare earth oxides in enough dilute sulfuric acid to make the resulting solution about 2–3 N in sulfuric acid when 0.1 N in oxidizing power; (2) by heating purified oxide (basic nitrate method) with an excess of sulfuric acid at approximately 200°. An appreciable portion of the oxide was unattacked. The resulting solution was approximately 0.1 N in oxidizing power and from 1.0-1.5 N in sulfuric acid. Both solutions were stable.

The solutions were standardized potentiometrically against pure sodium oxalate in hydrochloric acid solution of the concentration suggested by Willard and Young.[4]

Hydrogen peroxide solutions approximately 0.1 *N* were prepared by diluting pure 30% hydrogen peroxide (Merck's "Superoxol"). The solutions were kept in a smooth bottle of amber-colored glass, and were found to be stable for at least four hours. The normality of the hydrogen peroxide was determined by titration with potassium permanganate solution which had been standardized against sodium oxalate. All of the end-points were determined potentiometrically.

Titration of Hydrogen Peroxide with Ceric Sulfate.—Ten or 25 cc. of hydrogen peroxide were pipetted out and were generally diluted to 100 cc. after addition of acid. The nature and concentration of acid were found to be important factors; variations in initial volume or in rate of addition of ceric sulfate were minor factors. The titrations were made at room temperature. The results are summarized in the following table.

TABLE I

TITRATION OF APPROXIMATELY 0.1 N HYDROGEN PEROXIDE WITH CERIC SULFATE

A. In Hydrochloric Acid Solution

Determinations 1–6, 9 and 14–17 were made with 0.0991 N ceric sulfate which was prepared from commercial rare earth oxides. In the other instances the ceric solution, prepared from the purified oxide, was 0.0760 N.

---

[4] Willard and Young, THIS JOURNAL, 50, 1327 (1928).

The character of the titration graphs is indicated in Pig. 1. The downward trend just before the end-point that is shown in Curve 2 is usually a characteristic of titrations in hydrochloric acid solution.

When the initial concentration of sulfuric acid is below 1 N, the rate of reaction is very small, and the break in potential at the end-point is usually below 0.1 volt. The reaction was very sluggish at all of the concentrations of sulfuric acid that were used. From three to five minutes are required for the potential to become steady near the end-point. The voltage rise at the end varies from 0.15 to 0.25 volt per 0.05 cc. of ceric solution as the concentration of acid is increased.

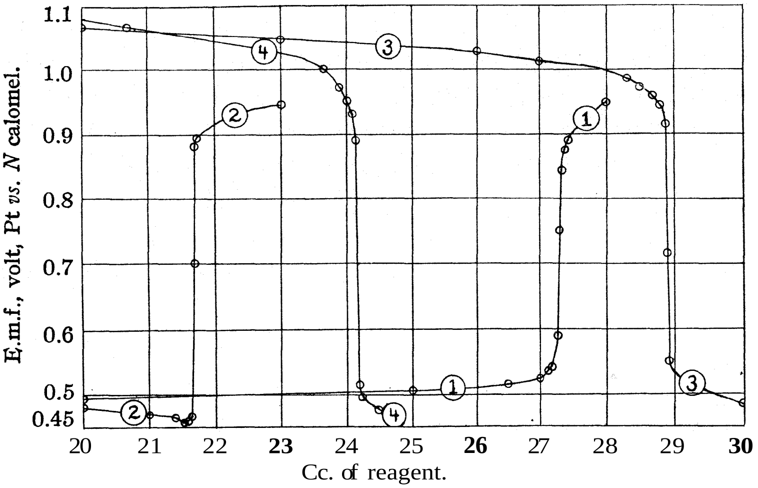

Fig. 1.—Curve 1. Titration of hydrogen peroxide in sulfuric acid solution (3.6 *N*). Curve 2. Titration of hydrogen peroxide in 1.2 *N* HCl solution. In 1 and 2 the ceric sulfate was 0.1051 *N*. Curve 3. Titration of 25 cc. (0.1051 N) ceric sulfate with peroxide. Initial acid concentration, 2.5 *N* (H_2SO_4). Curve 4. Titration of 25 cc. of 0.0991 N ceric sulfate with peroxide. Original acid concentration, 0.7 N.

The reaction proceeds very rapidly at all of the concentrations of hydrochloric acid that were tested. The rise in e.m.f. at the end-point is very sharp, and is of the order of 0.25–0.32 volt per 0.05 cc. of 0.1 N ceric solution. Acetic acid solutions give an equally rapid reaction rate and about the same rise in voltage at the end-point. When nitric acid is present the rise in voltage per drop of ceric solution is less, being of the order of 0.2–0.25 volt. The rate of reaction is somewhat slower than with hydrochloric acid.

The visual end-point was noted in a number of instances. In general it is 0.05 cc. beyond the potentiometric end-point. The presence of iron (about 1 mg. per 25 cc.) in the ceric solution obscures the end-point in solutions that contain high concentrations of hydrochloric acid.

The Reverse Titration.—The procedure was similar to that which has been described. The nature of the results is indicated in the following table.

TABLE II

TITRATION OF 0.0991 *N* CERIC SULFATE WITH 0.1027 *N* HYDROGEN PEROXIDE

Acid added		None	None	H_2SO_4	HNO_3	HNO_3	H_2SO_4
Initial concn., N		....	....	3	1.5	1.5	5
Ceric sulfate, cc.		25	25	25	25	25	10
H_2O_2, cc.	Calcd.	24.12	24.12	24.12	24.12	24.12	9.64
	Found	24.09	24.11	24.09	24.12	24.12	9.65
Error, cc.		−0.03	−0.01	−0.03	±0.00	±0.00	+0.01

When no acid was added the break in potential was about 0.4 volt per drop of hydrogen peroxide solution, and in the other instances it was about 0.2 volt per 0.05 cc. at the end-point. The nature of the graph is shown by Curves 3 and 4, Fig. 1.

Indirect Determination of Lead Peroxide

A determination of lead peroxide has been based upon the fact that an excess of hydrogen peroxide reacts with lead peroxide in nitric acid solution. The excess of hydrogen peroxide is then determined with permanganate.[5]

Our results showed that ceric sulfate could be employed to determine the excess of hydrogen peroxide.

Weighed samples of minium, ranging between 0.18 and 0.25 g., were transferred to a mixture of 25 cc. of approximately 0.1 N hydrogen peroxide (standardized against ceric sulfate) and 25 cc. of concentrated nitric acid of sp. gr. 1.42 (free from dissolved oxides of nitrogen). Solution of the lead oxide was complete after a few minutes' stirring. The excess of hydrogen peroxide was determined. The weight of PbO_2 was calculated from the amount of hydrogen peroxide that had been decomposed. The values which one of us (F) had obtained by Bunsen's iodometric method were unknown to the other (W) until after the determinations with ceric sulfate had been completed.

No. 1	Found, using $Ce(SO_4)_2$	33.71, 33.61, 33.95% of PbO_2
	Found, iodometrically	33.70, 33.89, 33.81, 33.65% of PbO_2
No. 2	Found, using $Ce(SO_4)_2$	25.68, 25.58, 25.61, 25.65, 25.81% of PbO_2
	Found, iodometrically	25.80, 25.73, 25.65% of PbO_2

After the end of a titration there was usually a slight precipitate of lead sulfate which did not interfere in any way with the convenience of the method.

The hydrogen peroxide–ceric sulfate procedure was not reliable in the determination of manganese dioxide in pyrolusite. The errors were in

---

[5] Schlossberg, *Z. anal. Chem.*, **41**, **743** (1902).

the direction that would be expected on the basis of catalytic decomposition of hydrogen peroxide during the slow process of dissolving the mineral.

Summary

The direct potentiometric titration of hydrogen peroxide with ceric sulfate has been shown to be accurate in solutions moderately acidified with hydrochloric, sulfuric, nitric or acetic acid. The reverse titration is also accurate in sulfuric and nitric acid solutions.

The hydrogen peroxide–ceric sulfate reaction may be applied in the indirect determination of lead peroxide.

REACTIONS IN LIQUID HYDROGEN SULFIDE. VI. REACTIONS WITH ORGANIC COMPOUNDS

BY R. W. BORGESON[1] AND J. A. WILKINSON

RECEIVED FEBRUARY 8, 1929 PUBLISHED MAY 6, 1929

Hydrogen sulfide has been found by different workers to be a good solvent for organic substances[2] and for this reason it was thought important to study the reactions between liquid hydrogen sulfide and members of the different types of organic compounds.

Experimental

Several examples of each of the types of organic compounds were placed in glass tubes of 50-cc. capacity and, after cooling to $-77°$ with a mixture of ether and solid carbon dioxide, liquid hydrogen sulfide was added. The tubes were then sealed and allowed to come to room temperature. After standing for several weeks they were again cooled, opened, the excess of hydrogen sulfide was allowed to evaporate and the residues were examined for evidence of reaction.

The following types of organic compounds were studied: saturated hydrocarbons, unsaturated hydrocarbons, alcohols, phenols, ethers, aldehydes, ketones, alkyl and aryl halides, acids, acid anhydrides, esters, sugars, nitro compounds, Grignard reagent, amides, amines and acyl halides.

Hydrocarbons.—Benzene, toluene, naphthalene, anthracene, gasoline, kerosene and vaseline are all soluble and non-reactive in liquid hydrogen sulfide. The unsatu-

[2] McIntosh and Steele, *Proc. Roy. Soc. London,* 73, *450* (1904); Archibald and McIntosh, *ibid.,* **73,** 454 (1904); Antony and Magri, *Gazz. chim. ital.,* **75,** 206 (1905); Steele, McIntosh and Archibald, *Phil. Trans. Roy. Soc.,* **205A,** 99 (1906); Magri, *Atti. accad. Lincei, (V)16,* 171 (1907); Quam, THIS JOURNAL, **47,** 103 (1925); Quam and Wilkinson, ibid., **47,** 989 (1925); Kalston and Wilkinson, *ibid* , **50,** 258 (1928).

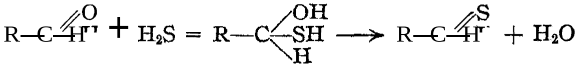
rated hydrocarbons amylene and trimethylethylene are miscible in liquid hydrogen sulfide but do not react with it unless the temperature is raised to room temperature and even then the reaction is a slow one. If after standing at room temperature for several weeks the tubes are again cooled to −77°, a white solid separates out which has a strong mercaptan odor. This solid decomposes and disappears on bringing it to room temperature. Since neither amylene nor trimethylethylene is a solid at −77, the formation of a solid is evidence that a reaction has taken place. Probably this is an addition reaction at the double bond, but no analytical data could be obtained because of the instability of the compounds.

Alcohols.—Methyl, ethyl, *iso*butyl, and *iso*-amyl alcohols and glycerin are miscible in liquid hydrogen sulfide at −77°, while allyl and furyl alcohols are miscible at room temperature. After standing for two months, the first three of these gave a precipitate of sulfur on cooling, showing that some decomposition had taken place. The allyl alcohol gave a small amount of a viscid liquid that had a strong mercaptan odor, which would indicate that an addition product had formed at the double bond.

Phenols.—Phenol, cresol, and m-aminophenol are soluble in liquid hydrogen sulfide, the latter but slightly, however; none of them gave any indication of reaction.

Ethers.—Ethyl ether, the only one tried, is miscible but non-reactive in liquid hydrogen sulfide.

Aldehydes.—Acetaldehyde, butylaldehyde, acrylaldehyde, benzaldehyde, m-nitrobenzaldehyde, trinitrobenzaldehyde, p-tolualdehyde, cinnamaldehyde and furfuraldehyde all dissolve in liquid hydrogen sulfide and react with it. In every case after standing for several days a second liquid layer formed and if the tube was again cooled white crystals of the compound $H_2S \cdot xH_2O$ were formed. This reaction took place with every aldehyde studied and was accompanied by the development of the odor of a mercaptan. With benzaldehyde, p-tolualdehyde, cinnamaldehyde and furfuraldehyde the reaction was carried to such an extent that after driving off the excess of hydrogen sulfide and bringing to room temperature a gelatinous mass remained. In the case of furfuraldehyde this was purified by recrystallizing from ethyl acetate and found to be furfural thioaldehyde, C_4H_3OCSH.[3] The reaction must consist of the addition of hydrogen sulfide to the aldehyde and then dehydration of the resulting compound.



$$\mathrm{R{-}C{\overset{\displaystyle O}{\diagup\!\!\diagup}}H} + H_2S = \mathrm{R{-}C}\begin{matrix}\diagup OH\\ -SH\\ \diagdown H\end{matrix} \longrightarrow \mathrm{R{-}C{\overset{\displaystyle S}{\diagup\!\!\diagup}}H} + H_2O$$

Ketones.—Acetone, diethyl ketone, acetyl ketone, acetophenone and benzophenone were all soluble in liquid hydrogen sulfide and, while the last two showed no evidence of reaction, the first three developed a small amount of pink color and a mercaptan odor.

Alkyl and **Aryl** Halides.—Ethyl chloride, bromide and iodide, methyl iodide, *iso*-butyl bromide, n-propyl iodide, *n*-butyl iodide, benzyl chloride, benzyl iodide, allyl bromide and iodide were all soluble in liquid hydrogen sulfide and, with the exception of the allyl halides, all were non-reactive. These latter reacted because of the presence of the double bond.

Acids.—A number of organic acids such as acetic, propionic, benzoic and cinnamic were found to be soluble but non-reactive except the last, which contains a double bond.

Acid Anhydrides.—Acetic, benzoic, succinic and malic acid anhydrides were soluble in liquid hydrogen sulfide, the latter being but slightly so. There was no evidence of reaction except a slight decomposition of the hydrogen sulfide giving free sulfur.

Esters.—Ralston and Wilkinson[4] have shown that esters are soluble in liquid hydrogen sulfide and are thiohydrolyzed just as they are hydrolyzed in water.

---

[3] Meints and Wilkinson, THIS JOURNAL, 51, **803** (1929).

[4] Ralston and Wilkinson, *ibid.*, 50, 2160 (1928).

Salts.—Most metal salts of organic acids are insoluble in liquid hydrogen sulfide.

Sugars.—Sucrose, glucose, maltose, lactose, mannose, arabinose and raffinose are insoluble in liquid hydrogen sulfide and show no evidence of reacting with it.

Grignard Reagents.—Ethylmagnesium bromide, phenylmagnesium bromide and benzylmagnesium chloride, either solid or dissolved in ether, all react vigorously with liquid hydrogen sulfide giving the corresponding hydrocarbon and a white solid suspended in the liquid. This solid, on evaporating the liquid slowly, gives off hydrogen sulfide and takes up water from the air readily. A study of the products of this reaction is being made.

Amides.—Acetamide, n-butyramide, acetanilide, benzanilide and phthalimide are all soluble but give no evidence of reaction. Picramide reacts slowly, liberating sulfur due to the presence of the nitro group.

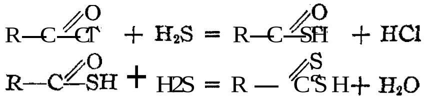
Amines.—Diethylamine, *sec.*-butylamine, *iso*butylamine and di-n-butylamine all react with liquid hydrogen sulfide and form either viscid liquids or crystalline solids which decompose readily, giving off hydrogen sulfide.

Dimethylaniline, diethylaniline, diphenylamine, a-naphthylamine, β-naphthylamine and benzidine are soluble but do not react with liquid hydrogen sulfide. Aniline and benzylaniline react similarly to the alkylamines, forming white crystalline compounds which decompose rapidly, giving off hydrogen sulfide and forming a red liquid which slowly decomposes. Phenylhydrazine reacts with liquid hydrogen sulfide to form yellow-white crystals of the compound $C_6H_5NHNH_2{\cdot}H_2S$. After evaporating off the hydrogen sulfide a red liquid is obtained which slowly gives off ammonia, deposits sulfur and leaves liquid aniline according to the equation

$$C_6H_5NHNH_2 + H_2S = C_6H_5NHNH_2{\cdot}H_2S = C_6H_5NH_2 + NH_3 + S$$

The red liquid is an intermediate product between the addition compound and aniline. This breaks down very slowly on standing and more rapidly if shaken vigorously. A similar red solution is obtained when phenylhydrazine is saturated with hydrogen sulfide gas. The odor of ammonia is not then perceptible until the mixture has stood for three or four days.

Acyl Halides.—All of the acyl halides studied dissolve in liquid hydrogen sulfide and react with it more or less readily. This corresponds to the reaction with water to form the acid. In addition a second reaction takes place whereby the oxygen of the halide is replaced by sulfur, forming the dithio-acid.



$$R{-}C\overset{/\!\!/O}{-}Cl + H_2S = R{-}C\overset{/\!\!/O}{-}SH + HCl$$

$$R{-}C\overset{/\!\!/O}{-}SH + H_2S = R - C\overset{/\!\!/S}{-}SH + H_2O$$

Benzyl chloride and bromide, α-bromopropionyl bromide, phthalic chloride, succinyl chloride, benzenesulfonyl chloride and phenylacetyl chloride all reacted and gave varying amounts of yellow to red liquids containing the dithio acids.

Acetyl chloride and acetyl bromide both reacted readily with liquid hydrogen sulfide, forming a deep orange-colored liquid. When the tubes were opened and the hydrogen sulfide pressure thus reduced, fine white crystals were formed mingled with the red liquid. These were purified by recrystallizing from ether.

Anal. Calcd. for $(CH_3CS)_2S$: S, 64.01; C, 31.97; H, 4.02. Found: S, 63.98. 63.84; C, 32.27, 32.6; H, 4.14, 4.12.

This would show that the compound is the anhydride of dithioacetic acid. This compound has not been prepared before. The following are the properties observed: melting point, 225°; readily soluble in acetone, benzene, carbon disulfide, chloroform, carbon tetrachloride and ethyl acetate. It is fairly soluble in ether, petroleum ether and hot alcohol. Cold solutions of aniline and the amines dissolve it. It is insoluble in water, dilute acids or alkalies and inorganic solvents in general. Molecular weight determinations by the freezing point lowering method, when dissolved in benzene, gave values of 269, 270 and 272, which show that it is somewhat associated in benzene solution since the simple formula for $(CH_3CS)_2S$ has a molecular weight of but 150.

Conclusions

1. The solubilities of the different types of organic compounds in liquid hydrogen sulfide have been observed.
2. The presence of a double bond in the organic compound is usually shown by the development of the odor of a mercaptan.
3. The aldehydes, amines and acyl halides are the only types that show much evidence of reacting with the liquid hydrogen sulfide.
4. The amines give unstable addition products with hydrogen sulfide.
5. The aldehydes tend to substitute a sulfur atom for the sulfur of the aldehyde group to form a thio-aldehyde.
6. The acyl halides tend to substitute an SH group for the halide and an S for the oxygen and form dithio acids to a small amount. Acetyl chloride and bromide form the dithioacetic acid, which then loses hydrogen sulfide and forms the thioanhydride.

NOTES

A Sensitive Test for Magnesium.[1,2]—K. Suitsu and K. Okuma[3] state that the azo dye, *o,p*-dihydroxy-azo-*p*-nitrobenzene gives a very sensitive test for the magnesium ion. This reagent has been used in the courses of qualitative analysis at this University for two years with excellent results. The authors claim to be able to detect $^1/_{500}$ mg. of magnesium by means of this test.

The dye is readily prepared by diazotizing *p*-nitraniline and coupling it with the theoretical quantity of resorcinol dissolved in dilute sodium hydroxide solution. The solution is acidified and the precipitated dye filtered off. The product may be purified by recrystallization from methyl alcohol as a dark red powder, m. p., 199–200°. A convenient concentration for ordinary use is a 0.5% solution of the dye in 1% sodium hydroxide. Some deterioration of the reagent occurs in solution after a year's standing.

The solution to be tested for magnesium is made slightly acid with dilute hydrochloric acid and one drop of the reagent added. On making

---

[1] Hahn, Ber., 57, 1394 (1924); 60, 975 (1927), describes a somewhat similar test for magnesium using 1,2,5,8-tetrahydroxy-anthraquinone.

[2] Since this note has been accepted for publication, the Eastman Kodak Company has informed me that they intend placing the reagent on the market.

[3] Suitsu and Okuma, *J. Soc. Chem. Ind. Japan*, 29, 132–138 (1926); *C. A.*, 20, 3000 (1926).

the solution alkaline with dilute sodium hydroxide, the characteristic sky-blue precipitate of the magnesium lake appears. If the amount of magnesium is very small, a drop of the stock reagent which has been diluted 4 to 5 times with water gives better results. In this case also the lake is rather slow in forming and shaking for two to three minutes is necessary to coagulate the precipitate.

Professor D. P. Smith of this University found that an excess of ammonium salts destroys the sensitivity of the reagent; hence in the regular course of analysis, the ammonium salts are "smoked off" in a casserole before applying the test.

Nickel and cobalt also give somewhat similar blue lakes which may lead to confusion. After the removal of the heavy metals by precipitation as sulfides, however, the test is absolutely characteristic and the confusion attending the use of the classical magnesium ammonium phosphate precipitate as a test, especially in elementary courses of analysis, is obviated.

The Preparation of **Selenic** Acid and its Salts.—A number of methods for the preparation of selenic acid have been reported in the literature.[1] As a rule the salts of this acid have been prepared by the oxidation of the selenites.

Meyer and Heider[1a] treated selenium dioxide with 30% hydrogen peroxide, warming the mixture on the water-bath and upon analysis found that 48% of the oxide had been oxidized to selenic acid. In another experiment using a larger amount of hydrogen peroxide an analysis showed an oxidation of 70%.

The experiments of Meyer and Heider suggested that it might be worth while to try to find the best conditions for preparing selenic acid, and possibly the selenates, by the hydrogen peroxide method.

A number of experiments were carried out, treating weighed amounts of selenium dioxide with varying amounts of hydrogen peroxide. The time and the temperature of the treatment were varied. Oxidation values all the way from 20 to 70% were obtained. Small amounts of the oxide

---

[1] The methods for the preparation of selenic acid and its salts are found in the following references: (a) Meyer and Heider, *Ber.*, 48, 1154 (1915); (b) Mitscherlich, *Pogg. Ann.*, 9, 623 (1827); (c) Wohlwill, *Ann.*, 114, 169 (1860); (d) *Wien Akad. Ber.*, 39, 299 (1860); (e) Thomsen, *Ber.*, 2, 598 (1869); (f) Diemer and Lenher, *J. Phys. Chem.*, 13, 505 (1909); (g) Mdller, *Ber.*, 36, 4262 (1903); (h) *Chem.-Ztg.*, 31, 630 (1907); (i) Meyer and Moldenhauer, *Z. anorg. Chem.*, 116, 193 (1921); (j) Worsley and Baker, *J. Chem. were then refluxed with 30% hydrogen peroxide, with the result that the oxidation values were much higher. These results were reproducible as is shown in the following table.

TABLE I

RESULTS OF EXPERIMENTS

Selenium dioxide, g.	0.2019	0.2000	0.2029
Hydrogen peroxide, 30%, cc.	10	10	10
Time of refluxing, hours	2	2	2
Oxidation, %	89.5	90.7	91.9

A quantity of selenic acid was prepared, adhering to the conditions shown in Table I, The small amount of selenious acid was reduced to selenium, filtered off and the filtrate concentrated, following the procedure of Cameron and Macallan.[2] In this manner selenic acid of high purity with a concentration of 84% was readily prepared.

Since hydrogen peroxide proved so effective in oxidizing selenious acid, it seemed desirable to try its use for the oxidation of selenites to selenates. Copper selenite was prepared by treating copper carbonate with selenious acid. The green, insoluble copper selenite remained. This salt was covered with 30% hydrogen peroxide and refluxed for three hours, during which time it was oxidized to the blue, soluble selenate. A small amount of the insoluble selenite was filtered off, leaving a clear blue filtrate from which copper selenate crystals formed, identical in appearance to those of copper sulfate. Using the same procedure selenates of nickel, cobalt, aluminum and magnesium were prepared. All of these salts were obtained in a well defined, crystalline condition, similar to the corresponding sulfates.

Use of Cresol Red in Acid Solutions.—As has been pointed out by Clark[1] and Cohen,[2] the sulfonephthalein indicator dyes undergo two distinct color changes at different points on the PH scale. However, of this series only thymol blue and meta cresol purple have been applied as indicators in both acid and alkaline solutions and the fact that the sulfonic acid dissociation of cresol red is sufficiently repressed so that it can be used in acid solutions has not been emphasized. This indicator is really

quite valuable in certain cases. The color change is from red at PH 0.2 to yellow at PH 1.8, the half transformation point occurring at a hydrogen-ion concentration of approximately 1.0×10^{-1}, or PH 1.0. The virage resembles those of thymol blue and meta cresol purple over their acid ranges.

Cresol red can be used to advantage in testing for free mineral acids in solutions of weak acids, such as citric or acetic, or hydrolyzable salts of an acidic nature, such as ferric chloride or sulfate. It can also be employed in adjusting solutions in qualitative analysis, so as to separate the sulfides of the second and third groups. Cresol red is superior to methyl violet in that it is quite stable in solution and also gives stable, reproducible colors.

The Rapid Concentration of Germanium and Gallium Contained in Zinc Oxide Carrying Them.—The method usually given for the extraction of germanium and gallium from zinc oxide carrying a small percentage of these elements, calls for solution in hydrochloric acid and the subjection of the whole solution to distillation, after oxidizing the arsenic with potassium chlorate or other suitable oxidizing agent. It has been found in the Laboratories of the University of New Hampshire that the two elements can be rapidly concentrated as follows.

The zinc oxide was dissolved in an excess of commercial hydrochloric. acid, allowed to stand for a short time and the precipitate of lead chloride removed by filtration. The hot solution, while being thoroughly stirred, was then rendered basic by the slow addition of some of the original zinc oxide. After continuing the stirring for some time to make certain of the precipitation of all the germanium and gallium, the precipitate carrying them was filtered off, dissolved in hydrochloric acid, distilled and treated in the usual manner to obtain the two elements.

In order to ascertain the completeness of their precipitation by the treatment with zinc oxide, large portions of the filtrates from several different runs were strongly acidified with hydrochloric acid, the arsenic was oxidized with potassium chlorate, a portion distilled off and hydrogen sulfide passed into the distillate. The absence of any germanium sulfide was considered evidence that all but negligible quantities at least of that element had been removed. The liquid remaining in the flask after distillation was examined by means of the spark spectrum for gallium after any traces of it had been concentrated by neutralizing with ammonum hydroxide and rendering basic with metallic zinc, etc. The violet lines characteristic of it were not visible.

By employing this preliminary concentration 100 lb. of zinc oxide could be put through the distillation process in four or five runs using a 12-liter Pyrex flask, whereas before this method was used it required 25 to 30 runs; also, the quantity of material from that process which had to be worked over for gallium was correspondingly decreased.

Determination of Ethylene by Absorption in a Solution of Silver Nitrate.—During the course of a study of the catalytic hydrogenation of acetylene[1] the author observed that a solution of silver nitrate is capable of absorbing ethylene. A preliminary test at that time tended to indicate that the reaction might be used for the quantitative determination of the latter gas.

A search of the literature revealed that reactions between ethylene and silver salts have been previously observed by Ross and Trumbull,[2] Gluud and Schneider[3] and Lommel and Engelhardt.[4] The feasibility of using a solution of a silver salt alone as an absorbing medium in the determination of ethylene has apparently never been investigated.

Reactions between ethylene and salts of a few other metals have also been observed. In this connection, attention may be directed to the suggestion[5] for the use of a solution of mercuric nitrate over mercury as a quantitative absorbing agent for this gas.

The apparatus used during a brief investigation of the usefulness of a solution of silver nitrate as an absorbent in the determination of ethylene has been described previously by the author.[6] In its use the absorbing solution is passed slowly over and around the gaseous sample and is removed continuously at the bottom. Such an apparatus is particularly advantageous in cases where, as appeared to be probable in this case, there is a tendency toward an equilibrium condition involving incomplete absorption.

The table below records the results of a comparison of the absorption of ethylene from a mixture consisting essentially of nitrogen and ethylene by solutions of silver nitrate of various concentrations. The volumes of

solutions and the time requirements shown, while not necessarily representing the exact minima in every case, do give indication of what may be expected in a satisfactory operation carried out as rapidly as a careful observation of the progress of the absorption appears to justify.

TABLE I

THE ABSORPTION OF ETHYLENE BY SOLUTIONS OF SILVER NITRATE

Concn. of soln., %	40	20	10	5

The absorption by the more concentrated solutions was more rapid. The use of concentrated solutions is also recommended as a consequence of the fact that the completion of absorption can be more readily judged when using them rather than the slower absorbing dilute solutions.

In an additional experiment a comparison was made between a solution of silver nitrate and other reagents commonly used in the quantitative absorption of ethylene. The value for the ethylene content of a mixture of this gas with nitrogen as indicated by absorption with fuming sulfuric acid agreed closely with that obtained on the same mixture when a 20% solution of silver nitrate was used. The fact that absorption by bromine gave a slightly different value was attributed to a change in the composition of the gaseous mixture during the time interval between tests.

There are certain advantages in the use of silver nitrate for this purpose. It is interesting to note, for instance, that, in accordance with the observation of Lommel and Engelhardt,[4] the ethylene may subsequently be removed from the solution by evacuation. Recovery of the absorbing solution is thus possible. Evaporation can readily be applied to restore it to the concentration desired for subsequent determinations. Whether heat alone would free the solution from ethylene as well as concentrate it remains to be investigated. A solution of silver nitrate has, moreover, a decided advantage over the commonly used absorbents, bromine and strong sulfuric acid, in that the chemical and physical properties of these latter make them anything but pleasant reagents to handle.

There are several points in connection with the reaction between ethylene and silver nitrate which seem to be worthy of further study. Of primary interest is the question of the composition and properties of the reaction product. The possibility of increasing the effectiveness of absorption by adding acids such as sulfuric or phosphoric to the solution of silver nitrate also merits investigation.* As a final consideration attention may be directed to the fact that acetylene may be determined by titration of the nitric acid released when this gas reacts with a solution of silver nitrate. The possibility of determining both acetylene and ethylene in a mixture of the two by the use of a single absorbing agent, a solution of silver nitrate, is at once apparent.

MENTHOL STUDIES. II. MENTHYL ESTERS OF THE 2-NITRO-4-CARBOXYPHENYLARSONIC AND PHENYLARSENIOUS ACIDS

BY K. LUCILLE McCLUSKEY

RECEIVED OCTOBER 3, 1928 PUBLISHED MAY 6, 1929

The first report[1] on the synthesis of aromatic terpene compounds to be used in chemotherapeutic studies in experimental tuberculosis included menthyl esters of the nitro- and aminocinnamic acids. Due to the great insolubility in water caused by the menthol, the menthyl esters of the aminocinnamic acids could not be made water-soluble through their hydrochlorides. Since a water-soluble product is desirable, the introduction of arsenic into the aromatic terpene group was thought to be desirable for two reasons; first, to increase the solubility in water and second, to confer probably greater therapeutic properties.

A few organic arsenicals have been used in experimental studies in tuberculosis therapy, and arsenic in the form of arsenic acid was tried early in the treatment of tuberculosis. Sodium cacodylate, atoxyl, arsacetin and neosalvarsan have no tuberculocidal properties, according to Arkin and Corper,[2] but earlier investigators (Buchner, Weismayr, Pokhorow)[3] comment favorably upon the worth of arsenic in the treatment of tuberculosis because of its favorable influence on metabolism, although they conclude that it is not a true chemotherapeutic agent with a specific action on human tubercle bacilli. .

The new menthol arsenicals described here were made with the hope that they might possess some favorable pharmacological action.

Experimental

2-Nitro-4-methylphenylarsonic Acid.—This compound was first prepared by Jacobs, Heidelberger and Rolf[4] using a different technique in the arsonation process from that described here. 3-Nitro-4-toluidine (110 g.) is stirred by means of a mechanical stirrer in 20% hydrochloric acid (500 cc.) until the hydrochloride is formed, and then diazotized at 0° with sodium nitrite (55 g.) dissolved in water (250 cc.). The diazo solu-

tion is filtered from a small amount of undissolved substance. Solutions of hydrated copper sulfate (25 g. in 375 cc. of water), sodium hypophosphite (35 g. in 500 cc. of water) and sodium arsenite (135 g. in 1 liter) are heated separately to 60 to 70°, and then poured into a large flask. At this temperature the cold filtered diazo solution is added slowly with vigorous stirring. Nitrogen is evolved copiously and in a short time a stormy reaction sets in and the arsonic acid is immediately precipitated Very little tarry material is formed. After the evolution of nitrogen has subsided the substance is collected and washed well with water; yield, 130 g. The arsonic acid is purified by solution in 4% potassium hydroxide, treatment with charcoal and precipitation with hydrochloric acid. Further purification from alcohol gives a substance melting in a closed tube at 253–255". It is insoluble in benzene and acetone, slightly soluble in hot ethyl alcohol and quite soluble in hot methyl alcohol.

Anal. Subs., 0.2082: 29.99 cc. of I_2 soln. (1 cc. = 0.001967 g. of As). Calcd. for $C_7H_8O_5NAs$: As, 28.74. Found: 28.34.

2-Nitro-4-carboxyphenylarsonic Acid.—Maschmann[5] prepared this compound through the oxidation of the corresponding methyl compound with potassium permanganate. A convenient method for the preparation in rather large quantities is as follows. Crude 2-nitro-4-methylphenylarsonic acid (390 g.) is dissolved in potassium hydroxide solution (390 g. in 7.5 liters of water) treated with charcoal and filtered. Mechanical stirring facilitates the process. To the clear filtrate is added a solution of potassium permanganate (390 g. in 12.5 liters of water) and the reaction mixture placed on a water-bath until the permanganate color is lost through oxidation. The manganese oxides are removed by filtration and the green colored filtrate is acidified with hydrochloric acid until acid to congo red. The green color changes to pink and finally disappears. The acid solution is evaporated to dryness on the water-bath and the desired arsonic acid extracted with hot ethyl alcohol. The alcohol is removed by evaporation and the nitrocarboxyphenylarsonic acid is purified by crystallization from boiling water after treatment with charcoal; yield, 80 to 90%. The glistening needle-like crystals contain one molecule of water of crystallization and melt with decomposition at 226–227°, which confirms Maschmann's findings.

Anal. Subs., 0.2484, 0.1987: 30.84, 24.67 cc. of I_2 (1 cc. = 0.001933 g. of As). Calcd. for $C_7H_6O_7NAs \cdot H_2O$: As, 24.27. Found: As, 24.01, 24.00.

The water of crystallization is lost at 115° and the following analysis is obtained.

Anal. Subs., 0.2126, 0.2030: 28.25, 26.93 cc. of I_2 soln. (1 cc. = 0.001967 g. of As). Calcd. for $C_7H_6O_7NAs$: As, 25.77. Found: As, 26.14, 26.10.

Sodium Salt.—This salt is prepared by titrating an alcoholic solution of 2-nitro-4-carboxyphenylarsonic acid with an alcoholic solution of sodium hydroxide. The sodium salt is very soluble in water.

Anal. Subs., 0.2076: 22.41 cc. of I_2 soln. (1 cc. = 0.001967 g. of As). Calcd. for $C_7H_3O_7NAsNa_3$: As, 21.01. Found: As, 21.23.

2-Nitro-4-carboxyphenyldichloro-arsine.—The phenyldichloro-arsine compound can be obtained by reduction of the corresponding arsonic acid in concentrated hydrochloric acid with either hypophosphorous acid, sulfur dioxide, hydroquinone or camelite. 2-Nitro-4-carboxyphenylarsonic acid (20 g.) is dissolved in concentrated hydrochloric acid (150 cc.) and after the addition of 10% potassium iodide (10 drops) sulfur dioxide is passed into the solution until precipitation is complete. The dichloro-arsine compound is collected under suction on hardened filter paper, washed first with concentrated hydrochloric acid and then with dilute hydrochloric acid. Partial drying is obtained

---

[5] Maschmann, *Ber.*, **57B**, 1759–1766 (1924).

by pressing the preparation on a porous plate, after which it is transferred to a vacuum desiccator and dried over sulfuric acid and sodium hydroxide sticks; amount of crude product, 20 g. For purification the crude dried material is dissolved in hot chloroform and precipitated by cooling. Twelve grams of a light yellow, fluffy product melting at 173–174° is obtained. Petroleum ether added to the filtrate gives an additional quantity of less pure material.

Anal. Subs., 0.1740: 21.80 cc. of I_2 soln. (1 cc. = 0.001936 g. of As). Calcd. for $C_7H_4O_4NAsCl_2$: As, 24.04. Found: As, 24.26.

To a solution of 2-nitro-4-carboxyphenylarsonic acid (10 g.) in concentrated hydrochloric acid (400 cc.), 50% hypophosphorous acid (20 cc.) and 10% potassium iodide (10 drops) are added. The reaction mixture is gradually warmed to 37–40° and shortly the solution becomes turbid, the iodine color gradually disappears and the dichloro-arsine separates. The precipitate is collected and treated as described above; yield of crude product, 9 g.

2-Nitro-4-carboxyphenyldihydroxyarsine (2-Nitro-4-carboxyphenylarsenious Acid).—This compound can be prepared either by the hydrolysis of the corresponding dichloro-arsine or by reduction of the corresponding arsonic acid in water by means of sulfur dioxide in presence of potassium iodide as catalyst.

2-Nitro-4-carboxyphenylarsonic acid (10 g.) is dissolved in hot water (225 cc.) and after the addition of 10% potassium iodide (20 drops) sulfur dioxide is passed into the solution until complete precipitation of the arsenious acid; yield, 7.5 g. or 85%. 2-Nitro-4-carboxyphenylarsenious acid is a light yellow substance which does not melt or decompose below 290°.

Anal. Subs., 0.1718: 24.19 cc. of I_2 soln. (1 cc. = 0.001936 g. of As). Calcd. for $C_7H_6O_6NAs$: As, 27.28. Found: 27.26.

2-Nitro-4-carboxyphenyldichloro-arsine (3 g.) is suspended in water (100 cc.) and the mixture shaken for an hour. A change in structure is visible. The dihydroxyarsine is collected and washed free from chlorides. The filtrate becomes strongly acid and silver chloride is precipitated upon the addition of silver nitrate.

Menthyl Ester of 2-Nitro-4-carboxyphenylarsenious Acid.—2-Nitro-4-carboxyphenyldichloro-arsine (42 g.) is refluxed with thionyl chloride (100 cc.) on a water-bath for one hour. Complete solution results after fifteen minutes. The excess of thionyl chloride is removed by distillation under reduced pressure. To the crude acid chloride, menthol (54.6 g.) is added and the reaction mass is heated under a reflux condenser on a water-bath for one to one and a half hours. The excess menthol is removed by distillation under reduced pressure (outside bath 140') and petroleum ether is added to the residue, which dissolves the menthyl ester and separates it from an insoluble, tarry by-product. The petroleum ether is removed by evaporation and the sticky semi-liquid mass is macerated with 4 *N* sodium carbonate, whereupon a semi-solid mass is obtained which is dissolved in ether and shaken with more 4 N sodium carbonate until the carbonate solution is chloride free, The ether solution is washed with water, dried over anhydrous sodium sulfate and evaporated to dryness. The sticky mass soon crystallizes on stirring. The amount obtained at this point is 50 g. which still contains a small amount of free menthol. This ester, like menthol, is very soluble in organic solvents and is separated only with difficulty from small amounts of menthol through fractional crystallization. The last traces of menthol were best removed by steam distillation. The menthyl ester is a light yellow, crystalline substance which does not have a sharp melting point but gradually evolves a gas above 100°.

Anal. Subs., 0.2882, 0.3060: 28.38, 29.92 cc. of I_2 soln. (1 cc. = 0.001843 g. of As). Calcd. for $C_{17}H_{24}O_6NAs$: As, 18.16. Found: As, 18.14, 18.02.

Menthyl Ester of 2-Nitro-4-carboxyphenylarsonic Acid.—The menthyl ester of this acid could not be made directly from the acid itself with thionyl chloride and menthol, as the thionyl chloride reduced the arsonic group. The menthyl ester of 2-nitro-4-carboxyphenylarseniousacid (10 g.) is dissolved in acetone (200 cc.) and 3% hydrogen peroxide (105 cc.) is added in small portions at room temperature. The heat of reaction raises the temperature to 27–29°. After reaction is complete and the temperature subsides, the solution is filtered if necessary and allowed to stand in an evaporating dish at room temperature. The solid which separates after the evaporation of the acetone is collected and sucked dry. The ester is a white, crystalline substance which decomposes at 210–211° and is soluble in alcohol and chloroform, not so soluble in ether when pure and insoluble in petroleum ether. Purification from chloroform and petroleum ether gave a product of the following analysis.

Anal. Subs., 0.3012: 28.46 cc. of I_2 soln. (1 cc. = 0.001843 g. of As). Calcd. for $C_{17}H_{24}O_7NAs$: As, 17.48. Found: As, 17.41.

Sodium Salt.—The pure menthyl ester of 2-nitro-4-carboxyphenylarsonic acid is dissolved in warm ethyl alcohol and titrated to the pink point of phenolphthalein with an ethyl alcoholic solution of sodium hydroxide. The salt begins to separate as soon as the alkali is added but comes down at first in a gummy form. The solvent is removed through slow evaporation in a warm place and the salt is obtained as a white, fluffy substance. It is suspended in ethyl alcohol and macerated well to remove any excess either of free acid or free alkali, then collected and washed with ether. Thus obtained, the salt crystallizes with 4 molecules of water of crystallization.

Anal. Subs., 0.3336: 24.42 cc. of I_2 soln. (1 cc. = 0.001843 g. of As). Calcd. for $C_{17}H_{22}O_7NAsNa_2 \cdot 4H_2O$: As, 13.76. Found: As, 13.50.

After drying at 110°, the following analysis is obtained.

Anal. Subs., 0.2863: 24.45 cc. of I_2 soln. (1 cc. = 0.001843 g. of As). Calcd. for $C_{17}H_{22}O_7NAsNa_2$: As, 15.85. Found: As, 15.72.

The hydrated salt is a pure white substance while the anhydrous form is a very light yellow. Both forms are very soluble in water.

Summary

The preparation of the following new compounds is reported: 2-nitro-4-carboxyphenyldichloro-arsine, 2-nitro-4-carboxyphenylarsenious acid, menthyl ester of 2-nitro-4-carboxyphenylarsenious acid, menthyl ester of 2-nitro-4-carboxyphenylarsonic acid, together with some of the sodium salts. The presence of the nitro and the carboxy groups favors the arsenious acid form rather than the arsenious oxide form.

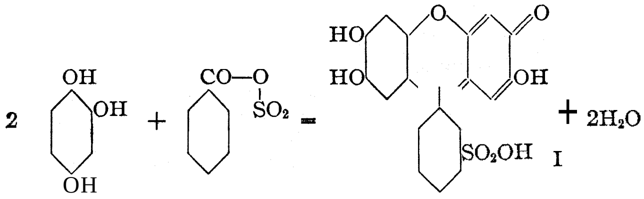
HYDROXYHYDROQUINOLSULFONEPHTHALEIN, 2',4',5'-TRIHYDROXYBENZOYLBENZENE-ORTHO-SULFONIC ACID (THE INTERMEDIATE ACID) AND SOME OF THEIR DERIVATIVES

By W. R. Orndorff and Mary L. Willard[1]

Received November 2, 1928 Published May 6, 1929

In 1900 Liebermann[2] and in 1901 Thiele and Jaeger[3] prepared hydroxyhydroquinolphthalein (dihydroxyfluorescein) from hydroxyhydroquinol and phthalic anhydride. The constitution of hydroxyhydroquinolphthalein was investigated by Feuerstein and Dutoit.[4] Hydroxyhydroquinolbenzein, the mother substance, was prepared and studied by Liebermann and Lindenbaum[5] in 1904 and by Ghosh and Watson[6] in 1913. Osorovitz[7] condensed hydroxyhydroquinol with tetrachlorophthalic anhydride and obtained hydroxyhydroquinoltetrachlorophthalein.

The reaction between hydroxyhydroquinol and o-sulfobenzoic anhydride is analogous to that of the phenols as a class with phthalic anhydride to form various phthaleins.



Analysis of the hydroxyhydroquinolsulfonephthalein shows that its composition corresponds to that of the pyrone ring structure and the fact that its alkaline solution is quite fluorescent indicates that it is 2,7-dihydroxysulfonefluorescein (I).

Like other sulfonephthaleins which have been studied, it is tautomeric and gives colored derivatives of the quinoid form and colorless derivatives of the lactoid form. Since the sulfonephthalein itself is highly colored, it has been assigned the quinoid formula and is presumably an inner carbonium or oxonium salt. The crystalline product contains about

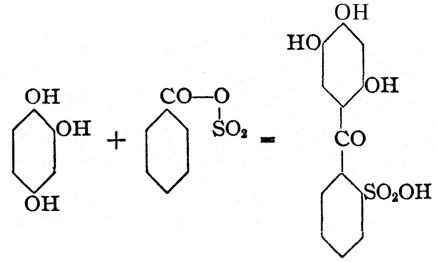
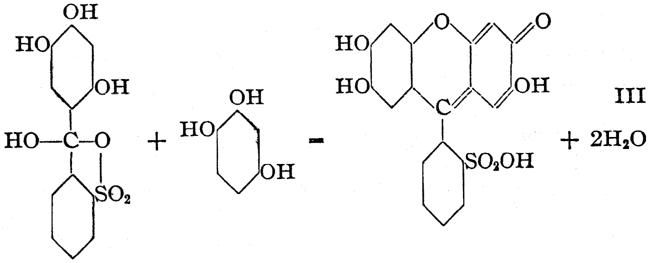
one-half a molecule of water per molecule of substance and is probably a solid solution of the quinoid, inner oxonium or carbonium salt, and the quinoid hydrate.

The formation of hydroxyhydroquinolsulfonephthalein takes place through an intermediate step, in' a manner similar to that observed with other sulfonephthaleins which have been prepared in this Laboratory. A tautomeric substance, 2',4',5'-trihydroxybenzoylbenzene-*o*-sulfonic acid, which is called the intermediate acid, is obtained by the action of one molecule of o-sulfobenzoic anhydride upon one molecule of hydroxyhydroquinol.



II

The second step in the formation of hydroxyhydroquinolsulfonephthalein is the condensation of 2',4',5'-trihydroxybenzoylbenzene-2-sulfonic acid (11) with a second molecule of hydroxyhydroquinol with the elimination of water (III).



III

That the intermediate acid is a tautomeric, y-ketonic acid is proved by preparing derivatives of both the ketone and lactone forms.

Hydroxyhydroquinolsulfonephthalein forms colored ethers, to which are assigned the quinoid structure.

Dibromohydroxyhydroquinolsulfonephthaleinwas isolated as a colored derivative which is also tautomeric. Since this dibromo derivative and its ammonium salt are colored, they are assigned the quinoid structure, while its tetra-acetate, which is colorless, is formulated as a derivative of the lactoid structure.

Concentrated sulfuric acid removes one molecule of water from the hydroxyhydroquinolsulfonephthalein, forming a violet-colored compound with a green luster, which has been given the name sulfoneviolein.

Hydroxyhydroquinolsulfonephthalein can be reduced with zinc dust, in formic acid solution, to hydroxyhydroquinolsulfonephthalin. The tetra-acetate of hydroxyhydroquinolsulfonephthalin and its silver salt have been prepared.

Experimental Part

In all calculations, 1925 atomic weights[8] were used. Carbon and hydrogen were determined by the usual combustion method with modifications of de Rhode for the presence of sulfur. Sulfur analyses were made in some cases with the Parr bomb, while in others Liebig's method of fusion with sulfur-free potassium nitrate and potassium hydroxide was used. Methoxyl and ethoxyl groups were determined by a modification of the Zeisel method.[9] Dennis' modification[10] of the Thiele apparatus was used to determine the melting points, which were uncorrected. A Bureau of Standards thermometer was used which was calibrated in 0.2°. In drying a substance to constant weight, an electrically heated tube[11] was used, through which was passed a slow current of dry air or carbon dioxide. The substance was introduced into this tube in a platinum boat on an asbestos support to prevent overheating by direct contact with the glass. The solubility of all salts was determined and classified according to Mulliken.[12]

All crystallographic data recorded were supplied by Professor Gill of the Department of Geology.

Preparation of Hydroxyhydroquinol.—Hydroxyhydroquinol was prepared from hydroquinol by oxidation to *p*-benzoquinone[13] with sodium dichromate in sulfuric acid solution and conversion of the latter into hydroxyhydroquinol tri-acetate according to a modification[14] of Thiele's method.[15]

The hydroxyhydroquinol tri-acetate was then hydrolyzed to hydroxyhydroquinol in the presence of hydrochloric acid.

2′,4′,5′-Trihydroxybenzoylbenzene-2-sulfonic Acid.—One hundred g. of hydroxyhydroquinol and **36** g. of o-sulfobenzoic anhydride[16] were heated at **100°** for eight hours. The orange-red mass was powdered and treated with distilled water. It was filtered

to remove the insoluble material, hydroxyhydroquinolsulfonephthalein. The filtrate was repeatedly boiled with bone black and filtered until the solution became colorless. The solution was carefully concentrated to about **100** cc. and **50** cc. of concentrated hydrochloric acid was added. The intermediate acid separated in small colorless crystals.

"Crystals of tabular, to thin, platey habitus reach a length of more than 2 mm. but are not perfect enough for gonimetric measurement. They are rhomboidal in shape, when well formed, and are certainly triclinic since extinction is not symmetrical and the bisectrix seen in converging polarized light is not normal to the surface of the plates. Double refraction is rather high and dispersion is strong."

The intermediate acid could also be separated from the fusion filtrate by precipitation of the barium salt with barium carbonate and subsequent acidification. The intermediate acid is very soluble in water; soluble in methanol, ethanol, acetone, ether and glacial acetic acid. It is difficultly soluble in benzene, xylene, petroleum ether and chloroform. The structure of the intermediate acid was proved by the method of Orndorff and Cornwell,[17] by fusion with potassium hydroxide at 210° for two hours. From the fused mass, after crystallization from 50% alcohol, small needles melting at 210° were obtained. This substance corresponded in properties to hydroxyhydroquinolcarboxylic acid (2′,4′,5′-trihydroxybenzoic acid).[18]

When 2′,4′,5′-trihydroxybenzoylbenzene-2-sulfonic acid was heated for three hours at 140°, it decomposed, forming hydroxyhydroquinolsulfonephthalein and o-sulfobenzoic anhydride. The intermediate acid reacted under similar conditions with hydroxyhydroquinol to form hydroxyhydroquinolsulfonephthalein. Several derivatives of the tautomeric forms of the intermediate acid **(2′,4′,5′-trihydroxybenzoylbenzene-2-sulfonic acid)** were made.

Ammonium Salt.[19]—Twenty-two *g.* of the acid ammonium salt of o-sulfobenzoic acid was heated with **12** *g.* of hydroxyhydroquinol at 190–195° for five hours. The fused mass was dissolved in hot water and recrystallized three times from hot water. The ammonium salt is very soluble in water, methanol or ethanol. It is insoluble in benzene, ether or petroleum ether.

Barium Salt.—Ten g. of the pure intermediate acid was boiled with **30** *g.* of barium carbonate for one hour. After the solution had been filtered, the barium salt of the intermediate acid crystallized from the concentrated filtrate. It was recrystallized

[19] Analyses of the following compounds can be found in the thesis in the Library, Cornell University, Ithaca, New York.

twice from hot water. The barium salt is easily soluble in water, methanol and ethanol but very difficultly soluble in other organic solvents.

Zinc Salt.—Five g. of the pure intermediate acid was boiled with *25 g.* of zinc carbonate for one hour. The excess of zinc carbonate was removed by filtration and the filtrate was concentrated almost to dryness, when plate-like crystals separated which were recrystallized once from water. The colorless zinc salt crystallized with 5 molecules of water of crystallization. The zinc salt is soluble in water, methanol and ethanol but difficultly soluble in other organic solvents.

Tetra-sodium Salt.—Five g. of the pure intermediate acid was treated with the calculated amount of 0.1 N sodium hydroxide. The solution was evaporated to dryness and the salt recrystallized from water. The sodium salt is very soluble in water, methanol and ethanol. It is insoluble in ether, benzene and xylene.

Tetra-acetate.—Ten g. of pure dry intermediate acid was boiled with 100 cc. of acetic anhydride for three hours. The solution was filtered and about 50 cc. of acetic anhydride was distilled from the filtrate. Upon standing for twelve hours the colorless crystals separated from the solution. These were recrystallized twice from anhydrous ether. The tetra-acetate is soluble in ether and acetone but insoluble in benzene and petroleum ether. It is slowly hydrolyzed by long heating with water or alcohol.

Preparation of Hydroxyhydroquinolsulfonephthalein

(1) From the Anhydride of o-Sulfobenzoic Acid and Hydroxyhydroquinol Triacetate.—Hydroxyhydroquinolsulfonephthalein was prepared in the best yields by heating 200 g. of hydroxyhydroquinol tri-acetate with 70 g. of o-sulfobenzoic anhydride for eight hours at 140°. The last traces of acetic acid were removed by the use of reduced pressure. The mass, consisting of tiny green crystals, was purified by dissolving it in hot dilute sodium hydroxide and acidifying with dilute hydrochloric acid. The yield was 80%.

Anal. Calcd. for $C_{19}H_{12}O_8S \cdot {}^1/_2H_2O$: H_2O, **2.20.** Found: **2.16, 2.28.** Calcd. for $C_{19}H_{12}O_8S$: S, **8.01.** Found: S, **7.94, 7.97.**

(2) From the Chlorides of o-Sulfobenzoic Acid and Hydroxyhydroquinol.—Twenty-four g. of *o*-sulfobenzoic acid chloride and 28 g. of hydroxyhydroquinol were heated for three hours on a steam-bath and three hours more at 120°, using reduced pressure during the last hour. The product was purified as before. The yield was 40%. A small amount of material was insoluble in sodium hydroxide which was probably, if analogous to other sulfonephthaleins, the ester of o-sulfobenzoic acid.

Anal. Calcd. for $C_{19}H_{12}O_8S \cdot {}^1/_2H_2O$: H_2O, **2.20.** Found: **2.12, 2.16.** Calcd. for $C_{19}H_{12}O_8S$: C, **56.97;** H, **3.02;** S, **8.01.** Found: C, **56.97, 56.53;** H, **3.10, 3.09;** S, **8.03,** 7.86.

(3) From the Anhydride of o-Sulfobenzoic Acid and Hydroxyhydroquinol.—Eighteen g. of o-sulfobenzoic anhydride and 28 g. of hydroxyhydroquinol were heated at 130" for thirty hours. The product was purified as before. If a temperature higher than 130" was used, tar was formed; if lower, the yield rapidly decreased. The yield was 30%.

Anal. Calcd. for $C_{19}H_{12}O_8S \cdot {}^1/_2H_2O$: H_2O, **2.20.** Found: **2.17, 2.08.** Calcd. for $C_{19}H_{12}O_8S$: S, **8.01.** Found: **S, 7.46, 7.52.**

When anhydrous zinc chloride was used as a condensation agent, the yield was reduced to 15%.

Properties and Crystalline Form.—Professor Gill examined crystals of hydroxyhydroquinolsulfonephthalein prepared by fusion of the chlorides of o-sulfobenzoic acid and hydroxyhydroquinol. He stated: "The crystalline aggregates show bright yellow-green surface color, but do not have sufficiently sharp crystal boundaries to permit determination of the crystal system. They are nearly opaque except in very fine powder, when they appear to transmit a little reddish-brown colored light."

The green crystals of hydroxyhydroquinolsulfonephthalein, when ground in an agate mortar, formed a reddish-orange powder. Hydroxyhydroquinolsulfonephthalein is difficultly soluble in water, forming a red solution with green fluorescence. It is soluble in dilute (2%) sodium hydroxide, forming a red solution with green fluorescence. With concentrated (30%) sodium hydroxide, a fuchsin-colored solution is obtained. Concentrated sulfuric acid forms a yellow solution which is not fluorescent. Hydroxyhydroquinolsulfonephthalein is soluble in methanol, ethanol, acetic acid and acetone. It is insoluble in benzene, toluene, ether and petroleum ether. It can be precipitated from cold dilute alkaline solutions with dilute acid as a reddish powder and from hot solutions as fine green crystals. The PH was determined by Clark's colorimetric method[20] using a color chart found in Mulliken.[21] There was a change from OY to R at 7.2 and from VR to RV at 12.0.

The following derivatives of the tautomeric forms of hydroxyhydroquinolsulfonephthalein were made.

Ammonium Salt.--Samples of pure dry hydroxyhydroquinolsulfonephthalein absorbed 4 molecules of ammonia gas, a bluish-brown powder resulting, the aqueous solutions of which were fuchsin colored. When the tetra-ammonium salt was allowed to stand in an evacuated desiccator over sulfuric acid, a red stable mono-ammonium salt resulted. Hydrogen chloride gas did not form a stable compound with hydroxyhydroquinolsulfonephthalein.

Barium Salt.—Five g. of hydroxyhydroquinolsulfonephthalein and 30 g. of barium carbonate were boiled with 3 liters of water until all the sulfonephthalein had dissolved. After filtration and concentration of the filtrate, red crystals separated. The barium salt is very soluble in water, methanol and ethanol. It can be hydrolyzed with concentrated hydrochloric acid to the sulfonephthalein.

Zinc Salt.—An aqueous suspension of pure hydroxyhydroquinolsulfonephthalein was boiled with zinc dust until the solution became bright orange in color. After filtration, concentration and recrystallization from water, orange-red crystals were obtained. The zinc salt is soluble in water, methanol, ethanol and butanol.

Potassium Salt.—A sample of pure hydroxyhydroquinolsulfonephthalein was dissolved in the calculated amount of potassium hydroxide solution. The solution was filtered and the filtrate was concentrated. Reddish crystals separated. The potassium salt is readily soluble in most organic solvents.

Tetra-acetate.—A sample of pure dry hydroxyhydroquinolsulfonephthalein was heated for one hour with excess acetic anhydride. After solution had taken place,

---

[20] Clark, "The Determination of H-Ion Concentration," Williams and Wilkins Company, Baltimore, Maryland, 1922.

[21] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, 1908, Vol. 1.

about one-half the solvent was distilled off. Brownish-yellow needles separated from the remaining solution upon cooling. After three recrystallizations from acetic anhydride, colorless needles were obtained. The tetra-acetate was slowly hydrolyzed with water and more rapidly hydrolyzed with alkalies.

Tetra-benzoate.—A sample of pure dry hydroxyhydroquinolsulfonephthalein was boiled with excess benzoyl chloride for five hours. It was filtered and the filtrate was evaporated to dryness; the residue was extracted with hot benzene. The benzene extracts were concentrated in the presence of a little bone black. From the filtered suspension, small crystals separated upon cooling. They were twice recrystallized from benzene. The colorless tetra-benzoate is soluble in methanol, ethanol, ether, toluene, benzene and xylene. It is readily saponified with dilute sodium hydroxide and also boiling ethanol.

Sodium Salt of Trimethyl Ether.—Twenty g. of pure dry hydroxyhydroquinolsulfonephthalein was treated with methyl iodide and sodium methylate according to Claissen's method as used by Orndorff and Fuchs[22] in the preparation of pyrogallolsulfonephthalein and sulfonegallein ethers. About **20** g. of a dry green powder was obtained from the ether. The green powder was extracted with acetone. The acetone extracts were assembled and concentrated and a few red crystals were obtained which were recrystallized from acetone.

Anal. Calcd. for $C_{19}H_8O_5SNa(OCH_3)_3$: Na, **4.95; CH_3O, 20.05.** Found: Na, **5.07, 5.07; CH_3O, 20.05, 20.17.**

The sodium salt is easily soluble in most organic solvents. It does not form a blue solution with sodium hydroxide since the hydroxyl positions are already occupied and do not permit the formation of poly salts.

Trimethyl Ether.—The material left undissolved after the acetone extractions was dissolved in water and reprecipitated with hydrochloric acid. It was dried and extracted with boiling glacial acetic acid. The extractions were concentrated and a few reddish crystals were obtained which were recrystallized from methanol.

Anal. Calcd. for $C_{22}H_{18}O_8S$: S, **7.25.** Found: S, **7.40,** 7.50.

The trimethyl ether of hydroxyhydroquinolsulfonephthalein is soluble in most solvents except benzene and ether.

Dimethyl Ether.—The reddish material left undissolved after the extraction with boiling acetic acid was recrystallized four times from methanol.

Anal. Calcd. for $C_{19}H_{10}OS(OCH_3)_3$: **CH_3O, 14.49.** Found: **CH_3O, 14.39, 14.28.**

The dimethyl ether is soluble in water, methanol and ethanol. It is insoluble in ether, acetic acid, benzene and toluene.

Aniline Salt,—Ten g. of pure dry hydroxyhydroquinolsulfonephthalein was dissolved in **200** cc. of aniline on a steam-bath. The solution was then heated for twelve hours at 120°. When the solution was cooled red needles separated. The crystals were filtered off and washed with ether. They did not melt below **300".**

"The dark reddish spongy masses appear to be made up of very small crystals, not more than 0.002 or 0.003 mm. in diameter. Nothing could be determined further than that the sparkling reflection from the surface indicated crystalline character."

Anal. Calcd. for $C_{19}H_{12}O_8S(C_6H_5NH_2)$: S, 6.50. Found: S, **6.38, 6.46.**

The red aniline salt is soluble in hot water and methanol. Aniline was liberated when the salt was treated with sodium hydroxide.

---

[22] Orndorff and Fuchs, THIS JOURNAL, **48,1939 (1926).**

Dibromohydroxyhydroquinolsulfonephthalein.—No reaction was observed between bromine and hydroxyhydroquinolsulfonephthalein in glacial acetic acid solution. Ten g. of pure dry hydroxyhydroquinolsulfonephthalein was dissolved in 300 cc. of absolute ethanol and 20 g. of bromine in 100 cc. of absolute ethanol added. The solution was heated on a steam-bath for eight hours. When it had cooled green crystals separated which were purified by dissolving in water and precipitating with hydrochloric acid.

Anal. Calcd. for $C_{19}H_{10}O_8Br_2S\,2^1/_2H_2O$: H_2O, 7.48. Found: H_2O, 7.48, 6.90. Calcd. for $C_{19}H_{10}O_8Br_2S$: S, 5.75; Br, 28.65. Found: S, 5.82, 5.92; Br, 28.46, 28.20.

The dibromo derivative was soluble in water. It dissolved in dilute sodium hydroxide forming a red solution or a blue solution with more concentrated alkali. A color change was noted at P_H 6.4 from RO to VR.

Action of Ammonia.—Several samples of pure dry dibromohydroxyhydroquinolsulfonephthalein, when exposed to a stream of dry ammonia, absorbed 5.5 molecules of ammonia. After standing over sulfuric acid for some time a stable tri-ammonium salt resulted.

Tetra-acetate.—Ten g. of pure dry dibromohydroxyhydroquinolsulfonephthalein was boiled with 100 cc. of acetic anhydride for one hour. The solution was filtered into ice water. A brownish solid separated upon standing, which was purified by repeated recrystallization from benzene using bone black. This salt is very easily hydrolyzed with alkalies or water. It is soluble in benzene.

Sulfoneviolein.—Ten g. of pure dry hydroxyhydroquinolsulfonephthalein was dissolved in 10 cc. of concentrated sulfuric acid. The solution was heated for twelve hours at 120°. It was cooled and poured into ice water; a brownish-blue solid separated. It acquired a green luster upon drying and was recrystallized from nitrobenzene as fine green crystals.

Anal. Calcd. for $C_{19}H_{10}O_7S$: S, 8.39. Found: S, 8.46, 8.45.

It was insoluble in most organic solvents. It was slightly soluble in ethanol to a brown solution. It was soluble in acids to a red solution but was insoluble in alkalies.

Hydroxyhydroquinolsulfonephthalein.—Five g. of hydroxyhydroquinolsulfonephthalein was dissolved in about 200 cc. of formic acid. The solution was boiled with 10 g. of zinc dust. After about fifteen minutes it was completely decolorized. It was filtered in the presence of carbon dioxide. Upon cooling minute colorless crystals separated which were recrystallized from 50% formic acid.

Anal. Calcd. for $C_{19}H_{14}O_8S$: S, 7.97. Found: S, 8.22, 8.03.

"This substance is ocher yellow in mass, and a few of the larger crystals show pleochroism from buff to colorless. It is composed of sharply defined crystals, mostly 0.01 to 0.03 mm. in diameter. These have rather low double refraction and oblique extinction. The shape would seem to be monoclinic, though they may be triclinic."

The reduction product is soluble in most organic solvents. It oxidizes readily and becomes red upon standing in the air.

Tetra-acetate.—Ten g. of pure dry hydroxyhydroquinolsulfonephthalein was dissolved in 200 cc. of glacial acetic acid. Five g. of zinc dust and a few drops of copper sulfate (10%) solution were added. The mixture was boiled on a sand-bath for three hours. The acetic acid solution was filtered, concentrated to half the original volume and poured into ice water. A nearly colorless precipitate separated which was crystallized from 95% ethanol. The tetra-acetate of the reduction product was difficultly soluble in methanol, ethanol, benzene and acetone.

Anal. Calcd. for $C_{27}H_{22}O_{12}S$: S, 5.61. Found: S, 5.66.

Silver Salt of Tetra-acetate.—Five g. of hydroxyhydroquinolsulfonephthalein tetra-acetate dissolved in 200 cc. of absolute ethanol was added to 25 g. of silver nitrate dissolved in this alcohol, which had been previously boiled with other silver nitrate for one hour. After a few minutes' standing, fine colorless crystals separated. They were filtered off and allowed to dry in the absence of light. The silver salt was soluble in methanol and benzene but insoluble in most organic solvents.

Summary

1. 2′,4′,5′-Trihydroxybenzoylbenzene-2-sulfonic acid has been prepared. It has been shown that it is the intermediate step in the preparation of hydroxyhydroquinolsulfonephthalein. This intermediate acid is a γ-ketonic acid and acts as a tautomeric substance, giving derivatives of the ketone form and of the lactone form.

2. The preparation and properties of pure hydroxyhydroquinolsulfonephthalein have been studied. The best results were obtained by the condensation of hydroxyhydroquinol tri-acetate and o-sulfobenzoic anhydride. The product is dihydroxysulfonefluorescein formed by elimination of a molecule of water, with the production of a pyrone ring. Dilute alkaline solutions are fluorescent.

3. Since hydroxyhydroquinolsulfonephthalein is a highly-colored substance, it is represented as having the quinoid structure. It is tautomeric and yields colorless derivatives of the lactoid modification, as the tetra-acetate and tetra-benzoate, and colored derivatives of the quinoid structure, as the barium, zinc or potassium salts.

4. Colored di- and trimethyl ethers of hydroxyhydroquinolsulfonephthalein have been prepared, both of which are assigned the quinoid structure.

5. Dibromohydroxyhydroquinolsulfonephthalein and its ammonium salt were obtained as colored substances, to which the quinoid structure is assigned. The colorless tetra-acetate is considered to be a derivative of the lactoid structure.

6. Sulfuric acid removes a molecule of water from hydroxyhydroquinolsulfonephthalein, forming sulfoneviolein.

7. Hydroxyhydroquinolsulfonephthalin, the reduction product of hydroxyhydroquinolsulfonephthalein, its tetra-acetate and the silver salt of the tetra-acetate have been prepared. They are colorless and are easily oxidized.

STUDIES ON GOSSYPOL. V. THE ACTION OF CHROMIC ACID UPON SOME GOSSYPOL DERIVATIVES

BY E. P. CLARK[1]

RECEIVED NOVEMBER 3, 1928 PUBLISHED MAY 6, 1929

In a former paper[2] experiments were reported in which attempts were made to oxidize gossypol. The experience gained in this work indicated that, before this approach to the structural nature of the substance could be successful, the hydroxyl groups in the molecules would have to be protected.
