Several derivatives fulfilling this requirement have been prepared, and their behavior toward various oxidizing reagents has been studied. This report is concerned with the products obtained by the action of chromic acid upon hexa-acetylgossypol, hexa-acetylapogossypol and apogossypol hexamethyl ether.

When dissolved in acetic acid and oxidized with an aqueous solution of chromic acid, hexa-acetylgossypol yields a bright yellow neutral compound which begins to darken at 210° and becomes a black mass at 230" without definitely melting. This substance has the molecular formula $C_{33}H_{30}O_{12}$. It possesses no carboxyl or free hydroxyl groups but has four acetyl groups and is, therefore, a tetra-acetyl derivative of a substance, $C_{25}H_{22}O_8$, to which the name *gossypolone* has been given. The derivative obtained is, therefore, tetra-acetylgossypolone. From a consideration of the foregoing it follows that in the formation of tetra-acetylgossypolone from hexa-acetylgossypol two acetyl groups are replaced by two quinone groups, and carbon and hydrogen are lost in such proportions that gossypolone has a lower molecular weight than gossypol by C_5H_8.

Tetra-acetylgossypolone readily condenses with aniline in much the same manner as does gossypol. The condensation product is a chocolate-colored micro-crystalline substance which imparts a deep wine-red color to solvents capable of dissolving it. It would appear from this that the two carbonyl groups originally in gossypol have not been affected by the oxidation.

When hexa-acetylapogossypol is treated in the same manner as hexa-acetylgossypol, except that Kiliani's chromic acid mixture[3] is used, a substance similar in appearance to tetra-acetylgossypolone is obtained. This is a neutral material having a melting point of 230° and a molecular formula

---

[1] This work was done under a research fellowship supported by the Interstate Cottonseed Crushers' Association.

[2] Clark, *J. Biol. Chem.*, **77, 81 (1928).**

[3] Kiliani, **Ber., 46, 676** (1913).

of $C_{30}H_{28}O_{10}$. It has been shown to be a tetra-acetyl derivative of a compound $C_{22}H_{20}O_6$. The name assigned to this substance is *apogossypolone*. In the reaction by which this material is formed, as in the previous one, two quinone groups have been substituted for two acetyl groups and the new non-acetylated derivative has a lower molecular weight than apogossypol by C_6H_{10}. One property of this new acetyl derivative which distinguishes it from tetra-acetylgossypolone is its inability to condense with aniline.

The oxidation of apogossypol hexamethyl ether with chromic and sulfuric acids (Kiliani's mixture) gave a bright yellow neutral crystalline compound, $C_{32}H_{34}O_8$, having a melting point of 210°. It has been established that this material is a tetramethyl ether of a tetraquinone, $C_{28}H_{26}O_8$. The name *pseudogossypolone* has been assigned this substance, and hence the C_{32} compound isolated is tetramethoxy-pseudogossypolone. The process by which it is formed is analogous to the reactions involving the acetyl derivatives discussed before, in that two quinone groups have been substituted for two methoxyl groups. On the other hand, methoxy derivatives of gossypol in general are far more resistant to reagents than the corresponding acetyl derivatives. In this experiment chromic acid did not attack the apogossypol molecule in such a manner as to cause a loss of carbon. Two quinone groups, however, were substituted for two hydrogen atoms.

The observations recorded concerning these new substances cannot be interpreted at present, since the loss of the elements, C_5H_8 and C_6H_{10}, without the introduction of oxygen into the molecule is a condition which could be explained by several possible types of reaction. Furthermore, the substitution of quinone groups for hydrogen atoms, or acetyl or methoxyl groups, as the case may be, points at present to the existence in the molecule of only aromatic nuclei. This conclusion, of course, has already been arrived at from previous work.

Some interesting observations relative to Zeisel determinations were made upon several gossypol derivatives. In the estimation of the methoxyl content of tetramethoxy-pseudogossypolone and of certain related compounds to be reported upon at a future time, difficulties arose which at first seemed to render the determinations impossible. Later, results were obtained, but they failed to harmonize with other information available. Finally, however, successful determinations were made but the rather unusual and anomalous data leading thereto were such that it was deemed desirable to record them separately in the report which follows.

Experimental

Tetra-acetylgossypolone.—Two grams of hexa-acetylgossypol dissolved in 50 cc. of boiling acetic acid was treated with 10 cc. of a 10% aqueous solution of chromium trioxide. The mixture was kept boiling for one minute after the addition of the reagent and then the oxidation was stopped by the addition of about 100 g. of crushed ice. The dilution caused the reaction product to separate as a bright yellow amorphous precipitate. It was freed from the mother liquor, washed with water and dried. The yield was 1.6 g. When this material was digested with approximately 20 cc. of boiling methanol, it quickly dissolved, but almost immediately a crystalline fraction began to separate. After some time the crystals were removed from the mother liquor, washed with methanol and dried. The yield of this product was 0.6 g. Crude amorphous acetylgossypol obtained directly from acetylating gossypol in pyridine solution gave the same results as the crystalline material. In a series of experiments 28 g. of the crude acetyl derivative gave 23 g. of the amorphous oxidation product, which yielded 11 g. of crystalline substance.

This material was purified by dissolving one part of the substance in ten parts of acetic acid-and adding five volumes of ether to this solution. Crystallization began immediately and was completed in a short time.

Thus purified, the substance consists of long bright yellow rods and needles which begin to darken at 210° and become a black mass at 230° without melting. Its indices of refraction are $n_\alpha = 1.559$; $n_\gamma = 1.676$ both ±0.003. The elongation is negative and the extinction is essentially straight (the extinction angle is very small).[4] The analytical data relative to this and to the other compounds under consideration are presented in Table I.

TABLE I

ANALYSIS OF OXIDATION PRODUCTS

Tetra-acetylgossypolone—Aniline Condensation Product, $C_{33}H_{30}O_{12} + 2\ C_6H_5NH_2 \longrightarrow C_{45}H_{40}N_2O_{10} + 2H_2O$.—Tetra-acetylgossypolone was suspended in methanol and an excess of aniline was added. The quinone dissolved with the formation of a deep wine-colored solution from which the condensation product soon began to crystallize. The process was completed after several hours. The material was purified by dissolving it in a large volume of boiling benzene, filtering the hot solution and allowing the substance to crystallize from the filtrate. Thus purified, it consisted of clusters of minute spindle-shaped chocolate-colored crystals which began to soften at 250° and melted at 255–256° (corr.).

---

[4] The optical data reported in this communication were determined by Mr. George L. Keenan of the Food, Drug and Insecticide Administration of the Department of Agriculture.

Anal. Calcd. for $C_{45}H_{40}N_2O_{10}$: N, 3.64. Found: N, 3.61, 3.57.

Tetra-acetylapogossypolone.—Two g. of hexa-acetylapogossypol was dissolved in 100 cc. of boiling acetic acid and treated with 15 cc. of Kiliani's solution,[5] the reagent being added from a pipet during the course of half a minute. The reaction, which was vigorous, was terminated by adding about 300 g. of crushed ice. The yellow amorphous product was then treated with methanol as outlined in the foregoing experiment. The yield of the crude crystalline product was 0.45 g. or 29%. The material was recrystallized from boiling methanol. Thus purified, it consists of oblique prisms suggesting the common crystalline forms of gypsum. It begins to sinter at 220° and melts completely at 230° (corrected); $n_\alpha = 1.530$; $n_\gamma = 1.645$ (both ±0.003). The extinction on the elongated forms is straight and the sign of elongation is positive.

Tetramethoxypseudogossypolone.—This compound was prepared by essentially the same process that was used for the two substances just described. Two g. of apogossypol hexamethyl ether was dissolved in 100 cc. of boiling acetic acid and treated with 20 cc. of Kiliani's mixture in such a manner as to prevent too energetic boiling. After two minutes the reaction was stopped by adding about 200 g. of crushed ice. The yellow precipitate, which weighed 1.5 g., was dissolved in 20 cc. of boiling methanol and allowed to crystallize. The yield of the crystalline quinone was 0.4 g. It was recrystallized from its solution in 10 parts of acetic acid by the addition of 5 parts of methanol. Thus obtained, it consists of long yellow needles melting at 210° (corr.). Its indices of refraction are $n_\alpha = 1.585$; $n_\gamma = 1.700$ (both ±0.003). The extinction is inclined and the birefringence is strong.

Summary

Upon oxidation with chromic acid, hexa-acetylgossypol is converted into tetra-acetylgossypolone. In the reaction two acetyl groups are replaced by two quinone groups and the new non-acetylated substance has a lower molecular weight than gossypol by C_5H_8.

Hexa-acetylapogossypol yields by treatment with Kiliani's chromic acid mixture a new quinone, tetra-acetylapogossypolone. In this reaction two quinone groups are substituted for two acetyl groups and the apogossypol molecule loses the elements C_6H_{10}.

When oxidized with chromic and sulfuric acids, apogossypol hexamethyl ether loses two methoxyl groups, which are replaced by two quinone groups. Two hydrogen atoms are also oxidized to quinone groups. The new substance, $C_{32}H_{34}O_8$, is, therefore, a tetramethoxy derivative of a tetraquinone, $C_{28}H_{26}O_8$.

STUDIES ON GOSSYPOL. VI. THE ACTION OF BOILING HYDRIODIC ACID AS USED IN THE ZEISEL METHOD UPON GOSSYPOL AND SOME OF ITS DERIVATIVES. A SEMI-MICRO ZEISEL METHOXYL METHOD

BY E. P. CLARK[1]

RECEIVED NOVEMBER 3, 1928 PUBLISHED MAY 6, 1929

In the preceding report[2] it was stated that difficulties arose in determining the methoxyl content of various methylated derivatives of gossypol, especially tetramethoxypseudogossypolone. When treated in the usual manner with hydriodic acid in a Zeisel apparatus, this substance gave practically no silver iodide. The addition of acetic acid or acetic anhydride to the hydriodic acid was also without appreciable effect. For example, in one experiment about 4% of methoxyl was obtained after the substance was boiled for four hours; whereas, if there are 4 methoxyl groups in the compound, as other evidence indicates, the theory demands a methoxyl content of 22.7%. In another experiment, phenol was added to the hydriodic acid, as recommended by Weishut.[3] When this was done, the white double compound of silver nitrate and silver iodide immediately formed. Since the first experiments indicated the advisability of running the determination for a longer time than is usually required, boiling was continued for three and one-half hours. When the final result was obtained, it was found rather unexpectedly that the methoxyl content corresponded to five groups more closely than to four.

In view of the combustion results and other information available, it seemed improbable that the compound had more than four methoxyl groups and, therefore, some other cause was responsible for the high value. Further investigation revealed that, when phenol was used with hydriodic acid in the Zeisel method, all gossypol derivatives tried, as well as gossypol itself, gave upon prolonged boiling a small quantity of silver iodide. When the silver iodide was calculated to methoxyl, an average of 81% of that required for one methoxyl group was obtained. This result was unusual since the oxygen in all the substances investigated was accounted for in forms other than alkoxyl groups. It was then demonstrated that the silver iodide was not derived from methyl iodide or from the reagent and, further, that the apparatus was not responsible for it.

These facts were proved by running blank determinations on the reagents

[3] Weishut, *Monatsh.*, 33, 1165 (1812).

and by using the method of Willstatter and Utzinger[4] in which the alkyl iodide was caught in trimethylamine and the solubility of the addition product was studied. In performing this experiment, hexa-acetylapogossypol was employed. From analysis it was known that this material gives silver iodide equivalent to 3.9% of methoxyl. With this in mind, a quantity of the acetyl derivative equivalent to 7 mg. of methoxyl was treated in the Zeisel apparatus as described under "Experimental," and the alkyl iodide was collected in trimethylamine solution. No insoluble addition product formed, however, although in a control experiment with a quantity of a known compound equivalent to **3** mg. of methoxyl, sufficient tetramethylammonium iodide was precipitated to make it possible to obtain 10 mg. of the material in a pure dry condition. These facts showed, although indirectly, that the alkyl iodide was not methyl iodide and hence was not derived from a methoxyl group. This does not in itself exclude the possibility of the presence of other alkoxyl groups, but their existence seems impossible since all of the oxygen in the gossypol derivative used in this experiment is accounted for as acetyl groups.

In view of these results, the most plausible explanation of this unusual situation is that prolonged heating of these compounds with the reagents used causes the gossypol nucleus to decompose in such a manner as to yield an alkyl iodide. One process by which this could be accounted for is the formation of formaldehyde which, with hydriodic acid, would yield methylene iodide, finally resulting in the production of silver iodide.

In this work it was not feasible to use the ordinary macro-Zeisel method on account of the lack of a plentiful supply of the material. Neither was a strictly micro-Pregl methoxyl determination possible because of not having the necessary equipment, especially a micro-balance. A method based largely upon Pregl's work, however, was adopted in which samples of about 20 mg. were successfully analyzed, employing an ordinary analytical balance sensitive to 0.1 mg. Since this procedure was developed for this investigation, the following description of the apparatus and the technique employed in the determination is given.

Incidentally, by this method the methoxyl content of apogossypol hexamethyl ether, previously reported[5] as entirely resistant to boiling hydriodic acid, has been determined.

Experimental

Determination of Methoxyl Groups on Samples of Approximately 20 **Mg.**—The apparatus employed for this purpose is shown with all necessary specifications in Fig. 1.

Approximately 20 mg. of substance upon a balanced piece of cigarette paper 2 by **3** cm. is weighed on an ordinary analytical balance sensitive to 0.1 mg. The paper containing the substance is placed in the bottom of the boiling flask, **A,** together with a

boiling rod.[6] About 2.5 cc. of melted phenol and 5 cc. of constant boiling hydriodic acid solution of the quality employed in Zeisel determinations are added. The flask is connected by tension springs to the remainder of the apparatus, which consists of the trap B containing a small quantity of red phosphorus, suspended in water, and the receivers C, and D, containing alcoholic silver nitrate. The phosphorus is purified according to the directions of Pregl[7] and is used in the same manner except that one charge may be employed for four or five determinations. The alcoholic silver nitrate solution is also prepared according to Pregl. Seven cc. are used in C and 4 cc. in D. A slow, uniform stream of carbon dioxide is passed through the capillary side arm of the boiling flask and the liquid is gently boiled by means of a mantled microburner at such a rate that the vapors of the boiling liquid rise to approximately 8 cm. from the first bend in the air condenser. After about three minutes the white double compound of silver nitrate and silver iodide appears in the first silver nitrate tube. For most substances thirty minutes is sufficient to complete the reaction and sweep out the apparatus. The contents of both the tubes C and D and any precipitate adhering to the adapter are washed into a 150-cc. beaker with approximately 75 cc. of water. The liquid is made acid with nitric acid and allowed to stand on a steam-bath overnight, or until all of the silver iodide has separated and the mother liquors are entirely clear.

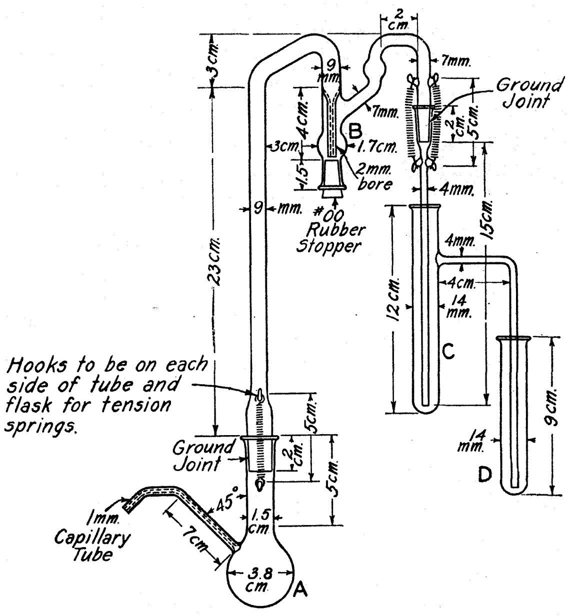

Fig. 1.—Semi-micro Zeisel methoxyl apparatus.

---

[6] The boiling rod used here is a glass tube approximately 60 mm. long, 3.5 mm. outside diameter, with a 1-mm. bore. It is sealed at one end and also closed about 10 mm. from the other. The open end is fire polished. When this is placed in the flask with the open end down, it will cause uniform boiling indefinitely so long as sufficient heat is constantly applied to the liquid.

[7] Pregl, "Quantitative Organic Microanalysis," Translated by Fyleman, P. Blakiston's Sons and Company, Philadelphia, 1924, p. 155–156.

The precipitate is transferred to a sintered-glass Pregl filtering tube having a porosity less than 7, in accordance with the technique of Pregl.[8] After the silver iodide is thoroughly washed, it is dried at 100° to constant weight. Usually half an hour is sufficient for this purpose. When the tubes are being weighed before and after collecting the silver iodide, another tube of the same type and size is always used as a tare.

The apparatus and procedure were tested on pure vanillin and α-methylglucoside. The results obtained are recorded in Table I.

TABLE I

RESULTS OBTAINED IN TESTING THE SEMI-MICRO ZEISEL METHOD

Substance	Sample, mg.		AgI, mg.		Methoxyl, % Calcd.	Methoxyl, % Found	
Vanillin	21.2	20.3	32.3	31.4	20.40	30.23	20.44
or-Methylglucoside	21.4	20.6	25.6	24.9	15.98	15.81	15.97

When these experiments were repeated without phenol, the results were uniformly about 0.5% low.

TABLE II

METHOXYL VALUES OF SOME GOSSYPOL DERIVATIVES AS INFLUENCED BY THE DURATION OF BOILING

Substance	Sample, mg.	AgI obtained, mg.	Period of boiling. hours	OCH_3 found. %
Tetramethoxypseudogossypolone; mol. wt.,	20.9	37.6	0.5	23.77
546.4; calcd. for 4 OCH_3 groups, 22.7%	20.5	36.9	0.5	23.79
of methoxyl	21.8	44.5	3	27.0
	21.8	44.7	3	27.1
	25.4	52.7	6	27.4
Apogossypol hexamethyl ether; mol. wt.,	21.1	54.8	0.5	34.32
546.5; calcd. for 6 OCH_3 groups, 34.07%	20.5	53.0	0.5	34.17
of methoxyl	20.4	58.4	4	37.83
	20.3	58.0	4	37.76

In Table III data are given showing the quantity of silver iodide obtained from several gossypol derivatives upon prolonged boiling (three to four hours). The oxygen in all of these substances is accounted for in forms other than alkoxyl groups.

TABLE III

SHOWING THE YIELD OF SILVER IODIDE OBTAINED FROM SOME GOSSYPOL DERIVATIVES

Substance	Mol. wt.	Sample, mg.	AgI obtained, mg.	Calcd. to methoxyl, %
Gossypol	518.4	21.4	9.2	5.7
Apogossypol hexa-acetate	714.5	20.2	5.9	3.9
Apogossypolone tetra-acetate	548.4	20.7	8.1	5.2
Hexa-acetylgossypol	770.5	21.6	3.3	2.0
Tetra-acetylgossylpolone	618.4	20.0	5.9	3.9

From the figures presented before concerning tetramethoxypseudogossypolone and apogossypol hexamethyl ether, it will be seen that in the former

---

[8] Ref. 5, p. 113.

instance three to six hours' boiling gave results from 4.4 to 4.7% high; whereas in the latter case the results were 3.7% high. These quantities, in excess of that demanded by theory, are of the same order of magnitude as those obtained on the products recorded in Table III.

Summary

In the Weishut–Zeisel methoxyl determination, gossypol and some of its derivatives, although containing no *alkoxyl* groups, yield upon prolonged boiling a small quantity of silver iodide.

The silver iodide thus formed is responsible in some cases for the abnormally high values obtained in the Zeisel determination of the methoxyl groups in several oxymethylgossypol derivatives.

The explanation has been advanced that under the conditions of the Weishut–Zeisel determination the gossypol nucleus is disrupted in such a manner as to yield an alkyl iodide. This iodide, however, is not methyl iodide.

A description is given of an apparatus and a procedure for the determination of methoxyl groups in samples of the order of 20 mg. In this method an ordinary analytical balance sensitive to 0.1 mg. is employed.

THE PREPARATION AND PROPERTIES OF THE ISOMERIC HEPTANES. PART I. PREPARATION[1]

BY GRAHAM EDGAR, GEORGE CALINGAERT AND R. E. MARKER

RECEIVED NOVEMBER 7, 1928 PUBLISHED MAY 6, 1929

I. Introduction

In connection with a study in this Laboratory of certain properties of aliphatic hydrocarbons, it was decided to investigate each of the nine isomeric heptanes. This group includes nearly every type of structure which an aliphatic hydrocarbon may have, and yet is not too large to make its synthesis impracticable.

Only one of the heptanes, the normal, was available in reasonable quantity, from Jeffrey pine oil.[2] The others were synthesized in considerable quantities by methods described below.

Inspection of the literature showed that the data on physical properties of even normal heptane leave much to be desired, although the work of Kremers and others in recent years has increased considerably our knowledge of this hydrocarbon. Few reliable data were available in the older

---

[1] Presented at the Symposium on Organic Chemistry, Columbus, Ohio, December 29. 1927.

[2] E. Kremers, J. Am. *Pharm. Assocn.*, 9, 857 (1920).

literature on the properties of any of the other isomers. Chavanne and his co-workers[3] have recently synthesized several of the isomers and determined some of their properties. The amounts synthesized, however, were small, and the authors scarcely attempted to determine the properties of the compounds beyond what was necessary for identification. It was therefore decided to measure with reasonable accuracy such physical properties of these hydrocarbons as could be conveniently measured in this Laboratory, and to enlist the aid of other laboratories well equipped to measure other properties. From these investigations there has resulted a rather complete collection of data concerning these heptanes. The data are of particular interest in that all of them were obtained on the same actual samples of material. Some of the data have been already published,[4] and other data will be published later.

Part I of this paper presents the methods of preparation of the heptanes and such physical properties as are commonly employed for purposes of identification. Part II will summarize the entire data, published and unpublished, referred to above, and will discuss the effect of structure upon physical properties in general, and upon certain physical properties in particular.

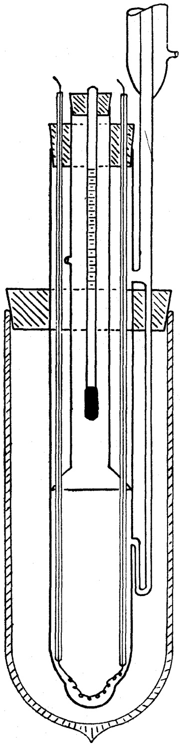

Fig. 1.

II. Experimental

(1) Methods of Synthesis.—Six of the nine heptanes were prepared by the method which has become classical since its systematic use by Chavanne and his co-workers.[3] It consists in the condensation by means of a Grignard reaction of two suitably chosen radicals, one being present as alkyl halide, the other as aldehyde, ketone or ester. The resulting secondary or tertiary alcohol is dehydrated, and the unsaturated hydrocarbon or hydrocarbons so formed, hydrogenated. This general method had to be modified slightly to fit each individual case. A complete description is given therefore in one case, only the variations being specified for the other preparations.

Of the three other heptanes, the normal is already available from Jeffrey pine oil.[2] The other two, 2,2-dimethylpentane and 3,3-dimethyl-

[4] C. P. Smyth and W. N. Stoops, THIS JOURNAL, 50, 1536 (1928); G. W. Stewart, *Phys. Rev.*, 32, 1153 (1928); Freyer, Hubbard and Andrews, THIS JOURNAL, **51**, 759 (1929); M. S. Kharasch, *Bureau of Standards Journal of Research*, 2, *373* (1929).

pentane could not be obtained pure by the general method of preparation (see Note 2, p. 1487) and their synthesis is fully described hereunder.

The main object of the work being the preparation of the heptanes in a state of high purity, comparatively little attention was paid to the intermediate products. The boiling points and specific gravities mentioned here for the alcohols and olefins are to be taken more as indications of the distillation cuts which were used than as accurate physical constants of these compounds. The boiling range given for the heptanes, however, represents the *entire boiling range* of the refractionated sample, temperatures being taken at the top of an efficient column. The alcohols obtained are always individual compounds, while the olefins may be mixtures of two or more isomers, differing only by the position of the double bond. The quantities given here refer to the size of a batch in each preparation, the total amount of heptanes prepared and purified being given at the end. The yields given are those obtained on the preparations as described. No doubt some of them at least could be improved by a careful study of the reaction.

The general method of preparation is fully described in the case of 2-methylhexane. The other preparations are given in tabular form.

2-Methylhexane

(a) 2-Methyl-2-hexanol.—To a solution of the Grignard reagent prepared from 6.5 moles of magnesium and 6.5 moles of n-butyl bromide in 2500 cc. of anhydrous ether was added slowly with stirring 6 moles of very pure acetone in an equal volume of anhydrous ether. After standing overnight, the mixture was decomposed by water and ice. More ice was added and the precipitated magnesium compounds dissolved in 10% hydrochloric acid. The ether layer was separated, washed with dilute sodium carbonate, with distilled water, then dried with anhydrous sodium sulfate and fractionated; yield. 640 g. (92%); b. p. 137–141°; d_{20}^{20}, 0.815.[5]

(b) 2-Methyl-2-hexene.—A mixture of 580 g. of the carbinol (a) and 1 g. of iodine was slowly distilled, keeping the distilling temperature at 81–83°. The distillate was washed with a sodium thiosulfate solution, with distilled water, then dried with calcium chloride and twice fractionated over metallic sodium; yield, 465 g. (95%); b. p. 94.5–96°.[6]

(c) **2-Methylhexane.**—By means of a nickel catalyst at 150°, 465 g. of the olefin (b) was hydrogenated. One passage over the catalyst gave nearly complete reduction, as shown by titrating a sample with bromate–bromide solution. The product was shaken with several portions of concd. sulfuric acid until a fresh lot of acid showed no yellow color. It was washed with water, then dried over calcium chloride, refluxed over sodium for several hours and then fractionated from sodium; yield 385 g. (82%); b. p. 89.7–90° (760 mm.).

---

[5] The density of the carbinols was determined roughly by means of a Westphal balance.

[6] It was found inadvisable to dehydrate the alcohol by means of *p*-toluenesulfonic acid because the introduction of sulfur compounds caused poisoning of the catalyst. The use of the sulfonic acid also gave a product of much wider boiling range, indicating the presence of isomeric olefins.

Preparation of the Carbinols

The following carbinols were prepared by the Grignard reaction as outlined above.

TABLE IA

REAGENTS

Halide	Moles	Carbonyl compound	Moles
n-Propyl bromide	4	Methylethyl ketone	4
Ethyl bromide	4	Ethyl propionate	2
Isobutyl bromide	4.5	Acetone	4
Sec.-butyl bromide	3	Acetone	3
Tert.-butyl chloride	4	Acetone[a]	3

[a] The acetone used must be of very high purity; otherwise polymerization occurs and no alcohol is obtained.

3-Methyl-3-hexanol	297	64	137–139	0.823
3-Ethyl-3-pentanol[a]	194	83	140–142	.839
2,4-Dimethyl-2-pentanol	252	54	127–129	..
2,3-Dimethyl-2-pentanol	122	35	129–130.5	.805
2,2,3-Trimethyl-3-butanol[b]	97	28	130	..

[a] This alcohol dehydrates very easily. If it is desired to isolate it pure, it is advisable to avoid entirely the presence of iodine.

[b] The carbinol melts at 17°. It is very hygroscopic and forms a hydrate with m. p. around 80°. When it is distilled in small amounts and without special precautions, only the hydrate is obtained. When larger quantities are handled, the distillate is a mixture of the liquid carbinol and of acicular crystals of its hydrate. The carbinol crystallizes instantly when shaken with a small amount of water. The hydrate loses its water readily when kept in a desiccator over barium oxide.

Preparation of the Olefins

The olefins were prepared from the corresponding carbinols as described above.

TABLE II

REAGENTS, PRODUCTS AND DATA

Carbinol used	G.	Product	Yield g.	Yield %	B. p., °C.
3-Methyl-3-hexanol	297	3-Methyl-3-hexene	234	93	93–96
3-Ethyl-3-pentanol	116	3-Ethyl-2-pentene	93	95	95–97
2,4-Dimethyl-2-pentanol	232	2,4-Dimethyl-2-pentene	178	91	81–83
2,3-Dimethyl-2-pentanol	588	2,3-Dimethyl-2-pentene	324	54	92–95
2,2,3-Trimethyl-3-butanol	348	2,2,3-Trimethyl-3-butene	279	95	76–78

Reparation of the Heptanes

The olefins were hydrogenated as described above.

TABLE III

REDUCTION OF OLEFINS

Olefin	G.	Product	Yield g.		B. p., °C. (760 mm.)
3-Methyl-3-hexene	234	dl-3-Methylhexane	206	87	91.4–91.7
3-Ethyl-3-pentene	292	3-Ethylpentane	238	80	93.2–93.5
2,4-Dimethyl-2-pentene	245	2,4-Dimethylpentane	202	81	80.5–81.1
2,3-Dimethyl-2-pentene	360	*dl*-2,3-Dimethylpentane	290	87	89.5–89.9
2,2,3-Trimethyl-3-butene[a]	284	2,2,3-Trimethylbutane	250	86	80.9–81.2

[a] The heptene hydrogenated very readily on one passage through the catalyst tube.

2,2-Dimethylpentane.—To the Grignard reagent prepared from 4 moles each of magnesium and n-propyl bromide were added with vigorous stirring 4 moles of *tert.*-butyl chloride and 30 g. of mercuric chloride. Some gas was evolved and the mixture soon settled to a compact solid. After standing overnight the mixture was decomposed as usual. The ether layer was washed, dried and fractionated. The fraction boiling above 50° was washed with cold concd. sulfuric acid several times, with sodium carbonate solution, then dried with calcium chloride, refluxed over sodium for several hours and finally fractionated from sodium; yield, 84 g. (21%); total hydrocarbon prepared, 240 g.; b. p. 78.2–79.5° (760 mm.).

3,3-Dimethylpentane.—This was prepared in a similar way by treating the Grignard reagent from 9 moles of ethyl bromide with 6 moles of *tert.*-amyl chloride and 30 g. of mercuric chloride; yield, 77 g. (13%); total hydrocarbon prepared, 77 g.; b. p. 85.7–86.1° (760 mm.).

NOTE 1.—The low yields obtained with the last two hydrocarbons are due to side reactions giving octane and hexane in one case, and decane and butane in the other, and also to the removal of halogen acid to form olefins in both cases. In a second preparation of 3,3-dimethylpentane a yield of 27% was obtained.

NOTE 2.--Several attempts were made to prepare these two hydrocarbons by the methods employed with the other hydrocarbons. These attempts were unsuccessful due to rearrangements which took place on dehydrating the alcohols.

(a) 2,2-Dimethyl-3-pentanol, from 5 moles of *tert.*-butyl chloride and 1.65 moles of propionaldehyde by the Grignard reaction; yield, 116 g. (60%); b. p. 136–137°; d_{20}^{20}, 0.826.

(b) Over 400 g. of this carbinol was dehydrated either with iodine, zinc chloride or *p*-toluenesulfonic acid. The corresponding bromide was also changed to the olefin by heating with quinoliie. In every case the resulting heptene showed a very wide boiling range (80–90°, mostly 88–90°). No heptane of satisfactory purity could be obtained from it. A study of the physical properties of the product showed it to be a mixture of 2,2-dimethyl- and 2,3-dimethylpentane.

(c) 3,3-Dimethyl-2-pentanol from 4 moles each of *tert.*-amyl chloride and acetaldehyde; yield, 144 g. (36%); b. p. 147–148°; d_{20}^{20}, 0.829.

(d) Dehydration and hydrogenation again gave a mixture of heptanes, 3,3-dimethyl- and 2,3-dimethylpentane, the latter predominating.

These experiments indicate that on dehydration 2,2-dimethyl-3-pentanol and 3,3-dimethyl-2-pentanol rearrange to a large extent, either by direct migration of a methyl group, or by intermediate formation of a cyclopropane ring. The latter course does not seem unlikely to be the one followed, in light of the rearrangements discussed by Brooks.[7]

Normal **Heptane.**—This is now available in large quantities from Jeffrey pine oil.[2]

---

[7] Brooks, "The Non-Benzenoid Hydrocarbons," The Chemical Catalog Co., Inc., New York, 1922, p. 70.

A product of this origin was purified from a small amount of terpene and aldehyde either by treatment with iodine[2] or by shaking with sulfuric acid and then with aqueous potassium permanganate. The final product, fractionated over sodium, showed a very sharp boiling point, indicating the absence of other hydrocarbons of the paraffin series. It may also be prepared by either one of the methods outlined above. Another method which has been used successfully by the authors is the reduction of n-heptyl bromide by sodium in liquid ammonia, according to the method described elsewhere for the preparation of *n*-butane.[8]

(2) Measurement of Boiling Point, Refractive Index, Specific Gravity, Freezing Point and Critical Temperature of Solution in Aniline

Boiling points were measured in an apparatus outlined in Fig. 1, employing internal electric heating, vapor lagging of the thermometer, protection from radiation losses by a vacuum flask and, of course, appropriate corrections for thermometer error and barometric pressure.

Refractive indices were measured in an Abbé refractometer, employing sodium light. Since the data were later determined with greater precision by Smyth,[4] his data, which agreed very well with those of the authors, have been employed. Specific gravities were determined in a 25-cc. Sprengel pycnometer at two temperatures near 20°. The data are practically identical with those determined later by Smyth and Stoops.[4]

Melting points were determined by Dr. R. N. Pease, of Princeton University, to whom the authors are much indebted for the actual measurements and for permission to include them in this paper. The method employed was the use of a three-junction copper–constantan thermocouple and a sensitive potentiometer carefully calibrated against the melting

TABLE IV

PHYSICAL PROPERTIES OF THE HEPTANES

	B. p. (760 mm.), °C.	M. p., °C.	d_4^{20} [a]	n_D^{20}	C.T.S. (aniline), °C.
n-Heptane	98.4	− 90.5	0.6836	1.38777	70.0
2-Methylhexane	90.0	−119.1	.6789	1.38509	74.1
3-Methylhexane	91.8	.....	.6870	1.38873	70.5
3-Ethylpentane	93.3	.....	.6984	1.39366	66.3
2,2-Dimethylpentane	78.9	−125.6	.6737	1.38233	77.7
2,3-Dimethylpentane	89.7	.....	.6952	1.39201	68.1
2,4-Dimethylpentane	80.8	−123.4	.6745[b]	1.38233	78.8
3,3-Dimethylpentane	86.0	−135.0[c]	.6934	1.39114	71.0
2,2,3-Trimethylbutane	80.9	− 25.0	.6900	1.38940	72.4

[a] The average temperature coefficient of specific gravity is 0.00085 per degree.

[b] A later preparation gave a material of d_4^{20}, 0.6731, indicating a possible error in the earlier determination. The difference, however, is, not sufficient to affect any of the conclusions drawn in Part II of this paper.

[c] This value was determined by Dr. George S. Parks, of Stanford University, to whom the authors are very much indebted.

---

[8] G. Calingaert and L. B. Hitchcock, THIS JOURNAL, 49, 750 (1927).

points of monochlorobenzene, toluene, carbon disulfide, ethyl ether and the sublimation point of carbon dioxide. Unfortunately four of the isomers could not be frozen, but solidified to a glass. Apparently the increasing viscosity and low melting points of some of the isomers make it very difficult to freeze them, as the same difficulty has been reported by Timmermans?[9] It is hoped that the melting points of all of the isomers may eventually be determined.

Critical solution temperatures in aniline are frequently employed for identification of hydrocarbons and were therefore determined for the isomers in an air-jacketed test-tube, using freshly distilled C. P. aniline and making appropriate thermometer correction.[10] These data are summarized in Table IV.

III. Discussion

(a) Synthetic Methods.—While there is nothing particularly novel about the methods employed in the synthesis of these hydrocarbons, the results obtained serve to illustrate the value of the carbinol–olefin–paraffin method. It is theoretically possible to prepare any paraffin by these methods; in most cases the raw materials are available, not too expensive and the reactions direct and clean cut. It is clear, however, from the discussion in Note 2 that care must be taken in interpreting the course of the reactions, particularly when dehydrations are involved of carbinols in which the alcohol group is adjacent to a tertiary group. Rearrangement is usually indicated by a wide boiling range in the dehydrated product, but may be so complete as to be unnoticed. In the present work identification of the compounds was aided by the fact that all of the possible isomers were prepared.

When the raw materials involved are sufficiently inexpensive the present modification of the Würtz synthesis (preparations of 2,2- and 3,3-dimethylpentane) is time saving and fully satisfactory from the standpoint of purity, although the yields are low.

The two preparations in which this synthesis was employed involved the reaction of tertiary halides, and it is not established that other halides will behave similarly. The chlorides of other heavy metals have been employed by the authors for similar syntheses, with varying degrees of success.

(b) Probable **Purity** of **the** Hydrocarbons.—In a group of hydrocarbons like the heptanes the determination of purity is somewhat difficult. Absence of extraneous substances may be easily assured and the presence of paraffins other than heptanes is usually unlikely; the freedom from isomers is more difficult to detect. There are no specific chemical tests and the ordinary physical properties such as boiling point, refractive index and

---

[9] Timmermans, *Bull. soc. chim. belg.*, 36, 502 (1927).

[10] These values were determined by Mr. D. T. Flood of this Laboratory.

density, are little separated in some cases. Freezing point measurements would show more variation but these are not available in all cases. For preparations in question the sharpness of boiling points of the purified products, combined with the available data on melting points and other properties, indicates that the compounds were unusually pure and free from other isomers. This makes the data on their physical properties particularly valuable.

(c) Comparison of the Physical Data with the Literature.—In general there is good agreement with the most reliable data in the literature, though a few exceptions deserve mention.

3-ETHYLPENTANE

Data of	Konovalow[11]	"Int. Crit. Tables"	Authors
B. p., °C.	95–98	93.8	93.3
d_4^{20}	0.695 (extrapolated)	0.670	0.6984

Konovalow's data agree with those of the authors sufficiently for a product which was admittedly not very pure. The boiling point given in "International Critical Tables" from an unknown source appears to be a little high, while the density is so low as to suggest a typographical error. The detailed discussion of the variation of physical properties with structure, which will be presented in Part II, will show that it is highly improbable that this isomer should have a density lower than that of normal heptane.

2,2-DIMETHYLPENTANE

Observer	DeGraef[3d]	Timmermans[8]	Authors
M. p., °C.		-137.0	-125.6

A private communication from Professor Timmermans has advised the authors that the above figure was in error on account of a faulty thermometer. Professor Timmermans has recalculated his own data and reports the corrected value as -122.5".

2,4-DIMETHYLPENTANE

Data of	Chavanne and DeGraef[3]	"Int. Crit. Tables"	Authors
B. p., °C.	80.9	83.9	80.8
d_4^{20}	0.6731	0.681	0.6731
M. p., °C.	-119.4	......	-123.4

Here again the figures given in "International Critical Tables" appear to the authors to be of doubtful value. Both the boiling point and density are almost certainly too high. The discrepancy of 4° between the melting point reported by Chavanne and that of the authors does not seem to be accounted for by impurities in the authors' sample because of the nature of the cooling curve obtained, which could not be interpreted so as to change the recorded value by more than one degree.

[11] Konovalow, *Chem.* Centr., I, 2143 (1908).

Summary

The nine isomeric heptanes have been obtained in considerable quantity and excellent purity and have been identified with certainty. One was isolated from a natural product and the other eight were prepared by two methods, alcohol–olefin–paraffin and modified Wiirtz. Their boiling points, specific gravities, refractive indices and critical solution temperatures in aniline are presented, with the melting points of five of them.

THE REACTION OF ORGANIC MERCURY COMPOUNDS WITH ORGANIC HALIDES. II[1]

BY FRANK C. WHITMORE AND E. N. THURMAN

RECEIVED NOVEMBER 21, 1928 PUBLISHED MAY 6, 1929

The present research was undertaken to study the failure of organic halides to react "metathetically" with organic mercury compounds to give lengthened carbon chains according to the equations

$$R_2Hg + R'X \longrightarrow R{-}R' + RHgX$$
$$RHgX + R'X \longrightarrow R{-}R' + HgX_2$$

The original attempt at such a reaction was partly successful.[2] Mercury diphenyl heated with benzal chloride at 150° without a solvent gave some triphenylmethane. Almost all later attempts to extend this reaction have failed. These attempts have been very scattering and no systematic study of the reaction has been made.[3]

For the present study it was decided to treat a representative variety of organic halides with a single mercury compound under comparable conditions to determine the ease of reaction and the nature of the products formed. It seemed best to use an aromatic mercury compound for the following reasons: (1) aromatic mercury compounds being only slightly volatile are less dangerously poisonous, (2) they are more stable toward heat and (3) they give products more easily identified. The most readily available compound was mercury di-*p*-tolyl.[4] In one case mercury di-*n*-butyl was also used. After the projected study had been completed, work appeared which could be interpreted as indicating mercury diphenyl

to be much more reactive than mercury ditolyl.[6] Consequently, several of the reactions have been repeated with mercury diphenyl by F. L. Carnahan of this Laboratory. Mercury diphenyl was found to be only slightly more reactive than mercury ditolyl in the cases studied.

The mercury ditolyl proved to be extraordinarily unreactive in about half the cases studied. When reactions took place, the peculiarities of the mercury compound were found to differ only in degree from those of other types of bases in their reactions with organic halides. A thorough search of the literature showed that the types of bases represented by sodium hydroxide, sodium amide, sodium methylate, sodium hydride and sodium methyl, namely, aquo, ammono, alcoholo, hydro and hydrocarbo bases, often fail to give the "metathetical" reactions which would be represented by the equation

$$RX + MB \longrightarrow RB + MX \qquad (I)$$

in which R is any organic radical, X is a halogen, M is a metal and B is a "basic" radical such as hydroxyl, amino, methoxyl, negative hydrogen or methyl.

A much more general reaction with all types of bases is the removal of halogen acid to form an ethylenic linkage according to the equation

$$R_2CXCHR_2 + MB \longrightarrow R_2C{=}CR_2 + MX + HB \qquad (II)$$

in which the R's represent hydrogen atoms and organic radicals. A special case of the removal of halogen acid is given by the equation

$$2R_2CHX + 2MB \longrightarrow R_2C{=}CR_2 + 2MX + 2HB \qquad (III)$$

The "metathetical" reactions illustrated by Equation I probably consist in the union of the two free radicals liberated by the union of M and X to form a salt, MX. Sometimes when hydrocarbo bases are used the similar radicals combine according to the equation

$$2RX + 2MR' \longrightarrow R{-}R + R{-}R + 2MX \qquad (IV)$$

Another possibility with hydrocarbo bases is the disproportionation of the free radicals to form saturated and unsaturated compounds.

$$R_2CHCH_2X + MCH_2CHR_2 \longrightarrow R_2CHCH_3 + R_2C{=}CH_2 + MX \qquad (V)$$

Another type of reaction given by hydrocarbo bases but not by aquo, ammono or alcoholo bases is the removal of two halogen atoms from adjacent carbon atoms.

$$R_2CXCXR_2 + MR \longrightarrow R_2C{=}CR_2 + RX + MX \qquad (VI)$$

In this case R may also be hydrogen or even halogen.

In certain rare cases the metal takes the place of the halogen, $RX + MB \longrightarrow MR + BX$. Usually BX is a very reactive substance capable of reacting with another molecule of MB. The net reaction thus becomes

$$RX + 2MB \longrightarrow RM + B{-}B + MX \qquad (VII)$$

---

[5] Calvery, THIS JOURNAL, 48,1009 (1926).

The organic mercury compounds studied with various halides were found to give the reactions represented by Equations I, II, III and VI. The surprising fact noted in most of the work was the very slight reactivity of the mercury compounds with halides. In most cases it was necessary to heat the solutions at 110° for about **300** hours to bring about the reactions. Even under such drastic conditions more than half of the halides failed to react and were recovered unchanged.

The general procedure was to reflux the halide with an excess of the mercury compound in dry toluene solution for about **300** hours or until reaction had taken place. In a few cases, in which a lower boiling solvent seemed desirable, carbon tetrachloride or chloroform was used.

Of the thirty-two organic halides studied eighteen gave no perceptible reaction even after refluxing for **300–350** hours in dry toluene with an excess of mercury di-p-tolyl. In these cases the mercury compounds and the halide were recovered unchanged. The mercury compound was in each case tested qualitatively for halogen to see if any *p*-tolylmercuric halide had been formed, thus indicating some reaction. The mercury ditolyl was free from halogen in each case.

The halides which gave no reaction with mercury di-p-tolyl on refluxing in toluene for **300–350** hours may be classified as follows: alkyl halides (*sec.*-butyl iodide, lauryl bromide), alicyclic halide (cyclohexyl bromide), unsaturated halide (allyl iodide),[6] halogenated ketone (α-bromo-camphor), halogenated esters, (ethyl dibromo-acetate, methyl α-bromo-*iso*butyrate),[7] acid halide (benzoyl chloride),[8] polyhalogen aliphatic compounds (ethylidene chloride, ethylene dibromide, tetrachloro-ethane, hexachloro-ethane), halogenated ethers (β-bromo-ethyl phenyl ether, γ-bromopropyl phenyl ether), toluene halogenated in the side chain (benzyl iodide, benzal chloride, benzo trichloride) and aromatic halide (*sym.*-trinitrophenyl iodide (picryl iodide)).[9]

[6] Carbon tetrachloride was used as solvent, as the temperature of boiling toluene decomposed the halide. No reaction took place after 120 hours' refluxing in carbon tetrachloride.

[7] No action was noticeable after refluxing in carbon tetrachloride solution for 336 hours. Refluxing for 300 hours in toluene solution appeared to give a slight reaction, as evidenced by the formation of a trace of tolylmercuric bromide.

[8] Benzoyl chloride was also refluxed with mercury diphenyl in dry benzene for 86 hours according to the directions of Calvery (ref. 5) except that an excess of the mercury compound was used. No benzophenone was obtained. The mercury diphenyl was recovered unchanged. The benzoyl chloride was unchanged. It was identified by conversion to the amide. The result of this experiment is in marked contrast to that obtained with an excess of the acid chloride.

[9] The statement appears in the literature, THIS JOURNAL, 43, 2243 (1921), that 2,4,6-trinitrophenylmercuric chloride reacts with iodine to give a mixture of picryl iodide and "presumably" hexanitrodiphenyl. This might be taken as an indication that picryl iodide reacts with the mercury compound to give hexanitrodiphenyl. An ex-

Six of the halides reacted with mercury ditolyl to give tolylmercuric halides and tarry products from which no other known substance could be isolated. These halides were bromonitromethane, which reacted completely on refluxing in carbon tetrachloride for 200 hours (shorter treatments gave no more satisfactory results); acetyl iodide, which reacted vigorously with mercury ditolyl at room temperature; dibenzoylbromomethane, w-bromo-acetophenone, phenyliodo-acetylene, iodo-acetonitrile. Two of the halides gave indefinite results and should be studied more fully. They were triphenylchloromethane and methyl α-bromo-*iso*butyrate (in toluene).

Ethyl bromomalonate reacted only partly with mercury ditolyl after refluxing in toluene for 336 hours. A considerable amount of tolylmercuric bromide was formed. The other substances found included unchanged ethyl bromomalonate, ethyl malonate, p-tolyl bromide and a small amount of an unidentified ester boiling at 205–210° (8 mm.). Since these products were hard to explain, the experiment was repeated on a larger scale using 100 g. of the ester and 335 g. of the mercury compound. The same products were obtained. The products separated accounted for 91% of the starting materials.

Five of the halides gave definite reactions. These correspond to four of the general types of reactions given by halides with the various classes of bases.

Reaction I. "Metathesis."—Diphenylbromomethane reacted with mercury di-*p*-tolyl on refluxing in toluene solution for 200 hours to give an 80% yield of diphenyl-*p*-tolylmethane. The same product was obtained when the reaction was repeated using pure m-xylene as solvent. This result showed that the solvent did not react with any free radical formed in the reaction. When mercury diphenyl was substituted for the tolyl compound, triphenylmethane was obtained in 90% yield. When mercury di-n-butyl was used, the products after refluxing for 340 hours were n-butylmercuric bromide, metallic mercury, a trace of mercurous bromide, a little tetraphenylethane and a 35% yield of diphenyl-*n*-butylmethane. The metallic mercury was due to the thermal decomposition of the mercury dibutyl, and the tetraphenylethane resulted from the action of mercury on the original bromide. These reactions were confirmed by side experiments.

The reaction of diphenylbromomethane with organic mercury compounds is as follows

$$(C_6H_5)_2CHBr + R_2Hg \longrightarrow R(C_6H_5)_2CH + RHgBr$$

---

periment showed that these substances do not react with each other. Consequently, the original experiment was repeated. It was found that iodine reacts normally with both 2,4,6-trinitrophenylmercuric chloride and the corresponding mercuri-*bis* compound. In the latter case 66% alcohol had to be used as a solvent instead of water. Picryl iodide was formed in both cases. No hexanitrodiphenyl was found.

This halide reacts similarly with other types of bases. Alcoholic potassium hydroxide gives the ethyl ether of benzhydrol.[10] It also reacts "metathetically" with methyl- and ethylmagnesium bromides, giving the corresponding diphenylalkylmethanes.[11] It reacts with *p*-tolylmagnesium bromide to give good yields of *p*-tolyldiphenylmethane.[12]

Reaction II. Removal of HX.—*Tert.*-butyl bromide reacted almost quantitatively with mercury di-p-tolyl in carbon tetrachloride after refluxing for 340 hours. The products were tolylmercuric bromide, toluene and *iso*butylene. Mercury diphenyl gave similar results but seemed to react slightly more rapidly than the tolyl compound.

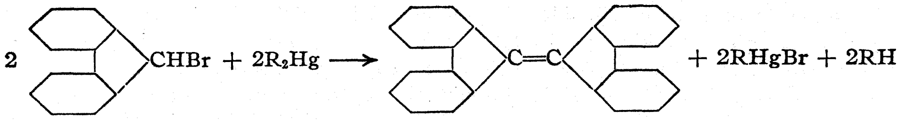
Tert.-amyl iodide gave similar results with mercury ditolyl and mercury diphenyl. When an excess of the iodide was used with mercury ditolyl, the products were mercuric iodide, toluene and trimethylethylene.

The tertiary halides react as follows

$$R_2CXCH_2R + R_2'Hg \longrightarrow R_2C{=}CHR + R'HgX + R'H$$

Tertiary halides react with other types of bases to give olefins.[13] These reactions differ from those with the mercury compounds in giving some of the "metathetical" product as well as the olefin. A similar reaction was obtained with mercury ditolyl and 1-bromo-1,1,2-tricarbethoxyethane, $(C_2H_5O_2C)_2C{=}CHCO_2C_2H_5$, being formed.

Reaction III. Removal of HX through "Methylene Dissociation."--Diphenylenebromomethane (9-bromofluorene), although it differs so slightly from diphenylbromomethane, reacts entirely differently with bases. After refluxing with mercury ditolyl and mercury diphenyl in toluene for 300 hours, the products isolated were the aryl mercuric bromides and *bis*-diphenylene ethylene.



To make sure that the mercury compound was necessary for the formation of the ethylene compound, 9-bromofluorene was refluxed alone in toluene for 120 hours. The halide was recovered unchanged. 9-Bromofluorene gives an entirely similar reaction with alcoholic potassium hydroxide.[14]

Reaction VI. Removal of Bromine.—Stilbene dibromide reacts with

mercury ditolyl after refluxing in toluene for 340 hours to give the tolylmercuric bromide, tolyl bromide and stilbene.

$$C_6H_5CHBrCHBrC_6H_5 + 2R_2Hg \longrightarrow C_6H_5CH{=}CHC_6H_5 + 2RBr + 2RHgBr$$

The tendency of stilbene dibromide to lose bromine is shown by its reactions with a number of other basic substances. Phenylmagnesium bromide gives stilbene and diphenyl.[15] Sodium malonic ester gives a quantitative yield of stilbene and ethane-tetracarboxylic ester.[16] Potassium sulfhydrate in a sealed tube at 100° gives large quantities of stilbene.[17] Sodium benzene sulfinate and sodium phenylmercaptide give stilbene and diphenylsulfone and diphenyl disulfide, respectively.[18] On the other hand, stilbene dibromide does not react with sodium ethylate, with alcoholic ammonia or with aniline and only slightly with metallic sodium. With alcoholic potassium hydroxide at room temperature it loses a molecule of hydrogen bromide and forms monobromostilbene.[19]

A study of the reactions of mercury di-*p*-tolyl and of mercury diphenyl with organic halides shows that they are far less reactive than the other types of bases. The use of higher temperatures and the omission of solvents would probably speed up the reactions appreciably. Most of the halides used would not withstand such severe conditions, however. When mercury compounds can be made to react with organic halides, the results are reasonably like those obtained with other types of bases, especially those of the hydrocarbo type.

Experimental Part

Only a few typical experiments will be given in detail to indicate the method of procedure.

Reaction of *sec.*-Butyl Iodide with Mercury Di-*p*-tolyl.—A mixture of 3.5 g. (1 mol) of *sec.*-butyl iodide (b. p. 119–122°), 12 g. (2 mols) of mercury ditolyl and 50 cc. of dry carbon tetrachloride (b. p. 76–77°) was refluxed for 380 hours. The condenser was provided with a trap containing bromine to absorb any unsaturated gaseous products. After refluxing, the contents of the trap were entirely soluble in dilute sodium hydroxide. This indicated that no butylene had been formed. The mixture was cooled and filtered. The precipitate of unchanged mercury ditolyl was washed with carbon tetrachloride and dried (wt., 10.4 g.). A sodium fusion test for halogen gave only a Slight opalescence, showing that not more than a trace of tolylmercuric iodide was formed.

The filtrate was concentrated to about 10 cc., cooled and filtered from more mercury ditolyl. Most of the filtrate distilled at 76–80°. Finally, unchanged butyl iodide distilled at 117–122°. No reaction had occurred

The experiment was repeated with the same weights of material in boiling toluene for 340 hours. No reaction occurred.

19	*Sym.*-trinitrophenyl iodide, m. p. 159–160°	5.3	3

[a] Mercury diphenyl was used in this experiment.

[b] The benzyl iodide was prepared by the action of benzyl chloride with sodium iodide in absolute methyl alcohol. The product was freed from alcohol by standing in a vacuum desiccator over solid potassium hydroxide for two weeks A trace of free iodine was removed by shaking the melted iodide with a little mercury. The product was almost colorless and melted at 27–30°.

[c] No product obtained with a boiling point appreciably higher than those of the solvent and the halide.

[d] When the reaction was carried out in toluene considerable tolylmercuric bromide was formed. The methyl ester of a-methylacrylic acid, which may have been formed, was not detected.

[e] In this experiment the molar ratio of halide to mercury compound was 2.1 instead of the ratio 1:2 used in the other experiments.

[a] Dry carbon tetrachloride was used as solvent in this experiment.

[b] No product obtained with a boiling point appreciably higher than those of the solvent and the halide.

[c] Bromine trap used. Contents entirely soluble in dilute sodium hydroxide, indicating that no olefin was formed during the refluxing.

[d] In some of the earlier experiments the recovered mercury ditolyl was not dried and weighed.

[e] The condenser was protected from moisture by a calcium chloride tube.

[f] Dry benzene was used as solvent in this experiment.

The next group of halides to be discussed reacted with mercury ditolyl but gave tarry products which could not be purified.

310	C_7H_7HgI, 6 g. ICH_2CN	Tar

[a] The mixture was allowed to stand at room temperature (about 20°).

Reaction of Ethyl Bromomalonate with Mercury Di-*p*-tolyl.—A mixture of 100 g. (1 mol) of ethyl bromomalonate (b. p. (20 mm.) 130–132°), 335 g. (2 mols) of mercury di-*p*-tolyl (m. p. 235–239°, free from iodide) and 950 cc. of dry toluene was refluxed for 336 hours. The mixture was cooled and filtered from a mixture of unchanged mercury ditolyl and tolylmercuric bromide. This was dried; wt., 300 g. The filtrate was concentrated by distillation to 400 cc. (b. p. of distillate 110–115°). The residual oil gave more of the mixed mercury compound on cooling. This was removed by filtration and dried; wt., 9 g. The filtrate was further concentrated to 150 cc. and filtered from more of the mercury compound; wt., 6 g. This filtrate was distilled at 58–60 mm. Toluene first came over at 44–55°. The temperature then rose rapidly to 125° and then more slowly to 149°. About half of the oil distilled at 140–149° (58–60 mm.). The liquid was water white; wt., 56 g. When the temperature was carried above 150°, considerable mercury ditolyl began to distil. The heating was then stopped. The residual oil solidified to a mush of brown crystals; wt.. 42 g.

The oil which distilled at 140–149° (58–60 mm.) was distilled at 38–40 mm. Three fractions were obtained as follows: b. p. 100–116° (mostly 107–116°), wt. 18 g.; b. p. 115–130° (mostly 123–127°), wt. 10.7 g.; b p. 137–145°, wt. 23 g. About 3 g. of charred residue remained in the flask.

The first fraction was redistilled at atmospheric pressure. It boiled at 180–205° (mostly at 190–195°, b. p. of ethyl malonate 198°). The entire fraction (16 g.) was treated with 40 cc. of concd. ammonium hydroxide. Part of the material was insoluble and this was separated; wt., 4 g. (b. p. 183–185°). It gave a qualitative test for bromine and had the characteristic odor of p-bromotoluene. The ammoniacal solution deposited white crystals on evaporation, m. p. 168–169°. A mixture with pure malonamide (m. p. 170–171°) melted at 169–171°.

The third fraction was unchanged ethyl bromomalonate, as shown by its b. p. and by conversion into 1,1,2,2-tetracarbethoxyethylene. Two g. of the oil, 6 g. of anhydrous potassium carbonate and 25 cc. of benzene were refluxed for twenty-four hours. The product melted at 55–57°. The melting point was not lowered by the addition of a known sample of the ester melting at 58°.

The second fraction was not separated into its components. It undoubtedly contained ethyl malonate, ethyl bromomalonate and @-bromotoluene.

The 42 g. of residue from the first distillation was too viscous to be filtered. Repeated extractions with alcohol left a residue of impure mercury ditolyl; wt., 20 g. After one crystallization from benzene it melted at 226–238'. The alcohol extracts gave a thick, viscous oil which contained organic mercury compounds. An attempt to distil this at 8-mm. pressure was only partly successful. There was much charring in the flask. About 10 g. of oil distilled at 195–230° (8 mm.), mostly at 205–210°. It contained some mercury ditolyl and tolylmercuric bromide in suspension. The liquid portion was perhaps 1,1,2,2-tetracarbethoxyethylene, b. p. 201° (2 mm.).

Reaction of Diphenylbromomethane and Mercury Di-*p*-tolyl.—Preliminary experiments using carbon tetrachloride, toluene, xylene and tetrachloro-ethane as solvents showed that a reaction took place.

A mixture of 50 g. (1 mol) of diphenylbromomethane (b. p. 180–182° (17 mm.), m. p. 40–42°), 120 g. (2 mols) of mercury di-p-tolyl and 250 cc. of dry toluene was refluxed for 170 hours. The mixture was cooled and filtered from 110 g. of mixed mercury compounds. The filtrate was concentrated to 75 cc. by distillation, cooled and filtered from 5 g. of mercury compounds. The filtrate was freed from toluene by distillation. The residual oil (wt., 43 g.) solidified on cooling. It gave no test for bromine (sodium fusion). Recrystallization from alcohol gave white needles, m. p. 64–66°. Part of the material was distilled at atmospheric pressure, b. p. above 360°. The distillate solidified and melted at 70°. The melting point was not lowered by mixing with a known sample of p-tolyldiphenylmethane (m. p. 71°) made from benzhydrol and toluene with stannic chloride. The product was further identified by oxidation to form *p*-carboxytriphenylcarbinol, m. p. 196–200°.[20]

Reaction in *m*-**Xylene.**—A mixture of 47 g. (1 mol) of diphenylbromomethane, 117.5 g. (2 mols) of mercury di-p-tolyl and 400 cc. of m-xylene (Eastman Kodak Co., b. p. 138–139°) was refluxed for 200 hours. The mixture was treated as in the preceding experiment. The crude p-tolyldiphenylmethane boiled at 225–232° (18 mm.). The distillate on recrystallization from a mixture of acetic acid and ether melted at 68–78°. The melting point was not lowered by addition of some of the known compound. No evidence of the formation of m-xylyldiphenylmethane was found.

Reaction of Diphenylbromomethane with Mercury **Di-*n*-butyl.**—A mixture of 20 g. (1 mol) of the halide, 50 g. (2 mols) of mercury di-n-butyl (b. p. 225–230°) and 100 cc. of dry toluene was refluxed for 340 hours. The top of the condenser was connected with a flask of concd. nitric and sulfuric acids to destroy any traces of organic mercury compounds which might escape from the condenser. The reaction mixture was separated as usual. The products obtained were 5 g. of metallic mercury, 15 g. of unchanged mercury di-n-butyl, 25 g. of n-butylmercuric bromide, 2 g. of mercurous bromide, 2 g. of tetraphenylethane and 6 g. of oil boiling at 277–278° (probably diphenyl-*n*-butylmethane).

Reaction of Diphenylbromomethane with Mercury.—Two g. of the halide, 15 g. of metallic mercury and 20 cc. of dry toluene were refluxed for twenty-four hours. The hot solution was filtered from a residue of mercury and mercurous bromide. On cooling it deposited white crystals of *sym.*-tetraphenylethane, m. p. 208–209° corr.; wt., 1 g. The melting point was not lowered by addition of known tetraphenylethane made from diphenylbromomethane and zinc dust.

Reaction of Diphenylbromomethane with Mercury **Diphenyl.**—A mixture of 10 g. (1 mol) of diphenylbromomethane, 21.72 g. (2 mols) of mercury diphenyl and 50 cc. of dry toluene was refluxed for 170 hours. The mixture was allowed to cool and the precipitated mercury compounds were filtered off and washed with a little toluene and dried; wt., 15 g. The filtrate was concentrated in *vacuo.* The residue solidified on cooling; wt., 15 g. Extraction with petroleum ether (b. p. 30–60°) left 6 g. of mixed mercury compounds. The soluble portion was found to be triphenylmethane. It crystallized from petroleum ether on standing, m. p. 85–90°. Recrystallization from petroleum ether raised the melting point to 88–90°. (Melting point of triphenylmethane, 92°.) The identity of the material was further established through the test given by Mulliken.[21] The material was nitrated by dissolving 0.1 g. in fuming nitric acid without the application of heat. The mixture was diluted with water and the precipitate filtered off. The precipitate was dissolved in 10 cc of glacial acetic acid and reduced by the successive additions of small quantities of zinc dust to the hot solution until the strong red color that at first appeared was nearly discharged. A portion of the supernatant Liquid was decanted and a little lead dioxide added. A very intense fuchsin-red colot (pararosaniline) formed at once, indicating that the substance tested was triphenylmethane. The yield of triphenylmethane was about 90%.

Reaction of *tert.*-**Butyl** Bromide with Mercury **Di-*p*-tolyl.**—1. A mixture of 10 g. (1 mol) of *tert.*-butyl bromide (b. p. 72–74°), 55 g. (2 mols) of mercury di-p-tolyl and 200 cc. of dry carbon tetrachloride was refluxed for 340 hours. The top of the con-

denser was connected with a trap containing 85% sulfuric acid. After twenty-four hours an oily layer separated above the acid. This was probably tri-isobutylene.

The reaction mixture was cooled and filtered from 53 g. of a mixture of unchanged mercury ditolyl and tolylmercuric bromide. The filtrate was concentrated to 90 cc. by distillation (b. p. 76–77"). The residue was cooled and filtered from 0.5 g. of mercury compounds. It was further concentrated to 15 cc. (b. p. of distillate, 76–80°). Cooling gave 0.5 g. more mercury compounds. The filtrate on distillation gave 10 cc. of product boiling at 80–110°. The temperature then rose rapidly to 155°, at which point charring took place. Less than 1 cc. of high-boiling oil was obtained. Treatment of the main distillate with fuming sulfuric and nitric acids proved the presence of toluene. The melting point of the nitration product was 69–70' (m. p. of 2,4-dinitrotoluene, 70.5").

2. The experiment was repeated using 66% sulfuric acid in the trap. No oily layer separated. At the end of 200 hours the contents of the trap was neutralized with sodium hydroxide and distilled. The distillate gave the red ring test for *tert.*-butyl alcohol.[22] This proved that isobutylene was formed in the reaction.

Reaction of *tert.*-Butyl Bromide with Mercury Diphenyl.—A mixture of 5 g. (1 mol) of *tert.*-butyl bromide, 24.9 g. (2 mols) of mercury diphenyl and 100 cc. of dry carbon tetrachloride was refluxed for 340 hours. A trap containing 70% sulfuric acid was used to catch any unsaturated gases. The reaction mixture was cooled and filtered from 12 g. of mercury compounds. The filtrate was distilled (75–81°), leaving a residue of 15 g. of mercury compounds in the flask. The distillate on treatment with fuming nitric and fuming sulfuric acids gave m-dinitrobenzene melting at 88–89°. The sulfuric acid in the trap was diluted with water and neutralized with sodium hydroxide solution. It gave the test for *tert.*-butyl alcohol, indicating that isobutylene had been formed.

Reaction of *tert.*-Amyl Iodide with Mercury Di-*p*-tolyl.—A mixture of 6.5 g. (2 mols) of the iodide, 6.3 g. (1 mol) of the mercury compoand and 45 cc. of dry carbon tetrachloride was refluxed for seventeen hours. Red crystals of mercuric iodide separated. The cooled mixture was filtered from 7.2 g. of mercuric iodide and tolylmercuric iodide. Distillation of the filtrate gave 3 cc. of a product boiling at 83–113°. This was mainly toluene, as was proved by conversion to dinitrotoluene (m. p. 68–70"). A small amount of unchanged amyl iodide was recovered.

Reaction of *tert.*-Amyl Iodide with Mercury Diphenyl.—A mixture of 6.5 g. (2 mols) of *tert.*-amyl iodide, 5.7 g. (1 mol) of mercury diphenyl and 45 cc. of chloroform was refluxed for seventeen hours. A trap containing 70% sulfuric acid was used to catch any volatile unsaturated compounds. The mixture of unchanged mercury diphenyl and phenylmercuric iodide left weighed 5.4 g. The contents of the trap gave a small amount of *tert.*-amyl alcohol. Benzene was identified as m-dinitrobenzene (m. p. 88–89'). A small amount of the amyl iodide was recovered unchanged. No mercuric iodide was formed.

Preparation of 1-Bromo-1,1,2-tricarbethoxyethane (Bromo-ethenyltricarboxylic Ester).—Ethenyltricarboxylic ester was prepared from ethyl chloro-acetate and sodium malonic ester. It boiled at 163–165° (17 mm.). It was brominated without a solvent. The bromo ester boiled at 175–177° (15 mm.); yield, 76%.

Anal. Subs., 0.4092, 0.3565: AgBr, 0.2348, 0.2032 Calcd. for $C_{11}H_{17}O_6Br$: Br, 24.6. Found: Br, 24.3, 24.4.

Reaction of 1-Bromo-1,1,2-tricarbethoxyethane with Mercury Di-*p*-tolyl.—A mixture of 25 g. (1 mol) of the ester, 58.8 g. (2 mols) of the mercury compound and 200 cc. of dry toluene was refluxed for 288 hours. The reaction mixture was dark brown and a small globule of mercury had appeared. The cooled mixture was filtered to

---

[22] Mulliken, ref. 21, Vol. I, p. 171.

separate 48.2 g. of mercury ditolyl and tolylmercuric bromide. The filtrate was concentrated to 25 cc. (b. p. of distillate mostly 110–112', a little up to 120'). The residue on cooling gave 4.8 g. of mixed mercury compounds. The filtrate freed from solvents weighed 16 g. It was twice distilled at 12-mm. pressure. A small amount was obtained which boiled at 157–159° (12 mm.). This was 1,1,2-tricarbethoxyethylene (ethenetricarboxylic ester).[23]

Reaction of 9-Bromofluorene with Mercury **Di-*p*-tolyl.**—A mixture of 4 g. (1 mol) of the halide (m. p. 102–103°), 12.4 g. (2 mols) of the mercury compound and 60 cc. of dry toluene was refluxed for 310 hours. The cooled mixture was filtered, leaving 11.1 g. of mercury ditolyl and tolylmercuric bromide. The filtrate was concentrated to 10 cc. (b. p. of distillate 109–112") and cooled. It was filtered from 1.1 g. of mixed mercury compounds. The filtrate was evaporated to a tarry mass; wt., 3 g. This was dissolved in benzene and treated with a concd. benzene solution of picric acid. On spontaneous evaporation beautiful crystals of the picrate of *bis*-diphenylene-ethylene separated, m. p. 176–177°.

Action of Heat on **9-Bromofluorene.**—Three g. of the halide and 25 cc. of dry toluene were refluxed for 120 hours. The original bromide was recovered unchanged. No trace of the orange ethylene compound was noted.

Reaction of 9-Bromofluorene with Mercury **Diphenyl.**—A mixture of 4 g. (1 mol) of the halide, 11.2 g. (2 mols) of mercury diphenyl and 60 cc. of dry toluene was refluxed for 238 hours. The mixture turned deep orange. It was cooled and filtered from the mixed mercury compounds. The toluene was distilled and the residue was extracted with petroleum ether (b. p. 30–60°). Evaporation of the solvent left an orange red oil which consisted mainly of bis-diphenylene-ethylene.

Reaction of Stilbene Dibromide with Mercury **Di-*p*-tolyl.**—A mixture of 4 g. (1 mol) of the halide (m. p. 226–229°), 10 g. (2 mols) of the mercury compound and 70 cc. of dry toluene was refluxed for 340 hours. The mixture was cooled and filtered from unchanged mercury ditolyl and tolylmercuric bromide. The toluene was removed by distillation in *vacuo*. The residue was extracted with absolute ethyl alcohol. Evaporation of the extracts gave crystals of m. p 103–115"; recrystallization from ligroin raised the m. p. to 113–115°. This was impure stilbene. Bromination of a sample gave stilbene dibromide, m. p. 224–225°. A small amount of oil having the odor of p-bromotoluene was obtained from the mother liquors of the crude stilbene.

Treatment of Mercuri-*bis*-2,4,6-trinitrophenyl with Picryl Iodide.—One g. (1 mol) of the mercury compound[24] (m. p. 271°), 1.1 g. (2 mols) of picryl iodide and 25 cc. of acetone were refluxed for nineteen hours. The mixture was evaporated spontaneously. Nothing but the original substances could be found in the mixture.

Reaction of 2,4,6-Trinitrophenylmercuric Chloride with Iodine.—One g. (1 mol) of the mercury compound, 0.6 g. (1 mol) of iodine, 4.5 g. of sodium iodide and 25 cc. of water were refluxed for two hours. The mixture was filtered. The residue was completely soluble in ether, m. p. 164°. The melting point was not lowered by addition of picryl iodide. The filtrate contained sodium mercuric iodide, sodium iodide and sodium chloride. No hexanitrodiphenyl was formed.

Reaction of Mercuri-*bis*-2,4,6-trinitrophenyl with Iodine.—A mixture of 0.6 g. (1 mol) of the mercury compound, 0.6 g. (2.2 mols) of iodine and 30 cc. of 66% alcohol was refluxed for eight hours. Practically all of the iodine had reacted. Less than 0.1 g. of unchanged mercury compound was recovered. Evaporation gave needles of picryl iodide melting at 162–163°. A mixture with the known substance melted at 162–164". The other product was mercuric iodide.

[24] Kharasch, This Journal, 43, 2242 (1921).

Summary

1. Thirty-two organic halides of widely varying types have been treated with mercury di-p-tolyl under very vigorous conditions.
2. Some of the halides have also been treated with mercury di-n-butyl sod mercury diphenyl.
3. In general the mercury compounds are extraordinarily unreactive toward the halides studied.
4. In the cases of the five halides which gave definite reactions the behavior of the mercury compounds was analogous to that of other types of bases with the same halides.
5. It has been shown that 2,4,6-trinitrophenylmercuric compounds react normally with iodine.

Chaulmoogric (I) and hydnocarpic (II) acids[3] in the form of their salts and esters are extensively used in leprosy therapy.[4] Notwithstanding the fact, however, that many cures have been effected through their application, many objections have been raised to their prolonged therapeutic use, and there is still much to be desired before an ideal germicidal agent is found for the treatment of patients suffering from leprosy. New compounds of high germicidal power and low toxicity are very much desired for clinical work in the study of methods to eradicate this disease. In view of the striking bactericidal properties of alkylresorcinols and the established clinical success of hexylresorcinol[5] it seemed desirable to prepare

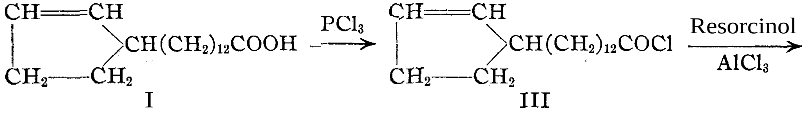
some resorcinol derivatives containing the cyclopentenyl group. As chaulmoogric acid was available[6] in quantity we have used it to prepare the first of this new type of compounds, namely, 1-cyclopentenyl-13-(2,4-dihydroxyphenyl)-*n*-tridecane, V. It is a derivative of chaulmoogric acid containing no carboxyl or ester group, and thus differs structurally from those previously used in leprosy treatment. The method of synthesis reported in this paper should lend itself equally well to the preparation of lower homologs of the series; their investigation is in progress in this Laboratory.

We have introduced the chaulmoogryl group into the nucleus of resorcinol by application of the Friedel and Crafts reaction, using carbon disulfide as the solvent when the dimethyl ether of resorcinol was used, and nitrobenzene[7] when using resorcinol directly. The method developed by Nencki and others[8] of heating resorcinol and the acid in the presence of anhydrous zinc chloride was entirely inapplicable, the zinc chloride reacting with the unsaturated part of chaulmoogric acid giving resinous decomposition products. However, this latter method proved entirely satisfactory with dihydrochaulmoogric acid.[9] The preparation of resorcinol-monochaulmoograte and the rearrangement of the chaulmoogryl group into the resorcinol nucleus were not successful. The methyl group of dimethly-resorcinol para to the entering chaulmoogryl group could not be removed without complete breakdown of the compound. It has been recognized previously that methyl groups para to a ketone group are removed with difficulty, but when ortho to a ketone group they are removed with comparative ease.[10] Only those ketones in which the carbonyl is ortho to a phenol group give a red color with ferric chloride.

These ketones were readily reduced to the corresponding alkylresorcinols by the Clemmensen method.[11] The synthesis and reduction of chaulmoogryl resorcinol, IV, is represented by the following steps



---

[6] We wish to thank Dr. Richard Wrenshall of the University of Hawaii for supplying a large portion of the chaulmoogric acid used in this research. The remainder was obtained from chaulmoogra oil purchased in the market.

IV V

The double bond in the cyclopentenyl group is not reduced in this process since after reduction both the mono- and di-methyl ether of IV show optical activity. The non-optical activity of the 1-cyclopentenyl-13-(2,4-dihydroxyphenyl)-*n*-tridecane, V, is probably due to internal compensation of the type shown by bromodihydrochaulmoogric acid, which is practically inactive though its esters show a decided optical activity.[12] The ketones which we have prepared show decreasing optical activity with decrease in methylation, and further decrease in optical activity upon reduction of the ketone group; thus it might be expected that V would show no measurable activity since the ketone IV is only slightly active.

1-Cyclopentyl-13-(2,4-dihydroxyphenyl)-*n*-tridecane has been prepared and found to differ from 1-cyclopentenyl-13-(2,4-dihydroxyphenyl)-*n*-tridecane, V, thus proving conclusively that the double bond in this compound is not reduced when it is treated according to the Clemmensen procedure. The great stability of the asymmetric carbon atom in chaulmoogric acid argues against racemization, and especially is this supported by the observation that the mono- and dimethyl ethers of the ketone, IV, show optical activity after reduction.

Experimental Part

Chaulmoogric Acid.—The chaulmoogric acid, which was brownish-yellow from slight oxidation, was distilled under 2–3 mm. pressure and crystallized once from ethyl acetate. Glistening white flakes melting at 68° were obtained. A 20-g. portion recrystallized repeatedly from ethyl acetate melted at 68–68.5° and gave $[\alpha]^{25°}_{D} = +62.2°$ in chloroform.

Anal. Subs., 0.0940: CO_2, 0.2656; H_2O, 0.0983. Calcd. for $C_{18}H_{32}O_2$: C, 77.07; H, 11.51. Found: C, 77.07; H, 11.67.

Fusion of Chaulmoogric Acid with Resorcinol and Zinc Chloride.—Eleven grams of chaulmoogric acid, 3.9 g. of resorcinol and 4.9 g. of anhydrous zinc chloride were heated at 100–105° with constant stirring for one hour. Resorcinol and zinc chloride were removed and the residue distilled at 2 mm. pressure, but only 0.8 g. (6% yield) of very impure chaulmoogrylresorcinol was obtained. After several crystallizations from an ether–petroleum ether mixture a few tenths of a gram of material remained which melted at 68–71°. It was soluble in 10% sodium hydroxide solution, very soluble in ether, alcohol and acetone. When dissolved in alcohol a deep red color resulted upon the addition of a drop of ferric chloride solution.

Dihydrochaulmoogrylresorcinol was prepared from dihydrochaulmoogric acid by the preceding method except that the temperature and time of heating were identical with those used in the preparation of hexylresorcinol. This gave a 50% yield of the desired ketone and 20% of the acid was recovered. After several crystallizations from 95% acetone it melted at 89.5°.

---

[12] Shriner and Adams, THIS JOURNAL, 47, 2731 (1925).

This ketone was also prepared from dihydrochaulmoogryl chloride and resorcinol by application of a Friedel and Crafts reaction in nitrobenzene. A 70% yield was obtained, the product melting at 89.5" after repeated recrystallizations from acetone. Both ketone preparations gave the same oxime.

Anal. Subs., 0.0947: CO_2, 0.2665; H_2O, 0.0877. Calcd. for $C_{24}H_{38}O_3$: C, 76.94; H, 10.23. Found: C, 76.74; H, 10.36.

The oxime of dihydrochaulmoogrylresorcinol was prepared according to the method used by Hill and Evans.[13] Two grams of dihydrochaulmoogrylresorcinol and 0.5 g. of hydroxylamine hydrochloride were added to 8 cc. of anhydrous pyridine and the solution heated on the steam-bath for ten hours. The oxime was obtained as an oil which crystallized on cooling. After several recrystallizations from benzene, it melted at 169–170°. The crystals were in the form of silvery flakes that turned yellow on exposure to light.

Anal. Calcd. for $C_{24}H_{39}O_3N$: N, 3.60. Found (Kjeldahl): N, 3.57, 3.49.

Chaulmoogryl chloride[M] was prepared most satisfactorily by the action of an excess of phosphorus trichloride on chaulmoogric acid at room temperature for twenty-four to thirty hours. The excess of trichloride was removed by vacuum distillation, when the acid chloride was obtained as a colorless liquid that'could not be purified by distillation.

Phosphorus pentachloride and thionyl chloride partly decomposed chaulmoogric acid. The potassium salt of chaulmoogric acid and thionyl chloride can be used satisfactorily for preparing the acid chloride except for the difficulty of preparing the anhydrous potassium salt.

Dimethyl and Monomethyl Ethers of Chaulmoogrylresorcinol.—Chaulmoogryl chloride from 26.0 g. of chaulmoogric acid and 12.5 g. of dimethylresorcinol were dissolved in 50 cc. of carbon disulfide and slowly added in small portions to 35 g. of powdered aluminum chloride covered with 25 cc. of carbon disulfide. The reaction was completed within two hours and water was then added to decompose any addition products formed. After extraction with ether and drying, the solvent was removed and the reaction product distilled under 2–3 mm. pressure. At 230–238° (uncorr.) 8.4 g. of a clear brownish-yellow oil was obtained (23% yield). Traces of chaulmoogric acid were removed from this and upon redistillation a bright yellow oil was collected that partially solidified on standing. By fractional crystallization from acetone silky needles were first obtained melting at 56–58" and a second more soluble fraction also crystallizing in needles melting at 34–36°. The two products were finally obtained in pure form by recrystallization from alcohol and acetone and melted at 65 and 46°, respectively. The higher-melting compound was less soluble, gave a red color when dissolved in alcohol and treated with a drop of ferric chloride solution, and gave a positive Millon's reaction. It was insoluble in sodium hydroxide solution and slowly developed a reddish color when exposed to the air. It was identified as 1-chaulmoogryl-2-hydroxy-4-methoxybenzene.

Anal. 1.2967 g. made up to 50.1 cc. in chloroform at 25" gave a rotation of $0.722" in a 4-dcm. tube; $[\alpha]_D^{25°} = +6.98°$. Subs., 0.1770: CO_2, 0.5001; H_2O, 0.1640. Calcd. for $C_{25}H_{38}O_3$: C, 77.66; H, 9.91. Found: C, 77.07; H, 10.34.

The compound melting at 46° gave no red color with ferric chloride solution and after careful purification no positive test with Millon's reagent. It was insoluble in sodium hydroxide and did not develop a red color on exposure to the air. It was identified as the methylated compound 1-chaulmoogryl-2,4-dimethoxybenzene.

[14] Powers and Gornall, J. *Chem. Soc.*, 85, 855 (1904).

Anal. 1.2470 g. made up to 27 cc. in chloroform at 25° gave a rotation of +3.47° in a 4-dcm. tube; $[\alpha]_D^{25°} = +18.78°$. Subs., 0.1310, 0.1174: CO_2, 0.3715, 0.3355; H_2O, 0.1207, 0.1083. Calcd. for $C_{26}H_{40}O_3$: C, 77.94; H, 10.07; Found: C, 77.34, 77.93; H, 10.30, 10.38.

Mol. wt. (in ethylene bromide). Solvent, 38.86, 38.86, 38.86; solute, 0.1213, 0.3074, 0.4090; Δt, 0.094°, 0.239°, 0.315°. Calcd. for $C_{26}H_{40}O_3$: 400.3. Found: 398, 397, 401; average, 398.

When the above procedure was modified by keeping the reaction temperature at 30–35° and adding the aluminum chloride to the chaulmoogryl chloride and resorcinol dissolved in carbon disulfide, yields of 40% were obtained, dimethylchaulmoogrylresorcinol being the only product identified. When anhydrous ferric chloride was used as the catalyst no demethylation took place by either procedure but the yields were much lower.

Esters of Resorcinol.—The anhydrous monopotassium salt of resorcinol was prepared by a procedure similar to that used by De Forcrand in preparing the monosodium salt.[15] It was a light colored, hard mass and was quite hygroscopic.

Seventeen and eight-tenths grams of this potassium salt of resorcinol was suspended in 125 cc. of dry ether and chaulmoogryl chloride (from 25 g. of chaulmoogric acid) dissolved in 75 cc. of ether slowly added. Immediate reaction occurred with the separation of potassium chloride. After this was complete water was added, the ether layer separated, washed first with water and then with sodium carbonate until free from chaulmoogric acid. The solvent was then removed, the reaction product dissolved in petroleum ether and washed with water to remove any unaltered resorcinol; it was dried and finally distilled under 2–3 mm. pressure. At 238–240° (uncorr.) 2.8 g. of a light yellow oil distilled over which immediately solidified; then at 270–281° (uncorr.), 11.7 g. of an almost colorless oil was obtained which also solidified. When crystallized from petroleum ether glistening plates were obtained melting at 51°. The compound is very soluble in hot petroleum ether, ether or acetone, but difficultly soluble in alcohol. Analysis and molecular weight determinations indicated that we were dealing with **resorcinol dichaulmoograte.**

Anal. 0.6158 g. made up to 27 cc. by chloroform at 25° gave +4.19° in a 4-dcm. tube. $[\alpha]_D^{25°} = +45.93°$. Subs., 0.0747, 0.0948: CO_2, 0.2140, 0.2715; H_2O, 0.0703, 0.0857. Calcd. for $C_{42}H_{66}O_4$: C, 79.42; H, 10.47. Found: C, 78.13, 78.10; H, 10.53, 10.12.

Mol. wt. (in ethylene bromide). Solvent, 32.53, 32.53, 32.53; solute, 0.0815, 0.1420, 0.2406; Δt, 0.045°, 0.078°, 0.134°. Calcd. for $C_{42}H_{66}O_4$: 634.5. Found: 668, 672, 660; average, 667.

Chaulmoogrylresorcinol.—Chaulmoogryl chloride from 50 g. of chaulmoogric acid and 26 g. of resorcinol were dissolved in 150 cc. of anhydrous nitrobenzene. The temperature was maintained at 30–35° while 29 g. of aluminum chloride was added in small portions followed by shaking. After standing for a few minutes the mixture was cooled and cold dilute hydrochloric acid and cracked ice were added. Ether extraction was then applied and the ether solution dried over anhydrous sodium sulfate. After removing all ether and nitrobenzene by vacuum distillation, the remaining oil was distilled under 2–3 mm. pressure, when we obtained thirty-eight grams of a light yellow oil which, on cooling, crystallized in long needles. On crystallization from acetone it was obtained in the form of small colorless needles melting at 83°. Removal of the nitrobenzene by vacuum distillation was more satisfactory than by steam distillation.

Anal. 1.284 g. made up to 50.8 cc. in chloroform at 25° gave a rotation of +0.14°

---

[15] De Forcrand, *Ann. chim. phys.*, [6] 30, 67 (1893).

in a 4-dcm. tube. $[\alpha]_D^{25°} = +1.38$. Subs., 0.0810: CO_2, 0.2286; H_2O, 0.0728. Calcd. for $C_{24}H_{36}O_3$: C, 77.36; H, 9.74. Found: C, 76.96; H, 10.05.

The oxime of chaulmoogrylresorcinol was prepared by the method previously described. It melted at 152–154° and after three crystallizations from benzene melted sharply at 161°. In appearance it was indistinguishable from the oxime of dihydrochaulmoogrylresorcinol and, like it, turned yellow on exposure to light.

Anal. Optical activity practically within experimental error, \$0.02 °, in a 4-dcm. tube. Calcd. for $C_{24}H_{37}O_3N$: N, 3.61. Found (Kjeldahl): N, 3.54, 3.55.

1-Cyclopentenyl-13-(2,4-dihydroxyphenyl)-*n*-tridecane.—Eight grains of chaulmoogrylresorcinol was reduced by the Clemmensen method, stirring constantly and keeping a small amount of an ether–benzene mixture returning to the reduction flask from a reflux condenser. When no solvent was allowed to reflux, the material soon formed a butter-like emulsion which completely prevented mixing by the stirrer. Only a few cubic centimeters of ether or ether–benzene mixture was needed to prevent emulsification. The ferric chloride test for unreduced ketone was negative after seven hours, though reduction was continued for one hour longer. The reduced material was dissolved in ether, washed with water and the solution dried over anhydrous sodium sulfate. After removal of the ether, the oil obtained was distilled under 2–3 mm. pressure. It distilled at 245–247° (uncorr.) as a colorless oil which immediately solidified on cooling. This was further purified by crystallization from a petroleum ether–ligroin mixture, separating as needles melting at 68°. It was very soluble in alcohol, acetone or ether and dissolved immediately in 10% sodium hydroxide solution. It was moderately soluble in chloroform, ligroin and petroleum ether.

Anal. 2.1038 g. made up to 27 cc. in chloroform at 25° showed very slight or no optical activity in a 4-dcm. tube. Subs., 0.1175, 0.1042, 0.0865: CO_2, 0.3458, 0.3061, 0.2551; H_2O, 0.1147, 0.1018, 0.0842. Calcd. for $C_{24}H_{38}O_2$: C, 80.38; H, 10.68. Found: C, 80.26, 80.11, 80.42; H, 10.92, 10.93, 10.89.

1-Cyclopentenyl-13-(2-hydroxy-4-methoxyphenyl)-*n*-tridecane.—Two and eight-tenths grams of the monomethyl ether of chaulmoogrylresorcinol (1-chaulmoogryl-2-hydroxy-4-methoxybenzene) was reduced by the Clemmensen method; reduction was complete in six hours. A practically pure product was obtained and after two crystallizations from petroleum ether it melted at 47.5°. It crystallized in the form of pearly flakes.

Anal. 0.3890 g. made up to 27.1 cc. with chloroform at 25° gave a rotation of +0.354° in a 4-dcm. tube; $[\alpha]_D^{25°} = +6.15°$. Subs., 0.1086: CO_2, 0.3204; H_2O, 0.1058. Calcd. for $C_{25}H_{40}O_2$: C, 80.58, H, 10.82. Found: C, 80.46; H, 10.90.

Mol. wt. (in ethylene bromide). Solvent, 33.08, 33.08; solute, 0.0730, 0.1472; At, 0.073°, 0.147°. Calcd. for $C_{25}H_{40}O_2$: 372.3. Found: 363, 364; average, 364.

1-Cyclopentenyl-13-(2,4-dimethoxyphenyl)-*n*-tridecane.—Fourteen and seven-tenths grams of the dimethyl ether of chaulmoogrylresorcinol melting at 40° and containing a trace of the mono-methyl ether, as indicated by the ferric chloride test, was reduced by the Clemmensen method. Since no color test could be used to show the presence of unreduced ketone, the reduction was continued for eighteen hours. After three distillations the reduced material was obtained as a practically colorless oil, boiling at 250–252" (uncorr.) under 2 mm. pressure. It failed to solidify when cooled in a freezing mixture; n^{28}, 1.5414; d_{25}^{25}, 0.955.

Optical Activity.—1.070 g. made up to 10 cc. in chloroform at 25° gave a rotation of +1.02°; $[\alpha]_D^{25°} = +9.53°$.

1-Cyclopentyl-13-(2,4-dihydroxyphenyl)-*n*-tridecane.—Two and three-tenths grams of dihydrochaulmoogrylresorcinol was reduced by the Clemmensen method. The reduction required about nine hours, as the ketone reduced much less readily than the other combinations containing the chaulmoogryl group. A light yellow product was obtained that crystallized from ligroin in hard crystalline masses melting at 73–74".

Anal. Subs., 0.0647: CO_2, 0.1886; H_2O, 0.0649. Calcd. for $C_{24}H_{40}O_3$: C, 79.93; H, 11.19. Found: C, 79.50, H, 11.23.

Bacteriological **Study**

Preliminary experiments with chaulmoogrylresorcinol indicate a very low toxicity when given by mouth to rabbits or intramuscularly to rats. Tested against B. *thyphosum* the compound exerts little bactericidal or antiseptic action. It seems not improbable that this compound and lower homologs may be bactericidal for the acid-fast organisms such as leprosy and tuberculosis bacillus, through the ability of the compound to dissolve in the fat complexes of these organisms, even though the substance appears to be inert against the typhoid bacillus. Its bactericidal study is now in progress and a clinical investigation will follow.

Summary

1. The preparation of chaulmoogrylresorcinol and some of its derivatives are described.
2. The ketones prepared have been shown to be easily reduced to the corresponding alkyl resorcinols by the action of zinc amalgam.
3. The cyclopentenyl group in chaulmoogric acid is not reduced by the action of zinc amalgam.
4. The investigation of lower members of this homologous series will be continued in the Sterling Laboratory.

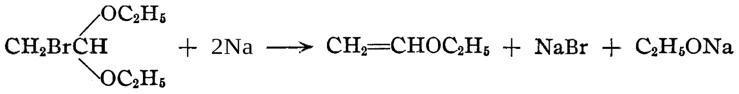
THE ACTION OF METALLIC SODIUM ON BROMINATED CYCLIC ACETALS[1]

BY HAROLD S. HILL[2] AND G. J. C. POTTER

RECEIVED DECEMBER 6, 1928 PUBLISHED MAY 6, 1929

Wislicenus[3] showed that the reaction of bromo-ethylal with metallic sodium proceeded according to the following equation



$$CH_2BrCH\begin{matrix} \diagup OC_2H_5 \\ \\ \diagdown OC_2H_5 \end{matrix} + 2Na \longrightarrow CH_2{=}CHOC_2H_5 + NaBr + C_2H_5ONa \qquad (1)$$

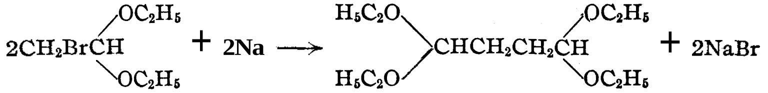
---

[1] This paper represents one of a series of publications carried out under the joint auspices of the Canadian Pulp and Paper Association, the Pulp and Paper Division of the Forest Products Laboratories of Canada and the Department of Industrial and Cellulose Chemistry, McGill University. The authors wish to express their appreciation of the facilities placed at their disposal by the three cooperating agencies.

[2] Research Fellow, Canadian Pulp and Paper Association.

[3] Wislicenus, *Ann.*, 192, 106 (1878).

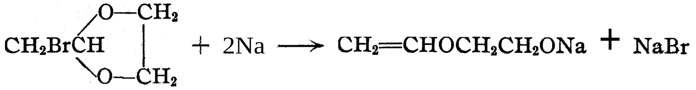
and that this unusual change took place to the exclusion of a Wurtz synthesis which might be expected to link up two molecules of the acetal



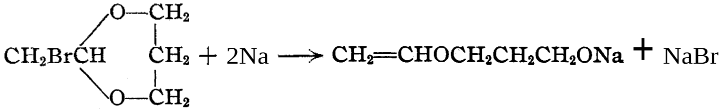
(2)

Quite recently the action of sodium on bromo-ethylidene ethylene glycol and bromo-ethylidene trimethylene glycol has been investigated.[4]

It has been found that these cyclic acetals in dry ether solution react smoothly at low temperatures with the metal and that a change similar to (1) takes place, yielding a vinyl derivative as the only product.



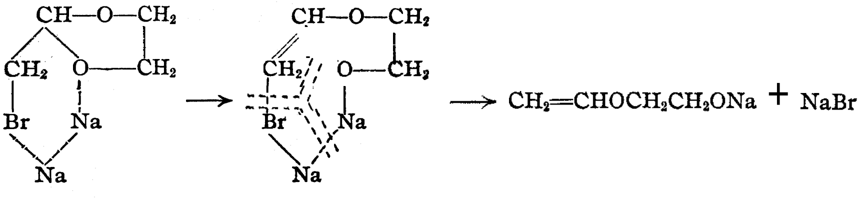
(3)



(4)

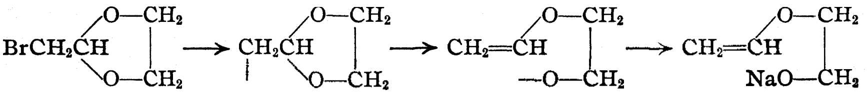
There are two obvious though nevertheless significant points regarding these reactions: (1) the absence of the usual Wurtz synthesis, as in (2); (2) the fact that the metal attacks the bromine and only one of the oxygen atoms. There may also be added the observations that: (3) without the oxygen in the molecule (substitution of O by CH_2, for example,) no unsaturation would have resulted; (4) without the bromine in the molecule no reaction at all would have resulted. (Ethylidene glycol may be refluxed over sodium without change.)

A conclusion may be drawn, therefore, that the above reactions are due to some combined influence of the bromine and oxygen atoms and that the role played by the one is dependent on that of the other. With these requirements in mind a mechanism scheme was proposed earlier[5] which embodied Erlenmeyer's theory of intermediate cyclization in chemical reaction as follows



(A)

An alternative series of changes may be



(B)

Hill and Pidgeon, This journal, 50, 2718, 2725 (1928).

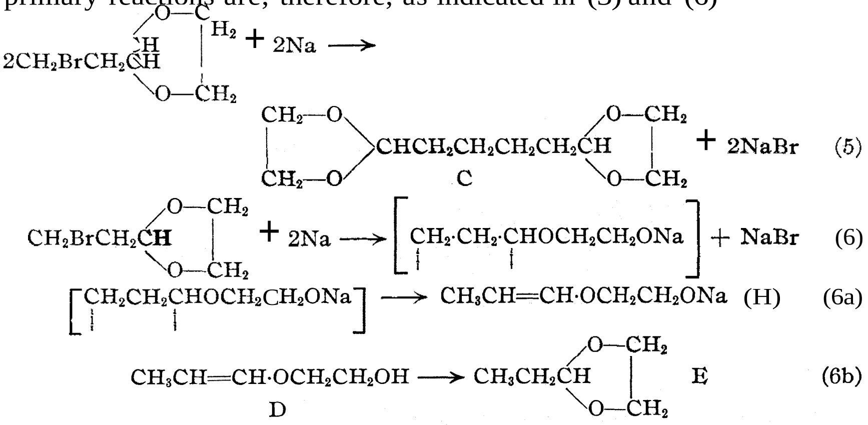
Hibbert and Hill, *ibid.*, 45, 740 (1923).

but in this scheme it is more difficultto account for the absence of a Wurtz synthesis.

In all of the above cases the bromine is on the α-carbon of the aldehyde residue. It seemed that similar reactions carried out with cyclic acetals having the halogen on the @-carbonmight throw further light on the nature of the changes taking place. Such information might also have a bearing on the question regarding the function of sodium as a polymerization catalyst.

For this investigation β-bromopropylidene glycol and β-bromobutylidene glycol were synthesized by the reaction of acrolein and crotonaldehyde, respectively, with ethylene glycol in the presence of an excess of dry hydrogen bromide.

The Action of Sodium on **β-Bromopropylidene Glycol.**—β-Bromopropylidene glycol was found to react smoothly with metallic sodium in dry ether solution. The product instead of being exclusively a vinyl derivative as in the case of the a-bromo homolog proved to be a mixture of di-1,6-hexylidene glycol, C, hydroxy-ethyl-0-methylvinyl ether, D, and propylidene glycol, E, as well as smaller amounts of indefinite products. Propylidene glycol is presumably a secondary product resulting from a partial rearrangement (6b) of the vinyl derivative during distillation. The two primary reactions are, therefore, as indicated in (5) and (6)



The latter transformation (Gb) takes place very rapidly in the presence of a trace of 50% sulfuric acid although it does not have the explosive or quantitative nature of the similar rearrangement of hydroxyethylvinyl ether.[4] Other products besides E are noticeable and it is possible that the rearrangement is complicated by a partial reversal of the reaction indicated in (6a).

Reaction (6a) is of interest since it is an example of unsaturation shifting from one atom to another, a process which undoubtedly takes place in the intermediate stages of many organic reactions.

In (5) a Wurtz synthesis has taken place and from this it may be concluded that the interdependence of the halogen and oxygen atoms is much less marked in the reaction of sodium with a β-bromo- than with an α-bromoalkylidene glycol. If Mechanism A is accepted, this may be explained as due to a less tendency to form the necessary seven-membered cyclic intermediate. On the other hand, if Mechanism B should prove correct, it means that the radical  is less stable than  in the presence of sodium.

The structure of the diacetal, C, was established by its hydrolysis to hexyl dialdehyde which underwent intramolecular "crotonization" to give A-cyclopentene aldehyde as described by Read and Hibbert.[6] The cyclic aldehyde was not isolated in a pure state but was identified by its semicarbazone.

The Action of Sodium on β-Bromobutylidene Glycol.—β-Bromobutylidene glycol reacted with sodium in an analogous manner to its lower homolog, β-bromopropylidene glycol. The reaction took a mixed course, effecting a union of two acetal residues on the one hand and attacking both the bromine and one oxygen atom to give a vinyl derivative and its rearrangement product, butylidene glycol on the other. Here also much of the unsaturated product underwent cyclization during isolation.

Conclusions

The results of the above and earlier experiments indicate that the position of the halogen in brominated cyclic acetals has a marked influence on the course of their reactions with metallic sodium. If the bromine is on the α-carbon a vinyl derivative is formed almost exclusively. A bromine attached to a β-carbon, however, causes more complicated changes, for in addition to the latter reaction, a Wurtz synthesis takes place. A bromine on a y-carbon would presumably still further increase the tendency toward the linking up of two molecules.

Experimental Part

Preparation of β-Bromopropylidene Glycol.—One hundred and sixty g. (2.5 moles) of ethylene glycol was put in a 1-liter three-necked flask equipped with a mechanical stirrer operating through a mercury seal, a calcium chloride drying tube, a dropping funnel cooled by an ice-bath and containing 112 g. (2 moles) of pure acrolein, and a delivery tube. The latter was connected with a source of dry hydrogen bromide (prepared catalytically by passing a mixture of bromine and hydrogen over an electrically heated platinum spiral). The flask was cooled in an ice-bath and about 100 g. of dry hydrogen bromide was bubbled into the glycol with stirring. At this point acrolein was allowed to drop in slowly, continuing the passage of hydrogen bromide until about 100 g. more had been passed in (2.5 moles in all). After this and all of the acrolein had been

---

[6] Read and Hibbert, THIS JOURNAL, 46, 1281 (1924).

added, the mixture was stirred for two hours, allowed to stand overnight without further cooling, and then stirred for two hours more at room temperature. The mixture was extracted three times with ether and the latter solution neutralized with solid sodium bicarbonate, filtered, washed several times with small amounts of cold water arid dried over potassium carbonate. Fractionation under reduced pressure gave a small fore-run of sharp smelling products and 236 *g.* of β-bromopropylidene glycol, b. p. 72–73° (10 mm.); yield, 65% reckoned on the amount of acrolein used. There appeared to be a slight amount of decomposition during distillation and the final product possessed a somewhat sharp odor. There is less decomposition if no air is admitted through the capillary tube used to aid boiling.

Anal. Subs., 0.1539: AgBr, 0.1577. Calcd. for $C_5H_9O_2Br$: Br, 44.17. Found: Br, 43.61.

Preparation of **β-Bromobutylidene** Glycol.—This was prepared in an identical manner to β-bromopropylidene glycol, substituting crotonaldehyde for acrolein. From 124 g. (2 moles) of ethylene glycol, 200 g. (2.5 moles) of hydrogen bromide and 140 g. (2 moles) of crotonaldehyde, there was obtained from the first distillation 278 g. of β-bromobutylidene glycol, b. p. 70–78° (10 mm.). Refractionation gave 220 *g.*, b. p. 76–78" (10 mm.), or 56% of the theoretical yield reckoned on the amount of crotonaldehyde used.

Anal. Subs., 0.1683: AgBr, 0.1667. Calcd. for $C_6H_{11}O_2$: Br, 41.02. Found: Br, 42.15.

This product on long standing decomposed, giving off hydrogen bromide. A sample in a well stoppered, brown glass bottle had changed to a black, solid mass on standing for one year.

Action of Sodium on **β-Bromopropylidene** Glycol.—Fifty-four g. of β-bromopropylidene glycol was dissolved in 100 cc. of absolute ether in a three-necked flask equipped with a reflux condenser and an efficient mechanical stirrer protected from the atmosphere. Fourteen g. of freshly cut sodium was added and the mixture warmed to gentle boiling for sixteen hours with vigorous stirring. The reaction was slower than in the case of α-bromo acetals. The sludge of accumulated salts was flushed with ether through a wire gauze to filter out unchanged sodium amounting to 6 g. The difference in the reaction of α- and β-brominated acetals is noticeable at this point from the relative amount of sodium used up by each. The β-bromo derivative used up considerably less sodium, indicating that more of the reaction linking up two molecules had taken place. Enough water to dissolve the salts was added cautiously, the mixture extracted three times with ether and the ether extract dried over potassium carbonate. Preliminary fractionation separated the product roughly into four parts: (1) b. p. 104–109° (760 mm.), yield, 7 g. (it is better to take this fraction off at about 100 mm. pressure in order to avoid overheating subsequent fractions); (2) b. p. 60–63° (16 mm.), yield, 2 g.; (3) b. p. 144–150° (11 mm.), yield, 5 g.; (4) residue, yield, 5 g.

Fraction (1). Propylidene Glycol.—This when refractionated gave pure propylidene glycol, b. p. 106–107" (760 mm.).

And. Subs., 0.2090: CO_2, 0.4470; H_2O, 0.1792. Calcd. for $C_5H_{10}O_2$: C, 58.82; H, 9.80. Found: C, 58.44; H, 9.52.

This product was identical in every way with propylidene glycol prepared from propionaldehyde and ethylene glycol.

Fraction (2). **Hydroxyethyl-8-methylvinyl** Ether.—The combined yield of this product from several runs was refractionated, giving a product of b. p. 60–61° (16 mm.).

Anal. Subs., 0 2021: CO_2, 0.4365; H_2O, 0.1742. Calcd. for $C_5H_{10}O_2$: C, 58.82; H, 9.80. Found: C, 58.90; H, 9.61.

The product was unsaturated against bromine in carbon tetrachloride and gave test reactions for the hydroxyl group. With a trace of 50% sulfuric acid it underwent a rapid reaction, from the product of which propylidene glycol was isolated, b. p. 106° (760 mm.).

The relative yields of Fractions (1) and (2) varied in different preparations, thus further indicating that the former is a secondary rearrangement product of the latter.

Fraction (3). **Di-1,6-hexylidene** Glycol.—This product on refractionation gave a colorless, viscous oil, b. p. 139–140° (10 mm.), which crystallized on cooling in an ice-bath.

Anal. Subs., 0.2074: CO_2, 0.4480; H_2O, 0.1662. Calcd. for $C_{10}H_{18}O_4$: C, 59.40; H, 8.91. Found: C, 59.02; H, 8.90.

Identification of **Fraction (3)**.—Two g., b. p. 139–140° (10 mm.), was heated for two hours under reflux with 5 cc. of 5% phosphoric acid. The reaction mixture was extracted several times with ether and the latter solution neutralized with potassium carbonate and dried over the same salt. Distillation of the solvent left a small amount of an oil having the pungent aromatic odor described by Read and Hibbert for Δ-cyclopentene. The semicarbazone prepared in the usual manner gave m. p. 209° (corr.) (R. and H. give 208–209°).

Anal. Subs., 0.1529; CO_2, 0.3062; H_2O, 0.0972. Calcd. for $C_7H_{11}ON_3$: C, 54.90; H, 7.19. Found: C, 54.61; H, 7.06.

Action of Sodium on **β-Bromobutylidene** Glycol.—The reaction was carried out in the same manner as with β-bromopropylidene glycol, and here also fractionation of the product yielded three main fractions and a residue.

Fraction (1), butylidene glycol, b. p. 128–135° (760 mm.), yielded for the most part butylidene glycol, b. p. 132–133° (760 mm.).

Anal. Subs., 0.2024: CO_2, 0.4589; H_2O, 0.1827. Calcd. for $C_6H_{12}O_2$: C, 62.07; H, 10.30. Found: C, 61.88; H, 10.03.

Fraction (2), **hydroxyethyl-β-ethyl** vinyl ether, b. p. 60–65° (10 mm.). This product was unsaturated against bromine in carbon tetrachloride, gave positive tests for the hydroxyl group and underwent cyclization in the presence of a trace of 50% sulfuric acid, yielding butylidene glycol, b. p. 135°.

Anal. (Fraction (2)). Subs., 0.1990: CO_2, 0.4521; H_2O, 0.1790. Calcd. for $C_6H_{12}O_2$: C, 62.07; H, 10.30. Found: C, 61.96; H, 10.00.

Fraction (3), dimethyl-di-1,6-hexylidene glycol (?), b. p. 150–170° (15 mm.). It was impossible to obtain a sharp boiling product from this fraction but it is presumably an impure diacetal derivative corresponding to the di-1,6-hexylidene glycol isolated in the similar reaction with β-bromopropylidene glycol.

For the purpose of preparing these diacetal derivatives it would probably be more advantageous to extract them with dry ether from the original reaction mixture before the addition of water. This would effect their separation from hydroxyvinyl products, which would be left in the residue in the form of their sodium salts.

Summary

1. The synthesis of β-bromopropylidene glycol and β-bromobutylidene glycol has been carried out.

2. The reaction of these compounds with metallic sodium is described and compared with corresponding reactions of α-bromo acetals.

3. The mechanism of these reactions is discussed.

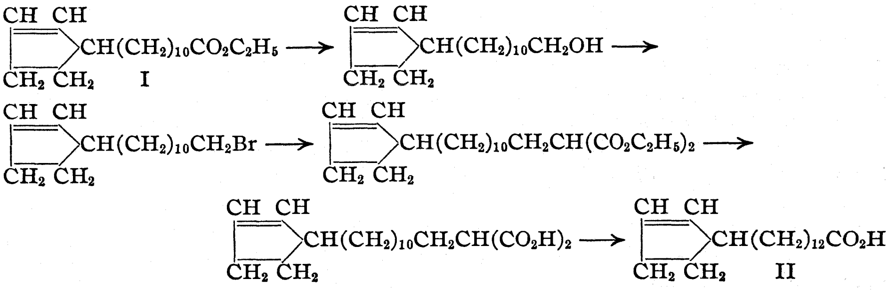
THE SYNTHESIS OF CHAULMOOGRIC ACID FROM HYDNOCARPIC ACID

By W. M. Stanley[1] and Roger Adams

Received December 7, 1928 Published May 6, 1929

In his early investigations on chaulmoogra oil and other oils of a similar character, Power[2] and his students isolated, in addition to chaulmoogric acid, hydnocarpic acid. This analyzed as a homolog of chaulmoogric acid. In order to confirm this conclusion, Power[3] oxidized hydnocarpic acid and isolated a di- and a tricarboxylic acid, the former of which proved to be n-decanedicarboxylic acid and the latter was assumed to be *n*-tridecane-α,α',γ-tricarboxylic acid. Since these oxidation products corresponded to those obtained from chaulmoogric acid, his conclusion was strengthened that the acids were homologs.

On account of the increasing importance of hydnocarpic acid and chaulmoogric acid, and on account of the fact that the correct structure for chaulmoogricacid, II, was found to be slightly different from that suggested by Power,[4] it seemed desirable to make further experiments to show the chemical relationship between these acids. This has been accomplished by conversion of hydnocarpic acid to chaulmoogric acid, II, through ethyl hydnocarpate, I, hydnocarpyl alcohol, hydnocarpyl bromide and hydnocarpylmalonic acid, successively.



No special comments need to be made concerning the well-known reactions involved. It should be stated, however, that the hydnocarpic acid used was not absolutely pure and consequently there was obtained in each step a certain amount of by-product which required careful fractionation for removal. No particular effort was made to purify completely each inter-

mediate step before conversion to the succeeding one, though each intermediate was purified for the determination of physical constants.

The hydnocarpylacetic acid obtained was contaminated with small amounts of other acids which were rather difficult to remove and required several fractional crystallizations. It was then possible to obtain a synthetic acid which had the same constants, melting point, rotation, etc., as the natural product (chaulmoogric acid). Moreover, the amides were compared and shown to be identical.

Perkins and Cruz[5] synthesized dl-chaulmoogric acid from simple organic compounds and showed that by oxidation the same decomposition products were obtained as from the natural, active form. The dl-form was not, however, resolved. Their investigation did not aid in the determination of the relationship of the natural hydnocarpic and chaulmoogric acids.

Experimental Part

Ethyl **Hydnocarpate.**—The hydnocarpic acid used in this investigation was kindly furnished by the Chemical Section of the Culion Leper Colony. The authors desire to express their appreciation for this material. The product had a melting point of 59.6" and a rotation of +69.4°.

A mixture of 250 g. of hydnocarpic acid, 400 g. of absolute ethyl alcohol and 7 g. of sulfuric acid was refluxed for two days. It was then cooled and poured into three times its volume of water containing 15 g. of sodium bicarbonate. The upper layer was separated and the slightly alkaline lower aqueous portion was extracted five times with ether and the ether extract washed twice with water. The ether extract was combined with the upper layer and again washed with water, dried over anhydrous magnesium sulfate, and distilled under diminished pressure. The yield was 246 g. (92%) of a product boiling at 160–165° (5 mm.) and having a rotation of +61.5° (0.5225 g. made up to 25 cc. in chloroform and used in a 1-dcm. tube). Twenty grams of hydnocarpic acid was recovered by acidifying the aqueous portion and extracting with ether. A 15-g. sample was fractionated and gave 9 g. of ethyl hydnocarpate, the physical constants of which did not change on further fractionation. The constants were: b. p., 143–144" (2 mm.); n^{25}_{D}, 1.4582; d^{25}_{4}, 0.9087; $[\alpha]_{\mathrm{D}}$, +70.5° (0.5186 g. made up to 25 cc. in chloroform and used in a 1-dcm. tube).

Power and Barrowcliff[2] report a boiling point of 211° (19 mm.) and a rotation of +51.6° on a 5-g. sample of ethyl hydnocarpate which they prepared. Sacks and Adams[6] report a boiling point of 217° (23 mm.) and n^{25}_{D}, 1.4577, on a 30-g. sample of ethyl hydnocarpate.

Hydnocarpyl Alcohol.—A total of 225 g. of ethyl hydnocarpate was reduced to hydnocarpyl alcohol in three separate reductions by the toluene method. In each experiment 75 g. of ethyl hydnocarpate, 500 cc. of absolute ethyl alcohol, 100 cc. of toluene and 70 g. of sodium were used.

A 5-liter, three-necked flask was fitted with a separatory funnel, a mechanical stirrer and an extra long condenser of large bore. In the flask were placed 70 g. of sodium and 100 cc. of toluene which had been dried over sodium, and the mixture was heated with a flame until the sodium melted. The stirrer was then started, the flame removed and the mixture allowed to cool until the molten sodium solidified into small

---

[5] Perkins and Cruz, THIS JOURNAL, 49, 1070 (1927).

[6] Sacks with Adams, *ibid.*, 48, 2395 (1926).

pellets. A mixture of 75 g. of ethyl hydnocarpate in 300 cc. of absolute ethyl alcohol was immediately run into the flask as rapidly as possible, followed immediately by 200 cc. of absolute ethyl alcohol. The stirring was continued and the mixture heated with a flame of sufficient size to keep the alcohol refluxing vigorously until practically all of the sodium had disappeared. The stirrer was stopped and the contents of the flask poured into an ordinary 5-liter flask. This was repeated twice and the three runs combined in the flask were heated on a steam-cone for ten hours. While still hot the mixture was washed with five times its volume of hot water or until the wash water was free of soap. It was washed once with water, then with water containing a small amount of sulfuric acid and finally with water. The wash water was combined and extracted four times with ether, the ether extract washed with water and then added to the main alcohol portion. The alkaline wash water was acidified and 25 g. of crude hydnocarpic acid was recovered. The solvent was removed and the alcohol distilled under diminished pressure. The yield was 90 g. (46%) of a product boiling at 170–175° (8 mm.) and having a rotation of +73.6° (0.7996 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube). Two high-boiling fractions consisting of 43 g. boiling at 185–210° (2 mm.) and 35 g. boiling above 210° (2 mm.) were obtained and probably consisted of dimolecular reduction products.

A 20-g. sample of the alcohol which was fractionated gave 15 g. of hydnocarpyl alcohol having the following constants: b. p., 144–145° (2 mm.); m. p., 23°; n_{D}^{25}, 1.4709; d_4^{25}, 0.8022; $[\alpha]_{\mathrm{D}}$, +75.2° (0.8592 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube). Further fractionation did not change these constants, although the high-boiling material from the first fractionation had a melting point of 27°, n_{D}^{27}, 1.4721, and $[\alpha]_{\mathrm{D}}$, +59.5. Sacks and Adams[6] report the following constants on a 12-g. sample of hydnocarpyl alcohol which was not subjected to further fractionation: b. p., 199.5° (14 mm.); m. p., 23°; n_{D}^{25}, 1.4733; $[\alpha]_{\mathrm{D}}$, +67.8° (0.8019 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube).

Hydnocarpyl Bromide.—A solution of 70 g. of hydnocarpyl alcohol in 150 cc. of dry toluene was placed in a 600-cc. flask fitted with a thermometer, calcium chloride tube and a separatory funnel, and cooled to 0° by means of an ice-bath. An ice-cooled solution of 65 g. of redistilled phosphorus tribromide in 70 cc. of dry toluene was then added sufficiently slowly so that the temperature of the reaction mixture did not rise above 5°. The reaction mixture was kept at 0° for six hours, then at room temperature for twelve hours and finally on a steam-cone for six hours. It was cooled and extracted with petroleum ether, the ether extract washed first with water and then with a solution of sodium carbonate, and finally dried for twelve hours over anhydrous potassium carbonate. The solvent was removed and the bromide was distilled under diminished pressure. The yield was 62 g. (70.5%) of a product boiling at 165–170° (5 mm.) and having a rotation of +19.4° (0.7521 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube). A 12-g. sample was fractionated to give 8 g. of hydnocarpyl bromide having the following constants: b. p., 156–157° (2 mm.); n_{D}^{25}, 1.4857; d_4^{25}, 1.0763; $[\alpha]_{\mathrm{D}}$, +27.4° (0.7604 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube). Further fractionation of the 8-g. sample did not cause any change in the constants. Sacks and Adams[6] report the following constants for hydnocarpyl bromide: b. p., 206–210° (14 mm.); m. p., 1°; n_{D}^{25}, 1.4871; $[\alpha]_{\mathrm{D}}$, +40.0° (0.5859 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube).

Monohydnocarpyl Diethyl Malonate.—The condensation of 50 g. of hydnocarpyl bromide with the sodium derivative of malonic ester was carried out in the usual way. The yield was 37 g. (59%) of a product having the following constants: b. p., 182–183° (2 mm.); n_{D}^{25}, 1.4601; d_4^{25}, 0.9519; $[\alpha]_{\mathrm{D}}$, $25.6" (0.6717 g. made up to 15 cc. in chloroform and used in a 1-dcm. tube).

Anal. Subs., 0.3200: CO_2, 0.8506; H_2O, 0.3018. Calcd. for $C_{23}H_{40}O_4$: C, 72.57; H, 10.60. Found: C, 72.49; H, 10.48.

Hydnocarpylacetic Acid (**Chaulmoogric** Acid).—Without isolating the intermediate malonic acid, 27 g. of monohydnocarpyl diethyl malonate was hydrolyzed to the malonic acid and then converted to the corresponding monobasic acid by the usual procedure.[7] The yield was 18 g. (92%) of a product boiling at 184–186° (1.4 mm.), melting at 61° and having a rotation of +38.3°. By careful fractional crystallizations from 80% ethyl alcohol (ethyl acetate and petroleum ether were used once each to remove any trace of ethyl chaulmoograte which might be formed), impurities of lower-melting products were eliminated and the least soluble chaulmoogric acid obtained which melted at 68° and had a rotation of +54.2°. Cold chloroform was added (about 10 cc. per g. of acid) until about two-thirds of the solid acid dissolved on shaking for two or three minutes. The insoluble portion was filtered and the product obtained by evaporation of the filtrate was recrystallized from 80% ethyl alcohol. After a second similar treatment with chloroform, the product obtained in the filtrate had a melting-point of 68° and a rotation of +61.9° which did not change on further treatment. A mixed melting point with pure natural chaulmoogric acid showed no depression.

Fractions obtained during the crystallization of the synthetic chaulmoogric acid had a melting point as low as 59° and a rotation as low as +19.5°. Apparently small amounts of impurities, presumably acids, were converted in each step in the process in a similar manner to the hydnocarpic acid and were not so easily removed from the final product as might have been expected.

Anal. Subs., 0.3162, 0.1200: CO_2, 0.8965; H_2O, 0.3196; 4.25 cc. of 0.1007 N alcoholic NaOH. Calcd. for $C_{18}H_{22}O_2$: C, 77.07; H, 11.51; neut. equiv., 280.26. Found: C, 77.32; H, 11.23; neut. equiv., 280.3.

Chaulmoogramide.—The amide of the synthetic chaulmoogric acid was made by the method described by Aschan[8a] and later by Power and Gornall[8b] and also by the method described by Shriner and Adams.[4] The melting point was 104° and a mixed melting point with chaulmoogramide made from natural chaulmoogric acid showed no depression.

Summary

Hydnocarpylacetic acid was prepared from hydnocarpic acid through hydnocarpyl ester, hydnocarpyl alcohol, hydnocarpyl bromide, hydnocarpylmalonic ester, and hydnocarpylmalonic acid. It proved to be identical with natural chaulmoogric acid.

THE COMPOSITION OF GUM ARABIC[1,2]

BY C. L. BUTLER AND LEONARD H. CRETCHER

RECEIVED DECEMBER 7, 1928 PUBLISHED MAY 6, 1929

Although a vast amount of research has been done in the field of carbohydrate chemistry, comparatively little attention has been given to the group of substances which may be classified under the heading of acid polysaccharides. In this group we find such substances as pectins, plant gums, hemicelluloses, mucilages, soluble specific substances produced by bacteria and alginic acid from algae. Most of these substances appear to be formed by modification of cellulose under the influence of enzymes, few, if any, of them being produced directly by photo-synthesis. Acid polysaccharides apparently play a very important, though poorly understood, role in natural processes. Any information that may be obtained regarding the structure of these substances should be of value in the elucidation of their functions in the immunology of infectious diseases and the physiology of plants. They are also of interest in connection with the problems of ropy bread, beer and wine. Among the members of this class of substances which we are investigating in this Laboratory are the plant gums.

Under the name of gums, a variety of substances have been described which differ considerably from one another both chemically and physiologically. The plant gums, as is well known, are salts of very complex organic acids usually with calcium, magnesium and potassium. These complex acids are built up of hexose, pentose and methylpentose units in combination with the acidic part of the molecule. The facts that many of them liberate carbon dioxide on heating with 12% hydrochloric acid[3] and that they give the naphtho-resorcin test[4] indicate that they contain uronic acid units.[5] In fact Anderson and his co-workers have reported the presence of glucuronic acid in mesquite gum and galacturonic acid in cholla gum.[6]

But little work has been done on the acidic nucleus of gums since the early researches of O'Sullivan. This author hydrolyzed arabic acid—

[6] Abstract of papers presented before the Organic Chemistry Division of the American Chemical Society at the St. Louis Meeting, April, 1928.

from gum arabic—with dilute sulfuric acid and isolated a stable acid of lower molecular weight which he called X-arabinosic acid.[7] He assigned to the substance the formula $C_{23}H_{38}O_{22}$. Similarly O'Sullivan prepared so-called C_{23} acids from gum tragacanth and from gedda gum.[8] Robinson, in 1906, also claimed to have isolated a C_{23} acid from the gum of *Cochlospermum Gossypium*.[9] Various other gums have been investigated, but as stated above with little, if any, emphasis placed on the acidic nucleus.

A botanically authentic sample of Gum Arabic Cordofan from Acacia Senegal (L.) *Willd.* was hydrolyzed with 2% sulfuric acid and the acidic reaction product isolated by methods which are set forth in the experimental part of this paper. Analysis of the dried, purified salt indicated an aldobionic acid of formula $C_{12}H_{20}O_{12}$. This acid was analytically identical with the X-arabinosic acid of O'Sullivan,[10] who assigned to it the formula $C_{23}H_{38}O_{22}$ though his own analytical figures correspond as well to $C_{12}H_{20}O_{12}$. It gives a strong naphtho-resorcin test and reduces Fehling's solution. On boiling with 12% hydrochloric acid the correct amount of carbon dioxide is liberated, and the amount of iodine consumed in oxidation, as well as the percentage of calcium found, corresponds to the requirements of a compound of the formula given, containing one free aldehyde and one carboxyl group.

From a consideration of these facts the authors are led to wonder if the other C_{23} acids produced from gums and referred to in this paper are not in reality aldobionic acids. This point is being investigated.

The identity of the sugar constituent of this aldobionic acid was determined by hydrolysis with 5% sulfuric acid. This sugar had the correct rotation for d-galactose and formed mucic acid on oxidation. The acidic fraction was too small in amount to serve for purposes of identification due to the fact that, under the conditions of the hydrolysis, the uronic acid was largely destroyed. Simultaneous hydrolysis and oxidation of the aldobionic acid[11] was accomplished by boiling with hydrobromic acid in the presence of bromine. This led to the formation of saccharic acid, as shown by the isolation of acid potassium saccharate. The aldobionic acid is, therefore, galactoso-glucuronic. It is isomeric with the aldobionic acids isolated by Heidelberger and Goebel[11] from the polysaccharides produced by Pneumococcus Types II and III and from Friedlander Bacillus Types A, B and C.

In order to throw further light on the structure of this aldobionic acid, it was oxidized by the method of Goebel[12] to the dibasic acid, glucurono-

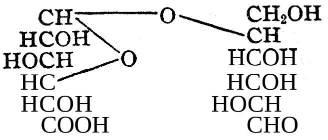
galactonic. This substance was isolated and analyzed as the calcium salt. It gave a strong naphtho-resorcin test and on boiling with 12% hydrochloric acid liberated one molecular proportion of carbon dioxide. It did not reduce Fehling's solution. It is thus apparent that the uronic acid residue is intact in the oxidized acid and that the linkage between the two residues in the aldobionic acid is between the aldehyde of the glucuronic acid and a hydroxyl group of the galactose. Nothing, of course, is known as to which of the galactose hydroxyl groups enters into the glucosidic linking. The following formula is, therefore, purely hypothetical.



An interesting fact about this aldobionic acid is that, unless gum arabic is of bacterial origin, it is the first compound of this sort to have been found except in products of bacterial metabolism. It has been affirmed[13] and denied[14] that gums are of bacterial origin. Our results are interesting in this connection, though we do not offer them in evidence one way or the other.

Heidelberger, Avery and Goebel[15] have reported that occasional samples of gum arabic possess specific activity which they were able to enhance greatly by hydrolyzing until about 50% of the pentose contained in the gum was removed. The same authors have obtained an acid hydrolysis product of this gum which on analysis gave figures indicating that it was a somewhat impure aldobionic acid.[16] Since these investigators have shown that aldobionic acids are components of other specific carbohydrates,[11] the occurrence of this type of substance among the hydrolysis products of gum arabic does not seem surprising.

It has long been known that d-galactose and l-arabinose are formed on hydrolysis of this gum, or of arabic acid prepared from it.[17] Votoček and Vondraček[17c] have also reported the presence of d-glucose in the gum. Although the work done by us on the sugar fraction of the gum arabic hydrolysis product is not complete, the presence of d-galactose and l-arabinose has been confirmed, and the presence of the methylpentose,

rhamnose, has been established. We prepared arabic acid (the ash-free gum) according to the method of Neubauer,[18] and analyzed it for pentose and methylpentose by the furfural-phloroglucid method;[19] for galactose by oxidation and isolation of mucic acid:[20] for uronic acid carbon dioxide by the Lefevre method;[21] and for carbon and hydrogen. The results are shown in Table I. The figures correspond roughly to 1 molecule of aldobionic acid, 2 of galactose, 3 of arabinose and 1 of methylpentose.

TABLE I

RESULTS OF ANALYSES

Galactoso-glucuronic acid	28.3%
Hexose (as galactose)	29.5%
Pentose (as arabinose)	34.4%
Methylpentose (as rhamnose hydrate)	14.2%
Total	106.4%

Titration of the acid with sodium hydroxide solution gave an equivalent weight of 1030. Titration with alkali in hot and cold solution also showed that arabic acid exists to the extent of about 22% as lactone.

Experimental Part

Hydrolysis of Gum Arabic by Dilute Sulfuric Acid.—Five hundred grams of gum arabic, $[\alpha]^{25}_{D} = -34.05°$ (dry basis), containing 2.72% of ash and 9.89% of moisture was dissolved in one and one-half liters of water and to this solution was added a solution of 64 g. of sulfuric acid in a liter of water. The solution thus prepared contained arabic acid dissolved in 2% sulfuric acid. It was refluxed gently and the course of the hydrolysis was followed by polarimetric readings. When the observed rotation ($l = 1$) reached +9.4°, further heating caused but slight increase in rotation and the hydrolysis was considered to be complete. This required about twenty hours.

Isolation of Calcium Aldobionate.—An excess of calcium carbonate was then added, the mixture warmed for several hours on a water-bath and allowed to stand overnight. It was filtered and the precipitate washed with a little water. After two treatments with "Nuchar" a clear, pale yellow liquid was obtained. This was evaporated *in vacuo* to a sirup and a crude separation into acidic and non-acidic parts was made by addition of ethyl alcohol. Some colored impurities were separated by fractional precipitation from water with ethyl alcohol.[11]

Final purification was accomplished by several precipitations from a concentrated water solution by pouring with stirring into about 10 volumes of methyl alcohol. The yield of calcium salt was 44 g. An additional 10 g. of salt was obtained from the methyl alcoholic mother liquors (see page 1524) making the total yield 54 g.

This salt was quite soluble in water. A sample of 1.25 g. dissolved in water and made up to 25 cc. had an observed rotation of +0.18° in a 2-decimeter tube; $[\alpha]^{25}_{D} = +1.8°$. It reduced Fehling's solution and gave a strong naphtho-resorcin test.[22]

Anal. Subs., 0.2437: CO_2, by Lefevre method, 0.0282. 0.2388 required 12.7 cc. of $N/10$ iodine for oxidation.[12,23] Subs., 0.1316: CO_2, 0.1830; H_2O, 0.0636. Subs., 0.9549: $CaSO_4$, 0.1872. Calcd. for $(C_{12}H_{19}O_{12})_2Ca$: CO_2, 11.7; $N/10$ iodine, 12.7 cc.; C, 38.33; H, 5.07; Ca, 5.33. Found: CO_2, 11.6; C, 37.91; H, 5.36; Ca, 5.76.

The alcoholic sugar solution resulting from the separation and purification of the calcium salt was saved for further investigation.

Free Aldobionic Acid.—Several attempts to prepare the free aldobionic acid were made. However, this acid has a strong tendency toward lactone formation. On evaporation of the solution obtained after removal of calcium from the salt by means of oxalic acid, a mixture of lactone and acid was obtained. This mixture—a white powder—was soluble in water and methyl alcohol.

On titrating 0.2000 g. with sodium hydroxide in the cold in the presence of phenolphthalein, 4.5 cc. of $0.1N$ sodium hydroxide was required. On warming the solution an additional 1.2 cc. of alkali was neutralized. These figures correspond to an equilibrium mixture of 79.5% of acid and 20.5% of lactone. The theoretical total titration for such a mixture is 5.6 cc. of $0.1N$ alkali.

Anal. Subs., 0.1411: CO_2, 0.2123; H_2O, 0.0730. Calcd. for 79.5% of $C_{12}H_{20}O_{12}$ and 20.5% of $C_{12}H_{18}O_{11}$: C, 40.95; H, 5.60. Found: C, 41.05; H, 5.78.

A 1.00-g, sample of calcium aldobionate dissolved in water, acidified with twice the calculated amount of hydrochloric acid and made up to 25 cc. had an initial observed rotation of $+0.19°$ in a 2-decimeter tube; $[\alpha]^{25}_{D} = +2.5°$ (calculated on the basis of free acid liberated). After seventeen hours the rotation was $[\alpha]^{25}_{D} = +1.71°$.

The Components of the Aldobionic Acid

The Identification of the Sugar.—The calcium was removed from about 1.0 g. of calcium aldobionate by the calculated amount of oxalic acid and the solution of free aldobionic acid was evaporated to dryness in *vacuo.* Fifty cubic centimeters of 1.0 N sulfuric acid was then added and the solution was refluxed gently for eighteen hours. The hydrolysis product was boiled with an excess of barium carbonate and after cooling was filtered. The filtrate was evaporated to dryness *in vacuo* and the residue extracted with alcohol, thus separating a small amount of alcohol-insoluble barium salt from the sugar formed on hydrolysis of the aldobionic acid. The alcoholic solution of the sugar was treated with a little Nuchar and evaporated to dryness. The observed rotation for $C = 0.6$ and $l = 2$ was $+0.94°$; $[\alpha]^{25}_{D} = +78.3°$; $[\alpha]_D$ (galactose) $= +80°$.

The sugar was submitted to oxidation with nitric acid. After cooling the reaction mixture and scratching the dish, fine crystals of mucic acid separated. The reaction mixture was allowed to stand overnight; the mucic acid was then filtered off, washed several times with saturated mucic acid solution and once with water and dried; m. p. 219–220° (corr.).

The Identification of the Acid Part of the Molecule.—The barium salt resulting from the hydrolysis above described was so crude and so small in amount that identification was impossible. A sample of aldobionic acid, prepared by decomposing 2.17 g. of the calcium salt with the calculated amount of oxalic acid, was, therefore, submitted to simultaneous hydrolysis and oxidation according to the method of Heidelberger and Goebel.[11] That mucic acid was not formed was shown by the fact that no insoluble dibasic acid separated out of the reaction mixture even after seeding with a few crystals of pure mucic acid. After neutralizing the concentrated solution with 50% potassium hydroxide solution, it was acidified with glacial acetic acid. After standing for several days in an ice box, 0.25 g. of crude acid potassium saccharate separated from solution. The material was recrystallized from 1.0 cc. of water, dried and analyzed,

[23] Willstätter and Schudel, Ber., 51, 780 (1918).

Anal. Subs., 0.1148: K_2SO_4, 0.0410. Calcd. for $COOH(CHOH)_4COOK$: K, 15.75. Found: K, 16.02.

The Stability of Galactoso-glucuronic Acid in 1 N Sulfuric Acid.—The very small amount of barium salt obtained by hydrolyzing galactoso-glucuronic acid with 1.0 N sulfuric acid indicated considerable decomposition of the aldobionic acid by the hot dilute sulfuric acid. An estimation of the extent to which this decomposition took place was obtained by weighing the carbon dioxide evolved during hydrolysis. A solution of 1.0 g. of calcium aldobionate in 50 cc. of 1.0 N sulfuric acid was refluxed gently for eighteen and one-half hours in the Lefevre carbon dioxide apparatus. The carbon dioxide evolved weighed 0.0520 g. Thus the aldobionate was decomposed to the extent of about 44%, since complete removal of carboxyl would yield 0.1173 g. of carbon dioxide.

Oxidation of the Aldobionic Acid to a Dibasic Acid.—A sample of galactoso-glucuronic acid was oxidized with barium hypo-iodite according to the method of Goebel.[12] Two grams of calcium aldobionate yielded about 1.5 g. of reprecipitated calcium glucurono-galactonate.

Anal. Subs., 0.5000: $CaSO_4$, 0.1681. Subs., 0.4000: CO_2, 0.0429 (Lefevre method). Calcd. for $C_{10}H_{18}O_9(COO)_2Ca$: Ca, 9.75; CO_2, 10.73. Found: Ca, 9.88; CO_2, 10.72.

Analysis of Arabic Acid.—This substance was prepared from gum arabic according to the method of Neubauer.[13] A sample of 0.9490 g. (dry basis) of acid containing 5.1% moisture made up to 25 cc. in water had an observed rotation of −1.23° in a 1-decimeter tube; $[\alpha]_D^{25} = -32\ 36°$.

Anal. Subs. (dry), 0.1235: CO_2, 0.1978; H_2O, 0.0680. Found: C, 43.67; H, 6.15. Subs. (dry), 1.000: CO_2 (Lefevre method), 0.0353. Found: 3.53% of CO_2, equivalent to 14.1% of uronic acid anhydride. Subs. (containing 5 1% of moisture), 1.0537 (1.000 dry subs) required 7.6 cc. of $N/10$ NaOH for neutralization at room temperature using phenolphthalein, and 9.7 cc. when titrated to a permanent end-point in hot solution. Equivalent weight based on hot titration, 1030. Subs., 0.2372: 0.0146 g. of alcohol-soluble phloroglucid and 0.0799 g. of alcohol-insoluble phloroglucid. From the latter figure was deducted 0.0112 g. to allow for the phloroglucid due to the uronic acid.[24] Found: methylpentose (as rhamnose hydrate), 14.2; pentose (as arabinose), 34.4. Subs., 0 9100, 0.9100: mucic acid, 0.2870, 0.2795.[25] Found: galactose, 42.9, 41.8, average, 42.4.

Preliminary Work on the Identification of the Sugars Formed on Hydrolysis of Gum Arabic

Galactose.—The presence of this sugar was shown both by analysis of arabic acid by the mucic acid method[24] and by isolation of the sugar. The methyl alcoholic mother liquors from the purification of the crude calcium aldobionate were concentrated to 100 cc. and poured into 350 cc. of methyl alcohol. An equal volume of ethyl alcohol was added and the mixture was allowed to stand to permit the precipitate to settle. An additional 10 g. of calcium salt was thus obtained.

The mother liquor from this precipitation was evaporated to about 75 cc.; it gave no further precipitate with methyl alcohol. The liquor was poured with stirring into 500 cc. of ethyl alcohol and a sirupy layer separated out. This became granular on grinding with absolute ethyl alcohol. The material, vacuum dried at 80°, was found to contain 1.07% of calcium, corresponding to 20.06% of calcium aldobionate. A

---

[24] Ref. 19, p. 75.

[25] Ref. 19, p. 123

sample of 0.8762 g. made up to 25 cc. in water had an observed rotation of +4.33° in a 2-decimeter tube. If the small rotation of the aldobionate be neglected and allowance be made for 20% of (practically) inactive calcium salt, c = 2 8; $[\alpha]_D^{25}$ = +77.4°; for galactose $[\alpha]_D$ = +80°. On oxidation with nitric acid, mucic acid melting at 220° (corr.) was obtained. The substance was therefore impure galactose.

Arabinose and **Rhamnose.**—Practically pure arabinose of melting point 155–156° was isolated by the method of Anderson and Sands.[3] A sample of 1.00 g. made up to 25 cc. in water had an observed rotation of +8.16° in a 2-decimeter tube; $[\alpha]_D^{25}$ = +102°.

The presence of both *l*-arabinose and rhamnose was demonstrated in the main bulk of mother liquor from the separation of crude calcium aldobionate after removal of two crops of crystals consisting of a mixture of pentose (probably arabinose) and hexose (probably galactose). A sample of the sirup was evaporated to dryness and treated with diphenylhydrazine according to Van der Haar.[26] A diphenylhydrazone separated, which after several recrystallizations melted at 210–202° (corr.), Van der Haar gives 204° as the melting point of pure arabinose diphenylhydrazone.[27]

A second sample of sirup was evaporated to dryness *in vacuo* and treated with *p*-bromophenylhydrazine, also according to Van der Haar.[28] A bright yellow *p*-bromophenylosazone was thus obtained which melted, after repeated washings with 90% ethyl alcohol and acetone, at 217–218°. The substance did not depress the melting point of a sample of pure rhamnose p-bromophenylosazone prepared from rhamnose which also melted at 217–218°. The observed rotation for c = 2.47 in a 20–80 pyridine–alcohol mixture and l = 1, was +1.0°; $[\alpha]_D^{25}$ = +40.5°. The value found for rhamnose p-bromophenylosazone made from rhamnose was $[\alpha]_D^{25}$ = +0.95 where 1 = 1 and c = 2.34; $[\alpha]_D^{25}$ = +40.6°.

Anal. Subs., 0.2000: AgBr, 0.1510 by Stepanow's method. Calcd. for $C_{18}H_{20}O_3N_4Br_2$: Br, 31.96. Found: Br, 32.13.

Summary

1. Gum arabic and arabic acid prepared from this gum have been studied analytically and polarimetrically.
2. Rhamnose, d-galactose and *l*-arabinose have been identified in the sugar fraction of the hydrolysis product.
3. The acidic nucleus of the gum has been shown to be an aldobionic acid whose components are d-galactose and d-glucuronic acid.

A STUDY OF THE GERMICIDAL ACTIVITY OF DIARYL-SULFIDE PHENOLS

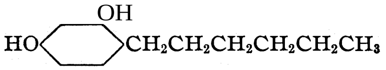
BY GUIDO E. HILBERT[1] AND TREAT B. JOHNSON

RECEIVED DECEMBER 11, 1928 PUBLISHED MAY 6, 1929

Introduction

The clinical success of hexylresorcinol, I, as a specific, internal antiseptic[2] was an incentive to extend our researches on germicides still further into the field of aromatic phenols. While various organic radicals have been incorporated into resorcinol with the object of increasing the phenol coefficient, no product has thus far been prepared in this series which has exhibited a higher germicidal value[3] than the hexyl compound. It is not to be assumed, however, that this hexyl combination represents the maximum in antiseptic efficiency that may be expected among organic constructions containing phenolic groups, and it was with the object of increasing this therapeutic or clinical value that we decided to extend our field of investigation along entirely new lines.

I



We have, therefore, inaugurated in this Laboratory a series of researches dealing with the question of the influence of sulfur linkages in organic combinations on germicidal activity. The study of the antiseptic properties of phenolic sulfur combinations has hitherto received little attention. The growing interest in the biochemistry of organic sulfur groupings[4] has stimulated a desire to acquire a better understanding of the influence of this element on antiseptic properties. The recent important work on

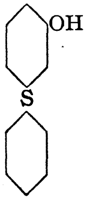
thyroxine[6] has clearly revealed the significance of the biological effect of incorporating an aromatic ether linkage into di-iodotyrosine[6] and the accepted conclusion regarding the constitution of thyroxine suggests that one might expect sulfur in aromatic sulfide combination to have an important and perhaps a favorable effect on the therapeutic action of phenols. A review of the literature reveals the fact that practically no attention has hitherto been paid to this clinical feature. Furthermore, our knowledge of the chemistry of aryl-sulfide phenols and their derivatives is very limited. New methods of synthesis must be worked up before the development of this field biologically can be advanced.[7]

Aryl-Sulfide Phenols

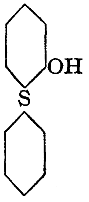
The feature of our research to which we desire to direct special attention in this paper is the high phenol coefficient of the sulfide-phenol represented by Formula II, and the influence on germicidal activity by changing the structural position of the phenolic hydroxyl group in diphenyl sulfide. The degree of germicidal activity of the three isomers II, III and IV,

II

III



IV



is expressed in the order para>meta>ortho. An account of the preliminary bacteriological and toxicity tests, thus far conducted, is given in the Experimental Part of this paper.

Of the three isomeric phenols represented by Formulas II, III and IV, the para- and ortho-compounds have been previously reported in the literature. The para-compound was first obtained by Hinsberg[8] by allowing phenol to interact with benzenesulfinic acid. He was unsuccessful, however, in his attempts to purify the phenol and described it

$$2C_6H_5SO_2H \longrightarrow C_6H_5SO_2OH + C_6H_5SOH$$
$$C_6H_5SOH + C_6H_5OH = C_6H_5SC_6H_4OH + H_2O$$

as an undistillable oil; he presented no experimental evidence in support of its constitution. Its formation has since been reported by different

[7] Two new researches in this field are already in progress in the Sterling Laboratory and are being carried on in cooperation with Messrs. Shailer Bass and George H. Law (T. B. J.).

[8] Hinsberg, *Ber.*, 36, 107 (1903); German Patent 147,634; *Chem. Zentr.*, 75, 130 (1904).

investigators,[9] but in no single case have the properties of this phenol been correctly recorded, or has the constitution of Hinsberg's phenol been established. We have repeated Hinsberg's work and have succeeded in obtaining by dealkylation of the methyl ether of this phenol the pure sulfide-phenol, II, and established conclusively its constitution. This was accomplished by heating the methyl ether of the phenol, or the phenol II, with hydrobromic acid in acetic acid under pressure. The sulfide is thereby destroyed with formation of *p*-bromophenol and diphenyldisulfide as is expressed below. This behavior on prolonged heating with strong hydrobromic acid clears up the observation made by Hinsberg that

$$CH_3OC_6H_4SC_6H_5 + HBr = HOC_6H_4SC_6H_5 + CH_3Br$$
$$HOC_6H_4SC_6H_5 + HBr = HOC_6H_4Br + C_6H_5SH$$
$$2C_6H_5SH + O = C_6H_5S_2C_6H_5 + H_2O$$

p-methoxydiphenylsulfide yields methyl iodide and diphenyldisulfide when heated with hydriodic acid.

We have also established the constitution of Hinsberg's phenol by a new synthesis of the compound according to the method described by Lecher,[9c] who investigated the action of phenyl sulfochloride on Grignard reagents. This chloride was found to interact smoothly with *p*-bromoanisolemagnesium, yielding p-methoxydiphenylsulfide. On demethylating by heating with hydrobromic acid we obtained the same phenol as was formed in the Hinsberg process. Lecher showed also that the sulfide phenol, II, is formed in small yield by direct interaction of phenol with phenyl sulfochloride, but he did not succeed in purifying the compound thus obtained and the method of synthesis is of no practical value.

For the preparation of our three phenols we have made use of the Ziegler reaction. This investigator[10] showed that thiophenols do not interact with diazonium salts in a manner similar to phenols, but combine to give diazothio-ethers which break down at 70° giving an aromatic sulfide and nitrogen. If the reaction is run below 70" the sudden decomposition of an accumulation of the diazothio-ether may result in a violent explosion. The Ziegler reaction is one

$$C_6H_5SNa + C_6H_5N_2Cl = C_6H_5SC_6H_5 + NaCl + N_2$$

that is possible of wide application, but has not been utilized for the preparation of sulfide-phenol combinations. The reaction has been used by Graebe and Schultess,[11] Weedon and Doughty[12] and Mayer,[13] who applied it successfully with anthranilic acid, thereby leading to the later

development of the chemistry of phenylthiosalicylic acid and the thioxanthones. Mauthner,[14] however, reports no success in his attempts to apply the Ziegler reaction. We likewise have had no success in applying the Ziegler reaction with diazotized aminophenols. However, by treating thiophenol with the diazotized anisidines it is possible to obtain the methoxydiphenyl sulfides in good yields. For the practical application of the Ziegler reaction, two experimental conditions are essential: (1) that the interaction between diazonium salt and thiophenol take place at a temperature at which the former is stable, and thus prevent the formation of a phenol; (2) that the diazonium salt be soluble in water. If the diazonium salt is unstable at 70°, the reaction is best carried out at a lower temperature in the presence of copper powder, which was found to catalyze the decomposition of the diazothio-ether, thus avoiding a possible explosion.

In our study of this reaction we observed that a diazothio-ether can break down with formation of a sulfide and nitrogen and also with production of a diphenyldisulfide and nitrogen. The mechanism of this second change is not correctly understood. For a successful application of the Ziegler reaction it is necessary, therefore, to operate under experimental conditions which favor the decomposition expressed by the first equation.

$$C_6H_5N_2SC_6H_5 \longrightarrow N_2 + C_6H_5SC_6H_5 \quad (1)$$

$$C_6H_5N_2SC_6H_5 \longrightarrow N_2 + C_6H_5S_2C_6H_5 \quad (2)$$

Experimental Part

Benzenesulfinic Acid.—This acid was prepared according to a slight modification of the method of Knoevenagel,[15] by passing sulfur dioxide into a mixture of benzene and aluminum chloride. The sodium benzenesulfinate was isolated and recrystallized twice from water. Because of the instability of the free acid it was kept in the form of the sodium salt until shortly before the acid was required, which was then obtained in the usual manner.

_p_-Methoxydiphenylsulfide.—This was prepared after a modification of the Hinsberg method,[8,16] by treating freshly distilled phenol with 2 moles of dry benzenesulfinic acid melting at 83°. Dimethyl sulfate was used as the methylating agent instead of methyl iodide. The crude *p*-methoxydiphenylsulfide was found to contain methylphenylsulfone and an oil which was probably o-methoxydiphenylsulfide. The methylphenylsulfone separated out of the crude distilled oil, from which it was filtered. It was crystallized from a mixture of ethyl alcohol and water and separated in thin plates melting at 88°.

Anal. Calcd. for $C_7H_8O_2S$: S, 20.50. Found: S, 20.48.

This sulfone results from the methylation of benzenesulfinic acid. Its formation was prevented by shaking, before methylation, an ether solution of the crude *p*-hydroxydiphenylsulfide with a solution of sodium carbonate.

The crude p-methoxydiphenylsulfide was purified by repeated fractional distillation

and boiled at 194–195° at 13 mm. A 10% yield of a colorless oil having a slight ethereal odor was obtained.

Anal.[17] Calcd. for $C_{13}H_{12}OS$: S, 14.80. Found: S, 14.97.

Attempts to improve the yield by a variation of the proportions of reactants and of the reaction temperature were without success. The use of a catalyst such as calcium chloride increased the amount of resinification.

Demethylation of *p*-Methoxydiphenylsulfide.—Hinsberg[8] used hydrochloric acid at 180° as the demethylating agent. His work was repeated and the method found to be unsatisfactory, because of the poor yield obtained (17.3%). Attempts to improve it by raising the temperature or increasing the amount of hydrochloric acid led to still further decomposition. The use of aluminum chloride to demethylate was investigated and also found to be unsatisfactory.

The use of a solution of hydrobromic acid in glacial acetic acid under pressure proved to be satisfactory, but a simpler and better procedure is to use a mixture of acetic anhydride and 48% aqueous hydrobromic acid in which the use of pressure bottles and the solution of hydrobromic acid in glacial acetic acid is obviated.

Ninety grams of 48% hydrobromic acid was slowly added to 224 g. of acetic anhydride with cooling in an ice–salt bath. Fifty grams of p-methoxydiphenylsulfide was dissolved in this solution, which was contained in a round-bottomed flask provided with a reflux condenser fitted with a calcium chloride tube, and heated at 80–90° for six hours. After completion of the reaction the excess of hydrobromic and acetic acids was removed by distillation under diminished pressure. The remaining oil was treated with a 10% sodium hydroxide solution and heated on a steam-bath for one hour, in order to hydrolyze any acetylated product. After removing the unchanged methoxy compound with ether, the alkaline solution was acidified with hydrochloric acid, when *p*-hydroxydiphenylsulfide separated as an oil. This was extracted with ether and dried over sodium sulfate. After removal of ether, the sulfide was purified by repeated distillation. It boiled at 164–165° at 3 mm. and the yield was 32 g. (68.5%) of a colorless oil, which crystallized in long prisms. They belong to the monoclinic system[18] and have good cleavage into rhomboid fragments. It was recrystallized from petroleum ether, in which it is slightly soluble, and melted at 50–51°. p-Hydroxydiphenylsulfide is exceedingly soluble in alcohol, acetic acid, ether and benzene, and soluble to the extent of 34 parts in 100,000 of water. It gives no color test with ferric chloride and Millon's reagent and yields a yellowish-green color with concentrated sulfuric acid, which turns dark blue on heating. The Folin and Denis phosphotungstic acid reagent[19] gives a positive test.

Anal. Calcd. for $C_{12}H_{10}OS$: S, 15.86. Found: S, 15.64, 15.50.

***p*-Diphenylsulfide-*p*-nitrobenzoate.**—This was prepared by application of the Schotten–Baumann reaction to *p*-hydroxydiphenylsulfide and *p*-nitrobenzoyl chloride. It crystallized from 95% alcohol in large, yellow prisms melting at 74–75°.

Anal. Calcd. for $C_{19}H_{13}O_4NS$: S, 9.19. Found: S, 9.28.

Destruction of the Sulfide Linkage.—Sixteen grams of *p*-methoxydiphenylsulfide was dissolved in 62 g. of a 21% solution of hydrobromic acid in glacial acetic acid and then heated for twenty hours at 60° in a pressure bottle. After removal of excess hydrobromic acid and acetic acid, the remaining oil was shaken with 10% sodium hydroxide solution. A white flocculent precipitate separated which was removed with ether. The ether was distilled off and the solid, after recrystallization from 80%

[18] The crystallographic examination was kindly made by Dr. E. J. Roberts.

[19] Folin and Denis, *J. Biol. Chem.*, 12, 240 (1912).

alcohol, was identified as diphenyldisulfide. The above 10% sodium hydroxide solution was acidified with hydrochloric acid, extracted with ether, the ether removed and the remaining oil distilled, which proved to be p-bromophenol.

Refluxing *p*-methoxydiphenyl sulfide with a 48% hydrobromic acid solution also yielded p-bromophenol, diphenyldisulfide and a considerable amount of a resinous product.

Modification of Hinsberg's Reaction to Obtain *p*-Hydrodiphenylsulfide Directly.—By this process the steps of methylation and demethylation and their attendant losses are eliminated. Thirty-two grams (2 moles) of benzenesulfinic acid was mixed with 11.5 g. (1 mole) of phenol and heated on a water-bath for two hours. The dark red reaction mixture was shaken with a sodium carbonate solution and distilled with steam to remove the excess of phenol. The contents of the flask were then acidified with hydrochloric acid, which precipitated a resin and caused an oil to separate. This oil was extracted with ether, the ether extract repeatedly washed with sodium carbonate solution, finally with water and then dried over sodium sulfate. After removal of ether the remaining oil was distilled under diminished pressure; 8 g. of crude *p*-hydroxydiphenylsulfide boiling at 165–167° at 4 mm. was obtained. The yield was 30% of the theoretical. By repeated distillation and crystallization this yield was considerably reduced. Three grams of a pale yellow oil boiling at 160–165° at 4 mm. and which did not crystallize on cooling was also obtained. It is probable that we were dealing here with the ortho isomer of our reaction product, but its structure was not established.

***p*-Methoxydiphenylsulfone.**—A modification of Hinsberg's method[20] for the oxidation of sulfides to sulfones by hydrogen peroxide was used. Ten grams of *p*-methoxydiphenylsulfide dissolved in 100 g. of glacial acetic acid, purified by the method of Orton and Bradfield,[21] was treated with 13 g. of 30% hydrogen peroxide solution. The reaction mixture was allowed to stand at room temperature for one hour and finally heated on a hot-plate for another hour. After the acetic acid had been removed the resulting dark brown oil, which solidified on cooling, was dissolved in hot 60% alcohol, treated with boneblack and the solution cooled, when p-methoxydiphenylsulfoxide and its sulfone crystallized. The sulfone was obtained free from the sulfoxide by recrystallization from alcohol until the product gave no color with concentrated sulfuric acid. *p*-Methoxydiphenylsulfone[22] crystallizes from alcohol in clusters of colorless needles melting at 90–91° and is soluble in ether, benzene, alcohol and insoluble in petroleum ether and water. A yield of 6 g. of the pure sulfone was obtained (52%).

Anal. Calcd. for $C_{13}H_{12}O_3S$: S, 12.92. Found: S, 13.03.

***p*-Hydroxydiphenylsulfone.**—Six grams of p-methoxydiphenylsulfone was dissolved in a mixture of 48% aqueous hydrobromic acid and 20.4 g. of acetic anhydride and heated for six hours at 90°. After removal of the excess of hydrobromic acid and acetic acid, the remaining oil, which solidified on cooling, was treated with a 10% sodium hydroxide solution and extracted with ether. The alkaline solution on acidifying with hydrochloric acid yielded an oil which was dissolved in ether, washed with sodium carbonate solution, water and dried over sodium sulfate. The ether was removed and 3 g, of a brown solid recovered. This was purified by crystallization from alcohol when the sulfone separated in clusters of colorless needles melting at 136–137°. It is difficultly soluble in water and petroleum ether and soluble in hot alcohol and benzene. A water solution gave no color with ferric chloride.

p-Hydroxydiphenylsulfide by Application of the Grignard Reaction.—Phenylsulfochloride was prepared from diphenyldisulfide according to the method of Lecher.[9c] This was modified slightly by using carbon bisulfide instead of carbon tetrachloride as the solvent during chlorination. Better results were also obtained by distilling the phenylsulfochloride in an atmosphere of carbon dioxide. It boiled at 60–61° at 3 mm. and the yield was 73.5% of the theoretical.

Twelve and one-half grams (1 mole) of *p*-bromo-anisole was slowly added to 1.75 g. of magnesium turnings in 150 cc. of cold dry ether and the reaction started by means of Gilman's activated magnesium-copper alloy.[23] After refluxing the final reaction mixture for six hours, it was cooled and 9.5 g. of phenylsulfochloride dissolved in 20 cc. of ether slowly added. After the vigorous reaction had subsided, it was digested for an hour on a water-bath and then poured into a mixture of ice and sulfuric acid. The ether layer was separated, washed with 5% sulfuric acid, 5% sodium hydroxide and finally dried over sodium sulfate. After removal of ether the *p*-methoxydiphenylsulfide was distilled and boiled at 161–163° at 6 mm. pressure. The yield was 4.5 g., corresponding to 31.6% of the theoretical.

The p-methoxy phenylsulfide was demethylated according to the directions already given and the resulting *p*-hydroxydiphenylsulfide proved to be identical with that obtained by Hinsberg's method.

Preparation of **p-Methoxydiphenylsulfide by** a Modification of Ziegler's **Method.**[10]—71.5 g. of thiophenol was dissolved in a solution of 50 g. of sodium hydroxide and 300 cc. of water. 100 g. of *p*-anisidine was dissolved in 17 g. of hydrochloric acid and 600 cc. of water and then diazotized in the usual manner with a solution of 56 g. of sodium nitrite in 250 cc. of water. After completion of diazotization a solution of sodium acetate was added to reduce the free hydrochloric acid.

The solution of diazotized anisidine was slowly dropped with constant stirring into the alkaline thiophenate solution which was held at 70°. A yellow precipitate was formed which rapidly decomposed with the evolution of nitrogen and the formation of a brown oil. After the major portion of the diazonium salt solution had been added, the reaction mixture became quite viscous because of the emulsification of the oil. It was finally heated upon a steam-bath for one hour to allow any remaining diazothioether to decompose completely. The final reaction product had a slightly aromatic ethereal odor.

The mixture was then acidified with hydrochloric acid and after adding zinc was refluxed for one hour in order to reduce any diphenyldisulfide to thiophenol, which was removed by distilling with steam. The contents of the flask were cooled and extracted with ether. A brown, solid tar, which was insoluble in acid. alkali or ether remained behind. The brown ether extract was repeatedly washed with 5% sodium hydroxide solution until the alkaline solution no longer turned brown, then with dilute hydrochloric acid, water and finally dried over sodium sulfate. After removal of ether, the remaining oil was distilled when a yield of 67 g. of p-methoxydiphenylsultide was obtained boiling at 150–152° at 3 mm. pressure. This corresponds to 66.0% of the theoretical.

After removal of p-metlioxydiphenylsulfide, the distillation was continued and 11.5 g. of a yellowish-brown oil with a mercaptan odor and boiling over a range of 152–212° at 3 mm. was obtained. Above 212" decomposition set in. From this oil was isolated a solid, which crystallized from 95% alcohol in colorless, matted plates melting at 130–131°. Neither of these substances was further investigated.

An attempt to prepare *p*-hydroxydiphenylsulfide directly by treating sodium thiophenate and diazotized p-aminophenol was unsuccessful.

[23] Gilman and Harris, THIS JOURNAL, 49,546 (1927).

o-Methoxydiphenylsulfide.[16]—This was prepared according to a new procedure from sodium thiophenate and diazotized o-anisidine in a manner similar to that described for p-methoxydiphenylsulfide. o-Methoxydiphenylsulfide is a colorless, refractive oil boiling at 150–152° at **3** mm., having a slight aromatic ethereal odor, and was obtained in good yield.

Anal. Calcd. for $C_{13}H_{12}OS$: S, **14.8.** Found: S, **14.52.**

***o*-Hydroxydiphenylsulfide.**[9b]—The o-methoxydiphenylsulfide was demethylated in a manner similar to that described for p-methoxydiphenylsulfide. A yield of 68.5% of o-hydroxydiphenylsulfide boiling at 140° at **3** mm. was obtained. It was a colorless oil with a phenolic odor and resisted all attempts to effect crystallization. Its solubility in various solvents and its color tests were the same as those described for the para-isomer.

Anal. Calcd. for $C_{12}H_{10}OS$: S, **15.85.** Found: S, **15.87, 15.35.**

o-Diphenylsulfide-p-nitrobenzoate was prepared and it crystallized from 95% alcohol in large pale yellowish-green prisms melting at **72–73°.**

Anal. Calcd. for $C_{19}H_{13}O_4NS$: S, **9.19.** Found: S, **9.53.**

***m*-Methoxydiphenylsulfide.**—Diazotized m-anisidine was treated with an alkaline solution of sodium thiophenate in a manner similar to that described for the preparation of p-methoxydiphenylsulfide. In this case the diazothio-ether formed was of a dark red color and the solution rapidly turned dark brown, finally becoming so darkly colored that it was impossible to follow the course of the reaction. As the reaction was taking place there was always a strong odor of aromatic ethers present, evidently due to the formation of m-methoxyphenol. **A** large amount of resin and dyes was also formed. As the diazonium salt of m-anisidine is less stable than those of o- and *p*-anisidine, the yield was correspondingly lower. m-Methoxydiphenylsulfide is a colorless oil boiling at 156° at **4** mm. and the yield was **25.2** g. or 34.7% of the theoretical.

Anal. Calcd. for $C_{13}H_{12}OS$: S, **14.8.** Found: S, **14.72.**

***m*-Hydroxydiphenylsulfide.**—This was prepared by demethylating the above compound with hydrobromic acid. *m*-Hydroxydiphenylsulfide is a colorless oil which has a slight phenolic odor and boils at 159–161° at **3** mm. The solubility and color tests were the same as those for the para-isomer.

Anal. Calcd. for $C_{12}H_{10}OS$: S, **15.85.** Found: S, **15.86.**

m-Diphenylsulfide-p-nitrobenzoate crystallizes from **95%** alcohol in large, yellow plates melting at 103°.

Anal. Calcd. for $C_{19}H_{13}O_4NS$: S, **9.19.** Found: S, **9.28.**

***p*-Methoxy-*p*-methyldiphenylsulfide.**—This was prepared by treating an alkaline solution of sodium thiocresate with diazotized p-anisidine. In this case, however, the oil obtained after removal of the excess of thiocresol solidified on cooling. *p*-Methoxy-*p'*-methyldiphenylsulfide was obtained as an oil boiling at 181–182° at **4** mm. **It** solidified on cooling and was purified by recrystallizing from **95%** alcohol, separating as colorless plates melting at 45–46°. The compound is very soluble in benzene and hot ethyl alcohol.

Anal. Calcd. for $C_{14}H_{14}OS$: S, **13.9.** Found: S, **13.84.**

***p*-Hydroxy-*p*-methyldiphenylsulfide.**—This was prepared from the above methyl ether by demethylation with hydrobromic acid in glacial acetic acid solution. p-Hydroxy-*p'*-methyldiphenylsulfide distilled as a yellow oil boiling at **178–180°** at **3** mm., which quickly solidified on standing. It crystallizes from petroleum ether in colorless, oblong plates melting at 67–68°. **It** is soluble in the common organic solvents and is difficultly soluble in water. **It** gives no color test with ferric chloride.

Anal. Calcd. for $C_{13}H_{12}OS$: S, 14.82. Found: 14.50, 14.52.

General Method for Preparation of Sulfides.—The method as outlined for the preparation of the methoxydiphenylsulfides is not applicable for the preparation of many aromatic sulfides, as many diazonium salts are very unstable at 70° and immediately break down to form the corresponding phenols. A modified method which promises to be applicable for the general preparation of sulfides of the aryl type, was found by using copper as a catalyst for the decomposition of the diazothio-ether.

Fifteen grams of aniline was dissolved in 19.75 g. of concentrated sulfuric acid and 300 cc. of water; 100 g. of ice was added and the mixture diazotized at 0° with a solution of 12 g. of sodium nitrite in 100 cc. of water. The free sulfuric acid was neutralized with sodium acetate.

To a solution of 17.75 g. of thiophenol, 19.3 g. of sodium hydroxide and 100 cc. of water was added 11.5 g. of copper powder. This mixture was constantly stirred during the cooling to 5° and the benzene diazonium salt solution then slowly added through a dropping funnel. The yellow diazothio-ether rapidly broke down with the evolution of nitrogen.

The remainder of this procedure was the same as that for preparing *p*-methoxydiphenylsulfide. After distillation from copper powder, diphenylsulfide was obtained as a colorless oil in a yield of 12.5 g. boiling at 162° at 20 mm.

Preliminary Examination of the Bacteriological Behavior of the Aromatic Sulfide Phenols.—A preliminary investigation of the germicidal activity of the sulfide-phenols described above was made by using B. *typhosum* as the test organism and determining the phenol coefficient according to the method developed by the Hygienic Laboratory.

The same results were also obtained with *p*-hydroxydiphenylsulfide after its aqueous solution had been allowed to stand for one year.

TABLE II

COMPARATIVE PHENOL COEFFICIENTS

p-Hydroxydiphenylsulfone	Less than	10
o-Hydroxydiphenylsulfide		33
p-Hydroxy-*p*'-methyldiphenylsulfide		50
m-Hydroxydiphenylsulfide		68
p-Hydroxydiphenylsulfide		115

The phenol coefficients of o-hydroxydiphenylsulfide and *p*-hydroxy-*p'*-methyldiphenylsulfide were determined by using them in 20% alcohol solution. Experiments using p-hydroxydiphenylsulfide showed that its phenol coefficient factor was only slightly decreased in 20% alcohol. The phenol coefficient of p-hydroxydiphenylsulfone was shown to be less than 10 and as it consequently could have no use as an antiseptic, work on this was discontinued.

The case of *p*-hydroxy-*p'*-methyldiphenylsulfide represents an anomaly to a quite general rule that an increase in the carbon chain in a phenolic compound increases its bactericidal action. Its phenol coefficient was calculated by the method of Tilley and Schaffer[24] to be about 300.

The antisepticity of the isomeric hydroxydiphenylsulfides increased in the order of ortho, meta and para substitution. This is in agreement with the work of Schaffer and Tilley[25] on the isomeric cresols and cyclohexanols.

A comparison of the results obtained with p-hydroxydiphenylsulfide and p-hydroxydiphenylsulfone indicates that the sulfide linkage is the most favorable construction for stimulating high germicidal activity.[26]

Toxicity of *p*-Hydroxydiphenylsulfide.—The minimum lethal dose on small rabbits was determined by administering with a stomach tube definite weights of p-hydroxydiphenylsulfide until a large enough dose had been given to cause death. These experiments were carried out on young rabbits weighing one pound. Administration of a dose of 1 g. of this sulfur combination produces no apparent effect on the animal. However, when a dosage of 1.4 g. was administered the animal became paralyzed but recovered within twenty-four hours. The test animals died a few hours after the administration of 1.5 g.

The minimum lethal dose for small rabbits, which are no doubt more susceptible than adult rabbits, is 1.5 g. per pound. The phenol is, therefore, comparatively non-toxic. These preliminary toxicity tests were kindly carried out for us by Dr. Paul Pittenger, Pharmacologist, of Baltimore, Maryland.

Summary

1. In this paper are described methods for obtaining in a pure state the three isomeric monophenols of diphenylsulfide.

2. A preliminary bactericidal and toxicity study of the phenols has been made.

3. The p-hydroxydiphenylsulfide shows the highest phenol coefficient of any phenol thus far studied and is a non-toxic substance.

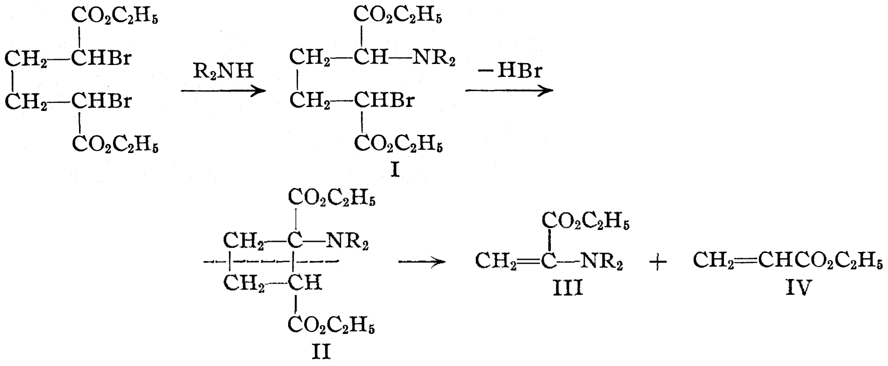
THE MECHANISM OF THE CLEAVAGE OF DIETHYL α,α'-DIBROMO-ADIPATE BY SECONDARY AMINES. A NEW SYNTHESIS OF CYCLOBUTANE DERIVATIVES[1]

By Reynold C. Fuson and Tsi Yu Kao

Received December 13, 1928 Published May 6, 1929

According to evidence presented in previous papers by Fuson[2] and Fuson and Bradley,[3] the cleavage of diethyl α,α'-dibromo-adipate by secondary amines discovered by von Braun, Leistner and Münch[4] probably takes place in the following manner



The first step in the reaction is assumed to be the normal replacement of one of the bromine atoms by a dialkylamino group. The cyclobutane intermediate (II) is then produced by the elimination of a molecule of hydrobromic acid. This aminocyclobutane derivative, being unstable under the conditions of the experiment, undergoes dissociation into ethyl acrylate (IV) and ethyl α-dialkylamino-acrylate (III).

The cleavage products actually isolated are ethyl pyruvate and ethyl β-dialkylaminopropionate and are satisfactorily accounted for by the assumption that the α-dialkylamino-acrylic ester is hydrolyzed to the pyruvic ester and that ethyl acrylate unites with the dialkylamine to give the β-dialkylaminopropionic ester.

---

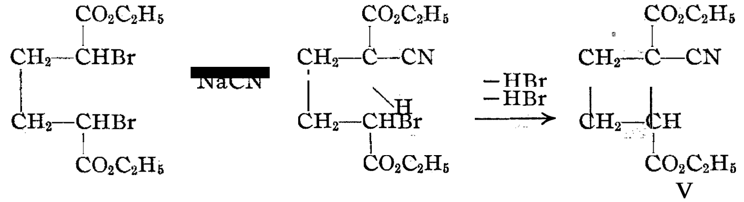
[4] Von Braun, Leistner and Munch, *Ber.*, **59B,** 1950 (1926). See also von Braun, Jostes and Wagner, *ibid.*, **61B,** 1423 (1928).

In an attempt to demonstrate the intermediate existence of II, the authors undertook to prepare it from the corresponding cyclobutanedicarboxylic acid. Although this has as yet not been accomplished, an improved method of synthesis of cyclobutane acids has been worked out which apparently bears out the cleavage mechanism in question. The present article deals with a preparation of the *trans*-1,2-cyclobutanedicarboxylic acid, which not only represents a new type of synthesis but which as intimated above sheds considerable light upon the mechanism of the cleavage of the adipic ester molecule by secondary amines.

It will be noticed that the second step in the mechanism outlined above involves the closure of the cyclobutane ring by the elimination of hydrobromic acid between the two a-carbon atoms. Moreover, since the yield of cleavage products is frequently very high, it is implied by the mechanism in question that the ring closure proceeds smoothly and in good yield. This assumption is at variance with experience inasmuch as closures of the cyclobutane ring by such means have been found to take place with difficulty and generally in small yield.

The authors have made the assumption that the great ease with which the ring closes in this case is due to the presence of the dialkylamino group, which probably activates the hydrogen atom attached to the carbon atom holding the amino group. It is evident that, if the mechanism is the-correct one and if the activation of the hydrogen atom is responsible for the ease of the ring closure, it ought to be possible to carry out the synthesis of cyclobutane derivatives in which the dialkylamino group is replaced by some group known to have an activating effect on the hydrogen atoms on the adjacent carbon atom.

Accordingly, to test these speculations, *meso*-diethyl α,α′-dibromoadipate was treated with sodium cyanide. The expected reactions were as follows



V

The cyclobutane derivative formed in this case (V) should differ from that formed when secondary amines are used (II) only in having a cyano group in place of the dialkylamino group. It was to be expected that V would be more stable than II on this account, and the experiment was undertaken with the hope that V might not undergo the cleavage and so could be isolated and studied.

Experiment has verified these predictions. When refluxed with sodium cyanide, diethyl α,α′-dibromo-adipate gives a 70 to 80% yield of a diethyl 1-cyanocyclobutane-1,2-dicarboxylate which has been shown to have the structure represented by V.

The proof of the structure of V was carried out in the following manner. When this compound was hydrolyzed and the resulting mixture of acids was heated above its melting point, carbon dioxide was eliminated and a mixture of acids was obtained which melted at 98–115°. This mixture, which was assumed to contain the cis- and *trans*-cyclobutane-1,2-dicarboxylic acids, was treated with concentrated hydrochloric acid—a method used by Perkin[5] to transform the cis acid into the tmns isomer. The product after several recrystallizations from concentrated hydrochloric acid melted at 129–130°.[6] By means of a mixed melting-point determination, this acid was shown to be identical with the *trans*-1,2-cyclobutanedicarboxylicacid obtained by Perkin.[5]

The effect of *amino* groups on the stability of cyclobutane derivatives is being investigated.

Experimental Part

Diethyl 1-Cyanocyclobutane-1,2-dicarboxylate.—This ester was obtained when an absolute alcohol solution of *meso*-diethyl-α,α′-dibromo-adipate (m. p. 67°) was refluxed with an excess of sodium or potassium cyanide on the steam-bath. The cyanide used was of commercial grade which had been finely powdered. Preliminary experiments indicated that sodium cyanide gave somewhat better yields than did potassium cyanide and, accordingly, in subsequent work only the sodium cyanide was used. It was found that the progress of the reaction could be followed by testing the solution from time to time for halogen. When the ester no longer showed a positive test for bromine the reaction was complete. A number of runs were made in which the amount of materials used and the time of treatment were varied. The results are shown in the following table.

TABLE I

RESULTS OF RUNS

Run	Refluxing, hours	Abs. ethanol, cc.	NaCN, g.	Bromo-ester, g.	Yield of cyano ester, g.	Yield, %
1	96	15	8	20	8.5	68
2	48	15	8	20	8.6	69
3	48	15	8	20	6.2	50
4	24	25	16	40	19.9	80
5	28	25	16	40	20.0	80
6	30	50	40	100	50.0	80
7	30	25	20	50	22.0	73

There was apparently always a little decomposition, because at the end of the reaction the mixture was dark in color. The dark brown alcohol solution was filtered from the mixture of alkali bromide and unchanged cyanide. The alcohol was removed by distillation at atmospheric pressure and the residual oil was then distilled under

---

[5] Perkin, J. *Chem. Soc.*, 65, 585 (1894).

[6] Perkin gives 131° as the melting point of the *trans* acid.

diminished pressure. It passed over at 160–169° (17 mm.). Redistillation gave a product boiling at 152–154° (9 mm.); d^{20}, 1.1103; n^{20}_{D}, 1.4519.

Anal. Calcd. for $C_{11}H_{15}O_4N$: N, 6.2. Found: N, 6.0%.

Hydrolysis of **Diethyl 1-Cyanocyclobutane-1,2-dicarboxylate.**—The ester was hydrolyzed by hot concentrated barium hydroxide solution (20%) according to Perkin's method.[7] The reaction took place rapidly with the evolution of ammonia. The yield of barium salt is about 85 to 95% of the theoretical.

Preparation of **Trans-cyclobutane-1,2-dicarboxylic Acid.**—The barium salt of the cyclobutane-1,1',2-tricarboxylic acid was treated with slightly less than the theoretical amount of sulfuric acid according to the directions of Perkin. The crude acid, which crystallized from the concentrated water solution after one or two weeks in a vacuum desiccator, was heated above its melting point in an oil-bath whose temperature was maintained at 150° for three to four hours. The brown mass which solidified on cooling was recrystallized from a mixture of benzene and ethyl acetate. The product was nearly colorless.

The crude acid which melts at 98–115° was apparently a mixture of *trans* and *cis* forms. It was treated with concentrated hydrochloric acid at 190° according to Perkin's method in order to convert it into the pure *trans* acid. The acid obtained melted at 129–130° and was shown to be identical with the *trans* acid obtained by the synthesis of Perkin.

Summary

When diethyl-α,α'-dibromo-adipate is treated with sodium cyanide, it is converted into diethyl 1-cyanocyclobutane-1,2-dicarboxylate, which on being hydrolyzed loses carbon dioxide to yield a mixture of acids. On treatment with concentrated hydrochloric acid, this mixture is converted into *trans*-cyclobutane-1,2-dicarboxylic acid. The identity of the latter has been established by comparison with a specimen of this acid prepared by the method of Perkin.

This synthesis is interpreted as evidence in favor of the cyclobutane mechanism proposed for the cleavage of diethyl α,α'-dibromo-adipate by secondary amines.

THE PREPARATION AND PROPERTIES OF THE ISOMERIC HEPTANES. PART II. PHYSICAL PROPERTIES

BY GRAHAM EDGAR AND GEORGE CALINGAERT

RECEIVED DECEMBER 20, 1928 PUBLISHED MAY 6, 1929

I. Introduction

In Part I of this paper[1] the preparation and purification of the nine isomeric heptanes were reported, together with certain data on the physical properties commonly employed for purposes of identification. In Part II there are presented measurements obtained in this Laboratory on other properties, together with a summary of the data of other investigators to whom samples of these hydrocarbons were loaned. Some of these data have been published and others are presented prior to publication elsewhere by the courtesy of the investigators in question, to whom acknowledgment is made below. The entire available data are summarized for the purpose of discussing the effect of structure upon the physical properties, since few trustworthy data are available on this point for the paraffin hydrocarbons and since the group in question is large enough to cover a wide variety of structural types. Further data are being accumulated on other properties of these hydrocarbons, but as the results of these investigations seem likely to be unavailable for some time to come, it has not been thought advisable to delay further the present publication.

II. Experimental Methods

(a) Densities, boiling and melting points are discussed in Part I of this paper.

The data on refractive indices, dispersions, dielectric constants and viscosities are taken from Smyth and Stoops,[2] where data additional to those quoted herein may be found.

(b) Surface tensions were measured in this Laboratory, employing essentially the technique of Richards, Speyers and Carver.[3]

In order to check the accuracy of the data, measurements were made of the surface tension of normal octane, which agreed well with those of Richards, Speyers and Carver, and of pure benzene, which agreed well with the data in "International Critical Tables." The measurements were made at one or more temperatures within a degree or two of 20°, and were extrapolated to this temperature.[4]

[2] Smyth and Stoops, *ibid.*, 50, 1883 (1928).

[3] Richards, Speyers and Carver, *ibid.*, 46, 1196 (1924).

[4] These measurements were made by Mr. F. J. Dykstra, to whom the authors are indebted. The authors also desire to acknowledge the loan of a cathetometer for this work by the Department of Physics of New York University.

(c) Critical temperatures and pressures were measured by Professor F. G. Keyes and Dr. R. V. Kleinschmidt, to whom the authors are much indebted both for the measurements and for permission to include the data in this paper, prior to publication elsewhere. The apparatus and technique were essentially those described by Keyes, Taylor and Smith.[5] At the time these measurements were made, 3,3-dimethylpentane had not been prepared and no critical data concerning it are available. The coefficient *a* and b of van der Waals' equation (Cols. 12 and 13) were calculated from these data, as were the values of the Guldberg function T_c/T_B (Col. 11).

(d) The coefficients of thermal expansion were measured in this Laboratory by Mr. O. R. Dorion, to whom the authors are indebted. The apparatus consisted of a dilatometer of Pyrex glass, with a bulb of about 6 cc. capacity and a capillary of such dimensions as to give about 30 cm. rise in the liquid level of the hydrocarbons for 20" temperature rise. The dilatometer was calibrated by filling it with a known weight of distilled water and reading the liquid level in the capillary at different temperatures, readings being made with a cathetometer. Density data for water were taken from "International Critical Tables," and appropriate corrections were made for the thermometer employed and for the expansion of the glass. The dilatometer was then filled with weighed amounts of the hydrocarbons and the liquid level in the capillary was measured at various temperatures from 10 to 30°. Since for the purpose of this paper the relative coefficients of expansion of the hydrocarbons were more important than their absolute values, the following method was employed in treating the data. The liquid level readings in the capillary were plotted on large scale coordinate paper against the temperature and from the curves thus obtained temperature differences were read corresponding to the same definite segment of the capillary between two fixed marks. The bulb was in all cases filled to such an extent that the segment corresponded approximately to the temperature range of 15 to 20°. The hydrocarbons are so nearly alike in their expansion coefficients that the actual temperatures involved were seldom as much as a degree different for the different hydrocarbons. A value for the coefficient of expansion of normal heptane was then selected as a mean from density determinations at temperatures above and below 20° by the authors (Part I), from the data of Smyth and Stoops[2] and from the dilatometer dimensions. The values for the isomers were then computed by comparing the temperature differences above mentioned with that for normal heptane. The data are given to four significant figures and are almost certainly correct to three. The supply of 3,3-dimethylpentane was exhausted when these measurements were made, and its density–temperature coefficient was taken as the average for the other eight isomers, that is, 0.000848. This value is probably very nearly correct,

---

[5] **Keyes, Taylor and Smith, J.** *Math. Phys., Mass. Inst. Tech., 1, 311* **(1921).**

since it is equal to that of the 2,3-isomer, which, as will be shown in the discussion below, shows properties very similar to those of the 3,3-isomer.

The temperature coefficients of density in the neighborhood of 20" had already been determined for most of the hydrocarbons, but it was felt that values calculated from the coefficients of thermal expansion were more nearly accurate than the direct measurements, and the figures in Col. 4 are calculated in this way.

(e) The velocity of sound through the hydrocarbons and the coefficient, β_φ, of adiabatic compressibility, were measured by E. B. Freyer, J. C. Hubbard and D. H. Andrews.[6]

The coefficients of isothermal compressibility, β_T, were calculated by the equation $\beta_T = \beta_\varphi + \dfrac{(\mathrm{d}v/\mathrm{d}t)^2\,\mathrm{d}T}{J\,C_p}$, where J is the mechanical equivalent of heat, C_p the specific heat, v the specific volume and d the density. In the absence of specific heat data for most of the isomers the value of 0.50 cal. per g. for normal heptane was employed in all calculations. Later data on actual specific heats may alter the computed values slightly.

(f) Heats of combustion were determined by the U. S. Bureau of Standards.[7] They were made in a bomb calorimeter and are defined as the heat liberated in 20° calories per gram of liquid hydrocarbon weighed in air, the products of combustion being cooled to the initial temperature and the water condensed to the liquid state. The data are believed to be accurate to 0.2% or better.

(g) Molecular diameters and lengths were calculated by Stewart from X-ray diffraction data.[8]

(h) Critical solution temperatures in aniline were determined in this Laboratory. Aniline was dried over solid potassium hydroxide and was freshly distilled before each determination. The hydrocarbons were also dried over solid potassium hydroxide.

The mixtures of aniline and hydrocarbon were heated in a small test-tube fitted with an Anschütz thermometer, the whole being jacketed by another test-tube, which in turn was immersed in a water-bath. The aniline and hydrocarbon were weighed into the test-tube and the weight was checked after the determination in order to ascertain whether appreciable loss due to volatilization of hydrocarbon had occurred. The proportions of aniline and hydrocarbon were altered through a range sufficient to pass through the maximum point on the solubility–temperature curve.[9] The data are expressed graphically in Fig. 1.

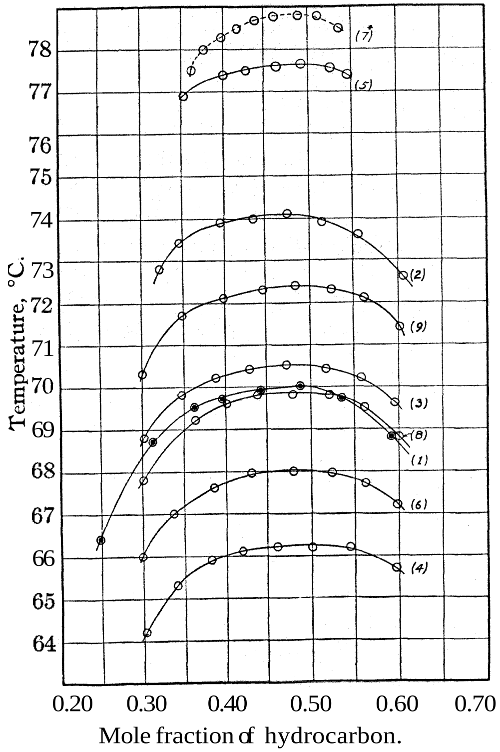
III. Experimental Data

Table I contains the experimental data referred to above, together with certain functions derived from the data. Table II summarizes the order in which these properties and functions vary with the structure of the hydrocarbons. Table III contains such data as are available from the literature on the properties of the hexanes, octanes, nonanes and decanes. Only such data are given as are available for a number of the isomers, since the data are used for comparison of the effect of structure on the properties of the hydrocarbons as compared with the heptanes. The data have been taken from what seemed to be the most reliable sources, some from "International Critical Tables," some from Beilstein and some from the original literature. The data have been extrapolated when necessary.



(1), *n*-**Heptane**; (2), 2-methylhexane; (3), 3-**methylhexane**; (4), 3-ethylpentane; (5), 2,2-dimethylpentane; (6), **2,3-dimethylpentane**; (7), **2,4-dimethylpentane**; (8), **3,3-dimethylpentane**; (9), **2,2,3-trimethylbutane.**

Fig. 1.—Critical solution temperatures of the heptanes in aniline.

* Because of the extremely small amount of **2,4-dimethylpentane** which was available when these measurements were made it was not possible to determine accurately the values of the mole-fractions corresponding to the temperatures given. The curve must therefore be regarded as approximate as far as the mole-fraction data are concerned.

IV. Discussion

(a) **General.**—Very few of the data given in Table I are available in the literature. With the exceptions noted in Part I of this paper, the data in general agree very well with the most reliable data which are available. Since the chief purpose of this paper is to discuss the effect of structure upon physical properties, further comparison of the individual data with those in the literature has been omitted.

Very few generalizations have been possible heretofore concerning any relations which may exist between the structure of paraffin hydrocarbons

[a] Chavanne, *Bull. soc. chim. Belg.*, 31, 331 (1922); [b] Lowry, *J. Chem. Soc.*, **105**, 91 (1914); [c] "International Critical Tables;" [d] Chavanne and van Risseghem, *Bull.*

and their physical properties, since the experimental data have been very fragmentary and none too reliable. Most generalizations previously reported have referred to the effect of increasing molecular weight in the normal hydrocarbons, to such facts as that the boiling point of the normal hydrocarbon is higher than those of the known isomers and to a few scattered facts concerning the relations between the normal hydrocarbon and the simple "iso"-hydrocarbons. The data herein presented give an opportunity for a much more complete analysis of such relationships.

Thus inspection of Tables I and II shows certain striking regularities in the order in which the physical properties vary with the structure. For the purpose of simplifying the discussion each hydrocarbon has been given a number, and the structures corresponding to these numbers are contained in Table I.

(b) Density, Refraction and Dielectric Constant.—If we consider first density, index of refraction and dielectric constant, the isomers fall in an order which is essentially identical for all the properties. The order is still noticeable in properties which are known with less accuracy, coefficient of expansion and dispersion, and even in functions calculated from these constants and which are considered in general to be independent of structure, molecular refraction, molecular dispersion and polarization.

It would seem, therefore, that they must correspond to a definite influence of the structural arrangement of the atoms in the molecule. Thus the values of each function of this group for the normal hydrocarbon occupy an intermediate position. A methyl group located in the 2-position decreases the value of each function below that of the normal hydrocarbon, while a methyl group located in the 3-position increases the value of each function. Similarly, two methyl groups in the 2-position (either on the same carbon atom, or at corresponding positions at each end of the pentane chain) decrease still further the values of the function, while two methyl groups in the 3-position, or an ethyl group in the 3-position, increase still further the values of the functions above those of the normal hydrocarbon. When two groups are adjacent, however, the values of the various functions are always quite high relative to the normal. This effect appears in 2,3-dimethylpentane and in 2,2,3-trimethylbutane, and will be discussed further below.

The order in which the hydrocarbons fall when arranged in accordance with the variation of their properties of this group is essentially 5 7 2 1 3 9 8 6 4, which will be referred to as Order 1.

Chem.*, 19, 145 (1927); [k] Smyth and Stoops, THIS JOURNAL, 50, 1883 (1928); [l] Morgan, Carter and Duck, J. *Chem. Soc.*, 127, 1252 (1925); Lowry, *ibid.*, 127, 1215 (1925).

(c) Internal Pressure.—It has been shown by Hildebrand[10] that relative internal pressures may be calculated approximately from surface tension, from the boiling point, from van der Waals' constant, a, from the ratio of the coefficients of thermal expansion to isothermal compressibility and from the critical solution temperatures in a non-polar solvent. If we consider these various functions (Cols. 19, 20, 22 and 23), we find the isomers falling in a nearly identical order 5 7 9 2 8 **3** 6 1 4, which will be referred to as Order 2.

Considering the uncertainty underlying the assumptions involved in the calculation of these functions, the agreement in Order 2 is striking.

As would be expected, the fundamental properties employed in the calculation of the internal pressures (Cols. 1, 9, 15, 16, 17 and 21) follow in general the same order, with somewhat greater variation, particularly with reference to the normal hydrocarbon, which varies between the extreme end position and the third position from the end.

(d) Van der Waals' constants a and b follow an order very close to that of the ratio of the critical temperature to the boiling point, which may indicate that their values vary with the temperature, and at corresponding temperatures might fall in line with the other properties.

(e) The critical pressures and the viscosities show no evidence of relation to any other property.

(f) The heats of combustion are clearly identical within the limit of error, 0.2% or 2000 cal. per mole. The heats of formation calculated therefrom are thus also identical, their value being 57,000 ± 2000 cal. Obviously the experimental accuracy is not sufficient to determine whether or not small differences exist among the heats of formation of the isomers. It has been shown by Parks[11] that in the case of three isomeric octanes very substantial differences exist in the entropies, but the differences in the heats of formation must be small, if they exist at all.

(g) Regarding the arrangement of the atoms in space, some conclusions may be drawn from the X-ray diffraction data of Stewart. The addition of methyl or ethyl groups as side chains decreases the apparent length of the main chain and increases the apparent diameter by more than would be expected. It seems probable, therefore, that the substitution causes a twisting or bending back of the otherwise straight chain. The only exception to this rule is 9, in which the butane chain keeps its normal length. This is also the only case which has been investigated in which every carbon between the ends of the chain is substituted, which suggests that in that case the bending of the chain may be hindered by the closely packed side chains.

---

[10] Hildebrand, "Solubility," Chemical Catalog Co., Inc., New York, 1924.

[11] G. S. Parks, paper delivered at American Chemical Society meeting at Swampscott, Massachusetts, September, 1928.

(h) It will be noted that the difference between Order 1 and Order 2 is entirely due to the change of position of the normal hydrocarbon (1) and the 2,2,3-trimethylbutane (9). If these two be omitted, the order of variation of the properties of both classes becomes surprisingly constant. These two compounds represent, of course, the two extremes of structural arrangement; nevertheless, the cause of their variation from the general arrangement is not clear.

It is interesting to speculate on the reasons for this orderly variation of physical properties with structure. From the thermodynamic standpoint no data are at present available, although it is hoped that the entropies of these compounds will be determined later. Judging from the data of Parks on three octanes,[11] the entropies of the branched-chain isomers should be lower than those of the normal hydrocarbons, but the relation to structure cannot be more than guessed at.

(i) Hydrocarbons other than the **Heptanes.**—The data discussed above for the heptanes is particularly useful for determining the effect of structure, because of the fact that each individual property was measured for all of the isomers by one experimenter, and hence the data are much more comparable than most of those given in the literature and taken from scattered sources. Nevertheless, consideration of the data in Table III on the properties of the hexanes, octanes, nonanes and decanes shows that the considerations indicated above for the heptanes hold very well for the other hydrocarbons.

Thus a methyl group in the 2-position decreases the specific gravity and refractive index below the normal hydrocarbon (with the exception of the hexanes, the data on refractive index are somewhat uncertain, and have been omitted entirely for the nonanes and decanes), while a methyl group in the 3-position increases these functions above that of the normal hydrocarbon. Two methyl groups in the 2-position (2,2-dimethylbutane, 2,5-dimethylhexane, 2,6-dimethylheptane and 2,7-dimethyloctane) decrease still further the specific gravity, while 2,3-dimethylbutane shows the effect of adjacent carbon atoms, as do 2,3- and 3,4-dimethylhexane.

Three methyl groups in the 2-position (2,2,4-trimethylpentane, 2,2,5-trimethylhexane and 2,2,6-trimethylheptane) have the lowest specific gravities reported, but when the groups are adjacent, as in the corresponding 2,2,3-trimethylbutane, the latter effect predominates.

In the octanes, nonanes and decanes a methyl group in the 4- or 5-position has an effect similar to one in the 3-position. An extreme case of the effect of substitution in the 3-position is shown by 3,3-diethylpentane.

Such other properties as are available agree well with the order of variation shown by the heptanes. Thus for the hexanes the critical solution temperatures in aniline follow the order shown for corresponding heptanes, as do the two which are available for the octanes. The available compressibilities and surface tensions follow the usual order, while the viscosities (available only for the hexanes) show the irregular variation exhibited by the heptanes.

The boiling points of the normal hydrocarbons are invariably the highest for the isomers, but the 2-substituted isomers always boil lower than the 3-substituted isomers, and those containing two or three methyl groups in the 2-position (at the same or opposite ends of the chain) boil lowest of all.

Altogether, although the data on the other paraffin hydrocarbons are not sufficiently complete to lay down any definite laws relating their structure to their properties, it is clear that so far as the data are available the regularities found in the heptanes are also found in the other hydrocarbons. It would appear probable, therefore, that approximate values of most of the physical properties of the paraffin hydrocarbons can be predicted with reasonable assurance when their structure is known.[12]

It is hoped that this investigation may be helpful in interpreting the characteristics of the paraffin hydrocarbons, and may eventually lead to clarifying these characteristics in terms of the energy relations and molecular dimensions involved.

Summary

1. Data on a number of the physical properties of the nine isomeric heptanes are presented, together with functions derived from the data.

2. Certain definite regularities are found relating the physical properties of the isomers to their structure.

3. The relationships between the structure of the heptanes and their physical properties exist also for the hexanes, octanes, nonanes and decanes, as far as the data are available.

4. These relationships enable the physical properties of paraffin hydrocarbons to be predicted with reasonable assurance from their structures.

YONKERS, NEW YORK

---

[12] An interesting example of such prediction is found in the case of normal decane. The specific gravity given in "International Critical Tables," Vol. I, seemed to the authors to be probably too high, as it is greater than that of any of the isomers. Examination of the literature confirmed this suspicion, and judging from the data on normal decane in Vol. III of "International Critical Tables," the value of the density in Vol. I is really for 0° instead of 20° as stated.

SYMMETRICAL TETRABROMO-ETHYL ETHER AND "SO-CALLED" TETRABROMOBUTYRALDEHYDE

BY HAROLD HIBBERT, STANLEY Z. PERRY* AND K. AUSTIN TAYLOR[2]

RECEIVED DECEMBER 28, 1928 PUBLISHED MAY 6, 1929

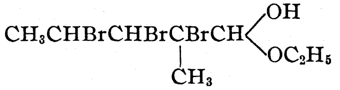
Freundler,[3] in the preparation of bromo-acetaldehyde by the bromination of paracetaldehyde isolated a crystalline product which from the analysis he was led to believe was tetrabromobutyraldehyde ($CH_2BrCHBrCBr_2CHO$), although as specifically pointed out by him, the compound possessed none of the usual aldehydic properties. He assumed that it was formed by the crotonization of the bromo-acetaldehyde, followed by addition of a second mole of bromine

$$2CH_2BrCHO \longrightarrow CH_2BrCH{=}CBrCHO + H_2O$$
$$CH_2BrCH{=}CBrCHO + Br_2 = CH_2BrCHBrCBr_2CHO$$

The same type of reaction is indicated in the work of Kramer and Pinner[4] and of Freundler[5] on the chlorination of acetaldehyde. The trichlorobutyraldehyde isolated by these workers is presumably formed from the primary monochloro-acetaldehyde by condensation of this with acetaldehyde, followed by crotonization and subsequent addition of chlorine:

$$CH_3CHO + Cl_2 = CH_2ClCHO + HCl$$
$$CH_3CHO + CH_2ClCHO = CH_3CH{=}CClCHO + H_2O$$
$$CH_3CH{=}CClCHO + Cl_2 = CH_3CHClCCl_2CHO$$

More recently, Dworzak and Pfifferling,[6] by brominating parapropionaldehyde and treating the reaction mixture with alcohol, obtained a compound, the analysis and molecular weight of which corresponded to the half acetal



$$CH_3CHBrCHBr\underset{\displaystyle CH_3}{\underset{|}{C}}BrCH\left\langle\begin{matrix}OH\\OC_2H_5\end{matrix}\right.$$

apparently formed by a series of reactions similar to those above. This type of reaction, therefore, appears to be a general one.

However, while the other halogenated aldehydes referred to above possess characteristic aldehydic properties, and there would seem to be no

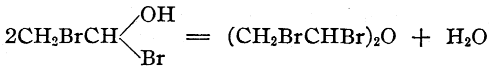
reason to doubt the structures assigned to them, these same properties are entirely absent in the case of the tetrabromobutyraldehyde isolated by Freundler.

From a consideration of the polarities of the groups present, and of the effect of strongly negative groups, such as Br, on the reactivity of the carbonyl group,[7] it is to be expected that a compound such as Freundler's tetrabromobutyraldehyde would show a remarkable degree of reactivity, especially with regard to properties associated with the aldehyde group.

Further evidence against the aldehydic formula is available from Freundler's data. Heating with alcohol gave ethyl bromide, bromo-acetaldehyde and bromo-acetal. Cold fuming nitric acid oxidized it, giving bromo-acetic acid and hydrobromic acid but no tetrabromobutyric acid. These are not the reaction products one would expect from tetrabromobutyric aldehyde.

Stepanov, Preobrashenski and Shchukina,[8] in continuing the work of Hibbert and Hill[9] on the bromination of paracetaldehyde, pointed out that the tetrabromo compound of Freundler might possibly be tetrabromoethyl ether, formed by the loss of water from two moles of bromo-acetaldehyde bromohydrin

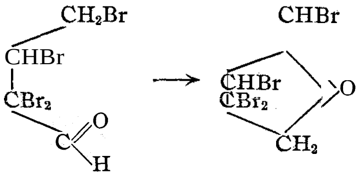


$$2CH_2BrCH\begin{matrix}OH\\Br\end{matrix} = (CH_2BrCHBr)_2O + H_2O$$

A B

the intermediate addition compound (A) actually being isolated by them. This reaction is thus similar to the formation of dichloro-ethyl ether by the action of hydrochloric acid on acetaldehyde.[10]

There is, however, still a third possibility, namely, the formation of a butylene oxide ring derivative (III) obtained by ring closure due to wandering of a hydrogen atom



I III

This compound would be analogous to the *oxide ring form of a tetrose.*

It was to distinguish among these three formulas (designated below as I, II and III) that the present investigation was undertaken.

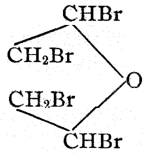
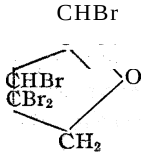
I



II



III

The substance (II) ($C_4H_6OBr_4$) contains two more hydrogen atoms than I and III ($C_4H_4OBr_4$). Analysis of the tetrabromo compound, prepared by Freundler's procedure, gave: C, 12.74; H, 1.60; Br, 52.2; calcd. for $C_4H_4Br_4O$: C, 12.36; H, 1.03; Br, 82.4; calcd. for $C_4H_6Br_4O$: C, 12.31; H, 1.54; Br, 82.0. The analysis thus favors the ether formula, II.

Further evidence for the ether formula, II, was obtained by condensing the compound with ethylene glycol; bromo-ethylidene glycol being obtained in 57.2% yield.

Final definite proof of the symmetrical tetrabromodiethyl ether formula II, was obtained by its direct synthesis and comparison with Freundler's compound. The product was obtained by the addition of bromine to divinyl ether, the latter being prepared by the action of powdered caustic potash on β,β'-dichloro-ethyl ether.

$$(CH_2ClCH_2)_2O + 2KOH = (CH_2{=}CH)_2O + 2KCl$$
$$(CH_2{=}CH)_2O + 2Br_2 = (CH_2BrCHBr)_2O$$

The melting points of symmetrical tetrabromo-ethyl ether prepared in this way, of Freundler's compound, and of a mixture of equal parts of the two, were found to be identical. The analyses were also in agreement, thus definitely establishing the identification of Freundler's compound as symmetrical tetrabromo-ethyl ether. It seems probable that *both* this and tetrabromobutyraldehyde are present in the reaction mixture obtained in the bromination of paracetaldehyde, but that the latter has not, as yet, been isolated.

The preparation of divinyl ether from dichloro-ethyl ether constitutes a new synthesis of this product and makes it easily available for investigation. It readily undergoes polymerization on warming, more rapidly in presence of a trace of benzoyl peroxide. These properties are being further investigated in connection with a general study on the nature of polymerization.

Experimental

Preparation of Freundler's Tetrabromo Compound.—The procedure followed was essentially that of Freundler:[3] 200 g. of bromine was added slowly from a dropping funnel to 70 g. of paracetaldehyde contained in a three-necked flask fitted with a stirrer and mercury seal and protected from moisture by a calcium chloride tube. The flask was surrounded by a freezing mixture of ice and salt and the temperature during addition was kept at −5 to −10° by adjusting the rate of addition of bromine. This required one and one-half to two hours. An additional 120 g. of bromine was then added at −5° during the course of about fifteen minutes. The temperature was allowed to rise gradually to 15°,[11] was held at this temperature for fifteen minutes, then allowed to rise to 20° and kept there until the red color of the bromine disappeared. The reaction product was then poured on a mixture of ice and finely ground sodium carbonate crystals, and the whole well stirred until all the hydrobromic acid was neutralized. The tetrabromo compound was deposited in white crystals. These were separated by filtration, dried between filter papers and recrystallized from ether; yield, 35%; m. p. 63–65".

Anal. Subs., 0.2414, 0.2040, 0.2008: CO_2, 0.1110, 0.0955, 0.0951; H_2O, 0.0370, 0.0278, 0.0298. Subs., 0.1385, 0.1017; AgBr, 0.2680, 0.1963. Calcd. for $C_4H_6Br_4O$: C, 12.31; H, 1.54; Br, 82 0. Calcd. for $C_4H_4Br_4O$: C, 12.36; H, 1.03; Br, 82.4. Found C, 12 54, 12.76, 12 91; H, 1.70, 1.51, 1.60; Br, 82.3, 82.1. Subs., 0.8415; benzene, 21.96 g ; *At*, 0.510°. Calcd. for $C_4H_6Br_4O$: mol. wt., 389.7. Found: 375.9.

Condensation with Ethylene Glycol.—One hundred and fifty-five g. of the tetrabromo compound and 300 g. of ethylene glycol were heated on the water-bath for six hours with constant stirring. The reaction mixture was extracted with ether, the ether extract first washed with saturated calcium chloride solution, then with saturated sodium bicarbonate, dried over calcium chloride and distilled under reduced pressure. The lower fractions (b. p. 65–80° at 27 mm.) still contained ethylene bromohydrin. They were redissolved in ether, the ether solution was thoroughly washed with water, dried over calcium chloride, redistilled and the distillate added to the main fraction; total yield, 75.5 g. (57.2%); b. p. 80–82° at 27 mm.

Anal. Subs., 0.1669, 0.1669, 0.1687: AgBr, 0.1867. 0.1911, 0.1909. Calcd. for $C_4H_7O_2Br$: Br, 47.83. Found: Br, 47.62, 48.28, 48.2.

Preparation of Divinyl Ether.—Two hundred grams of finely-powdered caustic potash contained in a small copper flask was strongly heated by a Bunsen burner and fifty grams of β,β'-dichloro-ethyl ether slowly dropped onto the heated alkali during the course of twelve hours. The flask was provided with a reflux water condenser kept at 40°, thus permitting the escape of the divinyl ether (b. p. 34–35°), but not of the intermediate product, vinyl chloro-ethyl ether (b. p. 106–108"). The first condenser was connected in turn to a second, and this with a well-cooled receiving flask. The refluxing was continued for about forty-eight hours; yield, 13.4 g. (54.9%); b. p. 34–35°.

Preparation of Symmetrical Tetrabromo-ethyl Ether.—One gram of divinyl ether was dissolved in 10 cc. of chloroform and a solution of 4.5 g. of bromine in 15 cc. of chloroform slowly added, the reaction flask being immersed in a freezing mixture during the addition.[12] On evaporation of the chloroform a product was left which crystallized on rubbing violently with a glass rod. It was recrystallized from ether; m. p. 63–64°. A mixture of equal parts of the compounds prepared by this, and by Freundler's method, respectively, melted at 62.5–64°.

Anal. Calcd. for $C_4H_6OBr_4$: Br, 82.03. Found: Br, 82.30, 81.75. Calcd. for $C_4H_6OBr_4$: C, 12.31; H, 1.54. Found: C, 12.68, 12.60; H, 1.77, 1.66.

Summary

1. The crystalline product obtained by Freundler in the bromination of paracetaldehyde and described by him as tetrabromobutyraldehyde is shown to be symmetrical tetrabromodiethyl ether.

---

[11] If temperature is allowed to rise too rapidly, the reaction gets beyond control and an explosion may occur.

[12] When working on a large scale it is possible to add free bromine directly to the carefully cooled divinyl ether. The reaction product is then poured onto a mixture of powdered ice and sodium carbonate as in Freundler's preparation.

2. The latter has been synthesized from divinyl ether and found to be identical with Freundler's compound.'

3. A new and simple synthesis of divinyl ether is described.

EMPLOYMENT OF PYRIDINE AS CATALYST IN PRODUCTION OF DIMETHYL-ALPHA-NAPHTHYLAMINE

BY FREDERICK G. GERMUTH

RECEIVED DECEMBER 28, 1928 PUBLISHED MAY 6, 1929

Introduction

Subsequent experimentation carried on by the author with the view of ascertaining means of increasing the yield of terpineol from a-pinene and benzenesulfonic acid in acetic acid solution by inducing catalysis, developed the interesting fact that the presence of a-picoline ($NC_5H_4CH_3$) tended to increase the rate at which production occurred, accompanied by an increase in the actual yield of the product. This increase, however, is not greatly in excess of the quantity of terpineol obtained by the usual method.

It has been shown[1] that when an increase in the moisture content obtains the effect of such treatment upon the production of the substance sought is not proportional to the amount of water added at varying temperatures. It is believed that higher temperatures compensate for the decided increase in water content. The addition of α-picoline in minute and larger quantities increased the yields to an average of 2.35% in excess of those previously furnished. Unsuccessful attempts were made to enlarge this figure by the application of pyridine, (C_5H_5N), and related substances, but without avail.

It was considered advisable to test the effect of adding pyridine and certain of its homologs to reacting proportions of a-naphthylamine and methyl sulfate in alkaline solution to ascertain what effect, if any, the aromatic compound might have upon the mechanism of the reaction involved in the production of dimethyl-or-naphthylamine. The addition of a-picoline and that of the β-variety having been previously resorted to without the attainment of the sought-for objective, the contemplated step appeared feasible.

The discovery was made by the author that the yield of this methylated substitution product of naphthalene is greatly increased when the heterocyclic base is utilized as carrier. This compound has been used successfully as catalyst in Perkin's synthesis of cinnamic acid in this country[2] as well

---

[1] Germuth, *Am. J. Pharm.*, 99, 402 (1927).

[2] Bacharach and Brogan, THIS JOURNAL, SO, 3333 (1928).

as in Europe,[3] publication of the respective investigations occurring almost simultaneously. The results observed by the employment of pyridine in the role of catalyst in the production of dimethyl-a-naphthylamine form the theme considered and presented in this paper.

Method Employed.—Fourteen and three-tenth grams (0.1 mole) of α-naphthylamine was suspended in 25 cc. of water (temperature approximately 80°); to this was added 15 cc. of 40% sodium hydroxide and 25.3 g. (0.2 mole) of methyl sulfate. Each of these was added to the suspension of a-naphthylamine in water at equivalent rates, the temperature being maintained between 57 and 60°. The mixture was thoroughly stirred and the oil separated. Distillation in *vacuo* was then carried out. After this step was accomplished, about 25 g. of acetic anhydride was added. (A slight excess of the anhydride should be added until a constant temperature is maintained. The production of acetyl monomethyl-a-naphthylamine from monomethyl-α-naphthylamine present in solution is then attained.)

The mixture is poured into sufficient 28% sulfuric acid to provide for the presence of free hydrogen ions. The temperature of the acid should not be greater than 15°. This is then rendered slightly alkaline with a 28% solution of sodium hydroxide and thoroughly agitated. The separated oil is vacuum distilled. Dimethyl-α-naphthylamine passes over at 130–132° under a pressure of 8 mm. of mercury.

Purity of Materials.—The pyridine utilized in this work was of C. P. grade, possessing a boiling point of 116.5" and a specific gravity of 1.0035 at 0°. It was deemed unnecessary to attempt further purification.

The methyl sulfate employed possessed a boiling point of 188.5" and the specific gravity was 1.3278 at 20°. This compound was free from methyl sulfuric acid.

A very pure grade of α-naphthylamine was obtained by the action of sodamide upon naphthalene at a temperature of 215–220°. This substitution product possessed a specific gravity of 1.2230 at 24.8" and melted sharply at 50.2".

The sodium hydroxide was further purified and upon analysis was found to contain but a trace of carbonate.

Experimental Work

Ten portions of dimethyl-a-naphthylamine were prepared, using the method given in this paper. Table I enumerates the results observed, showing the corresponding quantities of material produced in the treated samples.

TABLE I

YIELD OF DIMETHYL-α-NAPHTHYLAMINE OBTAINED (WITHOUT PYRIDINE)

Sample no.	1	2	3	4	5	6	7	8	9	10
Actual yield, g.	9.0	8.9	8.9	8.8	9.0	8.9	8.8	8.9	8.6	8.9
% of theoretical	52.1	51.4	51.4	50.8	52.1	51.4	50.8	51.4	49.7	51.4

Average, 51.3.

It will be observed that the differences existing in percentages of yields obtained are not in excess of those usually encountered in experimental work of this nature, particularly when small amounts of materials are utilized.

---

[3] Kalnin, *Helv. Chim. Acta,* 11, 2416 (1928).

Ten additional samples were now prepared and treated precisely as those constituting the former series except that 0.1 g. of pyridine was added to the contents of each container before the addition of sodium hydroxide and methyl sulfate. The percentage yield of dimethyl-a-naphthylamine was so increased by this procedure that further experimentation, employing varying quantities of pyridine, was immediately undertaken. Continued investigation disclosed the fact that when four drops (approximately 0.2 cc.) of pyridine, equivalent to eighty drops or approximately 4 cc. of pyridine per mole of a-naphthylamine, was added to the mixture, most gratifying results were noted.

Table II shows the increased yield of dimethyl-a-naphthylamine produced by the application of pyridine to the test solutions.

TABLE II

YIELD OF DIMETHYL-α-NAPHTHYLAMINE OBTAINED

Addition of pyridine, 4 cc. per mole of a-naphthylamine

Sample no.	1	2	3	4	5	6	7	8	9	10
Actual yield, g.	11.4	11.3	11.4	11.5	11.3	11.5	11.3	11.5	11.3	11.5
% of theoretical	65.9	65.1	65.9	66.4	65.1	66.4	65.1	66.4	65.1	66.4

Average, 65.8.

In each instance the purity of the dimethyl-a-naphthylamine was determined by the usual tests (reaction, specific gravity and boiling point), and the high degree of purity of the product confirmed.

Summary

The employment of pyridine as catalytic agent in the production of dimethyl-a-naphthylamine from a-naphthylamine and methyl sulfate increases the yield of the compound from an average of 51.3% to 65.8%, when this base is utilized in the proportion of four cubic centimeters of pyridine per mole of a-naphthylamine.

Smaller quantities than that advocated do not furnish the yield attained by the amount of pyridine stipulated. Larger proportions fail to increase the quantity of dimethyl-a-naphthylamine obtained under the conditions maintained. The material produced in the presence of pyridine is of high quality.

THE ACTION OF AROMATIC GRIGNARD REAGENTS ON ARSENIC TRIOXIDE

BY F. F. BLICKE AND F. D. SMITH[1,2]

RECEIVED DECEMBER 28, 1928 PUBLISHED MAY 6, 1929

This investigation is the first part of a study of certain arsenicals which we synthesized in the hope that they might be found to be of value as spirocheticides.

Tetra-arylarsyl oxides,[3] which were required for the preparation of other compounds, can be obtained quite readily by the interaction of aromatic Grignard reagents and arsenic trioxide; in addition to the oxides there are usually obtained varying amounts of triarylarsines. Hitherto there has been lack of agreement among various investigators regarding the optimum conditions for the formation of these compounds and the reaction mechanism by which they are produced.

Sachs and Kantorowicz[4] state that at a low temperature phenylmagnesium bromide and arsenic trioxide react to form tetraphenylarsyl oxide, while at a higher temperature triphenylarsine is produced. They claim, furthermore, that p-tolylmagnesium bromide and arsenic trioxide yield only tri-ptolylarsine, regardless whether the reaction is carried out at a low or high temperature.

Recently, Matsumiya and Nakai[5] found that phenylmagnesium bromide and arsenic trioxide yield invariably a mixture of tetraphenylarsyl oxide and triphenylarsine, both at low and high temperatures; similar results were obtained with p-tolylmagnesium bromide, but in the case of α-naphthylmagnesium bromide only one product seemed to be formed, a compound stated to be either $(C_{10}H_7)_4As_2O \cdot H_2O$ or $(C_{10}H_7)_2As(OH)$. Experimental evidence which we obtained indicates that neither of these formulas is correct. If the compound possessed the first of the above formulas it should react with ethylmagnesium bromide with the liberation of two molecular equivalents of ethane; a compound of the second type should yield one equivalent of the gas. It was found that no gas was evolved when the

---

[1] This paper represents the first part of a dissertation submitted to the Graduate School by Mr. Smith in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

[2] The investigation was made with the assistance of the Parke, Davis and Company Fellowship and we wish to express our appreciation for the aid which has been given us.

[3] It seems to us that the use of the term "arsyl" [Steinkopf and Smie, Ber., 59, **1456 (1926)**] permits one to apply a more rational system of nomenclature to the arsenic compounds which we have investigated than that commonly used. We have called AsH_3 and AsR_3, arsine and triarylarsine, respectively; $—AsH_2$ and $—AsR_2$, arsyl and diarylarsyl; $H_2As—O—AsH_2$ and $R_2As—O—AsR_2$, arsyl oxide and tetra-arylarsyl oxide; $H_2As—AsH_2$, diarsyl and $R_2As—AsR_2$, tetra-aryldiarsyl.

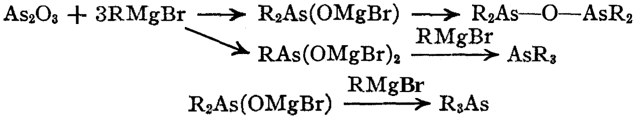
[4] Sachs and Kantorowicz, Ber., 41, **2767 (1908).**

[5] Matsumiya and Nakai, Mem. *Coll. Sci., Kyoto Imp. Univ.*, **8, 307 (1925).**

naphthyl compound was treated with ethylmagnesium bromide. Furthermore, we found the molecular weight of the substance to be 680. The naphthyl compound, therefore, seems to possess the normal structure $(C_{10}H_7)_2As\text{-}O\text{-}As(C_{10}H_7)_2$.

We have studied the action of arsenic trioxide on phenyl-, *p*-tolyl-, *p*-anisyl-, α-naphthyl- and biphenylmagnesium halides. In the case of some of the tetra-arylarsyl oxides we have greatly increased the yields obtained by other investigators by the use of procedures which are fully described in the experimental part of this paper. Tetrabiphenylarsyl oxide has not been prepared hitherto. With the first three Grignard reagents mentioned above, mixtures of tetra-arylarsyl oxides and triarylarsines were obtained, regardless of the way in which the experimental conditions were varied, but with the last two arylmagnesium halides only tetra-arylarsyl oxides were found to be formed.

Concerning the manner in which the tetra-arylarsyl oxides and the triarylarsines are produced, Sachs and Kantorowicz suggested the following scheme but gave no experimental evidence in support of their view.



$$As_2O_3 + 3RMgBr \longrightarrow R_2As(OMgBr) \longrightarrow R_2As\text{—}O\text{—}AsR_2$$

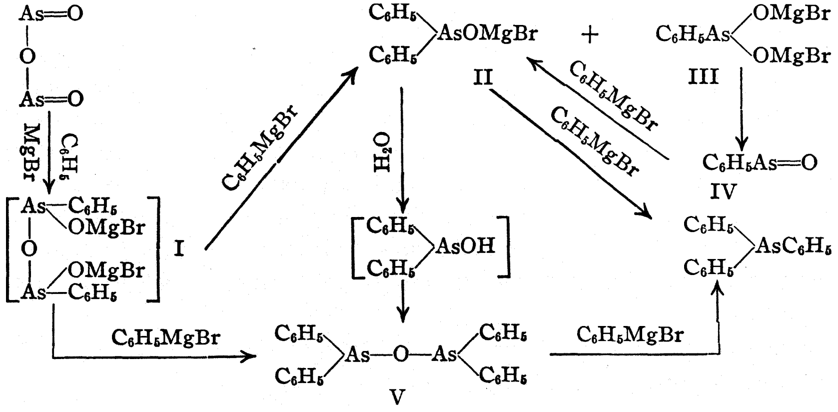
$$3RMgBr \searrow RAs(OMgBr)_2 \xrightarrow{RMgBr} AsR_3$$

$$R_2As(OMgBr) \xrightarrow{RMgBr} R_3As$$

Matsumiya and Nakai, as well as Gryszkiewicz-Trochimowski and Zambrzycki,[6] who studied the action of phenylmagnesium bromide on arsenic trioxide, considered it probable that the reaction proceeded in the following stages.

$$As_2O_3 \xrightarrow{4RMgBr} R_2As\text{—}O\text{—}AsR_2 \xrightarrow{2RMgBr} 2R_3As$$

A consideration of the various possible reactions which might take place when a Grignard reagent, phenylmagnesium bromide for example, reacts with arsenic trioxide leads to the following formulation.



---

[6] Gryszkiewicz-Trochimowski and Zambrzycki, *Roczniki Chemij*, 6, 798 (1926).

One of the first questions which arises in connection with the study of the mechanism of the reaction is this: Is tetraphenylarsyl oxide, V, formed directly from the inorganic oxide (possibly through intermediate formation of I) or is it produced from Compound II by the addition of water to the reaction mixture?

When phenylmagnesium bromide reacts with arsenic trioxide, in the presence of a mixture of ether and benzene, a heavy precipitate soon forms. After completion of the reaction and the removal of most of the ether, the precipitate was separated from the solvent and decomposed with water. Four-fifths of the total amount of tetraphenylarsyl oxide formed was obtained from the precipitate, while the remainder of the arsyl oxide and triphenylarsine was isolated from the benzene layer. If tetraphenylarsyl oxide had been formed directly from arsenic trioxide, and hence were present as such in the reaction mixture, it seems that all of the tetraphenylarsyl oxide should have been obtained from the benzene layer and none from the precipitate;[7] more than enough solvent was employed to hold in solution all of the tetraphenylarsyl oxide which could possibly have been formed from the amount of arsenic trioxide used.

It seems to us that the above phenomena may be accounted for if the assumption is made that $(C_6H_5)_2As\text{-}OMgBr$, a substance which might be expected to be only slightly soluble in benzene, is the precursor of tetraphenylarsyl oxide and that the latter compound is produced only after the addition of water to the precipitate mentioned above.

The same type of phenomenon was encountered in the case of α-naphthyl- and biphenylmagnesium bromide except that in the latter instance all of the tetra-aryl oxide was obtained from the precipitate after decomposition of the latter with water. No precipitates, however, were formed with the tolyl- and anisylmagnesium halides. We can only suggest that in these instances the compounds of the type $R_2As\text{-}OMgX$ may be more soluble.

Compound IV, which would probably be produced by spontaneous decomposition of III, could not be found among the reaction products from phenylmagnesium bromide and arsenic trioxide. We have shown that this substance reacts with phenylmagnesium bromide to form either a mixture of tetraphenylarsyl oxide and triphenylarsine or is converted quantitatively into triphenylarsine, depending on experimental conditions. It was found, also, that tetraphenylarsyl oxide, under proper conditions, reacts with phenylmagnesium bromide to form triphenylarsine in quantitative yield.

Finally, we prepared a number of diarylarsyl halides, some of which have not been described previously.

---

[7] This consisted, in part, of inorganic magnesium salts.

Experimental Part

Aromatic Grignard Reagents and Arsenic **Trioxide**[8,9] **Phenylmagnesium** Bromide.—The reagent was prepared from 62.8 g. of bromobenzene (0.4 mole), 9.7 g. of magnesium (0.4 mole) and 200 cc. of ether in a liter, three-necked flask, fitted with a reflux condenser and then diluted with an equal volume of benzene. The flask was cooled in an ice-bath and a mechanical stirrer introduced. In this experiment, as well as in all of the following ones, moisture was prevented from entering the apparatus. Nineteen and eight-tenths g. (0.1 mole) of dry arsenic trioxide was added as rapidly as possible while the mixture was stirred vigorously. It was found that rapid addition of the arsenic trioxide to the thoroughly cooled reaction mixture reduced the amount of triphenylarsine to a minimum. After all of the oxide had been added, the ice-bath was removed. A colorless precipitate, probably $(C_6H_5)_2AsOMgBr$ and inorganic magnesium salts, soon formed with the evolution of considerable heat.

After the mixture had been stirred for four hours, the solvent was removed under diminished pressure, in a stream of dry nitrogen, until the reaction mixture was reduced to about one-third of its original volume. When the solid material had settled, the benzene layer was decanted and the former substance was decomposed with ice and a small amount of acetic acid. The organic material was extracted with benzene, the benzene solution was shaken with dilute aqueous sodium hydroxide and then dried with fused sodium sulfate. The solvent was removed on a steam-bath and the oily residue allowed to solidify. The material was washed thoroughly with petroleum ether (40–60°) and then with a mixture of ether and petroleum ether; m. p. 92.5–93.5°. This substance was pure tetraphenylarsyl oxide. The yield was 21 g.

The solvents with which the tetraphenylarsyl oxide had been washed were now added to the benzene layer mentioned above and the mixture was treated with ice and a small amount of acetic acid. After separation of the benzene layer, the latter was washed with dilute sodium hydroxide solution, dried and the solvent removed. The oily residue solidified to an amorphous mass. After the latter had been treated with petroleum ether several times, it melted at 91–92° and hence was tetraphenylarsyl oxide; yield, 5 g. The total yield of this oxide was 26 g., or 55% of the calculated amount. The petroleum ether with which the above material had been washed was concentrated to a very small volume and then diluted with 25 cc. of dry ether. Upon the addition of mercuric chloride dissolved in ether the mercuric chloride addition product of triphenylarsine was precipitated. The latter weighed 10.2 g. and corresponds to 5.4 g. of triphenylarsine.

The following experiment shows that triphenylarsine is precipitated practically quantitatively by mercuric chloride: 6.12 g. of pure triphenylarsine was dissolved in a small amount of absolute ether. Upon the addition of 5.42 g. of dry mercuric chloride, dissolved in 250 cc. of ether, a precipitate was obtained which weighed 11.30 *g.;* calcd. weight of addition product, 11.54 g. Triphenylarsine can be obtained from the addition product if the latter is suspended in alcohol and then treated with hydrogen sulfide.

---

[8] Very little information is to be found in the literature regarding the action of aliphatic Grignard reagents on arsenic trioxide. Sachs and Kantorowicz, Ber., 41, 2769 (1908), state that iso-amylmagnesium bromide reacts with arsenic trioxide with the formation of an oil. Gryszkiewicz-Trochimowski and Zambrzycki, *Roczniki Chemij*, 6, 749 (1926), studied the action of methyl-, ethyl-, propyl- and allylmagnesium halides on arsenic trioxide and were able to isolate only trialkylarsines in rather poor yields.

[9] Recently, Matsumiya and Nakai, Mem. *Coll. Sci.*, Kyoto Imp. Univ., 10, 57 (1927), published their results on the action of arylmagnesium halides on arsenic trisulfide. They obtained triarylarsines and varying amounts of tetra-arylarsyl sulfides.

In one experiment an attempt was made to account for all of the material used. From 19.8 g. of arsenic trioxide and 62.8 g. of bromobenzene there were obtained 29 g. of tetraphenylarsyl oxide (equivalent to 12.1 g. of arsenic trioxide and 38.4 g. of bromobenzene), 10.2 g. of the mercuric chloride addition product of triphenylarsine (equivalent to 1.7 g. of arsenic trioxide and 8.3 g. of bromobenzene), 3.5 g. of biphenyl (equivalent to 7.1 g. of bromobenzene), 5.4 g. of unchanged arsenic trioxide and a small amount of phenol. The total amount of bromobenzene thus accounted for is 53.8 g., or 85.5% of that used; the amount of arsenic trioxide, 19.3 g., or 97% of that employed.

After conversion of the oxide into diphenylarsyl chloride, purification of the latter by distillation and hydrolysis of the chloride into the original oxide, the latter was recrystallized from alcohol; m. p. 95.5–96.5°. The highest melting point recorded previously was 92.5–93.5°.[10]

p-Tolylmagnesium Bromide.—After 68.4 g. of p-bromotoluene and 9.7 g. of magnesium in 200 cc. of ether had reacted completely, the solution was diluted with 200 cc. of dry benzene. The contents of the flask were then cooled, stirred vigorously and 19.8 g. of dry arsenic trioxide was added as quickly as possible. In this instance no precipitate formed. The mixture was stirred for four hours and then decomposed with ice and a small amount of acetic acid. The ether–benzene layer was separated, washed with dilute sodium hydroxide solution and then dried with fused sodium sulfate. The solvent was removed and the oily residue dissolved in absolute ether. The ether solution was treated with mercuric chloride dissolved in ether until a precipitate no longer formed. The precipitate, which was the mercuric chloride addition product of tritolylarsine, was removed by filtration. The filtrate was shaken with dilute hydrochloric acid to remove mercuric chloride, dried and the solvent removed. The solid residue was washed thoroughly with petroleum ether (40–60°). The yield of tetra-p-tolylarsyl oxide was 25.5 g., or 48% of the calculated amount. After recrystallization from alcohol the compound melted at 108.5–109.5°. The amount of tritolylarsine formed, calculated on the basis of the addition product, was 9 g.

Sachs and Kantorowicz[4] obtained only tritolylarsine but no arsyl oxide from p-tolylmagnesium bromide and arsenic trioxide. From the interaction of the two latter substances Matsumiya and Nakai[11] obtained a 10% yield of tetratolylarsyl oxide and recorded the melting point as 105–106°.

p-Anisylmagnesium Iodide.—The Grignard reagent was prepared from 93.6 g. of p-iodo-anisole,[12] 9.7 g. of magnesium and 250 cc. of ether. Two hundred and fifty cc. of dry benzene was then added; the subsequent procedure was the same as that described above for p-tolylmagnesium bromide.

There was obtained 33 g. of tetra-p-anisylarsyl oxide; m. p. 127–129°. This corresponds to a yield of 56%. In addition, 12 g. of trianisylarsine was formed.

Tetra-p-anisylarsyl oxide had been obtained previously by Michaelis and Weitz,[13] by the action of hydriodic acid on tri-p-anisylarsine and subsequent hydrolysis of the dianisylarsyl iodide. The substance obtained by them melted at 130°.

α-Naphthylmagnesium Bromide.—This reagent was prepared from 91 g. of pure α-bromonaphthalene[14] (0.44 mole), 9.7 g. of magnesium (0.40 mole) and 200 cc. of ether. An equal volume of benzene was then added to prevent the separation of solid naphthylmagnesium bromide from the solution. The mixture was stirred vigorously and 19.8 g. (0.10 mole) of arsenic trioxide was added. During the latter operation no external

cooling was necessary. After some time a heavy precipitate formed. The mixture was stirred for four hours and then ice and a small quantity of acetic acid were added. The mixture was shaken vigorously and after a short time two distinct layers formed rather suddenly. The ether–benzene layer was then decanted immediately. Within a few minutes tetra-α-naphthylarsyl oxide began to separate, and was completely precipitated after a few hours. The organic oxide was filtered and air-dried. The material was recrystallized from tetralin, suspended in hot benzene to remove any tetralin and filtered; m. p. 250–253° with decomposition. The yields of crude tetranaphthylarsyl oxide averaged 52 g., which corresponds to 77% of the calculated amount. No trinaphthylarsine could be discovered among the reaction products. From α-bromonaphthalene and arsenic trioxide Matsumiya and Nakai[15] obtained a 32% yield of the arsyl oxide. They found the melting point of the substance to be 240–241°.

p-Bromobiphenylmagnesium Bromide.—The Grignard compound was prepared from 31 g. of *p*-bromobiphenyl,[16] 4.0 g. of magnesium and 200 cc. of ether in a *500-cc.* round-bottomed flask which had been modified in the following manner. A glass tube 1 cm. wide and about 15 cm. long was sealed to the body of the flask a short distance from the neck of the latter. About 3 cm. beyond the point of attachment the glass side arm was bent at a right angle toward the bulb of the flask. During the preparation of the Grignard reagent the arm of the flask was closed with a cork. After the above mixture had been heated for about ten hours, the solution of the Grignard reagent was decanted through the side arm from unchanged magnesium and dibiphenyl into a liter 3-necked flask which had been fitted with a reflux condenser and a mechanical stirrer. Two hundred cc. of dry benzene and 100 cc. of ether were added to the mixture and the latter was cooled and stirred vigorously. Upon addition of the arsenic trioxide (6.6 g.) a vigorous reaction took place. A precipitate soon formed which coated the surface of the unchanged inorganic oxide. The reaction mixture was stirred for four hours and the precipitate was then allowed to settle. After twelve hours the liquid layer was decanted[17] and the solid material decomposed as usual. The organic matter was extracted with benzene; the benzene solution was dried and filtered. After removal of the solvent 10 g. of crude tetrabiphenylarsyl oxide was obtained; this yield corresponds to 39% of the calculated amount. The crude material melted about 132–138°. After conversion of the oxide into the chloride, recrystallization of the latter and hydrolysis into the tetra-arylarsyl oxide, the substance melted at 150–152°.

From the experiments described below it can be seen that in the interaction of phenylmagnesium bromide with phenylarsyl oxide, $(C_6H_5)As{=}O$ (or with $(C_6H_5)_2As\text{-}OMgBr$), a large excess of the arylmagnesium halide favors the formation of triphenylarsine to a very decided extent. In the first instance there was used twice the amount of phenylmagnesium bromide necessary for the formation of the arsine; in the second instance eight times the calculated amount of Grignard reagent.

Phenylmagnesium Bromide **and Phenylarsine** Oxide.—Presumably these two compounds react first in accordance with the following

$$C_6H_5MgBr + C_6H_5As{=}O \longrightarrow (C_6H_5)_2As\text{—}OMgBr$$

The diaryl compound then reacts with the Grignard reagent to form the tertiary arsine.

---

[15] Matsumiya and Nakai, Mem. *Coll. Sci.*, Kyoto Imp. *Univ.*, 8, 313 (1925).

[16] Gomberg and Bachmann, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 42.

[17] Upon evaporation of the solvent only biphenyl was obtained.

1. phenylmagnesium bromide was formed from 5.7 g. of bromobenzene (0.037 mole), 0.9 g. of magnesium and 25 cc. of ether. After the addition of 2.7 g. of phenylarsine oxide (0.016 mole), dissolved in 25 cc. of benzene, the mixture was refluxed for three hours. There was obtained 3.0 g. of tetraphenylarsyl oxide and 0.5 g. of triphenylarsine.

2. The Grignard reagent was prepared from 31.4 g. of bromobenzene (0.2 mole), 4.8 g. of magnesium and 100 cc. of ether. Four and two-tenths g. of phenylarsine oxide (0.025 mole), dissolved in 100 cc. of benzene, was added and the mixture was refluxed for four hours. No tetraphenylarsyl oxide was formed. The yield of triphenylarsine was 7.4 g., or 97% of the calculated amount.

The following experiments show that triphenylarsine is produced by interaction of phenylmagnesium bromide with tetraphenylarsyl oxide. Inasmuch as the Grignard reagent and the arsyl oxide react readily even at 0° to form the arsine, it seems impossible to prevent the formation of the latter substance in the preparation of the tetra-arylarsyl oxide.

Phenylmagnesium Bromide and Tetraphenylarsyl Oxide.—The Grignard reagent was prepared from 7.3 g. of bromobenzene (0.05 mole), 0.8 g. of magnesium and 30 cc. of ether. The solution was cooled to 0° and 4.7 g. of tetraphenylarsyl oxide (0.01 mole) was added. After the mixture had remained at 0° for four hours, a heavy crystalline precipitate had formed. The ether layer was decanted from the crystalline deposit and decomposed with ice and ammonium chloride. The ether solution was dried with fused sodium sulfate and the triphenylarsine was precipitated by means of mercuric chloride. The mercuric chloride addition product was removed by filtration and the filtrate was shaken with dilute hydrochloric acid to remove excess mercuric chloride. The ether solution was dried again and the solvent removed. The pasty residue was washed with low-boiling petroleum ether to remove biphenyl. The product which remained was tetraphenylarsyl oxide. The crystalline deposit was decomposed with ice and ammonium chloride and after the addition of a small amount of ether to dissolve the material the solution was treated as described above. Tetraphenylarsyl oxide and triphenylarsine were obtained. The total yield of oxide was 2.6 g.; that of arsine was 2.1 g.

In a second experiment the reaction mixture was kept somewhat above 35°. Phenylmagnesium bromide was prepared from 31.4 g. of bromobenzene (0.2 mole), 4.8 g. of magnesium and 100 cc. of ether. Eleven and eight-tenths g. of tetraphenylarsyl oxide (0.04 mole), dissolved in 100 cc. of benzene, was added and the mixture was refluxed for four hours. The yield of triphenylarsine was 14.2 g.; the calculated amount is 15.3 g.

Finally, we found that arsenic trioxide and an excess of phenylmagnesium bromide react quantitatively to form triphenylarsine. Five g. of arsenic trioxide (0.025 mole) and the Grignard reagent (0.4 mole) obtained from 62.8 g. of bromobenzene, 9.7 g. of magnesium and 200 cc. of ether were refluxed for four hours. There was obtained 15.0 g. of triphenylarsine; the calculated amount of triphenylarsine is 15.2 g.

Summary

A reaction mechanism has been suggested to account for the products which are formed from the interaction of aromatic Grignard reagents and arsenic trioxide.

Improved methods have been described for the preparation of tetraphenyl-, tetra-p-tolyl-, tetra-p-anisyl- and tetra-α-naphthylarsyl oxides. Tetra-p-biphenylarsyl oxide has been synthesized.

A number of diarylhalo-arsines have been prepared and described.

THE ACTION OF SULFUR ON NORMAL-HEPTANE AND NORMAL-BUTANE

BY R. B. BAKER[1] AND E. EMMET REID

RECEIVED JANUARY 11, 1929 PUBLISHED MAY 6, 1929

Introduction

The action of sulfur on organic compounds has been the subject of many investigations.[2] Friedmann[3] investigated the action of sulfur on n-octane when heated under pressure. He obtained a thiophene, $C_8H_{12}S$, and a thiophthene compound, $C_8H_8S_2$.

The Present Investigation

n-Heptane and n-butane were heated with sulfur. The results obtained, so far as they go, are analogous to those of Friedmann. Heptane gives a substituted thiophene and n-butane seems to give thiophene itself, though the yields from both hydrocarbons were very small.

Experimental

***n*-Heptane.** Sealed Pyrex Tubes.—Three g. of sulfur and 11 g. of heptane were heated in each tube at temperatures varying from 150 to 250° for periods of four to twenty-four hours. On cooling the tubes were placed in "dry ice" before opening. The liquid was fractionated and consisted mostly of unchanged heptane. A very small residue boiling above 100° was obtained.

Steel Bombs.—Much larger amounts of materials were used in the bombs, which were heated to temperatures of 300–350° for periods of twenty-four to forty-eight hours. A charge consisted of 12.8 g. of sulfur and 40 g. of heptane. The residues from the bombs, after distilling off the unchanged heptane, were not much greater in proportion than those obtained from the glass tubes. There is very little indication of reaction under these conditions. However, the various residues were combined and fractionated. A fraction (about 2 g.) boiling at 160–161° was collected. A few drops of this liquid when treated with alcoholic mercuric chloride gave a pale yellow precipitate (test for thiophenes). Reasoning from the results of Friedmann's work on n-octane, heptane should give a thiophene of the empirical formula $C_7H_{10}S$. A Parr bomb determination of sulfur gave the result: calcd. for $C_7H_{10}S$: S, 25.40; found: S, 24.89, 25.04 The density was $d_{4^\circ}^{0^\circ} = 0.9332$; $d_{4^\circ}^{25^\circ} = 0.9221$.

This liquid gave positive tests for thiophenes by the methods of Fletcher and Hopkins,[4] Bauer[5] (indophenin reaction), Laubenheimer[6] and Steensma.[7] Negative tests were obtained when the liquid was examined for mercaptans[8] and sulfides.[9]

[9] Steinkopf, *Ann.*, **403**, 1 (1914).

Considerable solid matter was left in the tubes after the removal of the liquid. This proved to be sulfur mixed with some carbon.

n-Butane.—Steel bombs were used with butane and sulfur, the charge being 32 g. of butane and 15 g. of sulfur. As butane is a gas at ordinary temperatures the bomb was first well cooled in an ice-salt mixture before adding the hydrocarbon. The charge was heated for twenty-one hours at 335°.

On opening the bomb (after again cooling in ice water), a considerable amount of hydrogen sulfide was given off and the unreacted butane was volatilized. The gas evolved smelled like a low-boiling gasoline high in sulfur content. Upon opening the bomb very little residue was left (less than 1 g.). This was taken up in ether, and gave all of the above-mentioned color tests for thiophene.

Conclusions

The results obtained are analogous to those obtained by Friedmann on octane. From heptane and sulfur a thiophene and sulfur of the formula $C_7H_{10}S$ is formed in small amounts.

Similar results were obtained with butane and sulfur.

THE CLAISEN ESTER CONDENSATION WITH ETHYL THIOLACETATE[1]

BY R. B. BAKER[2] AND E. EMMET REID

RECEIVED JANUARY 11, 1929 PUBLISHED MAY 6, 1929

Introduction

This investigation was undertaken with the idea in mind of comparing ethyl thiolacetate with ethyl acetate in the ordinary Claisen condensation. No sulfur esters have ever been subjected to such a reaction, and it appeared of interest to compare the products obtained with those resulting from the condensation of ethyl acetate with itself, and of ethyl acetate with a ketone and a nitrile.

Ethyl thiolacetate, $CH_3COSC_2H_5$, in the presence of sodium metal condenses in a manner quite similar to ethyl acetate, and forms a sulfur analog of acetoacetic ester, $CH_3COCH_2COSC_2H_5$. The yield of ester is rather low, being about 15% of the theoretical (calculated on the amount of ethyl thiolacetate used).

At ordinary temperatures ethyl acetothiolacetate contains about 31% of enol (determined by the bromo-titration method of Kurt Meyer),[3] as compared to about 7% in acetoacetic ester.

---

[1] Presented at the Swampscott Meeting of the American Chemical Society, September, 1928.

[2] From a part of the Ph.D. dissertation of R. B. Baker, 1928.

[3] Kurt Meyer, Ber., 44, 2718 (1911).

Acetothiolacetic ester forms metallic salts as does acetoacetic ester,[4] but the copper salt is the only one found that is stable. The others that were prepared decompose on short standing with the formation of metallic sulfides.

The conditions of hydrolysis of this ester are the same as those for acetoacetic ester. With dilute alkalies acetone is formed, and in the presence of concentrated alkalies, two molecules of acetic acid are liberated.

Like acetoacetic ester[5] the new ester decomposes on heating, but much more readily, with the formation of dehydracetic acid, $C_8H_8O_4$.

An equal molar mixture of ethyl thiolacetate and ethyl acetate condenses in the presence of sodium, and a liquid is obtained having a composition of 98% of acetothiolacetic ester (by analysis for sulfur) and 2% of acetoacetic ester. This would show that ethyl thiolacetate is more reactive than ethyl acetate in this condensation.

The Claisen condensation also takes place between an ester and a ketone. Ehrhardt and Claisen[6] prepared acetylacetone, $CH_3COCH_2COCH_3$, by condensing ethyl acetate with acetone. In attempting the same reaction with ethyl thiolacetate and acetone, however, no acetylacetone is formed but only acetothiolacetic ester. The acetone apparently has no effect upon the ethyl thiolacetate, which merely condenses with itself.

Ethyl thiolacetate condenses with acetonitrile with the formation of cyanacetone, CH_3COCH_2CN, the yield amounting to 7%. This same compound is obtained from ethyl acetate and acetonitrile with the same yield.

Experimental

Ethyl Thiolacetate.—This ester was prepared by a modification of the method of **Michler.**[7] The calculated amount of acetyl chloride was added slowly from a dropping funnel through a reflux condenser to slightly more than the calculated amount of ethyl mercaptan, contained in a flask packed in ice. After the addition of the acetyl chloride, the dropping funnel was replaced by a piece of glass tubing leading to a flask containing water to absorb the hydrogen chloride and recover any mercaptan carried over. The mixture was kept at room temperature for several days and then heated under reflux. The product was poured into water. The upper layer was separated and was washed free of acids and dried over calcium chloride. It was then subjected to fractional distillation and the portion boiling at 116–117° collected; yield, 80% of theoretical. The following physical properties were obtained: $d_{4°}^{0°} = 1.0008$; $d_{4°}^{25°} = 0.9755$; $n_D^{28°} = 1.4503$; mol. refr. $[(n^2-1)/(n^2+2)]M/d = 19.31$. Michler gives the boiling point as 114–116°. There are no data on the other properties in the literature.

Ethyl Acetothiolacetate, $CH_3COCH_2COCS_2H_5$

Preparation.—To 17 g. of sodium wire contained in a large balloon flask, 200 g. of ethyl thiolacetate was added slowly, in portions, through a reflux condenser. The top

[7] Michler, *Ann.*, 176, 182 (1875).

of the flask was packed with ice, as in a Grignard reaction, while the bottom was heated gradually on the water-bath to 50°. After six hours the sodium had all reacted and a yellowish pasty mass was obtained. After cooling, 50% acetic acid was added to an acid reaction. An equal volume of cold saturated sodium chloride solution was then added, the top layer separated and dried over calcium chloride. The liquid was fractionated at 2 mm. pressure in apparatus similar to that of Martin[8] as modified by Rice and Sullivan.[9] The distillate going over up to 60° bath temperature was discarded. At 60° and 2 mm. 22 g. (15% yield) of ethyl acetothiolacetate was collected. Sulfur was determined by the Parr bomb method, the liquid being introduced in small, thin-walled bulbs.

Anal. Calcd. for $C_6H_{10}O_2S$: S, 21.93. Found: S, 22.04, 21.86, 22.08.

Properties.—Ethyl acetothiolacetate is a colorless liquid with a rather disagreeable odor, having the following physical properties: $d_{4°}^{0°} = 1.0917$; $d_{4°}^{25°} = 1.0684$; $n_D^{25°} = 1.4885$; mol. refr. $[(n^2-1)/(n^2+2)]M/d = 39.46$. It is insoluble in water but dissolves in ether and alcohol in all proportions. It gives a deep red color with ferric chloride solution (presence of enol form) as does acetoacetic ester. It forms a white crystalline compound with sodium bisulfite.

Percentage of Enol Form.—A determination of the enol content of the ester by Kurt Meyer's bromo-titration method gave a mean value of 30.8%.

Metallic Salts: Copper Salt.—This salt was prepared by adding the calculated amount of a 6% solution of copper acetate to the ester diluted with 2 parts of ether. The bright green precipitate was filtered off, washed with water, then with alcohol and dried in a vacuum desiccator over sulfuric acid. The very fine crystals were found to be insoluble in water and only fairly soluble in benzene, alcohol, ether, chloroform and carbon tetrachloride, both in the hot and in the cold. The crystals decompose on heating at 110°. Copper was determined by the potassium iodide method after decomposing the organic salt in concentrated sulfuric and nitric acids. Sulfur was determined by the Parr bomb method.

Anal. Calcd. for $Cu(C_6H_9O_2S)_2$: Cu, 17.97; S, 18.12. Found: Cu, 18.12, 18.09; S, 18.01, 18.10.

Hydrolysis of Acetothiolacetic Ester

Ketone Hydrolysis.—Acetone is formed from the ester by refluxing with dilute alkali. For this purpose, 1 g. of the ester and 10 cc. of a 5% sodium hydroxide solution were refluxed for two hours in a boiling water-bath. Some of the liquid was then distilled off and acetone identified in the distillate by Gunning's method,[10] which is a modification of Lieben's iodoform test for acetone applicable in the presence of alcohol. A considerable amount of iodoform was obtained.

Acid Hydrolysis.—Acetic acid is obtained by refluxing the ester with concentrated alkali. To a solution of 3.5 g. of potassium hydroxide in 3 cc. of water, 2 g. of the ester was added. After heating in the boiling water-bath for several hours the liquid was acidified with sulfuric acid. The clear liquid was poured off from some potassium sulfate and distilled. Acetic acid was detected by the addition of absolute alcohol followed by concentrated sulfuric acid.

Decomposition of Ethyl Acetothiolacetate.—The residue from a vacuum distillation of the ester solidified on cooling. This solid was found to be very soluble in hot alcohol but insoluble in cold. After several crystallizations from alcohol, pale straw-colored

[8] Martin, *J. Phys. Chem.*, **24**, 478 (1920).

[9] Rice and Sullivan, THIS JOURNAL, 50, 3048 (1928).

[10] Gunning, *Z. anal. Chem.*, **24**, 147 (1885).

needles were obtained, having a melting point of 109°. They were identified by melting point and molecular weight determinations as dehydracetic acid, $C_8H_8O_4$, a compound described by Geuther.[5]

Ethyl Thiolacetate and Ethyl Acetate.—A mixture of 50 g. of ethyl acetate and 59 g. of ethyl thiolacetate was added to 10 g. of sodium wire. After the metal had reacted, the product was worked up as above. The fraction coming over from 40–60° at 2 mm. (the boiling points of acetoacetic ester and acetothiolacetic ester, respectively) was collected. A Parr bomb analysis for sulfur gave 21.49%. As the theoretical value is 21.93%, this indicates 98% of ethyl acetothiolacetate. As a further check on this figure, the density of this liquid was taken at 25° and the value $d_4^{25} = 1.0657$ obtained.

From density measurements (at 25°) of a series of mixtures of the two esters (of known composition) a curve is obtained by plotting density against composition. The value of $d_4^{25} = 1.0657$ corresponds to a composition of 95% $CH_3COCH_2COSC_2H_5$, which agrees fairly well with the composition obtained by actual analysis.

Ethyl Thiolacetate and Acetone.—The method of Ehrhardt and Claisen[6] for the preparation of acetylacetone from ethyl acetate and acetone was used with the sulfur ester in the hope of forming the same compound but only ethyl acetothiolacetate was obtained. Apparently the acetone does not take part in the reaction, and the sulfur ester simply condenses with itself.

Ethyl Thiolacetate and Acetonitrile.—A cold mixture of 38 g. of the ester and 14 g. of acetonitrile was added to 5 g. of sodium wire. After the reaction was complete, the solid was put carefully into ice water, the lower alkaline layer separated and acidified with dilute hydrochloric acid. This was extracted several times with ether, the extract separated, and dried over calcium chloride. The ether was distilled off, and the residue fractionated. The portion boiling from 120–125° was collected. The yield of cyanacetone was 7% of the acetonitrile used.

Summary

1. Ethyl thiolacetate condenses in the presence of sodium to form a sulfur analog of acetoacetic ester, $CH_3COCH_2COSC_2H_5$.

2. The mean value of the enol content of the sulfur ester, as determined by the bromo-titration method, is 30.8% at ordinary temperatures.

'3. Acetothiolacetic ester forms metallic salts as does acetoacetic ester, but of those made only the copper salt, $C_{12}H_{18}O_4S_2Cu$, is stable.

4. Ethyl acetothiolacetate shows the ketone and acid hydrolysis, as does ethyl acetoacetate.

5. Upon heating, ethyl acetothiolacetate decomposes to form dehydracetic acid, $C_8H_8O_4$ as does ethyl acetoacetate.

6. An equal molar mixture of ethyl thiolacetate and ethyl acetate condenses with sodium to form 98% acetothiolacetatic ester and 2% acetoacetic ester.

7. Ethyl thiolacetate and acetone do not condense with sodium to form acetylacetone as would be expected; ethyl acetothiolacetate alone is produced.

8. Ethyl thiolacetate and acetonitrile condense with sodium to form cyanacetone.

THE FORMATION OF DI-PARA-TOLYL INCIDENTAL TO THE PREPARATION OF BENZYLMAGNESIUM CHLORIDE. THE PROBABLE PRELIMINARY FORMATION OF FREE RADICALS IN THE PREPARATION OF GRIGNARD REAGENTS

BY HENRY GILMAN AND JAMES E. KIRBY

RECEIVED JANUARY 21, 1929 PUBLISHED MAY 6, 1929

Introduction

In the course of some studies on the reaction between alkyl *p*-toluenesulfonates and RMgX compounds, Gilman and Beaber[1] obtained very small quantities of an unidentified hydrocarbon melting at 119–120° in all cases where benzylmagnesium chloride was used. Later Gilman and McCracken[2] isolated the same compound, again in very small amounts, from the reaction products of nitrobenzene and benzylmagnesium chloride. More recently, in connection with an investigation of the rearrangements[3] of some Grignard reagents like benzylmagnesium chloride, the same hydrocarbon was obtained as an extremely minor product of the reaction between formaldehyde and benzylmagnesium chloride.

Inasmuch as the hydrocarbon was obtained in three widely different reactions of benzylmagnesium chloride, it appeared probable that the compound was formed independently of the reagent brought into reaction with the benzylmagnesium chloride, and must have formed during the preparation of benzylmagnesium chloride. Several check experiments soon confirmed this, for the compound was obtained, again in very small quantities, when benzylmagnesium chloride was hydrolyzed. The compound was finally shown to be di-p-tolyl. Its identity was confirmed by a series of mixed melting-point determinations between the product of the several reactions[4] and with each of these compounds and an authentic specimen of di-p-tolyl.

The most reasonable explanation, at present, for the formation of di-*p*-tolyl is the preliminary formation of free radicals in the preparation of Grignard reagents. This idea finds support in some experimental work presented recently by Gilman and Fothergill[5] on the disproportionation of free alkyl radicals probably formed incidental to the preparation of some alkylmagnesium halides. These two independent series of observations

have set us in pursuit of the free radicals with the hope of capturing them before they have had an opportunity to couple or to disproportionate.[6] With such capture by so-called reliable reactions to give readily identifiable compounds, we would have unequivocable proof for the prior formation of radicals in the preparation of organomagnesium halides.[7]

The following reactions might account for the formation of di-p-tolyl and other products.

$$C_6H_5CH_2Cl + Mg \longrightarrow C_6H_5CH_2— + —MgCl \quad (I)$$

$$C_6H_5CH_2— + —MgCl \longrightarrow C_6H_5CH_2MgCl \quad (II)$$

$$C_6H_5CH_2— + C_6H_5CH_2— \longrightarrow C_6H_5CH_2CH_2C_6H_5 \quad (III)$$

$$C_6H_5CH_2— \longrightarrow p\text{-}CH_3C_6H_4— \quad (IV)$$

$$p\text{-}CH_3C_6H_4— + p\text{-}CH_3C_6H_4 \longrightarrow p\text{-}CH_3C_6H_4{\cdot}C_6H_4CH_3\text{-}p \quad (V)$$

The free radicals[8] formed in accordance with Reaction I combine to a very large extent to give benzylmagnesium chloride (Reaction II). Gilman, Zoellner and Dickey[9] have just shown that the yield of benzylmagnesium chloride is about 95%, and that this yield is independent of the rate of addition of benzyl chloride to magnesium and ether. The yield of dibenzyl formed in accordance with Reaction III is about 3 to 5%, and the yield of di-p-tolyl (see Reactions IV and V) is about 0.2 to 0.3%.

Reaction IV is illustrative of the rearrangement of the benzyl radical to a p-tolyl radical. It is highly improbable that the benzyl radical would rearrange to any appreciable extent to a *m*-tolyl radical. However, it is reasonable to expect that if a free benzyl radical is formed it should rearrange to an o-tolyl radical, and to an extent probably less than that of its rearrangement to a p-tolyl radical. Should the benzyl radical rearrange not only to the p-tolyl radical but also to the o-tolyl radical, then one might expect, in addition to di-p-tolyl, compounds like the following: *o*- and p-methyldiphenylmethane, 2,2′-dimethyldiphenyl and 2,4′-dimethyldiphenyl. The presence of an o-tolyl linkage should reveal itself in the formation of phthalic acid when the very small quantities of oils were oxidized. Evidence, in this manner, for the presence of an o-tolyl linkage was obtained by the characteristic sensitive fluorescein test with a quantity of material that was too minute for isolation. It is obvious from the

---

[6] A preliminary report of these studies was read by Gilman, Fothergill, Kirby and McGlumphy at the September, 1928, meeting of the American Chemical Society held at Swampscott, Massachusetts.

[7] A recent, very interesting, article by Bachmann and Clarke, THIS JOURNAL, **49**, 2089 (1927), on the mechanism of the Wurtz–Fittig reaction may be conveniently interpreted by assuming the intermediate formation of free radicals. They give references to other related studies on the Wurtz–Fittig reaction.

[8] The excellent work of Gomberg and Bachmann, *ibid.*, **49**, 2584 (1927), on magnesious halides has definitely added these abnormally valenced complexes to the growing series of free radicals.

[9] Gilman, Zoellner and Dickey, ibid., 51, 1576, 1583 (1929).

very large yield of Crignard reagent and the appreciable yield of dibenzyl that very little of the benzyl chloride remained to form other products.[10]

The very small percentage of di-p-tolyl made it desirable to study other possible explanations for the origin of this compound in the preparation of benzylmagnesium chloride, Quite naturally, a first consideration turns on the purity of the benzyl chloride. There is the possibility that' our benzyl chloride, even though of high purity, might contain some p-chlorotoluene. If such p-chlorotoluene were present, it might react with the magnesium[11] to form p-tolylmagnesium chloride and a small quantity of the normal[5] coupling product, di-p-tolyl. However, the possibility of the benzyl chloride being contaminated with a small amount of *p*-chlorotoluene was ruled out by two experiments. First, when a mixture of equivalent quantities of benzyl chloride and p-chlorotoluene was added to sufficient magnesium in ether to react with both halides, no p-tolylmagnesium chloride was formed[12] and, also, there was practically no di-p-tolyl. Second, the oxidation of our benzyl chloride gave benzoic acid, and none of the p-chlorobenzoic acid that might have been expected if p-chlorotoluene were present as an impurity.[13]

We would not have it understood that there is an inflexible ratio between the yields of dibenzyl and di-*p*-tolyl formed from the benzyl radical. Variations were noted in the several hydrolysis experiments. Furthermore, in two experiments that were purposely selected to give large quantities of coupling products, we found that the customary small amounts of di-p-tolyl were formed along with comparatively extremely large quantities of dibenzyl. These two experiments were the reactions with benzyl-

[10] We have little doubt that extremely large-sized preparations of benzylmagnesium chloride would reveal coupling products, in workable amounts, of compounds other than dibenzyl and di-p-tolyl. It is not a particularly inviting procedure for us to prepare very large quantities of any RMgX compound and then decompose it by hydrolysis. On p. 159 of Vol. **3** of the "Annual Survey of American Chemistry" we directed attention, in connection to the work of Bachmann and Clarke (see ref. 7 of this paper), to the special contributions to organic chemistry by manufacturers and dealers in research chemicals. For the immediate purposes of the present study, there is no imperative need for the isolation and identification of the several other possible compounds already mentioned, and which would be formed to a very small extent.

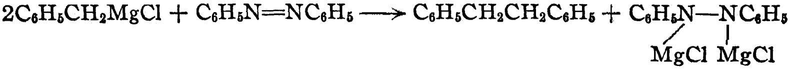
[11] Such reaction would be highly favored by the strong positive catalytic effect of benzylmagnesium chloride, a Grignard reagent that forms with great ease. See Gilman, Peterson and Schulze, Rec. *trav. chim.*, 47, 19 (1928), for a comparative study of various catalysts. Aryl chlorides form the corresponding Grignard reagents with great difficulty.

[12] This was shown by the absence of any p-toluic acid when the reaction mixture was treated with carbon dioxide prior to hydrolysis.

[13] See the Experimental Part for a discussion of the Beilstein flame test for our benzoic acid and that of several samples of "halogen-free benzoic acid" kindly supplied us by others.

magnesium chloride and cupric chloride[14] and azobenzene,[15] respectively. The following are typical reactions

$$2C_6H_5CH_2MgCl + 2CuCl_2 \longrightarrow C_6H_5CH_2CH_2C_6H_5 + Cu_2Cl_2 + 2MgCl_2 \qquad \text{(VI)}$$



$$2C_6H_5CH_2MgCl + C_6H_5N{=}NC_6H_5 \longrightarrow C_6H_5CH_2CH_2C_6H_5 + C_6H_5\underset{MgCl}{N}{-}\underset{MgCl}{N}C_6H_5 \qquad \text{(VII)}$$

Attention should also be directed to the possibility of the free radicals forming only with the hydrolysis of the benzylmagnesium chloride, and not being present prior to the formation of the Grignard reagent. For example, Gilman and Fothergill[15] obtained evidence for disproportionation and therefore for free radicals when they hydrolyzed some of the *alkyl*-magnesium halides studied by them. But they also showed that the same disproportionation took place to a greater extent *before* hydrolysis. By analogy, therefore, the greater part of the coupling products from benzylmagnesium chloride were formed prior to hydrolysis. Unlike the gaseous products of coupling and disproportionation that result from the preparation of alkylmagnesium halides having an R group of low molecular weight, it would be difficult to isolate the essentially non-volatile products like dibenzyl and di-p-tolyl without destroying the benzylmagnesium chloride, in whole or in part.[16]

Experimental Part

Hydrolysis of Benzylmagnesium Chloride.—A one-mole preparation of benzylmagnesium chloride was hydrolyzed by iced hydrochloric acid and the resulting mixture was steam distilled. The forerun of this steam distillate when separated, dried and distilled at atmospheric pressure gave 66.3 g. or a 72.1% yield of toluene. As soon as a sample of the original steam distillate gave crystals on cooling, the receiver was changed and the next liter of steam distillate gave 2.8 g. or a 3.1% yield of pure dibenzyl. The succeeding 550 cc. of steam distillate gave 0.25 g. (or 0.3%) of a crystalline solid melting unsharply between 85 and 90°. After 3 crystallizations of this solid from 95% alcohol, the compound melted at 119–120° and was identified as di-p-tolyl. A careful fractionation by crystallization of the dibenzyl mentioned above gave no di-p-tolyl. The 2.4 g. of dark brown non-steam distillable oil was oxidized by potassium dichromate in dilute sulfuric acid to give benzoic acid, no other carbonyl-containing compound and an oil. Oxidation of this oil by alkaline permanganate gave benzoic acid.

In a second one-mole run, the toluene fraction was distilled under reduced pressure in order to avoid the possible formation of *p*-benzyldibenzyl, inasmuch as Fuson[17] has shown that dibenzyl and benzyl chloride combine under the influence of heat to form

---

[14] Gilman and Parker, THIS JOURNAL, 46, 2823 (1924). This article contains leading references to earlier work on this coupling reaction.

[15] Gilman and Pickens, *ibid.*, 47, 2406 (1925). Gilman and Fothergill, *ibid.*, 50, 867 (1928) (see footnote 5 on p. 868 of this article by G. and F.). Also, Rheinboldt and Kirberg, *J. prakt. Chem.*, 118, 1 (1928).

[16] In this connection it is interesting to note that ethylmagnesium bromide can be refluxed in a *p*-cymene solution (b. p. 175°) without decomposition [see Gilman and Peterson, *Rec. trav. chim.*, 48, 247 (1929)]. Also, it is possible to prepare some ether-free Grignard reagents by the direct application of heat.

[17] Fuson, THIS JOURNAL, 48, 2937 (1926).

p-benzyldibenzyl. We wished to avoid the formation of this compound in order to restrict the origin of any terephthalic acid (resulting from oxidation of the small residues) to such coupling products as di-*p*-tolyl and *p*-benzyltoluene. From this run there was obtained 66.3% of toluene, 5.4% of dibenzyl and 0.2% of di-p-tolyl. Oxidation of the residues gave benzoic acid but no phthalic and no terephthalic acids. In a search for carbonyl compounds that might have resulted from such oxidation, a few drops of a light yellowish oily oxime was obtained; this showed no tendency to crystallize.

From a third one-mole run prepared by the very rapid[18] addition of benzyl chloride there was obtained 60.7% of toluene, 3.85% of dibenzyl and 0.2% of di-p-tolyl. The 1.9 g, of non-volatile oil resulting from the steam distillation was oxidized by alkaline permanganate. When the filtered oxidation mixture was acidified a slight cloudiness indicative of a trace of terephthalic acid[19] appeared. However, the quantity was altogether too small to permit of isolation. The resulting water solution was thrice extracted with ether and the ether solution, after drying, was evaporated to dryness. The solid acids were extracted with chloroform in order to isolate any phthalic acid. Only a trace remained undissolved and this appeared to be phthalic acid, inasmuch as it gave a good fluorescein test when warmed with resorcinol and sulfuric acid. Evaporation of the chloroform extracts gave 0.13 g. of benzoic acid. It should be mentioned here that oxidations in search of acids were regularly carried out with all fractions, both of steam distillates and residues, that were not definitely shown to be toluene, dibenzyl or di-*p*-tolyl.

Benzylmagnesium Chloride, p-Chlorotoluene and Carbon Dioxide.—A mixture of 0.1 mole of benzyl chloride and 0.1 mole of p-chlorotoluene was added to 0.2 atom of magnesium in ether. The resulting solution of RMgCl compound or compounds was treated with carbon dioxide in the customary manner and then hydrolyzed. The phenylacetic acid (7.0 g. or 51%) melted sharply at 76–77°, and fractional crystallization of it yielded no p-toluic acid. The yield of recovered *p*-chlorotoluene was 87.3%.

Oxidation of Benzyl Chloride.—The benzoic acid obtained by the alkaline permanganate oxidation of 0.1 mole of the benzyl chloride used in these studies gave no positive sodium fusion test for halogen. However, it did give a weak Beilstein copper wire color test. The faint green flame test appeared momentarily and without excessive heating of the wire. Because of the very critical nature of this test (a positive test would indicate the presence of p-chlorotoluene in our benzyl chloride) it was also carried out with several samples of halogen-free benzoic acid.[20] To our great surprise all four samples of such halogen-free benzoic acid (which showed no halogen after a sodium fusion test) gave a slight positive Beilstein test.

The weak Beilstein test with our several samples of benzoic acid prompted a like test with other supposedly pure carboxylic acids. The faint Beilstein test is not shown by all carboxylic acids, for among the 9 acids tested there was no positive flame test with salicylic, diphenylacetic and terephthalic acids. Should our "halogen-free benzoic acids" actually contain a trace of halogen sufficient to give this very delicate flame test

---

[18] This was carried out prior to the experiments (see ref. 9) on the effect of rapid addition of halide on the yield of RMgX compound. At that time it was believed that a rapid addition would favor the formation of coupling products and so improve the opportunity of obtaining coupling products in addition to the dibenzyl and di-p-tolyl previously isolated.

[19] At the time these studies were carried out a technique had been acquired for the isolation and identification of small quantities of the phthalic and other acids. See ref. 3 of this paper.

[20] In this connection the authors wish to express their appreciation for samples provided by Dr. H. T. Clarke and Dr. E. K. Bolton.

it still would not affect seriously our conclusions in view of the experiment (described above) on benzylmagnesium chloride, *p*-chlorotoluene and carbon dioxide. The tests with the several benzoic acids are sufficiently important to warrant further study, and we are collecting samples of benzoic acid which (as well as we can determine) are free of any hereditary and acquired taint of halogen.

Benzylmagnesium Chloride and Cupric Chloride.—From the reaction carried out in the customary manner[1]* between 0.3 mole of benzylmagnesium chloride and 0.3 mole of cupric chloride there was obtained a 70% yield of pure dibenzyl and a trace of di-*p*-tolyl. The 4.6 g. of non-steam distillable tar gave only benzoic acid on oxidation.

Benzylmagnesium Chloride and Azobenzene.—From one mole of benzylmagnesium chloride and 0.44 mole of azobenzene there was obtained 52.3% of benzidine and 37% of dibenzyl.

Benzylmagnesium Chloride and Formaldehyde.—Formaldehyde was led over the surface of 0.4 mole of benzylmagnesium chloride until a negative color test[21] was obtained showing that all of the Grignard reagent had been used up. In addition to a 26.9% yield of o-tolylcarbinol there was obtained about 0.3 g. of di-p-tolyl.

The authors gratefully acknowledge helpful suggestions from Dr. N. J. Beaber and Dr. H. T. Clarke.

Summary

Di-*p*-tolyl is formed in very small quantities incidental to the preparation of benzylmagnesium chloride. The presence of this coupling product is advanced as additional evidence for the preliminary formation of free radicals in the preparation of Grignard reagents.

THE YIELDS OF SOME GRIGNARD REAGENTS. ALTERNATING PROPERTIES OF NORMAL ALKYL BROMIDES

BY HENRY GILMAN, E. A. ZOELLNER AND J. B. DICKEY

RECEIVED JANUARY 21, 1929 PUBLISHED MAY 6, 1929

Introduction

In connection with studies on the relative reactivities of alkyl and aryl halides toward magnesium in ether,[1] it was necessary to determine the yields of some Grignard reagents. These yields were determined under optimal conditions. They differ in several instances from the yields previously determined in this Laboratory.[2] In general, because of an improved mode of preparation and refinements in analytical procedure, the yields are

Marvel, Blomquist and Vaughn, THIS JOURNAL, 50, 2810 (1928), have determined the yields of some Grignard reagents prepared in di-n-butyl ether.

somewhat higher than those reported earlier. Where the same compounds have been analyzed, the present results are to be preferred. Also, determinations have been made of the yields of a number of compounds not previously studied by us,

An examination of the yields under these standard conditions reveals an apparent alternation with the first members of the *normal* alkyl bromide series. A consideration of this phenomenon together with some general conclusions are given in the Discussion of Results.

Experimental Part

Method of Analysis.—The general analytical procedure was one of the five methods investigated by Gilman, Wilkinson, Fishel and Meyers[3] for the quantitative estimation of Grignard reagents, namely, the acid titration method. Two variations were made.

First, phenolphthalein was used throughout as the indicator. Methyl orange is an unsatisfactory indicator because of individual differences on what constitutes a true end-point, and because of general difficulties in observing color changes when arylmagnesium halides are titrated. A comparative study was made of three indicators: phenolphthalein, methyl red and methyl orange. Three pairs of aliquots from a given preparation of phenylmagnesium bromide were titrated with phenolphthalein, methyl red and methyl orange, and the average titration values with these three indicators were 94, 95.9 and 97.1%, respectively. Also, two pairs of aliquots from a preparation of *n*-butyl chloride when titrated with phenolphthalein and methyl red as indicators showed the titration value with methyl red as the indicator to be about 1.5% higher than that with phenolphthalein.

These differences, selected from several comparative titrations with the different indicators, might have been predicted, in part. Variations of about the same order were noted when magnesium sulfate (of about the quantity and concentration present in a typical Grignard analysis) was titrated with standard alkali, using the three indicators specified.

These results are of decided importance with reference to the *actual* quantity of Grignard reagent present. Gilman, Wilkinson, Fishel and

---

[3] Gilman, Wilkinson, Fishel and Meyers, THIS JOURNAL, 45, 150 (1923). See also Gilman and Meyers, ***Rec. trav. chim.,*** 45,314 (1926), for a confirmation of our analytical procedure and a criticism of another method. The acid titration method has been extensively employed in a variety of studies in this Laboratory. (See refs. 1 and *2* in this paper and other studies from this Laboratory on organomagnesium halides.) It has also been used by others. More recent references to its application by others are to be found in studies by Marvel, Blomquist and Vaughn, THIS JOURNAL, 50, 2810 (1928), and Meisenheimer and co-workers, Ber., 61, 708, 720, 2079 (1928), who also used phenolphthalein as an indicator incidental to an acid titration that was combined with an analysis for halogen by the Volhard method. They (Meisenheimer and co-workers) recommend methyl red when no analysis is to be made for halogen.

Meyers[3] and Gilman and Meyers[2] showed that the quantity of Grignard reagent as determined by the acid titration method is generally about 4% too high, when reference is made to the more exact gas analysis method also studied by them.[2] This is so because the acid titration method, unlike the gas method,[4] is a measure of the Grignard reagent originally present, but not all of which is now available because of partial decomposition by traces of moisture, etc., to give basic compounds of the type formed from undecomposed Grignard reagent in the acid titration method of analysis. Accordingly, the use of phenolphthalein as an indicator removes almost entirely the sole serious objection to the acid titration method. This is so because with phenolphthalein the yield of a given aliquot is about 3% less than that determined when methyl orange is used as the indicator, and it was with methyl orange as an indicator that the earlier[2] quantitative studies showed the acid titration to give values about 4% higher than the gas method. Therefore, with phenolphthalein the results are only about 1% higher than those determined by the gas method.

A second variation in the acid titration procedure was in the heating with an excess of standard sulfuric acid prior to the back titration with standard alkali. In the earlier studies[2] it was recommended that the basic magnesium compounds be heated with the standard acid not over 60° in order to avoid any oxidation of hydriodic acid that might be present when alkyl or aryl iodides were used. It was shown, in the present study, that there is no difference (within experimental error) when aliquots are heated to 60° or boiled for fifteen minutes. This was demonstrated with n-butylmagnesium iodide and phenylmagnesium bromide.

Chemicals.—All of the halides, originally of the highest commercial purity, were carefully dried and distilled prior to use. The commercial magnesium turnings were crushed in a dry porcelain mortar and separated from the fine particles. The magnesium so obtained ($^1/_{12}$ to $^3/_8$-inch mesh) was essentially of uniform size. The commercial anhydrous ether was further dried by standing over sodium wire.

The following quantities of materials were used in each experiment: **0.05** mole of alkyl or aryl halide; **0.054** atom of magnesium; **30** cc. or about 6 molecular equivalents of ether and a crystal of iodine which weighed about **0.04** g.

Apparatus.—The special reaction flask used in previous[2,3] studies was simplified. The external delivery tube and stopcock, through which was forced (by gas pressure) the sample for analysis, was removed. These accessory parts for obtaining aliquots are not only unnecessary but also somewhat troublesome because of the need of freeing the open end of products formed by atmospheric decomposition of the Grignard reagent. Aliquots were quickly removed by means of clean 10-cc. pipets. With an ordinary refined technique there is very little opportunity for atmospheric decomposition.

The new simpler reaction flasks have a wider bore (15 mm. instead of 12 mm.) in the graduated necks. This did not decrease essentially the accuracy of a reading, but it did make it possible to use a more efficient stirrer.

---

[4] See Gilman and Fothergill, This Journal, 50, **3334** (1928), for additional comments (p. **3339**) on the gas method of analysis.

Procedure.—Inasmuch as this standard procedure will be referred to in several subsequent reports, it is given completely at this time.

The weighed magnesium turnings were placed in the clean reaction flask which had just previously been removed from an electric drying oven heated at about 110°.[5] The flask was then attached to an apparatus consisting of a mercury-sealed stirrer, a Hopkins condenser provided at its upper end with a drying tube filled with calcium chloride and a 100-cc. dropping funnel. After cooling the flask, 6.5 cc. of ether and the crystal of iodine were added. Then the halide, previously weighed out in a 50-cc. glass-stoppered Erlenmeyer flask, was added to the dropping funnel, and 20 drops (about 0.2 cc.) of the undiluted halide was added to the flask. This mixture was refluxed, without stirring,[6] by means of a water-bath kept at 45°.[7] The remaining 23.5 cc. of ether was used to rinse the halide from the Erlenmeyer flask, in which it was weighed, to the dropping funnel. The stirrer was then started and allowed to continue at about 750 r. p. m.

The ether–halide mixture was then added, at room temperature, over a thirty to thirty-five-minute period, by a carefully regulated rate of addition of about 15 drops per ten seconds. When all of the ether–halide had been added, the reaction continued of itself for about three to ten minutes with the alkyl halides and for about ten to forty-five minutes with the aryl halides. Stirring was continued during these additional periods as long as there was any evidence of reaction (as noted by bubbling on the surface of the reaction mixture when stirring was transitorily interrupted). When there was no further evidence of reaction, the mixture (while still being stirred) was refluxed by means of a hot-plate. The time of such refluxing was, in general, five and ten minutes for alkyl halides and fifteen and thirty minutes for aryl halides.[8]

The flask was then cooled in a bath of tap water (12–15°) and during the addition of the diluent (ether or benzene) to bring the contents up to about the 100 cc. mark, the rate of stirring was increased to about 2500 r. p. m. and kept there for two minutes to assure intimate mixing. The flask was then disconnected, stoppered and allowed to stand for five minutes[9] in the tap-water bath in order to permit settling of the magnesium particles. The volume was then read and two 10-cc. aliquots were pipetted off

---

[5] In this manner we were assured that the reaction flask was dry. The water condenser was also dry, because when not attached to the reaction flask the lower end was closed by a tight-fitting cork. The upper end was always provided with a drying tube filled with calcium chloride. Moisture has an anti-catalytic effect which must be considered in studies of relative rates of formation of Grignard reagents.

[6] See Gilman, Peterson and Schulze, Rec. *trav. chim.*, 47, 19 (1928).

[7] In this manner all reactions were permitted to start before adding the main portion of halide. This preliminary procedure also removes any incidental traces of moisture and contributes to a more uniform activation of the magnesium.

[8] By these times we mean that in one run of a given RX compound the period of refluxing was five minutes, for example, and in another run of the same halide the period of refluxing was ten minutes. In this manner it was possible to learn whether the mixture had been sufficiently refluxed so that additional refluxing would not increase the yield. In general, it was found that refluxing at the end of the reaction increased the yield 2–5%.

[9] A longer time of standing (up to one-half hour) showed no difference within the experimental error of two aliquots. The experimental error in titration of two aliquots of a given run is 0.1 to 0.2 cc. of the standard acid. If the variation were greater than 0.25 cc. of acid with the two aliquots, another aliquot was removed from the flask, which was kept in the tap-water bath for such rare variations. These variations are equivalent to 0.7–1.5% in the final yield of the Grignard reagent.

and added to 500-cc. Erlenmeyer flasks containing 150 cc. of distilled water. Sufficient standard acid (about 0.2 *N*) was added so that about 10 cc. of standard base was required in the back-titration with standard sodium hydroxide (about 0.2 N). Phenolphthalein was used as the indicator and the pipets, of course, were carefully rinsed with the acid solution and with water. Prior to the back-titration, the acid solution was heated at about 70–80° and the titration was carried out with this hot solution.

Number of Determinations and Accuracy of Method.—The yield of each alkyl halide was determined **3** times, and from each determination at least 2 aliquots were taken for analysis. The analyses checked in a surprisingly satisfactory manner when one considers the nature of the reaction. For example, in **3** separate experiments with ethylmagnesium bromide the average yields (based on at least 2 aliquots from a given experiment) were 93.4, 92.9 and 92.9%; with *n*-butylmagnesium bromide they were 94.0, 94.1 and 93.8%; and, with n-hexylmagnesium bromide 91.8, 91.6 and 92.7%.

A concordance of this high order indicates that 2 instead of **3** independent analyses of a given halide should have sufficed. However, for some reason as yet unknown, there was a greater variation with the *sec.*-butyl- and *sec.*-amylmagnesium bromides. For example, 4 runs of *sec.*-butylmagnesium bromide gave the following results: 78.4, 75.9, 79.7 and 75.5%.

Only two runs were made with each *aryl*magnesium bromide and the yields agreed within 1%.

The yields given in Table I are the averages of 2 or **3** or 4 separate runs, from each of which at least 2 aliquots were removed for analysis.

TABLE I

AVERAGE PERCENTAGE YIELDS OR RMgX COMPOUNDS

Halide used	Yield of RMgX compd., %	Halide used	Yield of RMgX compd., %
Ethyl bromide[a]	93.1	n-Heptyl bromide	88.8
n-Propyl bromide	91.7	n-Octyl bromide[c]	88.4
Isopropyl bromide	84.0	n-Butyl chloride[d]	91.2
n-Butyl bromide	94.0	n-Butyl iodide[e]	85.6
Isobutyl bromide	87.2	Benzyl chloride	93.1
Sec.-butyl bromide	77.7	Bromobenzene[f]	94.7
Tert.-butyl bromide	25.1	*o*-Bromotoluene[g]	92.7
n-Amyl bromide	88.6	*m*-Bromotoluene	88.0
Iso-amyl bromide	88.0	*p*-Bromotoluene	86.9
Sec.-amyl bromide[b]	66.8	α-Bromonaphthalene[h]	94.8
Tert.-amyl bromide	23.7	β-Bromonaphthalene	83.8
n-Hexyl bromide	92.0		

[a] Because of the volatility of ethyl bromide several runs were made with an extra condenser. However, this added precautionary measure did not give any higher results than those obtained with the one condenser used with all other halides.

[b] The 66.8% yield is the average of 4 experiments which in turn averaged 69.5, 69.6, 65.8 and 62.3%.

[c] The original pure commercial sample of n-octyl bromide boiled between **197–200.5°** (uncorr.). This was distilled before use and the fraction boiling between **198–**

200.5° gave yields of 87.4 and 88.5%. On redistillation of the halide a fraction boiling at 200–201° was collected and this gave a yield of 89.2%.

[d] The average yields of 3 runs were 89.8, 92.1 and 91.6%. In the 89.8% yield run there was evidence of a reaction one hour after all of the halide had been added, and in this run the mixture was refluxed for twenty minutes. In the 92.1% yield run there was evidence of reaction after one hour and ten minutes. This mixture was then stirred an additional one and one-half hours and then refluxed for thirty minutes. The 91.6% yield run was like the 92.1% run with the exception of a two-hour (instead of a thirty-minute) period of refluxing.

[e] The 85.6% yield of n-butylmagnesium iodide is from freshly distilled iodide. In two other runs where the iodide was distilled one month prior to use the yield was 3–4% lower. Some bromides, like n- and *iso*butyl and phenyl, showed essentially no difference in yield whether the commercially pure compounds were distilled or not distilled.

[f] There was evidence of reaction ten minutes after all of the bromobenzene was added. The mixture was then refluxed for ten minutes. With the exception of *n*-butyl chloride, bromobenzene appeared to react for a longer time than any alkyl bromide after all of the halide had been added.

[g] The three bromotoluenes appeared to react thirty-five to fifty minutes after all of the halide was added. They were then refluxed for fifteen and thirty minutes, respectively, in alternate runs in order to assure completeness of reaction (see ref. 8 of this paper).

[h] The bromonaphthalenes appeared to react twenty to thirty minutes after all of the halide was added. They were then refluxed for fifteen and thirty minutes, respectively, in alternate runs. Benzene was used as a diluent in the experiments with the bromonaphthalenes in order to bring the solutions to the 100-cc. mark. Methyl orange is an unsatisfactory indicator under these conditions. The naphthylmagnesium bromides were, of course, prepared in the 30 cc. of ether, but like RMgBr compounds from p-bromoanisole and p-bromophenetole, they or their etherates are sparingly soluble in ether and more soluble in an ether–benzene mixture.

Discussion of Results

Alternation of Normal Alkyl Bromides.—A glance at the yields of *normal* alkylmagnesium bromides from propyl to heptyl reveals an apparent alternation. The even-numbered halides give yields higher than the *preceding* halides that have an odd number of carbon atoms. This alternation may be accidental. However, we are inclined to doubt that this is the case because the differences are well beyond any experimental error in the method of analysis.

If this alternation is not fortuitous, then methylmagnesium bromide might be expected, under the conditions of our experiments, to give a yield less than that of ethylmagnesium bromide. The difficulty of handling methyl bromide, although not overly serious, might be sufficient to throw some doubt on values obtained with it. Furthermore, results with it might be open to various interpretations because of the known irregularities of first members of homologous series.

Octyl bromide, on the basis of alternation, should give a higher yield of the Grignard reagent than heptyl bromide. The only indication of a higher yield is found in the single experiment described in Footnote (c) of Table I. Possibly, if the phenomenon of alternation is sound, it may become very weak or disappear entirely at the octyl bromide level.

It is interesting to recall that in the earlier studies by Gilman and McCracken[2b] attention was directed to an apparent alternation with normal iodides. Here, however, the odd-numbered iodide gave a higher yield than the preceding iodide having an even number of carbon atoms. This alternation broke down completely, as was mentioned at that time, in the case of propyl iodide, which gave a distinctly lower yield of Grignard reagent than did ethyl iodide.

For those who would seek an explanation of the observed alternations it is well to remember that the reaction of an RX compound with magnesium in ether is not simple. All that we have measured here is the quantity of Grignard reagent that formed. Several minor side reactions have been considered recently by Gilman and Fothergill.[4]

Decrease in Yield with Ascent of Series.—There is no doubt concerning the general and gradual drop in yield in a given series with the ascent of that series to halides of higher molecular weight. However, this drop is so gradual that it is necessary to revise drastically ideas that are still current concerning the decided drop in yield (to 50% or so) with hexyl or octyl

Effect of Branching.—With a given series, the order of decreasing yield is normal, secondary and tertiary. Special conditions are necessary for the preparation of tertiary Grignard reagents in distinctly satisfactory yields. These have been described by Gilman and Zoellner.[11]

Reactivity of Halogen.—With a given R group (the n-butyl, for example) the lowest yields are with the iodide and the highest with the bromide. The alkyl chlorides react quite slowly, and if sufficient time is taken it is possible that the chlorides will be found to give higher yields than (or yields at least as high as) the corresponding bromide.

The chlorine in benzyl chloride and the bromine in allyl bromide are decidedly more active than the chlorine in n-butyl chloride and yet all three have given yields in excess of 90%. Different types of halides must be handled differently in obtaining optimum yields of the corresponding Grignard reagents. This is strikingly illustrated with benzyl chloride and allyl bromide, each of which has a highly reactive halogen. For example, benzyl chloride can be added at once to magnesium in ether and yet give

[10] The sustained high yields are strikingly illustrated by the as yet unpublished work of Houben and Bodler, a brief account of which is given in Houben-Weyl, "Die Methoden der Organischen Chemie," 4, 725, second edition, published in Leipzig in 1924. It is interesting to note (private communication from Professor Houben) that phenolphthalein was used as an indicator in their titrations. See also ref. 4 in the article by Gilman and Meyers, *Rec. trav. chim.*, 45, 314 (1926).

[11] Gilman and Zoellner, THIS JOURNAL, 50, 425 (1928); Rec. *trav. chim.*, 47 (1928).

an excellent yield of benzylmagnesium chloride (see following paper); whereas if allyl bromide is added at once to magnesium in ether, very little allylmagnesium bromide results, and most of the allyl bromide couples to form diallyl. However, by the special conditions described recently by Gilman and McGlumphy[12] it is possible to obtain allylmagnesium bromide in greater than 90% yields.

The Naphthylmagnesium Bromides.—The yield of α-naphthylmagnesium bromide reported earlier[ab] is incorrect. This was very probably due to the sparing solubility of this Grignard reagent in ether (see footnote *h* to Table I). The comparatively high yield of β-naphthylmagnesium bromide is both interesting and valuable in view of the discouragingly low yields of this RMgBr compound reported by others.[13]

The authors gratefully acknowledge assistance from R. W. Borgeson and L. L. Heck.

Summary

The yields of a number of typical Grignard reagents have been determined. Where comparisons can be made with earlier determinations these revised yields are higher. Attention is directed to a number of generalizations, particularly the apparent alternation in yields with the n-alkyl bromides.

AMES, IOWA

THE EFFECT OF RAPID ADDITION OF HALIDE ON THE YIELDS OF SOME GRIGNARD REAGENTS

BY HENRY GILMAN, F. A. ZOELLNER AND J. B. DICKEY

RECEIVED JANUARY 21, 1929 PUBLISHED MAY 6, 1929

Introduction

In studies on the relative reactivities of alkyl and aryl halides toward magnesium in ether,[1] all of the halide is added at once to the magnesium in ether and the reaction is interrupted at regular intervals to determine the rate of reaction. This makes it necessary to have comparative values showing the yields of Grignard reagent when all of the halide is added at once. Yields under such conditions have been determined and are here reported. The results of such studies have an importance over and above

---

[12] Gilman and McGlumphy, *Bull. soc. chim.*, 43, 1322 (1928).

[13] Loevenich and Loesser, *Ber.*, 60, 320 (1927), reported a 28.5% yield of β,β'-dinaphthyl and no β-naphthoic acid when their reaction product of β-bromonaphthalene and magnesium was treated with carbon dioxide. Probably the highest yield of a compound from β-naphthylmagnesium bromide is a 50% yield of β-naphthaldehyde reported by Chichibabin, *Ber.*, 44, 443 (1911).

[1] A preliminary account of these studies has been reported by Gilman and Zoellner, THIS JOURNAL, 50, 2520 (1928).

their value for rate studies. These considerations are treated in the Discussion of Results.

Experimental Part

The general design of the apparatus,[2] the quantities of reagents, the starting of the reaction, the rate of stirring, the conclusion of the reaction and the method of titration were identical with the procedure described in the preceding paper by Gilman, Zoellner and Dickey.[3] The reaction was started with 20 drops (about 0.2 cc.) of halide in 6.5 cc. of ether and a crystal of iodine weighing about 0.04 g.

Then 23.5-cc. of ether was added to the remainder of the halide contained in the dropping funnel. The stirrer was started and kept at a rate of about 750 r. p. m., and the halide and ether were added as rapidly as possible. The time of addition was about ten seconds.[4] All reactions were allowed to continue at room temperature and from time to time stirring was interrupted to ascertain evidence of any reaction. When the reaction was apparently concluded, the mixture was treated in the manner described in the preceding paper.

Approximate times were noted when there was no evidence of reaction subsequent to the rapid addition of all of the halide. For the alkyl halides[5] and benzyl chloride this time was nine to twelve minutes; for bromobenzene it was about twelve to fifteen minutes; and for the other aryl halides the time was about one hour.

The average yields with rapid addition given in Table I are of at least two independent runs. The widest variation between any pair of runs was 2.5%. Each run in turn is an average based on at least two aliquots which agreed between 0.7% and 1.5%.[3] For purposes of comparison, Table I also includes the average percentage yield under optimal conditions and the difference between these two yields, namely, the average percentage drop in yield with rapid addition of halide.

Discussion of Results

A glance at Table I shows that there is a drop in yield with each of the compounds studied when the halide is added rapidly. This might have been predicted in view of the results obtained by Gilman and Meyers[6] in their study of the optimal conditions for the preparation of ethylmagnesium iodide. They showed that the yield of ethylmagnesium iodide was 93.3% when the ethyl iodide was added over a forty-five minute period and 85.2% when the ethyl iodide was added as rapidly as possible, which was about thirty seconds under the conditions of those experiments. With this result as a basis, all later investigations in this Laboratory[7] on optimal conditions for other Grignard reagents incorporated, among other factors, a slow rate of addition.

---

[2] The bore of the graduated neck of the reaction flask was 20 mm. instead of 15 mm. This greater width was necessary in order to reduce the accumulation of reaction mixture in the neck of the flask as a consequence of the vigorous reaction attendant on the rapid addition of halide.

[3] Gilman, Zoellner and Dickey, THIS JOURNAL, 51, 1576 (1929).

[4] In the earlier study by Gilman and Meyers, *ibid.*, 45, 159 (1923), the time for the rapid addition of ethyl iodide was about thirty seconds.

[5] See preceding paper for the slow reaction with n-butyl chloride.

TABLE I

AVERAGE: PERCENTAGE YIELDS OF RMgX COMPOUNDS APTER RAPID ADDITION OF HALIDE, AND DECREASE IN YIELDS FROM NORMAL ADDITION

Halide Used	Yield, opt. cond. %	Yield, hal. added rapidly, %	Diff. or drop in yield, %	Halide Used	Yield. opt. cond. %	Yield, hal. added rapidly, %	Diff. or drop in yield, %
Ethyl bromide	**93.1**	86.6	6.5	n-Heptyl bromide	88.8	72.9	15.9
n-Propyl bromide	**91.7**	82.5	9.2	n-Octyl bromide	88.4	73.3	15.1
Isopropyl bromide	**84.0**	70.5	13.5	n-Butyl chloride	91.2	90.6	0.6
n-Butyl bromide	**94.0**	79.2	14.8	*n*-Butyl iodide	85.6	67.8	17.8
Isobutyl bromide[a]	**87.2**	76.7	10.5	Benzyl chloride	93.2	92.9	0.3
Sec.-butyl bromide[b]	**77.7**	61.6	16.1	Bromobenzene	94.7	89.8	4.9
Tert.-butyl bromide[c]	**25.1**	17.8	7.3	b-Bromotoluene	92.7	88.3	4.4
n-Amyl bromide	**88.6**	73.2	15.4	m-Bromotoluene	88.0	81.3	6.7
Iso-amyl bromide	**88.0**	70.2	17.8	*p*-Bromotoluene	86.9	83.3	3.6
Sec.-amyl bromide[b]	**66.8**	49.2	17.6	a-Bromonaphthalene	94.8	91.7	3.1
Tert.-amyl bromide	**23.7**	19.1	4.6	β-Bromonaphthalene[d]	83.8	81.3	2.5
n-Hexyl bromide	**92.0**	77.2	14.8				

[a] The 10.5% drop in yield is the average of three independent runs. The third, which agreed closely with the other two, was made because it is difficult to understand why the drop in yield with isobutyl bromide should be less than the drop with *n*-butyl bromide and *iso*-amyl bromide.

[b] Three independent runs were made with *sec.*-butyl and *sec.*-amyl bromides in order to note any possible irregularity with these halides.[3] The several runs gave good checks.

[c] Three independent runs were made with *tert.*-butylmagnesium bromide and all checked within 0.6%.

[d] A greater drop in yield was expected with β-naphthylmagnesium bromide because Loevenich and Loesser, Ber., 60, **320** (1927), reported a 28.5% yield of β,β'-dinaphthyl and no β-naphthoic acid when their reaction product of β-bromonaphthalene and magnesium was treated with carbon dioxide (see ref. **13** of ref. **3.**)

However, the extent of the drop in yield could not have been predicted with any exactitude in several of the compounds studied. First, benzylmagnesium chloride shows practically no drop in yield with rapid addition. This is astonishing in view of the statements in the literature that unless special precautions are taken in the preparation of this Grignard reagent the yield of coupling product (in this case, dibenzyl) can reach 30%. Second, the drop in yield with *tert.*-butyl- and *tert.*-amylmagnesium chlorides is less than one might have expected in view of the studies by Gilman and Zoellner[8] on the optimal conditions for the preparation of these *tertiary* Grignard reagents. They found it necessary to add the tertiary halides extremely slowly (about two to three hours) in order to get a good yield of the RMgCl compound. However, consideration should be given to the fact that there is already a very marked drop in yield from the very special conditions of Gilman and Zoellner[8] for the two tertiary chlorides, and the

---

[8] Gilman and Zoellner, THIS JOURNAL, 50, **425** (1928); *Rec.* trav. chim., 47, **1058** **(1928).**

more general conditions of Gilman, Zoellner and Dickey[3] for all types of Grignard reagents. In the former case the yield was 58%[9] in a two-hour period of addition and in the latter case about 25% in a 30 to 35 minute period of addition.

In general the alkyl halides show a greater drop in yield on rapid addition than do the aryl halides. With the alkyl halides the iodide shows a greater drop than the bromide and the bromide, in turn, shows a greater drop than the chloride. With an R group of a given weight, the branched-chain isomers show a greater drop than the normal or straight-chain compound.[10]

The greater drop of the alkyl halides over the aryl halides makes an explanation based on the greater activity of the halogen in alkyl halides very attractive. However, over and against any rigid interpretation on this basis is the almost insignificant drop with benzyl chloride, a halide that contains halogen that is comparatively highly reactive.[11] Quite probably a correlation will be found on the basis of some studies now in progress on the preliminary formation of free radicals in the preparation of organometallic compounds.[12]

The results obtained in this study have a practical value for synthetic purposes. For example, benzylmagnesium chloride can be prepared in excellent yield by the rapid addition of halide, and a reasonably rapid rate of addition can be used for the preparation of the arylmagnesium halides investigated without serious impairment in yield. The results also emphasize the necessity of special methods for the preparation in optimum yields of different types of RMgX compounds.

It is interesting to note, particularly from a preparative viewpoint, that in a rapid addition of halide there is little to be gained in having the reaction start with *a* small part of the halide prior to the rapid addition of practically all of the halide. With all the experiments reported in Table I the reaction was started with 20 drops of the halide and a crystal of iodine. In other experiments with several typical halides (n-butyl bromide, benzyl chloride and bromobenzene) it was observed that the yield was only about 1% lower than those reported when *all* of the halide was added at once (with or without the addition of a crystal of iodine).

---

[9] The yield of *tert.*-butylmagnesium chloride is appreciably higher (at least 69.5%) in larger sized runs (about 2.5 moles).*

[10] We have no explanation at present for the lesser drop of isobutylmagnesium chloride (10%) when compared with that of iso-amylmagnesium chloride (17.8%); see footnote a of Table I,

[11] We should again like to direct attention to the fact that the rapid addition of allyl bromide to magnesium in ether gives little allylmagnesium bromide. However, Gilman and McGlumphy, Bull. *soc. chim.*, 43,1322 (1928), have shown that this Grignard reagent can be obtained in yields greater than 90% by the slow addition of allyl bromide to an excess of finely-divided magnesium.

[12] Gilman and Fothergill, THIS JOURNAL, 50,3334 (1928); also Giman and Kirby, *ibid.*, 51, 1571 (1929).

Summary

A study has been made of the drop in yield of Grignard reagents when the halide is added very rapidly to magnesium in ether and some generalizations have been drawn from these results.

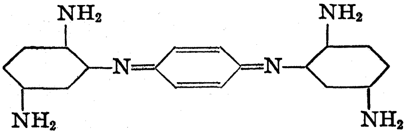
THE CONSTITUTION OF BANDROWSKI'S BASE

BY JOHN J. RITTER AND GUNTHER H. SCHMITZ

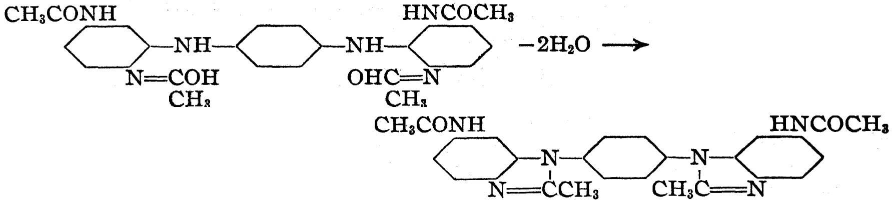
RECEIVED JANUARY 22, 1929 PUBLISHED MAY 6, 1929

Introduction

Bandrowski[1] obtained, on ferricyanide oxidation of p-phenylenediamine in aqueous ammoniacal solution, a product to which he assigned the structure shown. This constitution is based on elementary analysis, molecular

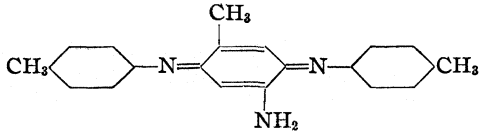


weight determination, production of p-phenylenediamine on zinc-dust distillation, the formation of a tetra-acetyl derivative, and ring-closure with the formation of a dipyrazole on reduction of the tetra-acetyl derivative, as follows



In view of the fact that p-toluidine has been shown by Barsilowski[2] and Green[3] to yield on oxidation a base of the formula (A), it appears quite

A



possible that p-phenylenediamine might behave similarly, to yield **the** following isomer (B) of the Bandrowski base. Its properties, as observed

---

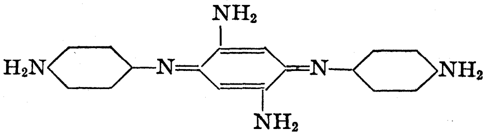
[3] Green, *ibid.*, 26, 2772 (1893).

B



by Bandrowski and by others,[4] up to the present fail to establish either structure as the correct one. Comparison of the two will show their ability to respond to all of the known reactions of the substance. Our attention was also arrested by the fact that the oxidation of p-phenylenediamine does not proceed further under the conditions of the experiment. The second structure, in which para-diamine groupings capable of assuming the quinoid structure are absent, is in closer harmony with this behavior than the first, in which the two non-quinoid nuclei might be expected to oxidize readily. The present work was undertaken to throw some light on this point.

We have now succeeded in obtaining evidence which confirms the structure already assigned to the substance. This was accomplished by the method of Willstatter and Dorogi,[5] in which quinone-imides were oxidized with yields of 85–95% to benzoquinone with lead peroxide and sulfuric acid. The benzoquinone obtained was determined by the method of J. Rzymkowski[6] by titration against sodium thiosulfate solution, using Wurster's indicator (pamidodimethylaniline). It is apparent, by comparison of the two alternative formulas, that one mole of the substance of the first formula can yield but one-third of a mole of quinone on oxidation, while one mole of a substance of the second formula should yield two-thirds of a mole of quinone. The results of several experiments confirm the former structure, which is therefore the correct one.

Experimental Part

Preparation of Bandrowski's Base.—This substance was prepared both by the use of potassium ferricyanide and of hydrogen peroxide as oxidizing agents; the latter was found to yield a pure product directly. In a typical experiment, 10 g. of *p*-phenylenediamine (recrystallized once from benzene) was dissolved in 750 cc. of water to which 3 cc. of concentrated ammonia solution had been added, and the solution was treated with 125 cc. (2.5 moles) of 3% hydrogen peroxide solution. After standing for twenty-four hours at room temperature, 2 g. of pure oxidation product was filtered off. Further portions were filtered off after similar time intervals. After seventy-two hours three portions thus separated totaled 3.6 g. The first portion, consisting of well-defined bronze leaflets, was of high purity. The material separating subsequently consisted of finer particles which seemed to be somewhat contaminated with foreign matter. In the experiments to be described, only that portion first separating was used, after drying to constant weight at 100°; m. p. 238° (corr.).

---

[5] Willstatter and Dorogi, *ibid.*, **42**, 2166 (1909).

[6] Rzymkowski, *Z. Elektrochem.*, **31**, 371–382 (1925).

Oxidation of the Base to **Benzoquinone.**—Five g. of lead peroxide and 5 g. of concd. sulfuric acid were ground together in a mortar until a uniform thin paste was obtained. This was added slowly, with cooling, to 25 cc. of 25% sulfuric acid, contained in a 100 cc. Erlenmeyer flask. To this mixture a weighed amount (about 0 3 g.) of the base was added, the mixture shaken until the base had completely dissolved, stoppered loosely and allowed to stand for twenty-four hours. At the end of this time, the resulting solution was of a clear yellow color. The benzoquinone was extracted from the aqueous acid solution by repeated shaking with small amounts of ether (10 cc. at a time), in the reaction vessel. The ethereal washings were separated by decantation and combined. This operation was repeated until a fresh portion of the ether extracted nothing further from the reaction mixture, six to eight such extractions being sufficient. The final extract is recognized by the fact that it is colorless and leaves no residue on evaporation. That the combined ethereal extracts contained pure benzoquinone was determined in one experiment by evaporation of a portion and determination of the melting point of the solid thus obtained, without recrystallization. It was found to melt at 115°, while pure benzoquinone has the recorded melting point of 115.7".

Analysis of the Ethereal Extracts.—An approximately equal volume of water and 3 cc. of glacial acetic acid were added to the ethereal solution of benzoquinone and the mixture was titrated against standard sodium thiosulfate solution. The ether–water mixture was well shaken after each addition of thiosulfate. The color of the quinone may be used as indicator, or *p*-amidodimethylaniline may be used externally. The latter method was found to give a sharper end-point and more concordant results and was used throughout. Benzoquinone and sodium thiosulfate react in dilute acetic acid solution as follows[e]

$$2C_6H_4O_2 + 4H^+ + 2S_2O_3^= = C_6H_2(OH)_2(S_2O_3H)_2 + C_6H_4(OH)_2$$

Standardization of the Sodium Thiosulfate Solution.—The thiosulfate solution used was standardized against twice resublimed benzoquinone, using *p*-amidodimethylaniline as indicator: (1) 0.2032 g. of quinone in 50 cc. of water and 3 cc. of acetic acid used 20.27 cc.; (2) 0.3342 g. of quinone in 50 cc. of water and 3 cc. of acetic acid used 33.40 cc.; therefore 1 cc. of thiosulfate = 0.0100 g. of quinone.

TABLE I

ANALYTICAL RESULTS

Sample, g.	Thiosulfate, cc.	Quinone. g.	Calcd. for $^1/_3$ mole	Calcd. for $^2/_3$ mole	% of $^1/_3$ mole	% of $^2/_3$ mole
0.3116	9.57	0.0957	0.1058	0.2116	90.4	45.2
.3045	9.00	.0900	.1034	.2068	87.0	43.5
.2901	9.00	.0900	.0985	.1970	91.4	45.7

Summary

1. The yield of benzoquinone obtained by oxidation of Bandrowski's base by lead peroxide and sulfuric acid has been determined.
2. The results of such determinations confirm the constitution previously assigned to the compound.

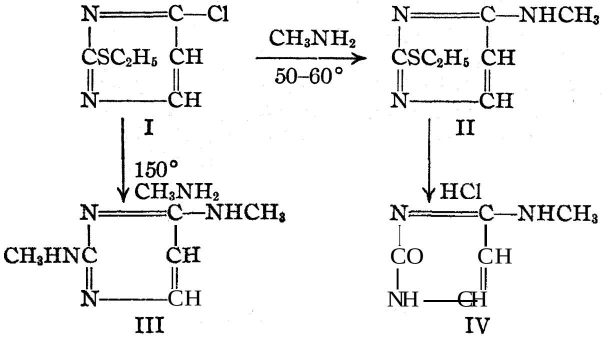
THE SYNTHESIS OF A NEW METHYLCYTOSINE

BY FRANCIS H. CASE WITH ARTHUR J. HILL

RECEIVED FEBRUARY 5, 1929 PUBLISHED MAY 6, 1929

Preliminary to a study of the action of diazomethane on certain nucleic acids and on the pyrimidine constituents[1] of the same it became necessary, for identification purposes, to synthesize a new methylcytosine, 2-oxy-6-methylaminopyrimidine, IV.

The method[2] which has been successfully employed utilizes as the starting material 2-ethylmercapto-6-chloropyrimidine, I. When this substance is treated with an absolute alcohol solution of methylamine in an autoclave the reaction proceeds in one of two ways, depending largely on the temperature factor.



At 50–60° the product is the hydrochloride of 2-ethylmercapto-6-methylaminopyrimidine, II, while at 150° the ethylmercapto group is displaced and the hydrochloride of 2,6-di-(methylamino)-pyrimidine, III, is formed. The free bases are easily obtained from the corresponding hydrochlorides by treatment with alkali.

The methylated cytosine, IV, is readily prepared, in the form of its hydrochloride, by digesting 2-ethylmercapto-6-methylaminopyrimidine, II, with concd. hydrochloric acid. The free base is obtained from the hydrochloride by careful treatment of the latter with potassium hydroxide in absolute alcohol. It gives a characteristic picrate and a positive color test[3] (purple) with bromine, indicative of the absence of a substituent in position 3.

Experimental Part

Hydrochloride of 2,6-Di-(methylamino)-pyrimidine.—Nine grams of 2-ethylmercapto-6-chloropyrimidine[2] was heated in an autoclave at 150° for four hours with

---

[1] Preliminary paper, *Proc. Nat. Acad. Sci.*, 8, 44 (1922).

[2] Wheeler and Johnson, Am. Chem. J., 29, 492 (1903).

[3] Wheeler and Johnson, J. *Biol.* Chem., 3, 183 (1907).

4 molecular proportions of methylamine in absolute alcohol solution. At the end of this period the autoclave was opened and a strong odor of ethyl mercaptan was observed. After removal of tarry material by filtration, the filtrate was evaporated to dryness and the residue crystallized several times from absolute alcohol. The hydrochloride melts at 262° and is soluble in water and alcohol, but insoluble in ether and acetone.

Anal. Calcd. for $C_6H_{11}N_4Cl$: N, 32.10; Cl, 20.33. Found: N, 31.88, 32.11; Cl, 20.50, 20.34.

2,6-Di-(methylamino)-pyrimidine, 111.—Four grams of the hydrochloride of 2,6-di-(methylamino)-pyrimidine was dissolved in absolute alcohol and treated with an absolute alcohol solution of potassium hydroxide to faint alkalinity. The potassium chloride was filtered off and the filtrate evaporated to dryness. The residual base, after three crystallizations from a ligroin-absolute alcohol mixture, melted constantly at 132°. It is soluble in water and absolute alcohol, and insoluble in ligroin, acetone and ether.

Anal. Calcd. for $C_6H_{10}N_4$: N, 40.57. Found: N, 40.13, 40.21.

The Hydrochloride of 2-Ethylmercapto-6-methylaminopyrimidine.—Nine grams of 2-ethylmercapto-6-chloro-pyrimidine was heated in an autoclave for four hours at 50–60° with an absolute alcohol solution of 3.5 molecular proportions of methylamine. There was no perceptible odor of ethyl mercaptan upon opening the autoclave and the solution was clear, with entire absence of gummy material. It was evaporated to dryness and the residue triturated with ether. The precipitate of methylamine hydrochloride was filtered off and washed with ether. Dry hydrogen chloride was then passed into the ethereal filtrate until precipitation was complete; the precipitate was filtered and weighed (9 g.). After two crystallizations from an acetone–absolute alcohol mixture, the hydrochloride melted at 216". It is soluble in water and absolute alcohol, but insoluble in ether and acetone.

Anal. Calcd. for $C_7H_{12}N_3S{\cdot}Cl$: N, 20.44; S, 15.57. Found: N, 20.58, 20.52; S, 15.62.

When this reaction was carried out at 105–110°, a mixture of 2,6-di-(methylamino)-pyrimidine and 2-ethylmercapto-6-methylaminopyrimidine was formed, with the latter considerably in predominance.

2-Ethylmercapto-6-methylaminopyrimidine, 11.—When the above-described hydrochloride was dissolved in water and treated with concd. ammonium hydroxide, the free base was precipitated as an oil, which solidified on standing. It was filtered and then dissolved in a mixture of ligroin and absolute alcohol. From this solvent it separated as an oil which solidified when triturated with ligroin. The pure base thus obtained melts at 58°; it is insoluble in water, sparingly soluble in ligroin and very soluble in alcohol.

Anal. Calcd. for $C_7H_{11}N_3S$: N, 24.85. Found: N, 24.95, 24.77.

Hydrochloride of **2-Oxy-6-methylaminopyrimidine.**—2-Ethylmercapto-6-methylaminopyrimidine was digested for eight hours with concentrated hydrochloric acid; the resulting solution was then evaporated to dryness and the residue crystallized from aqueous alcohol. It crystallizes in small prisms which decompose at 320°. It is soluble in water and insoluble in alcohol, acetone and ether.

Anal. Calcd. for $C_5H_8N_3OCl$: N, 26.01; Cl, 21.95. Found: N, 25.90, 26.07; Cl, 22.28, 22.21.

2-0x9-6-methylaminopyrimidine, IV.—One and six-tenths g. of crude 2-oxy-6-methylaminopyrimidine hydrochloride, suspended in absolute alcohol, was treated with absolute alcoholic potash until the solution was faintly alkaline. The potassium chloride was filtered off and the filtrate evaporated to dryness. The base was purified by crystallization from aqueous acetone, out of which it separated in cubes which melted at 270°. It is soluble in water and alcohol and insoluble in acetone and ether. Unlike cytosine, this base is not hydrated. It gives the Wheeler–Johnson color test.[3]

Anal. Calcd. for $C_5H_7N_3O$: N, 33.60. Found N, 33.38, 33.30.

The picrate of 2-oxy-6-methylaminopyrimidine crystallizes from water in slender prisms and melts at 220–225°.

Summary

1. The interaction of methylamine and 2-ethylmercapto-6-chloropyrimidine produces either 2-ethylmercapto-6-methylaminopyrimidine or 2,6-di-(methylamino)-pyrimidine, depending on the temperature employed.

2. A new methylcytosine, 2-oxy-6-methylaminopyrimidine, is formed by acid hydrolysis of 2-ethylmercapto-6-methylaminopyrimidine.

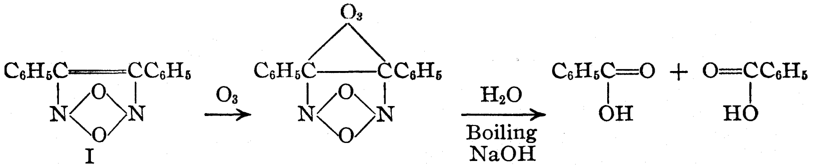
THE STRUCTURE OF FURAZAN OXIDES. II

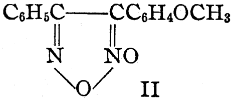
BY CORLISS R. KINNEY

RECEIVED FEBRUARY 13, 1929 PUBLISHED MAY 6, 1929

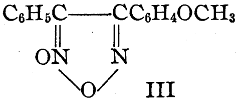
Furazan oxides (or furoxans) are attacked by ozone and the ozonized substances are decomposed with water and alkalies yielding acids. This behavior of these substances has been interpreted[1] on the basis of an ethylenic structure as follows



Meisenheimer, Lange and Lamparter,[2] however, have succeeded in isolating two substances which they believe to be isomeric furazan oxides. The isolation of two isomeric oxides does not permit an ethylenic formula, I, but necessitates an unsymmetrical structure, which in the case of Meisenheimer's oxides would have Formulas II and III.



II



III

The two isomeric oxides II and III were obtained by oxidizing the two *amphi*-dioximes of *p*-methoxybenzil. They appeared to be non-separable and isomorphous since recrystallization of a mixture from alcohol did not

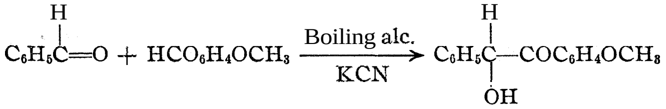
---

[1] Kinney and Harwood, THIS JOURNAL, 49, 514 (1927).

[2] Meisenheimer, Lange and Lamparter, Ann., 444, 94 (1925).

seem to change the melting point; the melting points of various mixtures was not lowered, but fell between the two extremes. In order to elucidate the mechanism of the reaction of furazan oxides with ozone, a study of Meisenheimer's two oxides has been made in this Laboratory and new and more convenient syntheses of these substances and of the oximes from which they are made developed.

Benzaldehyde and anisaldehyde have been condensed together to form *p*-methoxy-benzoin,[2a] but we are aware of no case in which an attempt has been made to condense the two aldehydes in satisfactory yields. The condensation takes place readily with the anisaldehyde adding to the benzaldehyde. This manner of reaction

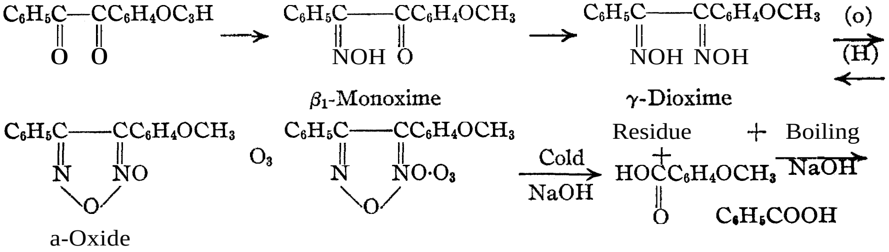


$$C_6H_5\overset{H}{\overset{|}{C}}=O + HCO_6H_4OCH_3 \xrightarrow[KCN]{\text{Boiling alc.}} C_6H_5\underset{OH}{\overset{H}{C}}—COC_6H_4OCH_8$$

is undoubtedly due to the difference in reactivity of the two carbonyl groups. Difficulty was experienced in oxidizing the benzoin derivative to p-methoxybenzil using the old nitric acid process for benzil, but the method outlined in "Organic Syntheses"[3] is to be highly recommended for *p*-methoxybenzil.

The earlier synthesis of the two oxides of phenyl-*p*-methoxyphenylfurazan involved the preparation of the two *amphi*-dioximes of *p*-methoxybenzil, which in turn were made from the two β-monoximes. When p-methoxybenzil was heated with one equivalent of hydroxylamine, the &-monoxime[4] was the exclusive product, due again to the difference in reactivity of the carbonyl groups. This prevented the direct synthesis of the α-dioxime and the β- or lower melting oxide, III; in order to synthesize this isomer we used two other methods.

Both carbonyl groups of p-methoxybenzil were oximated at once and the resulting product, which was largely the β-dioxime, was oxidized to a mixture of the α- and β-oxides. By means of persistent fractional



[2a] Ekecrantz and Ahlquist, *Arkiv. Kem. Min.* Geol., 3, (No. 13) 1–26 (1908). See also Staudinger, Ber., 46, 3535 (1913).

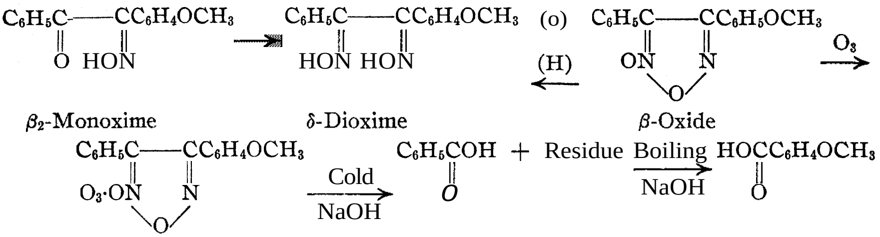
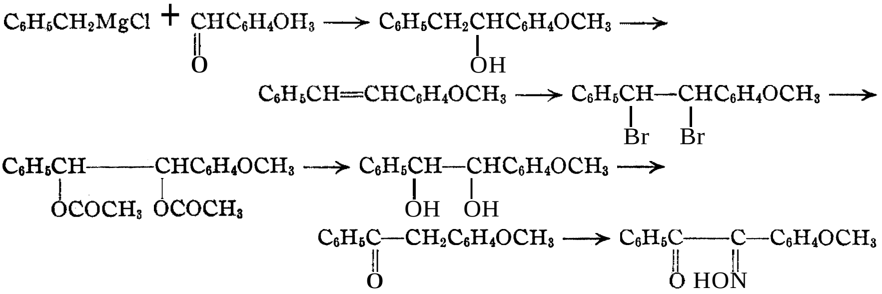
[4] We will use Meisenheimer's system of nomenclature.



crystallization from acetone (instead of alcohol) the two oxides were separated. About one-tenth of the product was the β-oxide.

The second method involved the synthesis of the β_2-monoxime from phenylanisyl ketone, in the following way. Owing to repeated small yields this method has little to recommend it over the above or over Meisenheimer's synthesis which involved p-methoxyphenylnitromethane as **a** starting material.



$$\mathrm{C_6H_5CH_2MgCl} + \underset{\substack{\| \\ \mathrm{O}}}{\mathrm{C}}\mathrm{HC_6H_4OH_3} \longrightarrow \mathrm{C_6H_5CH_2}\underset{\substack{| \\ \mathrm{OH}}}{\mathrm{C}}\mathrm{HC_6H_4OCH_3} \longrightarrow$$

$$\mathrm{C_6H_5CH{=}CHC_6H_4OCH_3} \longrightarrow \mathrm{C_6H_5}\underset{\substack{| \\ \mathrm{Br}}}{\mathrm{CH}}-\underset{\substack{| \\ \mathrm{Br}}}{\mathrm{CH}}\mathrm{C_6H_4OCH_3} \longrightarrow$$

$$\mathrm{C_6H_5}\underset{\substack{| \\ \mathrm{OCOCH_3}}}{\mathrm{CH}}-\underset{\substack{| \\ \mathrm{OCOCH_3}}}{\mathrm{CH}}\mathrm{C_6H_4OCH_3} \longrightarrow \mathrm{C_6H_5}\underset{\substack{| \\ \mathrm{OH}}}{\mathrm{CH}}-\underset{\substack{| \\ \mathrm{OH}}}{\mathrm{CH}}\mathrm{C_6H_4OCH_3} \longrightarrow$$

$$\mathrm{C_6H_5}\underset{\substack{\| \\ \mathrm{O}}}{\mathrm{C}}-\mathrm{CH_2C_6H_4OCH_3} \longrightarrow \mathrm{C_6H_5}\underset{\substack{\| \\ \mathrm{O}}}{\mathrm{C}}-\underset{\substack{\| \\ \mathrm{HON}}}{\mathrm{C}}-\mathrm{C_6H_4OCH_3}$$

In general we have found the work of Meisenheimer, Lange and Lamparter on the oximes and oxides of the p-methoxy series to be quite correct except for the purity of the two oxides. By repeated recrystallizations from acetone (instead of alcohol, in which these substances are fairly insoluble cold) the a-oxide was found to melt at 108–109" and in like manner the melting point of the β-isomer was raised to 104–105° with softening at 102". The @-oxide probably was not perfectly pure even then but was sufficiently so for most purposes. The melting point of mixtures of the two purified oxides were always lower, the eutectic point being the 95–97° mixture of Meisenheimer and designated by him as the β-isomer. The two substances behave similarly chemically and are undoubtedly the isomeric furazan oxides, II and III.

The appearance of two isomeric furazan oxides disproved the ethylenic structure, I, and demands an unsymmetrical formula such as II and III. On this basis the attack of these substances by ozone cannot be explained by means of an ethylenic linkage. The imino linkage did not react with ozone in the aromatic furazans (or oxazoles). Diphenylfurazan when treated with ozone reacted slowly and did not produce acids as did the furazan oxides. The only remaining point of attack was the side of the molecule holding the extranuclear oxygen atom, that is, the NO linkage or an endoxy linkage if that be preferred. Since carbonyl groups add on ozone, it seems possible that the NO Linkage would react likewise, followed by a stepwise decomposition of the molecule.

The two isomeric oxides of phenyl-*p*-methoxyphenylfurazan reacted with ozone in the same way as the diphenyl derivative.[1] Upon decomposition with cold sodium hydroxide the a-isomer yielded anisic acid while the *β*- produced benzoic acid. The residue from the a-, when boiled with sodium hydroxide, yielded largely benzoic acid and the residue from the *β*- largely anisic acid (see diagram, pp. 1593–1594). The structural difference between the two oxides is thus clearly demonstrated.

The process of oxidation has been shown to start on the side of oxidized nitrogen and to instigate a stepwise decomposition of the molecule. The aromatic group nearer the point of attack would be the first to appear as aromatic acid and the one farther removed to appear after boiling with sodium hydroxide. All of this may be used for determining which structure to give to the individual oxides and to the dioximes from which they are obtained and into which they may be transformed.

Meisenheimer based the structures of the oximes given in the diagram largely upon his work with triphenylisoxazole and ozone;[5] they are the reverse as determined by the Beckmann rearrangement. The fnrazan oxides obtained from the *α*- and *β*-dioximes by oxidation were given structures by him corresponding to the dioxime from which they were obtained. By means of our reaction with ozone the structures assigned to the oxides by Meisenheimer must be correct, since the process of ozonization and decomposition with alkali requires that the extranuclear oxygen atom be attached nearer the p-methoxyphenyl in the a- or higher melting isomer and nearest the phenyl group in the *β*-, as shown in the diagram. Thus we have proof from a still different source as to the correctness of the configuration of the dioximes as set forth by Meisenheimer.

Experimental Part

***p*-Methoxybenzoin.**[6]—Since benzaldehyde condenses in the presence of potassium cyanide much more rapidly than anisaldehyde, we allowed benzaldehyde, in our earlier experiments, to drop slowly into a boiling alcoholic solution of anisaldehyde and potassium cyanide. This procedure was found to be unnecessary and as good yields were obtained by mixing the aldehydes at the outset. The following was our best practice.

Fifty grams of potassium cyanide was dissolved in 350 cc. of water in a 3-liter flask. To this was added 272 g. (2 moles) of anisaldehyde,[7] 212 g. (2 moles) of benzal-

---

[5] Meisenheimer, *Ber.*, 54, 3206 (1921); see also Kohler and Richtmyer, THIS JOURNAL, 50,3105 (1928).

[6] Obtained in another way by Meisenheimer with Jochelson, *Ann.*, 355, 249–311 (1907).

[7] No particular advantage was noticed with redistilled aldehydes and in most of our work Eastman's "Practical" grade was used.

dehyde[7] and 700 cc. of 95% alcohol. The mixture formed a solution at the boiling temperature and was refluxed for one and one-half hours. Steam was then passed through the solution until all of the alcohol and nearly all of the unchanged aldehydes were removed. The condensed water was decanted from the product and the latter set away to crystallize. The product was then pressed as free as possible from oily material on a suction funnel and washed with cold alcohol. In this way about 350 g. of crude product was obtained. The crude mixture was dissolved in hot alcohol and allowed to crystallize slowly. The p-methoxybenzoin crystallized out first in large clumps of long needles, while the benzoin crystallized in small compact balls of needles. With some experience a good yield of nearly pure p-methoxybenzoin can be filtered out before the appearance of the benzoin. The yield of pure p-methoxybenzoin amounted to 100–110 g. For conversion into p-methoxybenzil only two or three recrystallizations were necessary, or until the melting point reached 102 or 103°.

***p*-Methoxybenzil.**—The usual method for making benzil from benzoin by nitric acid oxidation was not applicable to the oxidation of p-methoxybenzoin. The oxidation proceeded too far and considerable oily material made a separation of the benzil derivative impractical. However, the method described in "Organic Syntheses"[3] gave an 85 to 90% yield. The procedure followed in isolating the derivative was slightly different from that given there. After the oxidation had proceeded for two hours and the pyridine-copper sulfate solution was dark green in color, the mixture was transferred while still hot to a separatory funnel and the pyridine–copper sulfate solution drawn off. Ether and 10% hydrochloric acid were then added and the mixture shaken until the odor of pyridine had disappeared. After separation of the acid layer the ether solution was partially evaporated and alcohol and water added. The substance crystallizes readily when fairly pure in spite of its low melting point. It is best recrystallized from about 80% alcohol; m. p. 62–63°; bright yellow in color.

Anal.[8] Subs., 0.2013: H_2O, 0.0886; CO_2, 0.5783. Calcd. for $C_{15}H_{14}O_3$: C, 75.0; H, 5.0. Found: C, 75.0; H, 5.04.

The γ-Dioxime of *p*-Methoxybenzil and the Preparation of the a-Oxide of Phenyl-*p*-methoxyphenylfurazan.[9]—Meisenheimer, Lange and Lamparter[2] synthesized the β-monoxime of *p*-methoxybenzil by means of a rather long and laborious process. We found that p-methoxybenzil was readily changed to the above oxime in the following way.

Forty grams of p-methoxybenzil and slightly less than one equivalent of hydroxylamine hydrochloride were dissolved in a minimum of alcohol and refluxed for one and a half hours. The solution was then poured into water and the oxime extracted with benzene. The benzene solution was extracted with 10% sodium hydroxide and the oxime precipitated with carbon dioxide. After one crystallization from benzene the melting point was 120–124° but after two recrystallizations from carbon disulfide it was raised to 129–130°. The yield was 25 g.

Three or four grams of unchanged ketone was recovered, but no β_2-monoxime. The remainder of the product did not crystallize.

The preparation and properties of the γ-dioxime and the a-oxide prepared from it are correct as given by Meisenheimer except for the melting point of the latter substance which is discussed in detail under the separation of the oxides on page 1597.

The Preparation of the Mixed Oxides of Phenyl-*p*-methoxyphenylfurazan.—The oxidation of either the a- or β-dioxime of p-methoxybenzil yields a mixture of the two oxides of phenyl-*p*-methoxyphenylfurazan.[2] However, several attempts to prepare the a-dioxime using the method for making the a-dioxime of benzil resulted in poor

---

[8] By Marcel Mayhue.

[9] By G. E. Hinckley.

yields, but the α-dioxime obtained had the melting point given by Meisenheimer and not that of the product obtained by Ponzio[10] in an entirely different manner.

Also, attempts were made to oximate the ketone using pyridine solutions. The color of the ketone was rapidly discharged, but the separation of the reaction products was not very successful. This method of oximation appeared worthy of further investigation.

Our best method for getting a dioxime for oxidation to the oxides was as follows. Twenty-four grams (0.1 mole) of *p*-methoxybenzil was dissolved in 50 cc. of alcohol, 7 g. (0.1 mole) of hydroxylamine hydrochloride dissolved in 10 cc. of water added and the whole refluxed for thirty minutes. Then 10.5 g. (0.15 mole) of hydroxylamine hydrochloride in 10 cc. of water, 15 cc. of 6 N sodium hydroxide and 35 cc. of alcohol were added and the whole boiled for forty-five minutes. Finally, 30 cc. of 6 N sodium hydroxide was added and the solution refluxed for one hour and forty-five minutes. At the end of this time the solution was diluted with a liter of water and an insoluble precipitate, probably of the furazan, filtered out. Dilute acid was added to precipitate the oximes, which were separated by decanting the water from the sticky product. The oximes were dissolved in 300 cc. of 6 N sodium hydroxide and diluted to 4 liters. Sodium hypochlorite made from 10% sodium hydroxide and chlorine was added to the above solution (cooled by addition of ice) until no more precipitation occurred. The precipitated oxides were recrystallized from acetone and petroleum ether (or alcohol). The first crop weighed 12.7 g. (m. p. 99–102°); the second, 1.5 g. (m. p. 93–95"); the third, 0.6 g. (somewhat oily).

The preparation of the dioximes can undoubtedly be improved considerably. Too early addition of sodium hydroxide cut the above yield in half. Also, the oxidation of the dioxime should not be carried out before precipitating out the oxime from the solution containing hydroxylamine. Considerable material was lost earlier in this way, as a rather strange decomposition took place. The precipitate when allowed to warm up turned green, evolved gas and finally turned into a yellow-orange liquid product. Anisic acid was formed simultaneously.

The Separation of the Phenyl-p-methoxyphenylfurazan Oxides.—Eighty-three grams of the mixed oxides obtained much as described above was fractionally crystallized from acetone and a mixture of acetone and petroleum ether. The higher melting oxide crystallized first in considerable quantities and relatively pure (m. p. 102–105°). Repeated fractions were necessary to isolate the 95–97° mixture of Meisenheimer and to isolate a higher melting product which when mixed with the a-oxide was lowered. The mixed oxides were finally separated into fractions of 58 g. of the a-oxide and 8.6 g. of lower melting β-oxide. The a-oxide after repeated recrystallizations finally melted at 108–109°. The 8.6 g. of impure p-oxide upon further fractionation yielded 4 g. of oxide melting at 104–105° with softening at 102". This was probably not perfectly pure even then since it softened below the melting point and since the products of oxidation with ozone were not as clean as with the a-oxide.

The relatively smaller yield of the (3-oxide from the β-dioxime is difficult to explain since the mechanism of the process by which the oximes are transformed into the furazan oxides is obscure. However, it seems likely that the two hydrogen atoms of the oximino groups (or, if the oxidation is carried out in an alkaline solution, the two ionic charges) are removed, leaving an unstable arrangement which at once changes into the furazan oxide. In the case of the β-dioxime the influence of the *p*-methoxyphenyl group apparently shows up in the amounts of the two isomers actually formed. The yield of the β-oxide from the α-dioxime may be greater, but we have not tried this because of insufficient quantities of the α-dioxime.

---

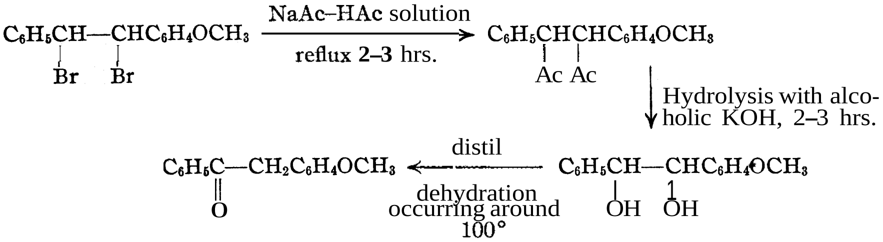
The Second Method for Preparing the β-Oxide and the Ozonization of Diphenyl Furazan[11]

p-Methoxyphenylbenzylcarbinol and p-Methoxystilbene.—p-Methoxyphenylbenzylcarbinol[12] was prepared using the Grignard reaction in the usual way. This compound has since been described in the literature and consequently will not be described here; however, we have analyses and molecular weight determination which are in good agreement. It is best recrystallized from ether and petroleum ether.

For our purpose of preparing p-methoxystilbene we did not attempt to isolate the carbinol in our later experiments, but simply distilled the crude reaction product under a water-pump vacuum. A yield of 90% of p-methoxystilbene is obtained from anisaldehyde in this way.

p-Methoxystilbene Dibromide.—Our best yield of dibromide was only 78% and often yields were much poorer. Better yields were obtained by cooling and stirring the reaction mixture (a chloroform solution was used) and by slow addition of bromine. The insoluble dibromide was purified by washing with ether.

p-Methoxydisoxybenzoin.—The p-methoxystilbene dibromide was changed into phenylanisyl ketone, $C_6H_5COCH_2C_6H_4OCH_3$, by the following reactions



$$\underset{\mathrm{Br}}{\mathrm{C_6H_5CH}}\text{—}\underset{\mathrm{Br}}{\mathrm{CHC_6H_4OCH_3}} \xrightarrow[\text{reflux 2–3 hrs.}]{\text{NaAc–HAc solution}} \underset{\mathrm{Ac}}{\mathrm{C_6H_5CH}}\underset{\mathrm{Ac}}{\mathrm{CHC_6H_4OCH_3}}$$

$$\Big\downarrow \text{Hydrolysis with alcoholic KOH, 2–3 hrs.}$$

$$\underset{\mathrm{O}}{\overset{\|}{\mathrm{C_6H_5C}}}\text{—}\mathrm{CH_2C_6H_4OCH_3} \xleftarrow[\text{dehydration occurring around 100°}]{\text{distil}} \underset{\mathrm{OH}}{\mathrm{C_6H_5CH}}\text{—}\underset{\mathrm{OH}}{\mathrm{CHC_6H_4OCH_3}}$$

No attempts were made to isolate intermediate substances. The diacetate was obtained from the acetic acid solution by diluting with water and decanting the solution from the sticky acetate. The mixed hydrobenzoin was obtained from the alcoholic solution in much the same way except that it was collected and introduced into the distilling flask using ether as a solvent. The yields were 30–40%.

β_2-Monoxime of p-Methoxybenzil.—Nine grams of phenylanisyl ketone was dissolved in 50 cc. of dry alcohol and 10 cc. of sodium ethylate solution, prepared from 1 g. of sodium, added. To this solution cooled to 0° was slowly added 7 g. of amyl nitrite. The orange-colored solution was set away in a cool place for twenty-four hours. The oxime was then extracted with 10% sodium hydroxide solution and precipitated by passing carbon dioxide into the solution until saturated.

The oxime was purified by solution in 10% sodium hydroxide and reprecipitation with carbon dioxide, followed by recrystallization from hot alcohol. The yield was 3.6 g. or 36% and the melting point 169–170°. Considerable amounts of p-methoxystilbene appeared at this point, probably coming from a different dehydration process than the one outlined for the hydrobenzoins; that is, our phenylanisyl ketone was not perfectly pure.

The Change of the **β_2-Monoxime** into the 8-Oxide.—The δ-dioxime of **p-methoxybenzil** is not very stable and the purification is complicated because of its tendency to form compounds with molecules of the solvent of crystallization. Consequently in

---

[11] By H. J. Harwood.

[12] The general method for preparing p-methoxydesoxybenzoin or phenylanisyl ketone was that as outlined in C. *A*., 20, 2324 (1926); abstract of a paper by Orekhoff and Tiffeneau, ***Bull.*** *soc.* chim., 37, 1410–1420 (1925).

our work we usually oxidized the freshly prepared crude δ-dioxime, prepared according to Meisenheimer, Lange and Lamparter.[2] It seemed advantageous to precipitate the dioxime either with very dilute sulfuric acid or by adding sodium bicarbonate and then redissolve the oxime in fresh 10% sodium hydroxide and proceed with the oxidation according to Meisenheimer. The product melted at 95–97° when recrystallized from alcohol. Several recrystallizations from alcohol, in which it is fairly insoluble when cold, did not change the melting point. However, carefully repeated fractionations from other solvents does change the melting point as described under the fractionation of the mixed oxides.

The Ozonization of **Diphenylfurazan.**—One gram of diphenylfurazan was ozonized in nearly the same manner as diphenylfurazan oxide in the earlier experiments. Since the ozonizer was giving about 4% ozone instead of 3% as formerly, the furazan was ozonized for six hours instead of seven. When treated with sodium hydroxide in the same way as the corresponding oxide, not a trace of benzoic acid was obtained and 0.72 g. of the unchanged furazan was recovered.

The Ozonization of the Oxides of **Phenyl-*p*-Methoxyphenylfurazan.**—The ozonization of the oxides of *p*-methoxydiphenylfurazan was carried out as before in pure dry carbon tetrachloride as a solvent. The presence of a drop of water did not materially alter the process of oxidation, although it slowed down the rate. One-gram samples were used and a stream of ozonized oxygen containing 3–4% of ozone was passed through for nine to twelve hours. Usually, after running the ozone for about six hours the solutions stood about twenty hours (overnight) and then ozone was passed through for three to six hours more. This procedure, of course, materially lengthened the time the oxides were in contact with the ozone.

A non-explosive, sticky yellow product separated in each case after six hours' running, which could not be purified even when larger runs were made. Starting with diphenylfurazan oxide only benzoic acid could be isolated from the insoluble substance. In contact with alkalies it turned red and slowly dissolved. From the alkaline solution only benzoic acid could be obtained.

In ozonizing the *p*-methoxydiphenylfurazan oxides no attempt was made to work with the insoluble product, but 10% sodium hydroxide was added at once and the whole shaken until the ozonides had dissolved, forming a red solution. The carbon tetrachloride solution was extracted a second time with a little sodium hydroxide and finally the mixed sodium hydroxide solutions were extracted with ether and acidified. In order to ascertain the total amount of acid product, especially where benzoic acid was concerned, the acidified solution was extracted with ether two or three times. After evaporating the ether the crude acid yield was determined. The kind of acids present was ascertained by recrystallization from hot water.

The carbon tetrachloride solution above was next evaporated to a yellow liquid, which was dissolved in alcohol containing some 10% sodium hydroxide. The solution became red and after boiling for thirty minutes was diluted with water and the water extracted with ether. The water solution was acidified, extracted and the amount and kind of acid present determined as before. The residue after the extraction with boiling alcoholic sodium hydroxide was small, usually about 0.1 g. and was not the unchanged oxide.

One gram of the α-oxide after ozonization and extraction with cold 10% sodium hydroxide yielded from 0.5 to 0.6 g. of crude anisic acid. After one crystallization from hot water the acid melted at 163–164°. A second crystallization raised the melting point to 173–176°, the product still retaining some color. In a mixed melting point with an authentic specimen of anisic acid the melting point rose to 179–180°. The weight of crude acid after boiling with sodium hydroxide varied from 0.35 to 0.43 g.

Upon crystallization from hot water the melting point was 115–118° and a mixture with benzoic acid melted at 118–119°.

One gram of the β-oxide yielded after the first treatment 0.35 g. of acid. The acid was dissolved in boiling water and after cooling slightly deposited a few crystals of anisic acid. The next crop was 0.1 g. of impure benzoic acid melting at 90–95°, while remaining in solution was fairly pure benzoic acid as determined by extraction and crystallization from a smaller volume of water. Thus the crude acid was found to be largely benzoic acid.

After boiling the residue with alcoholic potassium hydroxide for one and a half hours, 0.8 g. of crude acid was obtained. The crude acid was heated with water and 0.2 g. failed to dissolve. From the water 0.5 g. of impure anisic acid was obtained, m. p. 140–50°. Recrystallization and mixed melting point determinations showed it to be anisic acid. The remaining 0.2 g. in solution was impure benzoic acid.

The Action of the Grignard Reagent on the Oxides of **Phenyl-*p*-methoxyphenylfurazan.**—Phenylmagnesium bromide in excess reacted readily with the furazan oxides, the experiments of Wieland and Semper[13] notwithstanding. Considerable heat was evolved when the reaction with diphenylfurazan oxide was allowed to proceed without cooling. There was no apparent reaction for some time, but in the end it became violent, distilling out the ether and leaving a very tarry residue. The oxides were entirely altered by allowing them to stand for two or three hours with phenylmagnesium bromide cooled with ice water. Phenol and diphenyl appeared in relatively large amounts. The quantities of these products did not vary greatly whether the reaction mixture was kept cold, refluxed after addition of the oxide or the oxide added to a boiling benzene solution of phenylmagnesium bromide. The amount of diphenyl was usually about one-half mole per mole of oxide and the amount of phenol isolated as tribromophenol between one-half and one mole. By boiling the Grignard product with alcoholic potassium hydroxide, ammonia was evolved and a semi-solid acid fraction obtained which smelled of benzoic acid. The residue from this treatment when boiled with hydroxylamine and alcoholic potassium hydroxide yielded small amounts of oximes of the type of benzophenone-oxime.

Many attempts were made to get a reaction with the oxides of phenyl-*p*-methoxyphenylfurazan and phenylmagnesium bromide in a way that would show up their differences in structure. They both yield phenol and diphenyl, but mixtures of benzophenone-oxime and probably *p*-methoxybenzophenone-oxime were obtained. This was to be expected to a certain extent from the work of Angeli[14] and Bigiavi.[15]

Summary

A study of the isomeric oxides of phenyl-*p*-methoxyphenylfurazan has been made. It has been shown that the two substances are not isomorphous. The structural difference between them has been clearly demonstrated by the reaction with ozone followed by a stepwise decomposition. The determination of the individual structures of the oxides by means of the ozone reaction gives further proof that the configurations of the oximes, to which the oxides are closely related, are correct as set forth by Meisenheimer.

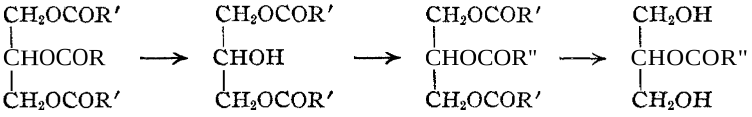
MECHANISM OF ORGANIC REACTIONS. I. THE WANDERING OF ACYL GROUPS IN GLYCEROL ESTERS

BY HAROLD HIBBERT AND NEAL M. CARTER[1]

RECEIVED FEBRUARY 20, 1929 PUBLISHED MAY 6, 1929

Introduction

Previous methods for the allocation of one or more free hydroxyl groups in derivatives of polyhydroxy compounds have often consisted in a primary esterification with an acid anhydride or halide, followed by selective hydrolysis, oxidation or degradation and, finally, identification of the resulting product as a substance of established constitution. An example of such a procedure is indicated in the following scheme



$$\begin{array}{ccccccc} CH_2OCOR' & & CH_2OCOR' & & CH_2OCOR' & & CH_2OH \\ | & & | & & | & & | \\ CHOCOR & \longrightarrow & CHOH & \longrightarrow & CHOCOR'' & \longrightarrow & CHOCOR'' \\ | & & | & & | & & | \\ CH_2OCOR' & & CH_2OCOR' & & CH_2OCOR' & & CH_2OH \end{array}$$

I II III IV

Selective hydrolysis of a glycerol ester of Type I leaves a free hydroxyl group in the β-position of II, which is then "ear-marked" by the introduction of a suitable acid radical —COR″, not readily hydrolyzable. The resulting new glycerol triacyl ester, III, is then further hydrolyzed to the glycerol monoacyl ester, IV, the constitution of which has been previously determined.

Similar schemes have been followed in the determination of the structure of fats[2,3] and of the ring forms of certain sugars and their derivatives.*

Conversely, the synthesis of mixed glycerol esters (including fats) has been accomplished by means of a primary esterification of glycerol dichlorohydrins, followed by replacement of the chlorine atoms by acyl groups either directly or through the medium of the free dihydroxy compound, as indicated below[3,5]

A similar, but more complex process has been utilized by Bergmann, Brand and Dreyer,[6] starting from n-dihydroxypropylamine.

The validity of the conclusions drawn from such decompositions and syntheses has, in view of an accumulating number of experimental anomalies encountered, been called into question, more especially in recent years. As long ago as 1871, Hübner and Müller[7] described the formation of allyl alcohol from α,α'-dichlorohydrin by the action of sodium in dry ether, pointing to the rearrangement at some stage of the atoms attached to an α-carbon atom. Among the more recent references to supposed migrations of substituents in glycerol derivatives may be cited the observation by Fischer[8] that glycerol α-iodohydrin-α',β-distearate, on the substitution of hydroxyl for iodine, gave glycerol α,α'-distearate. Gilchrist and Purves[9] found that the methylation of glycerol α,α'-dichlorohydrin and subsequent replacement of the chlorine atoms by hydroxyl yielded glycerol α-monomethyl ether instead of the expected β-isomer.[10] Grün and Limpacher,[11] in preparing synthetic cephalin were unable to detect any difference in the physical or chemical properties of the product prepared from either α,α'- or α,β-distearin.

The migration of a benzoyl group from the p- to the *m*-position during the hydrolysis of the acetyl groups in 3,5-diacetyl-4-benzoylgallic acid is another similar case.[12]

Attention has frequently been focused on this apparent group migration in the case of acyl derivatives of glycerol,[13] and a method for the avoidance of such in the preparation of glycerol β-esters is to be found in the proposal of Helferich and Sieber[14] to use glycerol α,α'-ditrityl ether as an intermedi-

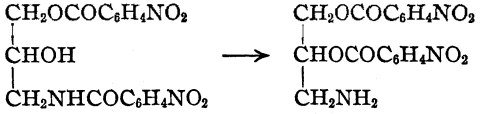
ate derivative, it being pointed out that trityl chloride (triphenylchloromethane) shows a preferential reactivity toward primary as compared with secondary alcoholic groups.

This tendency of groups to wander is not confined to the glycerol type. Thus the bromine atom in ethyl a-bromo-acetoacetic ester migrates to the y-carbon atom either on standing alone or in presence of a trace of hydrogen bromide;[15] 1,2-dibromo-3-butene on standing yields an equilibrium mixture with its isomer, 1,4-dibromo-2-butene;[16] the acetyl groups in octa-acetylmaltose are to be considered mobile,[17] and Karrer and Hurwitz[18] cite many acylated acetone sugars to which no definite constitution can be assigned, due to rearrangement of the acyl groups on scission of the cyclic ketal ring. The wandering of the half-acetal ring in the sugars and glucosides from one carbon atom to another is of common occurrence and may even be caused by the preference of acetone for adjacent hydroxyl groups in the formation of diacetone glucose and mannose.[19]

The migration of groups to, or from, atoms other than carbon, is of interest, although possibly of less immediate importance in the present connection. Thus the wandering of a *p*-nitrobenzoyl radical from a nitrogen to an oxygen atom[6]



$$\begin{array}{lcl} \mathrm{CH_2OCOC_6H_4NO_2} & & \mathrm{CH_2OCOC_6H_4NO_2} \\ | & & | \\ \mathrm{CHOH} & \longrightarrow & \mathrm{CHOCOC_6H_4NO_2} \\ | & & | \\ \mathrm{CH_2NHCOC_6H_4NO_2} & & \mathrm{CH_2NH_2} \end{array}$$

and the migration of an acyl group brought about by the introduction of a second acyl group[20] are instances of many other examples of this type to be found in the literature.

Migration of Acyl Groups During Cyclic Acetal Hydrolysis

These foregoing examples show that the proof of constitution by "earmarking" hydroxyl groups in tri- and poly-hydroxy compounds rests on a precarious basis. The investigations on cyclic acetal formation carried out in these Laboratories over a period of several years[13c,d,21] have had for one of their principal objects the accumulation of the necessary experimental data which might throw some light on (A) the true value to be placed on the two

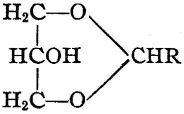
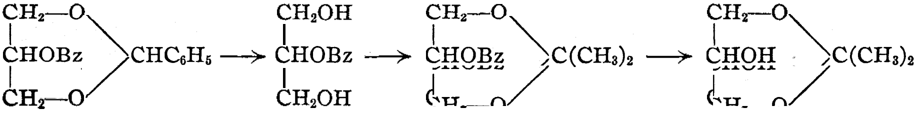
main processes of methylation, namely, (a) use of silver oxide and methyl iodide[z2] and (b) dimethyl sulfate and caustic soda[z3] as applied to carbohydrates and polysaccharides for the purpose of determining their structure, and (B) the tendency and ease of "ring-shift" in the furanose and pyranose rings present in such derivatives. In the course of these investigations, the constitution of the structurally isomeric cyclic acetals of glycerol was determined by the use as reference compounds of a- and β-monomethyl ethers of glycerol.[13c,d]



A consideration of the structure of a typical six-membered glycerol cyclic acetal would indicate that this should prove a valuable product for the preparation of glycerol β-derivatives as, for example, the pure glycerol β-esters, through the medium of which might be prepared the six-membered cyclic ketal from acetone and glycerol, VII, which has not as yet been obtained.[24] It is true that the type of six-membered ring indicated by Formula VII has already been obtained in the condensation of acetone with 1,3-propanediol,[25a] dihydroxyacetone,[25b] penta-erythritol[25c] and xylose,[19] but it was thought that its labile character in Compound VII, with its adjacent free hydroxyl group, might afford an interesting opportunity for studying the effect of methylating reagents when applied to carbohydrates or glucosides containing the equally labile pyranose ring.

The following synthesis suggested itself (Bz=Benzoyl)



V VI VII

Six-membered 1,3-benzylidene glycerol[13c] yields on benzoylation a pure, crystalline 0-benzoate, V, which readily undergoes hydrolysis of its acetal ring under the influence of a trace of acid to yield a glycerol monobenzoate, VI. This should condense with acetone to give a six-membered acetone glycerol benzoate whose ketal ring is considered sufficiently stable toward alkali to withstand the alkaline hydrolysis of the benzoyl group to yield the desired compound, VII.

In carrying out the above scheme, the supposed glycerol 0-benzoate was readily obtained, but in accordance with the advice given by Fischer that monoacyl glycerol derivatives intended for subsequent synthesis should not

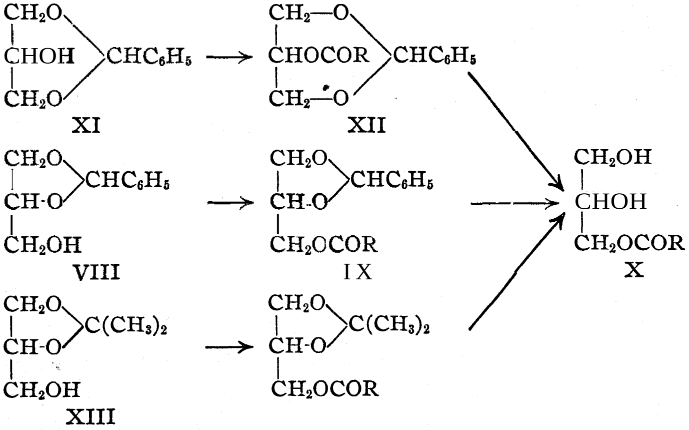
be distilled,[26] no criterion of its purity could be obtained since it would not crystallize. This same compound was recently prepared[14] in an impure, non-crystallizable state by a different method, and was characterized by converting it to the crystalline di-p-nitrobenzoate, which melted at 152–152.5°. A sample of the authors' supposed glycerol β-benzoate was p-nitrobenzoylated according to the procedure described, and in place of the expected glycerol β-benzoate-α,α′-di-*p*-nitrobenzoate (m. p. 152–152.5°), it yielded instead a p-nitrobenzoate melting at 115°, mixed with a small amount of a product with a slightly higher somewhat indefinite melting point. These products were undoubtedly glycerol α-benzoate-β-*p*-nitrobenzoate and glycerol α-benzoate-α,β-di-*p*-nitrobenzoate, melting at 115 and 123°, respectively, as previously recorded by Bergmann, Brand and Dreyer."

It would thus appear that during the hydrolysis of V under **acid** conditions a migration of the *beta*-benzoyl group had taken place, since non-acid media were used in the preparation of V and subsequent *p*-nitrobenzoylation of VI. This tendency of an acyl group to migrate during acid hydrolysis is analogous to that of the change in ring structure of the glycerol cyclic acetal ring itself, brought about under the influence of a trace of dry hydrogen chloride.[13c,d] The solid, crystalline six-membered acetals are in this way converted into an equilibrium mixture of the five- and six-membered isomers.

This wandering of an acyl (benzoyl) group during acid hydrolysis of the cyclic acetal ring was further confirmed in a more rigorous manner, as indicated below



Each of the structurally isomeric benzylidene glycerols VIII and XI was converted under non-acid conditions into a suitable ester of Types IX and XII, respectively. The acetal ring of each was then carefully hydrolyzed

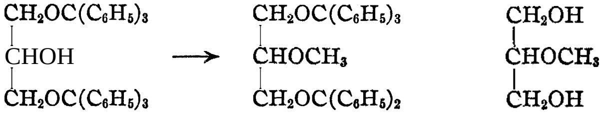
---

[26] Fischer, *Ber.*, 53, 1613 (1920).

so as to leave the newly introduced acyl group intact, resulting in a glycerol mono-ester. Both isomers yielded the same glycerol a-ester, X, indicating that a migration of the *β*-acyl group had taken place between stages XII and X. The identity of the glycerol a-ester was further confirmed by its synthesis from acetone glycerol, XIII, as indicated.

Two parallel sets of experiments were carried out, where R was *p*-nitrophenyl and *p*-bromophenyl, respectively, in order to ensure the presence of crystalline compounds and concomitant strict parallelism in regard to homogeneity at each stage; the benzylidene acetal was chosen on account of its ready ease of hydrolysis. In each case the migration of the acyl group was observed.

Additional proof of the structure of glycerol a-pnitrobenzoate is afforded by its synthesis[27] from a-sodium glyceroxide and p-nitrobenzoyl chloride, as well as from the oxidation of the *p*-nitrobenzoate of allyl alcohol. The recent isolation[28] of glycerol *β*-*p*-nitrobenzoate with a melting point (121°) fourteen degrees higher than its a-isomer should prevent any confusion in the identification of the two isomers. The structure of the intermediate compound, XIV, through which glycerol *β*-*p*-nitrobenzoate was obtained, has been linked up with the authors' investigations of glycerol @-derivatives by the following series of reactions



$$\begin{array}{lcll} CH_2OC(C_6H_5)_3 & & CH_2OC(C_6H_5)_3 & CH_2OH \\ | & & | & | \\ CHOH & \longrightarrow & CHOCH_3 & CHOCH_3 \\ | & & | & | \\ CH_2OC(C_6H_5)_3 & & CH_2OC(C_6H_5)_2 & CH_2OH \end{array}$$

XIV XV

On methylation of glycerol *α,α′*-ditrityl ether, XIV, a crystalline glycerol *α,α′*-ditrityl-*β*-methyl ether, XV, was obtained, from which the two trityl groups were readily removed by hydrobromic acid at 0°, yielding liquid glycerol *β*-methyl ether. The latter compound was then definitely identified by the method described in a previous communication.[29]

The above proof of the migration of *β*-acyl groups in glycerol, as well as that relating to the structure of the cyclic acetals themselves,[13c,d,24b] is based on the non-migration of the ether-linked methyl radical. Although extensive studies have been made on the wandering of alkyl and aryl radicals from carbon to carbon in the pinacolin transformation, and other similar cases[30] are known, the ether-linked alkyl groups seem to possess a very remarkable degree of stability and lack of tendency toward migration.[31] An excellent example of such inertness is afforded by the very recent ob-

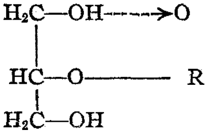
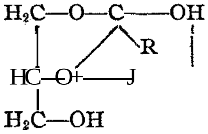
servation in this Laboratory[32] that the vinyl ether of glycol, $CH_2=CHOCH_2CH_2OH$, under the influence of a trace of hydrogen ion undergoes a molecular rearrangement with explosive violence, to form ethylidene glycol, the change involving a migration of the hydroxyl hydrogen atom. On the other hand, the corresponding vinyl methyl ether is quite stable under both acid and alkaline conditions.[33]

Mechanism of the Change Involved in the Migration of Acyl Groups

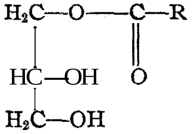
If the spatial configuration and nature of the polarities of the various groupings present in a glycerol β-derivative of Type XVI be considered, it is reasonable to assume that the strongly negative carbonyl group must have a strong affinity for the hydrogen atom of the a-hydroxyl group, resulting in the formation, under the catalytic influence of hydrogen ion, of the intermediate, unstable, five-membered cyclic acetal ring, XVII, postulated by Fischer.[8]



XVI



XVII



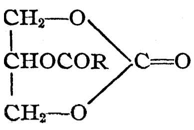
XVIII

This can then undergo ring scission, and with accompanying migration of the hydrogen atom in question, yield the a-derivative, XVIII. The cause of the "tendency toward migration" would seem to be the fact that the energy relations in glycerol derivatives seem best satisfied when the primary alcoholic groups are interacting. In agreement with this idea the ready formation of α,α′-derivatives from glycerol a-derivatives, such as the chlorohydrins, trityl ethers, sodium glyceroxides and others may be noted. If this theory be correct, then the more positive the substituent, R, the less should be the tendency toward migration. Thus the β-trichloro-acetyl group might be expected to wander readily; the β-trimethylacetyl group only with difficulty or not at

---

[32] Hill, This Journal, 50, 2725 (1928).

[33] It is proposed, having in mind the recent work of Haworth[19] on the sugar carbonates, to attempt the synthesis of a compound of the type shown. The ring of such a compound undergoes scission by the action of alkalies, and it will be of interest to ascertain if, under these alkaline conditions, migration of the acyl group from the β- to the α-position takes place.



[34] The possibility of isolating the intermediate compound, XVII, is at present under investigation in these Laboratories. Thus the condensation of methyl formate with glycerol might be expected to yield a stable derivative with the same ring structure as shown in Formula XVII (where R represents hydrogen). Hydrolysis of the methyl group should then lead to ring scission with simultaneous formation of glycerol *a*-monoformate. On the other hand, condensation of glycerol with carbonyl chloride, followed by catalytic reduction of the carbonyl group to a secondary alcohol, would

Conclusion

The experimental evidence submitted clearly indicates that in any operation where the acyl esters of tri- or poly-hydroxy compounds are subjected to acid conditions, great care is necessary in drawing any conclusions as to the constitution of the resulting compounds. It is equally true that conclusions regarding the structure of polysaccharides and carbohydrates drawn from a consideration of the structure of their acylated derivatives must also be regarded with suspicion. If, in addition to this, the remarkable ease of change in such ring structures is recalled, it is evident that great care is necessary in drawing conclusions from either acylation or methylation experiments, especially when there is any possibility of the latter having been carried out in the presence of a slight hydrogen-ion concentration, as advocated by certain workers.[35]

Experimental Part

The first two reactions described below for the attempted synthesis of 1,3-isopropylidene glycerol (2,2-dimethyl-5-*m*-dioxanol) follow the procedure adopted in a former investigation of the benzylidene glycerols,[13c] except for some slight modifications which considerably increase the yields.

Condensation of Benzaldehyde with Glycerol.—One hundred g. of benzaldehyde and 88.5 g. of glycerol (1% excess over the theoretical amount) were placed in a 300-cc. Claisen distillation flask and five drops of concd. hydrochloric acid added. The mixture was then heated to 85–90° at 60–70 mm., that is, sufficiently high to allow the water produced in the condensation to distil off with a minimum loss of unchanged benzaldehyde. In twenty minutes the reaction was complete, as evidenced by the non-separation of two layers when the flask was cooled to 10°. The condensation product was diluted with half its volume of ether and then well shaken with 800 cc. of a 1% solution of potassium carbonate to remove the acid catalyst and any remaining glycerol. The ether solution, without further washing, was dried over fused potassium carbonate and the ether removed by gentle heating under diminished pressure, leaving a mixture of the isomeric 1,2- and 1,3-benzylidene glycerols as a slightly viscous, yellowish oil; yield, 150.5 g. (87%). A solution (saturated at 30°) of this oil in a mixture of ligroin (b. p. 80–90°) and benzene in the proportion of 4:3, deposited the 1,3-isomer as white, fine, silky needles which acted much like wet absorbent cotton when being removed from the flask for filtration. The oily 1,2-benzylidene glycerol (2-phenyl-1,3-dioxolane-4-carbinol) remains dissolved in the mother liquor. The 1,3-benzylidene glycerol (2-phenyl-5-m-dioxanol) after recrystallization from ether at −10° melted at 83°, in agreement with that of previous preparations.

---

yield Compound XVII (where R represents hydrogen) directly, which would presumably then undergo a similar transformation to glycerol a-monoformate under the influence of an acid. A third, more direct, method is based on the observation by Tanasescu [*Bull. Soc. stiinte cluj*, 2,369 (1925)] that o-nitrobenzylidene gylcol undergoes a re-arrangement in direct sunlight, to 2-*o*-nitrosophenyl-2-hydroxy-1,3-dioxolane, which contains the same type of configuration as Compound XVII. Preliminary experiments with the corresponding glycerol derivatives are in progress.

[35] Haworth, "Constitution of the Sugars," Edward Arnold and Co., London, 1929, p. 55.

Preparation of **1,3-Benzylidene** Glycerol 2-Benzoate (2-Phenyl-5-m-dioxanol Benzoate).—Twenty g. of crystalline 1,3-benzylidene glycerol was dissolved in *25* g. of dry pyridine and a solution of 18 g. of benzoyl chloride in 15 g. of dry pyridine added, with constant stirring. The heat of reaction was slowly allowed to dissipate, after which the mixture stood for forty-eight hours at 18°. The semi-liquid product was poured into one liter of cold water, causing the separation of a mass of crystalline granules which were washed with water and dried at 60° under reduced pressure. Recrystallization from 300 cc. of a saturated, boiling ether solution yielded the pure benzoate as large, colorless, prismatic needles melting at 103°. Evaporation of the mother liquor to 100 cc. and cooling to −10° yielded a second crop with m. p. 99–100°. Total yield, 29 g. (93%).

Hydrolysis of **1,3-Benzylidene** Glycerol 2-Benzoate to Glycerol **Monobenzoate.**—Twenty g. of the benzoate was allowed to simmer in an open beaker at 80° for thirty minutes with 200 cc. of a 50% aqueous solution of ethyl alcohol containing 0.5 cc. of concd. hydrochloric acid. Benzaldehyde was freely evolved. After careful neutralization with 10% potassium carbonate, the alcohol, water and remaining benzaldehyde were removed by heating under diminished pressure and the residue was extracted from the inorganic salts with 150 cc. of ether. Drying over calcium chloride, followed by removal of the solvent, left 8 g. of a slightly brown, viscous oil which could not be induced to crystallize; yield, 60%. It was redistilled for the following experiments.

Identification of the Supposed Glycerol **β-Benzoate.**—One g. of the distilled oil, dissolved in 5 g. of dry pyridine, was added to a solution of 1.9 g. (two equivalents) of *p*-nitrobenzoyl chloride in 12 g. of dry pyridine. After standing for twenty-four hours at 18° the reaction mixture was poured into 400 cc. of cold water, which caused the separation of a gummy, yellowish mass. Upon vigorous stirring with fresh quantities of water, the product slowly became almost solid and was taken up in 50 cc. of chloroform, washed with cold, saturated potassium bisulfate and sodium bicarbonate solutions, then dried over fused potassium carbonate. Upon dilution of the chloroform solution with petroleum ether until it was cloudy at room temperature, then cooling slowly to −10°, a few small, white, nodular aggregates with indefinite m. p. 119–121° separated, followed by a deposit of straw-colored clusters of microscopic needles melting sharply at 115". The amount of the higher-melting compound did not permit of further recrystallization, but its melting point corresponds closely to that of glycerol α-benzoate-α′,β-di-*p*-nitrobenzoate (123°), while the lower-melting compound was evidently glycerol α-benzoate-β-*p*-nitrobenzoate.[6] Analyses were not made.

p-Nitrobenzoylation *of* **1,3-Benzylidene** Glycerol.—Two g. of 1,3-benzylidene glycerol was dissolved in *5* g. of dry pyridine and added to a solution of 2 g. of *p*-nitrobenzoyl chloride (slightly less than one equivalent, to avoid possible formation of *p*-nitrobenzoic anhydride)[36] in 10 g. of dry pyridine. The mixture was allowed to stand for fifteen hours at 30° and then poured into 400 cc. of cold water. The flocculent, pale yellow material which separated out on stirring was taken up in 50 cc. of chloroform, the solution washed with cold saturated potassium bisulfate and sodium bicarbonate solutions, and dried over fused potassium carbonate. Removal of the solvent left a crystalline mass which on recrystallization from ethyl acetate by cooling to —10" yielded 2 g. of straw-colored clusters of prisms. This compound, 1,3-benzylidene glycerol-2-p-nitrobenzoate (2-phenyl-5-m-dioxanol-p-nitrobenzoate), melts sharply at 156° and is apparently a new derivative. It is soluble in most organic solvents except alcohol, petroleum ether and ligroin and is insoluble in water.

Anal. Calcd. for $C_{17}H_{15}O_6N$: N, 4.25. Found (Micro-Dumas): 4.12, 4.38.

p-Nitrobenzoylation of **1,2-Benzylidene** Glycerol.—Thirteen and one-half g. of the

---

[36] See in this connection, Stather, ***Ber.***, 57, 1392 (1924).

1,2-benzylidene glycerol recovered from the benzene–ligroin mother liquor in the condensation of benzaldehyde and glycerol previously described, and which had been distilled within the range prescribed in a previous communication,[13e] was treated with 13.3 *g.* (slightly less than one equivalent) of *p*-nitrobenzoyl chloride in exactly the same manner as its 1,3-isomer. Upon cooling the ethyl acetate solution of the crude product, 3 g. of the isomer melting at 156° was obtained, identical with that obtained in the previous experiment.''' The solvent was removed from the mother liquor under reduced pressure and replaced by an acetone–alcohol mixture of approximately equal parts by volume which, by cooling to −10° and slowly adding water, a few drops at a time with shaking, yielded 8.3 g. of yellowish crystals with a very indefinite m. p. of 80–90". A small sample, recrystallized from acetone, gave only a minute quantity of white nodules[38] melting at 190–191°. The purification of the remaining product was effected by extraction with benzene, in which this high-melting impurity was found to be relatively insoluble. The extract, upon dilution with petroleum ether to the point of cloudiness at 0°, gave on long standing at −15° almost colorless crystals melting indefinitely between 84 and 90°. By further recrystallizations from ethyl acetate–petroleum ether at −15°, 5 g. of straw-colored needles melting at 90–91° was eventually obtained. This compound, 1,2-benzylidene glycerol-3-p-nitrobenzoate (2-phenyl-1,3-dioxolane-4-carbinol-*p*-nitrobenzoate), is apparently not recorded in the literature. The solubilities of this compound are similar to those of its isomer.

Anal. Calcd. for $C_{17}H_{15}O_6N$: N, 4.25. Found (Micro-Dumas): 4.28, 4.42.

Acid Hydrolysis of the Isomeric Benzylidene Glycerol *p*-Nitrobenzoates.—One *g.* of each of the isomers was dissolved in 10 cc. of ethyl alcohol, then diluted with an equal volume of water to which 0.5 g. of concd. hydrochloric acid had been added. The milky solution was allowed to simmer in an open Erlenmeyer flask for twenty minutes, during which time benzaldehyde was continually evolved. The solution was then evaporated almost to dryness under reduced pressure, neutralized exactly with 10% potassium hydroxide and the evaporation carried to dryness under 10-mm. pressure. The sirupy residue was separated from inorganic salts by extraction with 20 cc. of ethyl acetate, the solution after filtration diluted with petroleum ether to the point of cloudiness at 0° and then further cooled to −15°. Unless considerable care was exercised, the compound, despite its m. p. of 107°, tended to come out as an oil even at −15°. After a seeding crystal had once been obtained, beautiful crystals melting at 106.5' could be grown readily. In each case, the product proved to be identical with a sample of glycerol α-*p*-nitrobenzoate prepared from acetone-glycerol-p-nitrobenzoate following the procedure given by Fischer.[24a] A mixed melting-point determination of all three melted at 106–106.5°. Since in both cases an a-derivative resulted, a migration of the β-acyl group during the hydrolysis of 1,3-benzylidene glycerol-2-p-nitrobenzoateis indicated.

The various *p-bromo*benzoates were prepared by methods exactly analogous to those just described for the *p-nitro*benzoates. These compounds all possessed a considerable tendency to separate from solvents as oils until seeding crystals had been prepared, when beautifully crystalline, colorless

---

[37] This indicated that the original distilled compound contained at least 12% of the isomeric 1,3-benzylidene glycerol held in solution. This same impracticability of completely separating the two isomers by distillation was noted in previous preparation~'~of their methyl ethers.

[38] This compound is probably *p*-nitrobenzoic anhydride, although the possibility of the formation of glycerol tri-p-nitrobenzoate (m. p. 192") from traces of glycerol in the distilled original compound is not excluded.

compounds could usually be obtained, all of which are apparently new derivatives.

1,3-Benzylidene-glycerol-2-*p*-bromobenzoate (2-phenyl-5-*m*-dioxanol-*p*-bromobenzoate) was prepared from 2 g. of 1,3-benzylidene glycerol and a pyridine solution of 2.5 g. of *p*-bromobenzoyl chloride, in 80% yield. Recrystallization from 20 cc. of warm ethyl acetate gave colorless needles melting at 146°, soluble in chloroform, ether, benzene; insoluble in petroleum ether, ligroin, alcohol and water.

Anal. Subs., 9.150, 9.798: AgBr, 4.763, 5.166. Calcd. for $C_{17}H_{15}O_4Br$: Br, 22.01. Found: 22.15, 22.44.

1,2-Benzylidene-glycerol-3-*p*-bromobenzoate (2-phenyl-1,3-dioxolane-4-carbinol-p-bromobenzoate), isomeric with the above, was prepared from 1.7 g. of the impure, liquid 1,2-benzylidene glycerol and a pyridine solution of 2 g. of p-bromobenzoyl chloride. As expected, the product was contaminated with its higher-melting isomer. Successive recrystallizations from (a) hot methyl alcohol and (b) ethyl acetate–petroleum ether (1:2) finally yielded large, colorless crystals melting at 72°, which had a peculiar, greasy consistency when cut. These were soluble in most organic solvents except cold alcohol, petroleum ether and ligroin; insoluble in water.

Anal. Subs., 9.087, 8.920: AgBr, 4.695, 4.571. Calcd. for $C_{17}H_{15}O_4Br$: Br, 22.01. Found: 21.99, 21.81.

Acetone-glycerol-α-*p*-bromobenzoate (2,2-dimethyl-1,3-dioxolane-4-carbinol-*p*-bromobenzoate) was prepared from 2.5 g. of acetone-glycerol and 4.2 g. of *p*-bromobenzoyl chloride in pyridine solution. The colorless oil remaining after evaporation of the solvent from the chloroform solution of the reaction product was heated to 100° for a few minutes under 0.5 mm. to remove the last traces of solvent. After standing at 18° for three days, two small crystals had formed. Subsequent recrystallization from warm petroleum ether of the solid mass obtained with the aid of these seeding crystals yielded small, colorless needles melting at 39-40', soluble in most organic solvents except cold petroleum ether and low-boiling ligroin, and very prone to separate as an oil during crystallization; yield, 70%.

Anal. Subs., 8.551, 8.792: AgBr, 5.06 6,5.228. Calcd. for $C_{13}H_{15}O_4Br$: Br, 25.36. Faund: 25.21, 25.30.

Acid hydrolysis of small samples of each of the three compounds last described was carried out in exactly the same manner as with the corresponding *p*-nitrobenzoates, and yielded three identical specimens of glycerol-a-p-bromobenzoate, as shown by a mixed-melting point of 68-69 °. Since an a-derivative resulted in each case, a migration of a β-acyl group is again indicated during the hydrolysis of 1,3-benzylidene-glycerol-2-*p*-bromobenzoate.

Glycerol-a-p-bromobenzoate, apparently not hitherto described in the literature, was obtained on recrystallization from warm benzene as small clusters of transparent needles, m. p. 70°. Crystallization is only induced with difficulty, most readily by scratching a small sample of the oily form immersed in petroleum ether. It is soluble in most organic solvents except cold ether, benzene, petroleum ether and ligroin; insoluble in water.

Anal. Subs., 8.994, 8.435: AgBr, 5.983, 5.701. Calcd. for $C_{10}H_{11}O_4Br$: Br, 29.02. Found: 28.31, 28.77.

Preparation of Glycerol-α,α′-ditrityl-β-methyl Ether. **XV.**—Fifty g. of glycerol-α,α′-ditrityl ether, XIV, prepared by the method of Helferich and Sieber[28] (m. p.

175–176°; yield, 86%) was dissolved in a mixture of 80 cc. of benzene and 50 g. of methyl iodide and methylated in the usual manner by the slow addition, with constant stirring, of 40 g. of dry silver oxide during a period of three hours, during which the temperature was raised to 50°. The heating and stirring were continued for a further period of eight hours. The reaction mixture was filtered with suction and to the filtrate were added two warm benzene extractions of the silver oxide–silver chloride residue. The total filtrate was then evaporated under reduced pressure to a volume of 75 cc. and on cooling 38 g. of a white amorphous powder separated. Further evaporation and cooling of the mother liquor gave 11.7 g. of the same material. Recrystallization from hot ethyl acetate yielded large, colorless crystals of glycerol-α,α'-ditrityl-β-methyl ether, melting sharply at 158.5°. This compound, soluble in ethyl acetate, benzene, chloroform and ethylene bromide, insoluble in ether, ligroin and water, has not been previously described in the literature; yield, 49.7 g. (97%).

Hydrolysis of Glycerol-α,α'-ditrityl-β-methyl Ether, XV, to Glycerol–&methyl Ether.——Forty-three g. of glycerol-α,α'-ditrityl-β-methyl ether was dissolved in 100 cc. of an 80% solution of glacial acetic acid in benzene and cooled to 0°. Slow addition of 30 cc. of a cold, saturated solution of hydrogen bromide in glacial acetic acid caused immediate precipitation of trityl bromide, which was filtered off and sucked as dry as possible. The filtrate was neutralized with dry potassium carbonate and heated under reduced pressure to remove the bulk of the benzene and the water formed in the neutralization. The extremely bulky, frothy suspension of potassium acetate was extracted three times with a total of 150 cc. of acetone, which was then dried over calcium chloride and evaporated to a volume of 25 cc., resulting in the deposition of 3.5 g. of triphenylcarbinol (formed by hydrolysis of trityl bromide). After filtration, the acetone solution of the glycerol β-methyl ether was distilled under reduced pressure. The acetone readily evaporated and as the bath temperature was gradually raised to 150°, 1.5 g. of a colorless liquid was collected between 118–140° at 13 mm., leaving **a** residue of 1.5 g. of solid triphenylcarbinol in the flask. The wide range of temperature (glycerol-β-methyl ether has a b. p. of 123" at 13 mm.) is explained by the fact that considerable superheating was necessary to distil the ether from the unavoidable residue of solid triphenylcarbinol; yield, 19%.[39] For the positive identification[z9] of the distillate, **a** portion was condensed with p-nitrobenzaldehyde and yielded 0.9 g. of 1,3-*p*-nitrobenzylidene glycerol-2-methyl ether (2-*p*-nitrophenyl-5-*m*-dioxanol methyl ether), m. p. 138°, with no trace of the isomeric α-ether derivative.

Summary

1. A review of the literature shows that the β-acyl group in glycerol derivatives readily undergoes migration to the a-position.

2. The mechanism of such migration is apparently that first proposed by E. Fischer, namely, the intermediate formation of an unstable cyclic acetal. Three methods are suggested for the synthesis of the latter product.

3. There does not appear to be any reliable evidence in the literature indicating the migration of a methyl or other alkyl group, in the case of glycerol and other alkyl ethers.

4. Experimental evidence is given proving that in the hydrolysis of various β-acyl derivatives of glycerol cyclic acetals, a migration of the acyl

---

[39] This experiment is being repeated in an effort to perfect a more satisfactory procedure for the isolation of the glycerol β-methyl ether from the strongly acid hydrolysis mixture.

radical from the β- to the a-position takes place, giving as final product an α-glycerol ester.

5. The data submitted provide further convincing evidence as to the unreliability of deductions relating to the structure of glycerol, carbohydrates and polysaccharides based on conclusions drawn from experiments on the hydrolysis of their acyl derivatives.

MONTREAL, CANADA

NEW BOOKS

The Origins and **the** Growth **of** Chemical Science. BY J. E. MARSH, M.A., F.R.S., Fellow of Merton College. John Murray, 50A Albemarle Street, London, W. 1, England, 1929. x + 161 pp. Illustrated. 12.5 X 19 cm. Price, 5 **shillings,** net.

The history of chemistry, from the point of view of the author of this small but compact and well-filled book, is not a mere record of events. The events must be interpreted, correlated, put in order—for history itself is also a science and its data, however interesting they may be in themselves as data, still submit to a scientific treatment. Marsh interprets the history of chemistry as the history of two principal ideas—of the idea of salt formation, first clearly articulate with Boyle and even now presenting problems and influencing research, and of the idea of the fixation of gases, with the early work on which the names of Black, Priestley, Cavendish, Scheele and Lavoisier are associated.

In his preface Marsh says that "there was no science of Chemistry before the seventeenth century, but the art of Chemistry had progressed through long ages," etc. His first chapter is devoted to the "fire theories" of the ancient philosophers and of the alchemists and phlogistonists. Now it seems to the reviewer that, where we have theories, there we have data interpreted—and have science. Primitive chemical theories were chemical theories after all, not wilfully fantastic perversions of thought. We wish to know how they came to be and the reasons which led to their abandonment. Marsh points out that the phlogiston doctrine, which was the last stand of the ancient fire theory, was put forward in 1702 but "did not attract much attention from chemists in Stahl's lifetime or for some forty years after his death in 1734. The theory was then taken up by Priestley, by Scheele and by Cavendish, to explain the nature of the gases which they discovered." But the quantitative phenomena connected with the fixation of gases showed its inadequacy and created the necessity for the interpretations of Lavoisier.

The book contains a number of things such, for example, as the mention of Higgins's suggestions in 1789 relative to multiple proportions, which show that the author has a scholarly knowledge of his subject. One chapter details briefly the essential facts about the discovery of each of the known elements. The index is excellent and the names of men are generally followed by dates and often by a mention of a biography. Students will find that the book arouses their interest in the history of chemistry. Those who are already familiar with the subject will find it refreshingly different and will perhaps question, as the reviewer has done, whether the text has not determined the argument, whether the motives which run through the unfolding drama of chemistry are not more involved and far more numerous than Marsh's book would lead one to think. Yet Marsh has made an excellent study of two of these motives.

TENNEY L. DAVIS

Chemisches Fachwörterbuch für wissenschaft Technik, Industrie und Handel. (Chemical Dictionary for Science, Industry and Business.) Edited by A. W. MAYER. Otto Spamer, Leipzig, Germany, 1929. Vol. I. German–English–French. 826 pp. Price, unbound, M. 70; bound, M. 75.

A review of so complete and voluminous a work as this can cover little more than a certification of its extent, the evident care and efficiency of its production and the very complete field it covers. Prepared by one who has had special experience in translating, it really does cover more than a mere list of German technical words with their English and French equivalents, but while serving as a very complete scientific chemical dictionary, it "simultaneously introduces practical examples of the chemical and chemico-technical phraseology customary for the several industries in the three principal languages" and gives "special consideration to the requirements of trade and of the industrial and technical expert by giving appropriate equivalents, in the languages concerned, for the special professional terms and phrases for manufacturing processes, special machinery, apparatus, etc." The second volume which is to follow will be in English–French–German, and the third in French-German–English. Those who are fortunate enough to have this volume in their libraries should have no difficulty in obtaining the correct English or French equivalent for almost any German word or technical phrase.

CHARLES L. PARSONS

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. Vol. IX. Arsenic, Antimony, Bismuth, Vanadium, Columbium and Tantalum. By J. W. MELLOR, D.Sc. Longmans, Green and Company, 55 Fifth Avenue, New York; 1929. xiv + 969 pp. 113 figs. 25 × 16 cm. Price, $20.00.

The publication of this valuable handbook is progressing with commendable rapidity. The present volume exhibits the same treatment and embodies the same excellent qualities as the earlier volumes. Here as before the author has succeeded in making at once succinct and readable what is essentially and unavoidably an encyclopedia.

ARTHUR B. LAMB

Volumetric Analysis. Volume I. The Theoretical Principles of Volumetric Analysis. By DR. I. M. KOLTHOFF, Professor of Analytical Chemistry, University of Minnesota, with the collaboration of Dr. ING. H. MENZEL, Dresden, Germany. Translated from the German by N. Howell Furman, Associate Professor of Analytical Chemistry, Princeton University. John Wiley and Sons, Inc., New York, 1928. xvii + 289 pp. 20 figs. 15.5 × 23.5 cm. Price, $3.00.

Ostwald, in 1894, wrote an interesting little book showing some applications of physical chemistry to analytical chemistry and his ideas have been carried farther by Bottger, A. A. Noyes, Stieglitz, W. M. Clark, Erich Müller, Kolthoff and others. In fact, most teachers of analytical chemistry now believe that it is more important to stress the underlying theories rather than the laboratory procedure and have found that students actually do better work in the laboratory when they understand what they are doing rather than follow procedures blindly. The purpose of this new book by Kolthoff is to explain the reactions of analytical chemistry in terms of the mass-action law. From this principle it is possible to predict whether a reaction is suitable for quantitative work, to calculate the titration error on the assumption that the observations are correct and to determine the ideal conditions for carrying out an analysis. The book, therefore, is a welcome addition to the literature of analytical chemistry.

There is probably no one living today who has contributed so much to the scientific study of volumetric analysis; Kolthoff publishes about twenty-five papers a year, all of them having merit. A considerable part of this book has, therefore, been published already in his scientific papers. It is well to have the subject matter collected and published again.

It is undeniably wrong to teach chemical theory entirely apart from chemical practice and it is far better to teach physical chemistry to Freshmen and to Sophomores than to wait till the Junior or Senior year before attempting to discuss in detail the theories underlying all chemical work. Theory helps one to remember and correlate facts and the Freshman who is ready to study calculus is able to understand the mathematics of science and he has greater respect for both mathematics and science when the relationships are shown early in his career.

There is no mathematical equation given in this book but what is easily understandable by the average college student and there is little, if anything, that ought not to be taught to beginners in analytical chemistry. Equations, such as that of Nernst for showing the relation of electrolyte concentration to electrode potential, and which are derived with the aid of integral calculus, are not explained at all but the student is asked to take them for granted.

On the other hand, it is well known to teachers of chemistry that college students often have considerable difficulty in applying simple arithmetical principles to chemical reasoning and so it is necessary, in order to accomplish the best results, to introduce mathematical equations cautiously at first and with considerable explanation, seemingly unnecessary to the mathematical expert. In this way, Stieglitz and Clark have written books which are instructive and based on mathematical reasoning but are at the same time intensely interesting. The book under review was not written with this idea in mind; it will be read and understood easily only by one who is thoroughly conversant with the mathematical nomenclature of physical chemistry. Thus on page 245, the usual method of expressing concentrations in volumetric analysis is discussed at some length (something that every student of analytical chemistry is taught at the start) but throughout the preceding pages of the book concentrations are invariably expressed in moles per liter without any comment because this is something that every student of physical chemistry is supposed to know.

Chapter I is particularly difficult for the beginner; 107 numbered equations are given in 42 pages of text. This makes hard reading and unless one is familiar with the conventional terms of physical chemistry it is difficult to see exactly what some of the unexplained equations really mean. Thus on page 2, the idea of Sorensen's "ion exponent" is introduced and thereafter low concentrations are usually expressed in terms of negative logarithms. So instead of saying that the solubility product, S, of calcium carbonate is 1.2 X 10^{-8}, the expression $p_S = 7.92$ is advocated. This is all very well but it would almost seem as if more explanation should be given. To illustrate the extent to which the mathematical development has gone, it may be mentioned that pages 31 and 32 are devoted to the calculation of the extent to which calcium carbonate is hydrolyzed in pure water on the basis of the ionization constant of water and the secondary ionization constant of carbonic acid. This involves the solving of a cubic equation. Unfortunately, Kolthoff has used here a value for the ionization of carbonic acid which is ten times as large as the value he gives on page 276 and which is presumably correct.

The work of the translater is well done; the English is good and the meaning is clear, although at times the translation is a little too literal.

Without going into further details, the reviewer wishes to emphasize the fact that this is a good book and well worthy of publication. It is to be hoped, however, that both Kolthoff and Furman will try the experiment of teaching this sort of thing to beginners and then after a few years they will amplify and modify the book so that it will be easier reading.

WILLIAM T. HALL

Messen und Wägen, ein Lehr- und Handbuch insbesondere für Chemiker. (Measurement and Weighing. A Text and Handbook Especially for Chemists.) By Dr. WALTER BLOCK. Otto Spamer, Heinrichstrasse 9, Leipzig, Germany, 1928. viii + 339 pp. 109 figs. 17.5 × 25 cm. Price, unbound, R. M. 25; bound, R. M. 28.

In this volume the author carries out a project originally planned by Dr. Fritz Plato, director of the Reichsanstalt für Mass- und Gewicht, who has supplied the first section. This section (48 pages) deals with historical notes, with the units and fundamental standards of the metric system, with the British Imperial units and with the differences between these and the "customary" units of the United States. This is followed by valuable notes on the care and handling of standards, and on the various standard temperatures in use.

The second section (**32** pages) discusses the number of figures to retain in computations, the computation of "mean error" and of "probable error," the distribution of errors among the various measurements of a determination and simple approximation formulas for small correction and reduction factors. Nearly five pages are devoted to slide rules, computing machines, monographic charts and tables used in computation.

In the third section (**13** pages), are given what may best be called explanations of the fundamental units of mass, length, time, force, work, energy and pressure, with the standard value of gravity; then short definitions, with dimensional equations, of the units of the c. g. s. system, and a discussion of the most important physical constants—chiefly those of interest to the chemist.

The remaining three-fourths of the book deals directly with the various kinds of measurements, divided as follows: Time, 6 pages; Angle, 7 pages; Length, 25 pages; Surface, 4 pages; Volume and Capacity, 28 pages; Weighing, 22 pages; Density, **37** pages; Pressure, **14** pages; Humidity, **3** pages; Temperature, **29** pages; Heat (quantity), 7 pages; Photometry, 5 pages; Optics (refraction, interference, polarimetry), 14 pages; and Electrical Measurements, **38** pages.

There is also a classified list of over 200 references. In such a list it seems strange to miss the International Critical Tables. It also seems strange to find the Technological and the Scientific Papers of the Bureau of Standards classed as magazines devoted chiefly to methods of measurement.

An outstanding feature of the book is the careful explanation of principles involved. These give usable concepts rather than mere definitions or facts, and many items that tend to a broader culture than is likely to be gained from many mere "reference books."

A number of omissions are no doubt debatable, but some seem strange. For example, neither the Michaelson nor the Abbé-Fizeau interferometers are mentioned in connection with interference measurements; also the dew point instrument is not mentioned, nor are any methods of controlling humidity given.

On page 150 the emphasis on "relative" weighing, as opposed to finding values in correct units of mass, seems very unfortunate.

In the section on humidity, the author speaks of the amount of water vapor that *the air can take* up, thus continuing the old error. Later, a hair hygrometer is said to be checked by checking the saturation point, with no mention of any need for checking some other point also. Neither is there any mention of the fact that checking the **100%** point is likely to cause serious changes in reading for many days in the future.

The discussion of standard weights on pages 150 to **152** is greatly complicated, for American readers especially, by the inclusion of ordinary commercial standards. "Prazisionsgewichte," for which tolerances are given, are not laboratory weights. In fact there are *no* German tolerances for laboratory weights.

On page 44, and again on page **151,** it is stated that quartz weights are not suitable for precise standards because of the variable moisture film on the surface. Yet researches on adsorption show quartz to have as little as or less than the amount on highly polished metal.

In a book covering so wide a range of topics and such a large amount of detail, one can hardly avoid overlooking many points worth mentioning; and in the present case the reviewer must admit having given scant attention to the sections on electricity and heat, particularly. Neither was any special attention given to checking the accuracy of details, but the examples above show that caution must be exercised in using the book.

A. T. PIENKOWSKY

The Determination of Hydrogen Ions. By WILLIAM MANSFIELD CLARK, Ph.D., Professor of Physiological Chemistry, The Johns Hopkins University. Thiid edition. The Williams and Wilkins Company, Baltimore, 1928. xvi + 717 pp. 100 figs., 1 plate. 15.5 X 23.5 cm. Price, $6.50.

Clark's book since the appearance of its first edition in **1920** has been the standard on its subject. The new edition brings it abreast of the moment in its rapidly developing field. There are several entirely new chapters. New techniques are described, including the application of spectroscopy and colorimetry, and of metallic oxide, glass and oxygen electrodes. The theoretical treatment is broadened by chapters on the theory of titration, on changes of free energy and on the Debye-Hückel extension of Arrhenius' dissociation theory. Many chapters represented in the previous edition have been so completely revised that they constitute largely new material. The chapter on oxidation–reduction potentials has been nearly doubled to include new developments of the field, due in no small part to Clark's own investigations. The author has adhered to a style as condensed as is consistent with clarity. The precise choice of words gives continual satisfaction. The expansion of the entire book from the 480 pages in the second edition has been forced, despite the condensed form, by the new material demanding presentation. The printer's work is well done.

DONALD D. VAN SLYKE

Molecular Rearrangements. By C. W. PORTER, Professor of Chemistry, University of California. The Chemical Catalog Co., New York City, 1928. 167 pp. 16 × 23.5 cm. Price, $4.00.

The subject of molecular rearrangements is the family skeleton in the organic chemist's closet. Everyone knows that rearrangements occur but one is rather loath to talk about them. If they were the rule rather than the exception, organic chemistry would be a nightmare. As it is, the possibility of a molecular rearrangement haunts every series of transformations and all the pretty "proofs of structure" exhibited to our students should be followed not by the letters Q.E.D. but by B.M.R. (barring molecular rearrangements).

The appearance of Professor Porter's monograph will undoubtably serve to direct the attention of students and teachers to the subject of molecular rearrangements. It is now possible, for the first time, to refer an advanced student to a book dealing with the subject. The bibliography will be of value to investigators who wish to become oriented in regard to the published work on any particular type of rearrangement. The book makes no pretense of being a complete summary of the subject. This choice of a limited amount of material makes it a more readable book than would otherwise be the case and probably many who are not organic chemists will peruse it with interest and enjoyment.

The first four chapters deal with carbon to nitrogen, nitrogen to carbon, carbon to carbon and oxygen to carbon rearrangements. A special chapter is devoted to migrations between oxygen, nitrogen and sulfur, and the two final chapters deal with metatheses and certain reversible processes. There is an interesting preface giving one a glimpse of the author's point of view in regard to the much-debated subject of the mechanism of rearrangements. In this connection it seems strange that there is no discussion in the book of Meerwein's work on the mechanism of the Wagner rearrangement. This work seems to the reviewer to be one of the outstanding developments in the last ten years and to provide the experimental basis for a discussion of the mechanism of a large class of rearrangements.

JAMES B. CONANT

Organic Chemistry. A Brief Introductory Course. By JAMES BRYANT CONANT, Professor of Chemistry, Harvard University. The Macmillan Company, New York, 1928. ix + 291 pp. 30 figs. 14.5 × 22 cm. Price, $2.65.

This is an excellent book, designed for the shorter courses in organic chemistry. There is no text of its size which equals it, in the opinion of the reviewer. In fact, many larger books could be cited which fail to present an equally adequate idea of organic chemistry, its relations to other disciplines and to industry. In his preface, the author states that the book was planned to arouse an interest in the subject, as the first necessity in teaching it. On the testimony of students, the book is interesting—on the testimony of the reviewer, it is interesting, even after much reading of organic texts.

There are several points about the book which are worth some amount of discussion. Probably the most important one is the radical departure from the time-honored start-off with the saturated hydrocarbons. Whether this is an advantage or not is difficult to decide, since it is impossible to apply the experimental method! In the reviewer's opinion, there is a loss to be faced, in starting with the alcohols, which is not counterbalanced by the facility with which the student's interest may be seized, or the ready material for treating isomerism for the first time. With regard to the latter point, it must be admitted that it is easier to see differences in the formulas with an O in them, than in those containing only C's and H's. At any rate, the first chapter is most deftly handled, and will repay study by all who are interested in teaching organic chemistry, regardless of their predilections.

Another minor issue to be joined, is the amount of space which should be granted to the benzenoid–quinoid relationships, even in a text of this size. One is rather led to suspect that Dr. Conant has unduly limited himself in this discussion, through a desire to avoid over-emphasis of a field in which he is so effectively interested.

Perhaps it is time to mention the two points which have most impressed the reviewer. The first is the very great amount of information which has been compressed into a small compass, without any perceptible slackening of the even flow of the author's notable style. The book will require study, but it will be easy to study. The second point is the nice degree of emphasis which has been placed on industrial processes. Most texts, even much larger ones, leave much to be desired in this respect, either through the inadequacy of the space assigned to industrial processes, or through lack of up-to-dateness. It is certain that the latter fault does not appear here, in the cases of which the reviewer has personal knowledge.

All in all, this is not just one more organic text, but a new text, of considerable pedagogic importance, and it should be a success. The publishers have done their part well. The drawings are beautifully executed.

W. H. HUNTER

Das Anthracen und die Anthrachinone, mit den zugehörigen vielkernigen Systemen. (Anthracene and Anthraquinones, and their Polynuclear Systems.) BY DR. J. HOUBEN, Professor at the University of Berlin, with the cooperation of Dr. Walter Fischer. Georg Thieme, Antonstrasse 15/19, Leipzig C 1, Germany, 1929. xxiii + 890 pp. 17 X 25.5 cm. Price, unbound, M. 85; bound, M. 90.

In the introduction to this comprehensive treatise, Professor Houben states that he began collecting material for such a book over twenty-five years ago, when he was at the beginning of a period of experimental activity in the field of anthraquinone and alizarin chemistry. It is worth while pointing out that it is only because of the rather unusual nature of his association with an industrial firm that Professor Houben's name is little known in this connection, for the value of a book dealing with a phase of chemistry which has been so closely related to the growth of the German dyestuff industry is greatly enhanced by the knowledge that the author brings to the undertaking the authority of many years of collaboration in technical work. The German patent literature affords a source of information concerning anthracene and anthraquinone which is extremely fruitful, but which, because the observations are widely scattered and of unequal reliability, is rather difficult to use. A great service has been performed by Professor Houben in classifying all of this information (to January 1, 1928), in evaluating it in the light of his technical experience, and in combining it in masterly fashion with the material to be found in the non-technical literature.

The book considers first, in a general section, the history, the systems of nomenclature, the structure and the relationship between the structure and the fluorescence of the anthracenes and anthraquinones, while special sections are devoted to the derivatives of anthracene and dianthryl, the quinones, the condensed systems and the radicals of the anthracene series. The anthraquinone dyes are treated fully, though without the inclusion of details relative to the processes of dyeing. The work is characterized by the great care and thoroughness with which the extensive literature has been marshaled and the information systematized. There are over seventy tables summarizing the properties of groups of related compounds, while a useful index to the German patents precedes a very excellent general index. Professor Houben has dealt particularly skilfully with the arrangement of the chapters relating to the very complicated and diverse polynuclear systems; the general properties and methods of preparation of each type of compound are clearly set forth, together with an account of the useful dyestuffs falling within each group.

The book is written in a very clear style, and the reader will derive much satisfaction from the interesting and unhurried accounts of the major investigations of the chemistry of anthracene. The extensive use of full structural formulas and of well-planned diagrams, combined with the beauty of the printing, further adds to the reader's pleasure. There are, for example, no less than 147 formulas illustrative of the principles enunciated in the chapter on the relationship between color and constitution.

A further noteworthy feature of the book is the inclusion of several passages or notes, dealing largely with the technical preparation of alizarin, which were contributed by Professor Iljinsky. The most interesting of these is the account of his discovery of the catalytic action of mercury in the sulfonation of anthraquinone.

Professor Houben's work is not merely an excellent summary of anthracene chemistry, but it also represents a definite addition to this field of knowledge. It is only in this latter aspect that the reviewer can suggest a possible source of criticism, which is that the author has not always succeeded in properly relating the chemistry of anthracene to general chemical theory. On the one hand, the general theory might have been called on more in accounting for phenomena in the special field. Thus the accepted mechanism of the addition of hydrogen chloride and of aniline to quinone might have been applied with profit to the action of these reagents on anthraquinone-azine (pp. 719, 720), and the older mechanism suggested for the Bally benzanthrone synthesis might be revised in the light of the modern view of the ordinary Skraup reaction. Kehrmann's work on the relative oxidation potentials of simple hydroazines [Ber., **31,** 977 (1898)] is perhaps not generally recalled, but it may be said that this work admirably accounts for all of the facts known concerning the relative fastness to chlorine of the indanthrene dyes (p. 729). The reviewer feels that, on the other hand, the opportunity to extend general chemical theory from the facts known about the higher hydrocarbons has not always been utilized fully. The existence of addition products of anthracene with nitric acid and with bromine is surely of significance in connection with the theory of substitution in the benzene ring. Taken by itself, it is difficult to understand the fact that, of all of the monohydroxy derivatives of the simple hydrocarbons, meso-hydroxy-anthracene is the only one which exists largely in the keto form; but when it is recalled that meso-anthraquinone is far more stable than any of the other simple quinones, an adequate account of the stability of anthrone suggests itself: in each case the two benzene nuclei stabilize a quinonoid system.

There is one statement in the book which, though it involves a minor point, cannot be allowed to go unchallenged. It is to the effect that anthraquinone is no true quinone but a diketone. This frequently repeated view probably originated with Willstätter at the time of his brilliant discovery of the quinones of particularly high oxidation potential, and it is easy to see how he came to regard anthraquinone as, to use his conversational word, "trage." He might well have said "sehr trage," but the fallacy is that the adjective used was "zu." The facts are that anthraquinone is a diketone, if a rather inactive one; it is an inactive quinone in the sense that its reduction potential of 0.155 v. is quite low in comparison to the figure of 0.784 v. for a-benzoquinone, though it shares with this compound the distinctive property of undergoing reversible reduction with great rapidity.

THE VAPOR PRESSURE OF ISOPROPYL ACETATE[1]

BY CECIL J. HAGGERTY AND JOSEPH F. WEILER

RECEIVED JUNE 15, 1928 PUBLISHED JUNE 5, 1929

Introduction

While conducting some experiments recently on the physical properties of binary mixtures of ethyl, n-propyl and isopropyl acetates with acetic acid,[2] in order to make certain calculations with these mixtures it was necessary to know the vapor pressures of the esters. In searching through the literature we were able to find such data on the ethyl and n-propyl acetates,[3] but were unable to discover any vapor pressure work on the isopropyl acetate. In the absence of such data the following investigation was undertaken.

Experimental

The apparatus employed in this work was essentially the same as that recommended by Smith and Menzies,[4] mercury serving as the confining liquid in the U-tube. The thermostat was a glass vessel of about six liters' capacity, provided with a propeller type stirrer and a nichrome wire heating element which was so connected through a lamp bank that the current could be varied at will, and in addition, a small fraction of current operated through a thermoregulator and relay, maintaining the temperature to within ±0.01°. Small Anschütz thermometers were employed along with a Beckmann, which served to denote the variation of temperature of the water-bath. The small thermometers were calibrated against a Bureau of Standards thermometer at the temperatures employed in this work. The manometer was of the ordinary type used in vapor pressure measurements. With the usual precautions it was accu-

[4] Smith and Menzies, THIS JOURNAL, 32, 1419 (1910).

rate to within 0.2 mm. The bulblet and U-tube part of the apparatus were baked at 150° for twenty-four hours in order to remove as much adsorbed water as possible. It was then cooled in a desiccator over sulfuric acid and used immediately when cool.

Preparation of Materials.—*Iso*propyl acetate from the Eastman Kodak Company served as a starting point. This was treated with a solution of potassium carbonate (50 g. in 100 cc.) in order to remove any acid which might be present, and then with a strong solution of calcium chloride (100 g. in 100 cc.) to remove any alcohol. It was allowed to stand over anhydrous calcium chloride overnight and then carefully distilled. Only that fraction which boiled within 0.1° was taken. It is very difficult to purify an ester beyond this point, so this fraction served as a stock solution and the samples employed in the isoteniscope were freshly distilled from it each time. We did not attempt to obtain the boiling point of this fraction accurately for we expected to obtain the true boiling point from the vapor pressure data. The mercury used in the manometer was distilled several times according to the method of Hulett.[5]

Discussion of Error.—At the lower temperatures the main error is due to the variation in reading the manometer. This amounts to about 0.2 mm. At temperatures above 60° the error due to temperature variation should become noticeable and gradually increase up to the maximum temperature employed in this work. The maximum absolute deviation was 0.5 mm. This indicates that providing sufficient readings are made on the manometer the error due to temperature variation may be maintained within the error due to reading the manometer. In order to make sure that these errors were not larger than we anticipated, we ran a determination of the vapor pressure of water and compared the results with those of Smith and Menzies.[6] These results deviated at most by an absolute error of 0.3 mm. The average deviation from the mean of values at 5° intervals from 50 to 80° was 0.2 mm. This shows that our values on the vapor pressure of isopropyl acetate are probably correct to within 0.2 mm. The largest percentage error obtains at the lower temperatures, where it may amount to as much as 1.5%. This percentage error falls off gradually as the temperature is raised.

Method of Procedure.—After the bulblet and U-tube were removed from the desiccator, the bulb was charged with 5–6 cc. of isopropyl acetate and the mercury placed in position in the limb of the U-tube. This part of the apparatus was connected to the manometer and vacuum pump and the whole system evacuated with continuous pumping for about an hour, reducing the volume of isopropyl acetate to about 1–1.5 cc. The mercury was then tipped into position in the U-tube with the pump

---

[6] Ref. 4, p. 1430.

still running. The system was disconnected from the pump and the usual procedure followed for determining vapor pressure.

Experimental Data

The vapor pressure measurements on isopropyl acetate are given in Table I. The values in the second column are the average of several readings at the indicated temperatures, while those in Col. 3 are on a different sample and with a different U-tube and bulblet. The fourth column gives the average of the values in 2 and 3, and the last column the calculated values. The experimental readings at each temperature were all taken within a fifteen-minute interval along with the barometric pressure. All pressures are corrected to 0°.

TABLE I

VAPOR PRESSURES OF *ISOPROPYL* ACETATE

Temp., °C.	Vapor press., I	Obs., mm., II	Av. mm.	Calcd. mm.	Temp., °C.	Vapor press., I	Obs., mm., II	Av. mm.	Calcd. mm.
0.00	15.8	15.6	15.7	15.7	50.20	189.4	189.4	189.4	188.8
5.00	21.3	20.9	21.1	21.0	55.20	234.2	233.9	234.1	232.0
10.00	27.9	27.8	27.9	27.8	60.20	284.4	284.2	284.3	281.7
15.00	36.5	36.3	36.4	36.4	65.20	344.1	344.1	344.1	340.3
20.00	47.2	47.0	47.1	47.2	70.20	413.6	413.7	413.7	409.6
25.00	60.8	60.5	60.7	60.6	75.20	493.8	494.0	493.9	490.0
30.00	77.3	77.2	77.3	77.0	80.20	585.4	585.8	585.6	582.5
35.05	98.0	97.7	97.9	97.9	85.20	689.8	690.0	689.9	689.1
40.10	122.9	122.7	122.8	122.6	90.20	810.6	810.9	810.8	811.0
45.15	152.6	152.8	152.7	152.7					

Discussion of Results.—By substitution of the proper constants in the empirical equation of Kirchhoff[7]

$$\log_{10} P = A + B \log_{10} T + C/T$$

we obtained the following equation

$$\log_{10} P = 14.2517 - 2.0972 \log_{10} T - 2170.1/T$$

The values in Col. 5 of Table I were obtained from this equation by substituting the proper temperatures and solving for the vapor pressure. It will be seen that the calculated values agree fairly well with the observed, the maximum percentage error occurring at 65.20°, where it is a little over 1%. This equation may also be used to calculate the boiling point, which is found to be 88.2°.

We have also employed this equation along with the expression $d \ln P/dT = L/RT^2$ in order to determine the molal heat of vaporization at the boiling point. The value so obtained was corrected by deducting 4% according to Parks and Barton,[8] giving a final value of 7900 cal. per mole. This quantity substituted in the Trouton equation gives a molal

---

[7] Kirchhoff, Pogg. ***Ann.,*** 103, 185 (1858).

[8] Parks and Barton, THIS JOURNAL, **50,** 2G (1928).

entropy of vaporization of 21.8 cal. per degree, indicating that *iso*propyl acetate is a normal liquid.

Following Hildebrand,[9] we have also calculated the molal entropy of vaporization at that temperature (35.0° in the case of isopropyl acetate) at which the concentration of the vapor is 0.00507 mole per liter and obtained a value of 27.6 cal. per degree. As 27.4 cal. per degree is the mean value obtained by Hildebrand for normal liquids, this value also indicates that *iso*propyl acetate is a normal liquid.

Summary

Vapor pressure measurements have been made on *iso*propyl acetate from 0 to 90°, inclusive.

An equation has been obtained for the vapor pressure curve from which the boiling point has been determined.

From this equation the molal heat of vaporization has been determined.

The molal entropy of vaporization has been determined at the boiling point and also at that temperature at which the vapor concentration is 0.00507 mole per liter.

These molal entropies indicate that *iso*propyl acetate is a normal liquid.

EQUILIBRIUM BETWEEN THE CARBONATES AND BICARBONATES OF SODIUM AND POTASSIUM IN AQUEOUS SOLUTION AT 25°

BY ARTHUR E. HILL AND STERLING B. SMITH[1]

RECEIVED DECEMBER 3, 1928 PUBLISHED JUNE 5, 1929

A phase-rule study of the reactions between the carbonates and bicarbonates of sodium and potassium does not appear to have been published heretofore. Such a study may be regarded as including the more important part of the possible reactions of the two bases with carbonic acid, between the limits in which the carbonic acid varies from an amount just sufficient to form normal carbonates with all the base present and an amount sufficient to form bicarbonates with all the base present. For such a four-component study, four three-component studies are a preliminary essential; these are listed below. Three of them have been studied with more or less completeness at a number of times and places, and more recently at this

[9] Hildebrand, "Solubility," American Chemical Society Monograph, Chemical Catalog Company, New York, 1924, p. 94.

[1] The material of this paper was presented by Sterling B. Smith in partial fulfilment of the requirements for the degree of Doctor of Philosophy at New York University, June, 1927.

Laboratory with a special view toward their use in the four-component study here reported; the fourth has been studied elsewhere, the results not yet being published.

Na_2CO_3–K_2CO_3–H_2O[2]	K_2CO_3–$KHCO_3$–H_2O[4]
Na_2CO_3–$NaHCO_3$–H_2O[3]	$KHCO_3$–$NaHCO_3$–H_2O[5]

Data from these studies, recalculated so as to be of use in the four-component study, will be introduced later.

Experimental Methods.—The four salts used were Kahlbaum's preparations "zur Analyse." These were found by analysis, after drying, to be pure up to the limit of our most careful standardization, with the exception of the sodium bicarbonate, which showed decomposition into carbonate in amount varying from 0.5 to 3% in various samples. Since sodium carbonate is one of the components of the systems studied, it was necessary merely to correct the weights taken in some cases; in others the correction is wholly unnecessary.

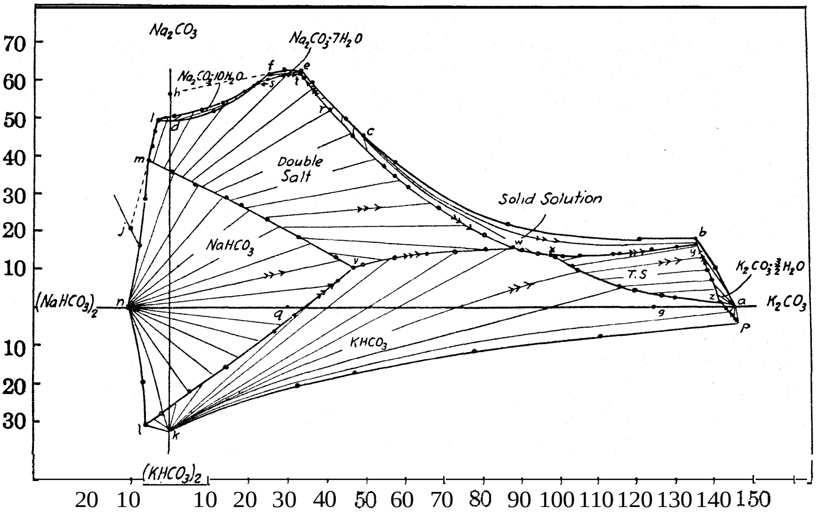

Fig. 1.—K_2CO_3–$NaHCO_3$–Na_2CO_3–$KHCO_3$–H_2O at 25".

In carrying out the solubility experiments, which were intended to give us the lines for saturation with respect to two solid phases later shown in Fig. 1, solutions were prepared corresponding to the isothermally invariant points in the three-component systems (Points 1, m, i, etc., in Fig. 1) or in the four-component system (Points v, w, etc.), with a small excess of the two solid phases present. To each of these was added a small amount of the necessary fourth component, the whole complex being contained in a 50-cc. glass-stoppered Pyrex test-tube. The solubility tubes were then rotated,

with suitable protection against entrance of water, in a thermostat at 25 ± 0.1°; sixteen hours sufficed for the attainment of equilibrium in the majority of cases, but from thirty-six to forty-eight hours were required where one of the phases is a solid solution. For the analysis of the saturated solutions, three samples were withdrawn by pipet in each instance, using a small filter of linen in cases where the liquid did not settle clear, and their weights ascertained. One sample was titrated for total alkali, using hydrochloric acid with methyl orange as indicator; by the use of a color blank for matching end-points, of a constant volume in the titration, and of sodium carbonate as the ultimate standard for the hydrochloric acid, errors in this titration were reduced to a minimum. The second sample was weighed into a platinum dish and evaporated under reduced pressure of about $^1/_6$ atmosphere in a vacuum oven at 80°; after apparent completion of the evaporation, the sample was heated to incipient fusion over a Bunsen burner and brought to a constant weight; the residue gives the total carbonates of the two metals obtained from the solution of carbonates and bicarbonates. The third sample was analyzed for its carbon dioxide content by acidification with sulfuric acid in a suitable train, the gas finally being absorbed by soda lime in a Morgan bottle. From these three operations the complete composition of the solution can be calculated, to be expressed in terms of whatever four components may be most convenient. It is estimated that the errors in the individual analyses are not greater than 0.1%, but the method of indirect calculation multiplies these errors to what may be as great as 1%; the smoothness of the curves, however, indicates that the total errors are less than this amount. Densities of the solutions were known from the weights of the pipetted samples, usually 5 or 10 cc. in volume.

The analysis of a series of solutions by the above method gives a saturation curve for solutions saturated with two solid phases, such as the line m–v in Fig. 1. The terminus of such a curve, detected experimentally by a break in the course of the curve, represents an isothermally invariant point, at which a third solid phase has appeared. Such points were determined from the analysis of two or more solutions obtained by following the curves leading to that point. In all such cases except the Points x, y and z, where one of the solid phases cannot be prepared pure, the invariant composition was checked further by preparing a solution of the composition found, adding the three solid phases believed to be in equilibrium with the solution and rotating the system in the thermostat; if the analysis of the solution was found unchanged after forty-eight hours' rotation of the sample, the point was considered definitely fixed.

Experimental Results

In Table I are given the data for the four three-component systems, recalculated from the original papers so as to show composition in terms of moles of the components per 1000 moles of water. These data appear in part in Fig. 1 upon the boundary lines of the drawing. The abbreviations used to indicate the more complex solid phases are indicated at the head of the table. In accordance with custom, the two bicarbonates are assigned a double molecular weight.

The figures for the fourth of the systems ($NaHCO_3$–$KHCO_3$–H_2O) in Table I have been newly determined here and are in fair agreement with those reported to us privately by Mr. Oglesby.[5]

In Table II are given the data found for the four-component system. The three components necessary (with water) to define the composition are arbitrarily chosen so as to be of greatest convenience for the part of the complete diagram represented. An additional abbreviation for a new tetragene salt, described later in the paper, is included in the table.

Discussion of the 25° Isotherm

The preceding table gives the eleven curves for solubility equilibria with two and with three solid phases. In addition there are the three curves b–y, e–t and f–s which are so short that only their end-points could be determined. All fourteen are shown in Fig. 1, together with the fields representing saturation with respect to a single solid phase; the results are plotted according to the conventional method of Löwenherz.[6] The points

---

[6] Löwenherz, *Z. physik. Chem.*, 13, 459 (1894).

s, t, v, w, x, y and z represent the seven isothermally invariant points, at which the solution is in equilibrium with three solid phases.

Of the eight fields of saturation with a single salt, seven represent salts found in the four three-component systems. Of these the field bounded by the lines b–e–t–w–x–y–b represents the phase recently shown[zd] to be a solid solution, of the formula $(K_2,Na_2)CO_3 \cdot 6H_2O$, and previously thought to be a definite compound of the formula $KNaCO_3 \cdot 6H_2O$. The field for the decahydrated sodium carbonate, $Na_2CO_3 \cdot 10H_2O$, is bounded by the lines i–d–f–s–i; its apparent extension beyond the boundary line for the three-component system (d–f) is, of course, wholly a matter of the Lowenherz method of representation. The eighth field, x–y–z, represents a new tetragene salt, $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, which does not occur in any of the three-component systems at this temperature.

The Tetragene Salt.—Upon finding the existence of the field x–y–z, experiments were conducted to determine the composition of the salt which crystallized out within that area. A number of isothermal evaporations of such solutions were carried out, for the purpose of studying the crystallization paths described later. The crystals thus obtained were filtered off, centrifuged at a rate of 1000 r.p.m., which unfortunately was too slow to secure very complete expulsion of the mother liquor, and analyzed in this slightly moist condition. The results of the analysis are given in Table III.

TABLE III

ANALYSIS OF TETRAGENE SALT

Calculated for the formula $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$: K_2CO_3 = 53.52; $NaHCO_3$ = 32.53; H_2O = 13.95%

wt. % K_2CO_3	wt. % $NaHCO_3$	wt. % H_2O	wt. % Na_2CO_3	wt. % K_2CO_3	wt. % $NaHCO_3$	wt. % H_2O	wt. % Na_2CO_3
52.80	31.17	15.17	0.90	54.32	32.05	14.68	−1.05
52.87	31.24	15.24	0.65	55.49	33.29	14.90	−3.68
52.39	28.49	18.48	0.64	55.29	29.86	14.79	0.06
54.17	32.66	14.37	−1.20	53.54	30.19	16.82	−0.55
53.80	32.34	15.05	−1.19	53.63	36.55	14.63	−4.81

In the above table the fourth column is included to represent the actual results as calculated for a possible four-component body. The variations from the composition assumed are not inconsiderable. How far they may be due to occlusion of mother liquor or to precipitation of metastable salts we are not in a position to estimate, but the evidence seems to us convincing that the salt has the formula $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$. This would put the compound in the comparatively small class of salts built up of two cations and two anions, to which Meyerhoffer[7] has given the name of "tetragene salts." It is perhaps also worthy of note that the composition of the salt is that of the well-known double salt Trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$), with

---

[7] Meyerhoffer, *Z. anorg. Chem.*, 34, 147 (1902).

the substitution of a molecule of potassium carbonate for one of sodium carbonate.

In order to verify the formula by a different method, 200 g. of solution was prepared of a composition known to fall in the desired area. **A** small amount of the solid was added and the mixture rotated in the thermostat at 25° for 120 hours. At the end of that time the solid phase had not disappeared, indicating that equilibrium existed between the solid and liquid phases. The crystals were then allowed to settle and the liquid was analyzed. The composition of this solution is represented by a point within the field x–y–z and is as follows: $Na_2CO_3 = 3.26$; $NaHCO_3 = 1.87$; $K_2CO_3 = 46.62$; $H_2O = 48.25$. To the above equilibrium mixture was added 13.82 g. of K_2CO_3, 8.4 g. of $NaHCO_3$ and 3.6 g. of H_2O, corresponding to the composition of the alleged salt, $K_2CO_3{\cdot}NaHCO_3{\cdot}2H_2O$. The mixture was again rotated in the thermostat for forty-eight hours and the solution analyzed. This solution gave the following analysis: $Na_2CO_3 = 3.30$; $NaHCO_3 = 1.85$; $K_2CO_3 = 46.71$; $H_2O = 48.14$. Since the analyses of these two solutions agree within a small experimental error, the composition of the liquid phase may be regarded as unchanged and the solid phase is shown to have the composition $K_2CO_3{\cdot}NaHCO_3{\cdot}2H_2O$.[8]

Crystallization Paths.—In Fig. 1 the lines drawn within the fields represent crystallization paths of solutions undergoing isothermal evaporation. Except for the field x–y–z, for which experimental data will be given later, these lines have been drawn according to the conventional *a priori* reasoning, assuming that solid phases are withdrawn as formed; they therefore can represent only in a qualitative way the course of such evaporations. In the case of the four salts $Na_2CO_3{\cdot}10H_2O$, $K_2CO_3{\cdot}3/2H_2O$, $KHCO_3$ and $NaHCO_3$, the solubilities in water are represented by the four points d, a, k and n, falling on the respective axes; the crystallization paths for these salts are therefore drawn as radiating from these points. The heptahydrate, $Na_2CO_3{\cdot}7H_2O$, is not stable in water at this temperature, but its solubility may be estimated by extrapolation of its solubility curve e–f to the point h, from which center its crystallization paths radiate. The point for the crystallization paths of the double salt Trona also has to be found by extrapolation of its solubility curve i–m to a point on a line representing its molecular composition, namely, the point j. For the solid

---

[8] Since this paper was written there has appeared Teeple's "The Industrial Development of Searles Lake Brines," Chemical Catalog Company, New York, 1929, in which appears (p. 132) a study of this four component system at 35°, carried out by Harald de Ropp. The field which we assign at 25° to the tetragene salt $K_2CO_3{\cdot}NaHCO_3{\cdot}2H_2O$ is assigned by them at 35° to a potassium sesquicarbonate, $K_2CO_3{\cdot}2KHCO_3{\cdot}3H_2O$. Without raising any question as to the correctness of de Ropp's findings at 35°, we have not found the potassium sesquicarbonate at 25°, and are sure that the salt found by us is a sodium–potassium salt in the atomic ratio of 1:2, as we have reaffirmed by repeated analyses.

solution $(Na_2,K_2)CO_3 \cdot 6H_2O$ we cannot speak of a definite solubility in water, for the solid phase has a varying composition; the crystallization paths therefore will radiate not from a single point but from a series of points. By drawing lines from the origin in the coordinate system so as to represent the atomic ratios of sodium to potassium in the extreme compositions found for the solid solution, it was found that the two lines intersect the solubility curve e–b close to the point e and at c; the crystallization paths will therefore radiate from a series of points between e and *c*. These lines are drawn in this area with a considerable curvature, to correspond with the curvature of the line e–b; elsewhere in the diagram they are drawn arbitrarily as straight lines, or lines with but a slight curvature.

The crystallization paths for the remaining phase, the tetragene salt, were investigated experimentally; a *priori* it could only be deduced that the center of the radiating lines would fall somewhere between the point representing the composition of the salt and the origin of the coordinate system. For the experiments large quantities of solutions were prepared of compositions lying near to the line x–z. Each of these was inoculated with a

small amount of crystalline tetragene salt and rotated in the thermostat for forty-eight hours to secure equilibrium; after being allowed to settle, the clear liquid was analyzed. The remaining material was then placed in an evaporating dish in a desiccator over concentrated sulfuric acid and maintained in an air thermostat at 25°. The solutions were stirred from day to day and were weighed at frequent intervals to follow the rate of evaporation. In the course of three weeks about 20 g. of water was lost by each and a quantity of solid phase obtained sufficient for analysis. The mixtures were then again rotated in the thermostat at 25° for forty-eight to seventy-two hours to secure equilibrium and the solid phase was filtered off; the analysis of ten such samples has been given previously in Table III. The liquid phases were then analyzed. The results of the initial and final analysis for six such experiments are given in Table IV and shown in Fig. 2 by the points within the area x–y–z; connecting these by straight lines (as the simplest assumption) we obtain a series of crystallization paths for the tetragene salt.

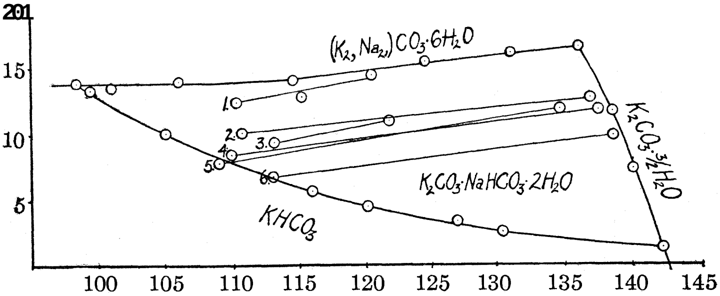

Fig. 2.—Crystallization paths for the tetragene salt, $K_2CO_3 \cdot NaHCO_3$-$2H_2O$ at 25°.

If the crystallization paths thus found and shown in Fig. 2 be extrapolated, they will fall close to the point in Fig. 1 represented by q.

With the crystallization paths for the eight single solids determined, the direction of the crystallization paths along the lines for two-solid equilibrium follows. Of these fourteen curves for isothermally univariant equilibrium, only three are not crystallization paths; these are the Curves m–v, s–f and x–z. At each of these curves resorption of the solid phase present takes place, with separation of a new solid phase; the changes represented are, respectively

$$NaHCO_3 \longrightarrow NaHCO_3 \cdot Na_2CO_3 \cdot 2H_2O \text{ (Trona)}$$
$$Na_2CO_3 \cdot 10H_2O \longrightarrow Na_2CO_3 \cdot 7H_2O$$
$$KHCO_3 \longrightarrow K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O \text{ (Tetragene salt)}$$

Isothermally Invariant Points.—The fourteen isothermally univariant curves meet at seven points, which represent saturation with respect to three solid phases in each case and are therefore isothermally invariant.

Inspection of the curves meeting at these points shows, however, that in only two of the seven cases are the points the termini of three crystallization lines; these are the points t and y, which are therefore crystallization end-points or drying-up points. Solutions of any possible composition will, therefore, under isothermal evaporation, go to dryness at one or another of these two points, with the precipitation of the three salts indicated, namely at t, $Na_2CO_3 \cdot 7H_2O$, Trona and the solid solution, and at y, $K_2CO_3 \cdot 3/2H_2O$, solid solution and the tetragene salt. The other five points are not points of congruent saturation.

There is also in the system a single point of congruent saturation with respect to two solid phases, namely, Trona and the solid solution; the point has been set arbitrarily, without experimental confirmation, at r. This point represents the position for dividing the possible solutions of the system into two classes: those falling to the right of the crystallization paths leading to r will dry up at the point y, and those to the left will dry up at t, the division depending chiefly upon the total amounts of sodium salts and of potassium salts which are present.

Summary

1. The 25° isotherm has been studied for the quaternary system made up from sodium carbonate, potassium bicarbonate and water, and the results have been plotted according to the method of Löwenherz.

2. The system has been found to contain eight fields of isothermally bivariant equilibrium, fourteen lines of isothermally univariant equilibrium and seven isothermally invariant points.

3. There is no "stable pair" in this system at this temperature; *i. e.*, neither Na_2CO_3 and $KHCO_3$ nor $NaHCO_3$ and K_2CO_3 can be in equilibrium as solid phases.

4. A new tetragene salt has been found, of the formula $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, not occurring in any of the three-component systems.

5. The crystallization paths for the tetragene salt have been studied experimentally, and the paths for the other salts have been deduced *a priori*.

6. There exist in the system at this temperature two crystallization end-points and one two-solid congruent point.

AN INTERFEROMETRIC INVESTIGATION OF ADSORPTION BY PURE CARBON FROM NON-AQUEOUS BINARY SYSTEMS[1]

By F. E. Bartell and C. K. Sloan[2]

Received December 10,1928 Published June 5, 1929

Measurements which have been carried out for the purpose of relating the change in concentration to adsorption have, in practically all cases, been made by means of volumetric or gravimetric methods. Surprisingly few of the investigators have made use of the measurement of refractive index. In the present investigation a Rayleigh interferometer (made by Hilger) was used. Standard methods were employed for the purification of liquids.

For one who is attempting to master the technique of the interferometric method as applied to liquids the papers of Adams,[3] Cohen and Bruins,[4] and Barth and Schaum[6] are of great value. Mitchell[6] and Macy[7] have recently described the use of the instrument for the measurement of the concentration of very dilute aqueous solutions. Others have found interferometry useful in adsorption problems. Odkn and Anderson[8] used the interferometer to study the adsorption of the cations of alkali and alkaline earth materials by carbon. In like manner, Ruff[9] determined the amount of phenol adsorbed from solution by a number of commercial carbons. Oliphant and Burdon[10] used the interferometer to measure adsorption of gas on mercury droplets. Others who have made use of interferometry in the study of adsorption from solution include Marc,[11] Wolff,[12] Arendt[13] (who studied the velocity of adsorption by this method), Berl and Wachendorff,[14] and Patrick and Jones.[15]

Preparation and Properties of Carbon.—Bartell and Miller[16] have

emphasized the importance of the use of pure carbon in adsorption experiments. They worked out a method for the activation of charcoal prepared by the carbonization of recrystallized sugar. This method, with but slight modification, was used for the preparation of a pure active carbon. The activity of the carbon was tested according to directions given by Miller.[17] It was found that a quarter of a gram of carbon was capable of removing 54% of the benzoic acid from 100 cc. of a 0.02 N solution during ten minutes of intermittent shaking. Miller states that a fairly active carbon will adsorb 50% of the benzoic acid under these conditions. It is possible to prepare a more active carbon but this involves a greater loss in carbon due to oxidation. Eor the present work it was thought advisable to limit the activation treatment to four hours. A sufficiently active carbon can be obtained during that period without too greatly cutting down the yield. One hundred grams of Merck's saccharose will give about twelve grains of char. Heating this char in nitrogen at 900° reduces the amount to nine grams. The four-hour intermittent activation leaves about five grams of active carbon. After a sufficient quantity is obtained, it should be heated to drive off adsorbed moisture and then kept in a desiccator. It was found that the carbon which had been used for the adsorption of volatile organic liquids can be recovered without changing its adsorptive capacity appreciably.

Modification of Apparatus.—Activated carbon was added to different aqueous solutions of such substances as pyridine, aniline, benzene and a number of acids and alcohols. After a small amount of activated carbon had been added to a saturated solution of benzene in water, the interferometer indicated that all of the benzene had been adsorbed. In each of the other cases a pronounced adsorption of solute occurred. Because of the very slight solubility of many of these substances in water, it was thought desirable to study adsorption from a non-aqueous solvent. The interferometer, however, cannot be used without modification for the analysis of such solutions since organic liquids usually have a higher volatility, a higher temperature coefficient of refractivity and a lower heat capacity than water. Unless certain precautions are taken, these factors result in distortion of the interference band system and uncertainty in the instrument reading. Cohen and Bruins[4] found it necessary to keep their interferometer (Zeiss type) in a water thermostat. A brass plug was made to fill all of the space above the liquid in their interferometer cell in order to prevent evaporation and distillation of liquid against the cover plate of the cell. A few attempts at measuring the concentration of non-aqueous solutions made evident the necessity of considering the precautions given by Cohen and Bruins. The compartments of the cell (Fig. 1) of the Hilger interferometer at first were covered with a plane glass plate. In many cases liquid filled the space between the cell and its cover even though great care was taken in filling the compartments. This liquid slowly evaporated. After the entire instrument had been placed in the large air thermostat used for temperature regulation, loss of liquid due to evaporation was still more pronounced because of the greater circulation of air around the cell. A steel cover was designed to fit over the top of the cell, permitting a mercury seal between the glass of the cell and the cover (Figs. 1 and 2). The under side of the latter carries a groove one-sixteenth of an inch wide extending

---

[17] Miller, *J. Phys. Chem.*, 30, 1162 (1926).

around the top of the glass cell and across the center between the two compartments. This groove is one-quarter of an inch deep and when filled with mercury serves as an effective means of preventing evaporation. A small hole at each end of the top of the cover permits filling the grooves with mercury after the cover is in place on the cell. Liquid is introduced into the compartments through two holes extending through the cover. Mercury seals around each of these holes prevent evaporation at these points.

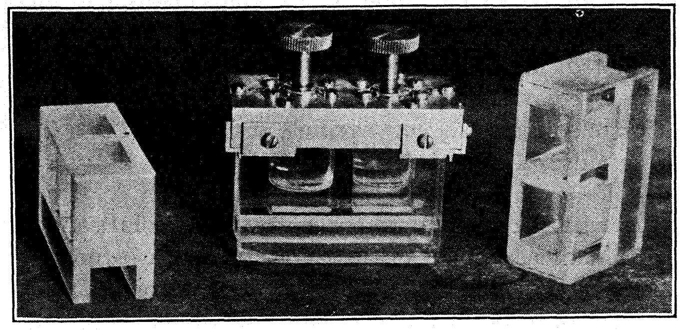

Fig. 1.

Preparation of Solutions and Method of Measurement.—All solutions were made up by weight, the most concentrated being made first and the others obtained by dilution of this with weighed amounts of solvent. The adsorption was carried out in long slender bottles with narrow necks tightly fitted with glass stoppers. The weight of carbon, m, was determined by weighing the flask before and after introduction of about a quarter of a gram of carbon. About 5 cc. of solution was then introduced and the increase in weight, N, determined. The adsorption bottles were then shaken for twenty hours and put in the air thermostat at 25°. The original solutions were also kept at this temperature for a few hours before making concentration determinations. A portion of the liquid was then removed from the carbon and compared with the original solution in the interferometer cell.

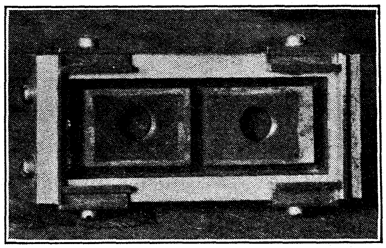

Fig. 2.

The solution of known concentration is always placed in the left-hand compartment of the cell. With this arrangement an interferometer reading greater than the zero reading indicates that the refractive index of the unknown solution is the greater. A calibration is required to determine the difference in concentration corresponding to this reading. This is made by comparing two solutions of known concentration which permits a calculation of the rate of change of concentration with instrument reading (dc/dR). It is highly desirable to compare the solution of unknown concentration with one of nearly the same concentration. If the concentration interval is too great, correction must be made for the change in appearance of the color fringes of the interference system. This phenomenon is fully discussed by Barth and Schaum.[5] A series of calibrations in the range between zero and one per cent. of α-bromonaphthalene in alcohol shows the sensitivity of the method. One division of the interferometer is equivalent to a difference in weight concentration of 0.0000205(dc/dR = 0.0000205). The concentration interval must be equivalent to less than fifty scale divisions; otherwise there may be some difficulty in matching the bands correctly. In many cases adsorption is so great that the equilibrium liquid has to be compared with a solution of known concentration which differs from it less than does the original solution.

Calculation of Data

The Freundlich adsorption equation has been found to apply to the adsorption of solutes when present in low concentration. The degree of adsorption from more concentrated solutions is lower than the equation would indicate. This equation states that the weight of solute removed per gram of adsorbent is proportional to a certain power of the equilibrium concentration of solute. Letting w represent the weight of solute adsorbed by m grams of adsorbent

$$w/m = a'c^n \tag{1}$$

where c represents the equilibrium concentration of solute and a' and n are constants. The measurement of the refractive index before and after adsorption gives directly the change in concentration of the solution rather than the weight of solute removed. For a small change in concentration of solute due to removal by adsorption, the change (Ac) is directly proportional both to the weight of solute removed (w) and to the concentration of solvent $(1 - c)$, whereas it is inversely proportional to the total amount of solution N. We have, therefore, the relationship

$$\Delta c = a''w(1 - c)/N \tag{2}$$

Solving for w and substituting in Equation 1 gives

$$N\Delta c/(1 - c)m = ac^n \tag{3}$$

or

$$N\Delta c/m = ac^n(l - c) \tag{4}$$

If we plot a curve from data obtained with the above equation, using $N\Delta c/m$ as one coördinate and c as the other, we find that the first portion of the curve is similar to the ordinary adsorption isotherm. The second term $(1 - c)$, however, soon becomes prominent and causes the curve to pass through a maximum and then decrease to zero when c becomes unity. In this extreme case there would, of course, be no change in concentration even though a maximum of solute were adsorbed. It is evident that the change in concentration at these higher concentrations must be measured very accurately to determine whether the Freundlich equation is applicable. The measurement of refractive index with the interferometer is sufficiently accurate for this purpose.

The adsorption was first expressed in terms of $N\Delta c/m$. In order to compare the adsorption of different substances on a common basis, it was thought desirable to substitute molar units for weight units. Letting x represent the molar concentration, M_1 the gram molecular weight of solute and M_2 the gram molecular weight of solvent, we have

$$x = \frac{1}{1 + M_1(1 - c)/M_2c}$$

Letting H represent the total number of millimoles in solution and Ax the change in molar fraction due to adsorption, it can be shown that

$$H\Delta x/m = (1000x/M_2c)(Nc/m)$$

Results

Some of the results obtained are given in the following tables.

TABLE I

Discussion

The foregoing tables and graph indicate that the adsorption by carbon of the three solutes, α-bromonaphthalene, benzene and ethyl carbonate from ethyl alcohol is in accordance with the Freundlich equation ($H\Delta x = ax^n(l - x)$) for the low concentrations investigated. The constants of the equations representing the adsorption of these substances from dilute alcoholic solution are given in the table below, together with the adhesion-tension[18] value of each against carbon.

Solute	a	n	Adhesion tension
a-Bromonaphthalene	12.1	0.42	89.2
Benzene	9.79	.53	81.1
Ethyl carbonate	4.9	.72	65.6"

[a] Unpublished data.

---

[18] Bartell and Osterhof, Z. *physik.* Chem., 130, 715 (1927); *Ind. Eng.* Chem., **19,** 1277 (1927).

The order of adsorption from dilute solutions is the same as that of the adhesion tension of the solutes investigated. The coefficient, a, of the Freundlich equation increases in the same order as the adhesion-tension values, while the exponents are in the inverse order. Each of these variations corresponds to an increase in adsorption with increase in adhesion tension. Adhesion tension (A_{12}) is defined as the difference between the surface tension (S_1) of the solid and the interfacial tension (S_{12}) existing at the solid–liquid boundary.

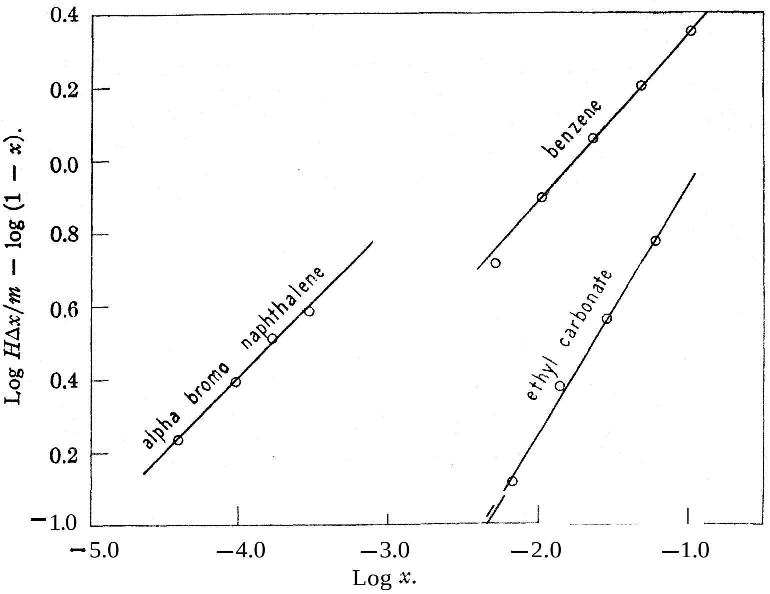

Fig. 3.—Adsorption by carbon from ethyl alcohol.

$$A_{12} = S_1 - S_{12}$$

The adhesion tension, then, is a measure of the decrease in free surface energy which occurs when the solid–liquid interface is substituted for the solid–air interface. It is a measure of the degree to which the solid is wetted by a liquid. The Gibbs principle indicates that greatest adsorption will occur from that system which will produce the greatest lowering of interfacial tension. It may accordingly be reasoned that a liquid which is highly adsorbed by a solid will give a low interfacial tension against that solid. Furthermore, a liquid which with a given solid has a low interfacial tension will in general show a high adhesion tension with it. It is to be expected, then, disregarding solubility effects, that a-bromonaphthalene will be adsorbed to a greater extent from ethyl alcohol than will either benzene or ethyl carbonate because there will be relatively a greater decrease in the free surface energy of the system when a-bromonaphthalene comes in contact with the carbon surface.

Summary

1. The use of the interferometer in measuring the change in concentration due to adsorption from non-aqueous solutions is discussed.

2. Data are given for the adsorption by carbon of α-bromonaphthalene, benzene and ethyl carbonate from dilute solutions in ethyl alcohol.

3. It is pointed out that the adsorption of these solutes by carbon tends to be in the same order as the adhesion-tension values of these same solutes (as pure liquids) against carbon. It is probable that this relationship would obtain in all cases were it not for the influence of other factors such, for example, as solubility of solute with solvent.

ADSORPTION BY PURE CARBON FROM NON-AQUEOUS BINARY SYSTEMS OVER THE ENTIRE CONCENTRATION RANGE[1]

BY F. E. BARTELL AND C. K. SLOAN[2]

RECEIVED DECEMBER 10, 1928 PUBLISHED JUNE 5, 1929

Since the accuracy in measurement of change in concentration by the interferometric method is practically independent of concentration, this method was used to study adsorption from non-aqueous systems over the entire concentration range. A series of dilute solutions of ethyl alcohol in benzene was prepared and adsorption by activated carbon measured (Table I) in the manner described in an earlier paper.[3]

TABLE I

ADSORPTION OF ETHYL ALCOHOL FROM BENZENE

First, consider the adsorption of benzene when present in relatively small concentration. When the values of log $H\Delta x/m$ are plotted against log x°,[4]

---

[1] The material presented in this paper is from a dissertation submitted by C. K. Sloan to the Graduate School of the University of Michigan, in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1928. This paper was presented at a meeting of the Colloid Division of the American Chemical Society at Swampscott, September, 1928.

[2] DuPont Fellow in Chemistry, 1927–1928.

[3] Bartell and Sloan, THIS JOURNAL, 51, 1637 (1929).

[4] The symbols used in this paper are the same as those used in an earlier paper: H = total number of millimoles in solution; x = molar concentration; Δx = change in molar concentration; m = weight of adsorbent; c_0 = initial concentration; c = final concentration; N = amount of solution; and a and n are constants.

a curve is obtained which is decidedly concave toward the concentration axis (Fig. 2). It has been shown that the Freundlich equation must be modified when the adsorption is measured in terms of change in concentration, the modified equation being, $H\Delta x/m = ax^{n}(1 - x)$.

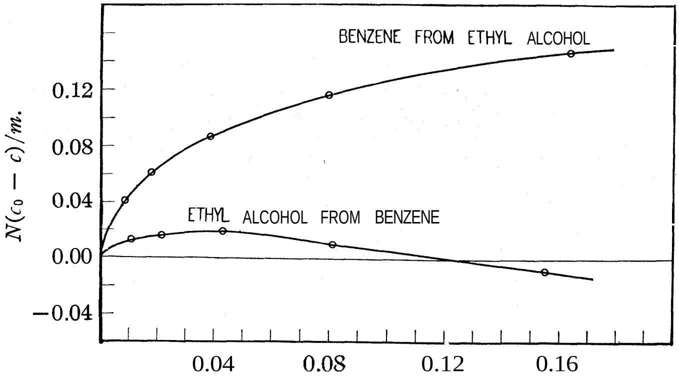

Fig. 1.—Benzene from ethyl alcohol.

The plot of the difference between log Hx/m and log $(1 - x)$ against log x should give a straight line if the adsorption of benzene follows the Freundlich equation and if no solvent is adsorbed simultaneously.

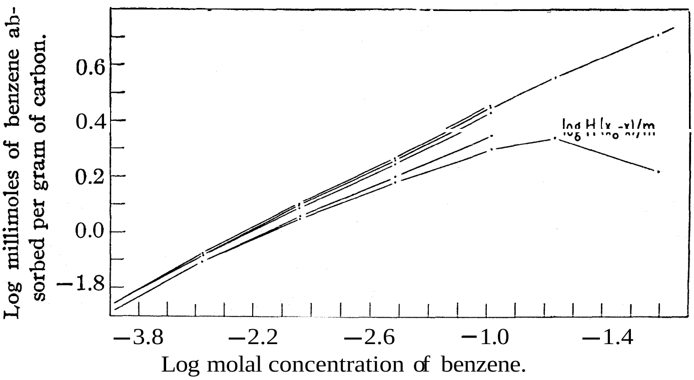

Fig. 2.—Benzene from ethyl alcohol by successive approximations.

A plot of log $H\Delta x/m$ − log $(1 - x)$ against log x gives almost a straight line, though there is still a tendency to concavity toward the concentration axis. This must be due either to a decrease in the adsorption of benzene caused by the presence of ethyl alcohol, or to the fact that simultaneous adsorption of ethyl alcohol and benzene results in a smaller change in concentration than would result if benzene alone were being removed from solution.

An insight into what occurs is obtained by considering the changes in concentration resulting when carbon is added to solutions containing small amounts of ethyl alcohol. The data show that there is an adsorption of ethyl alcohol in this range. This does not mean that benzene is not taken up by the carbon. The number of molecules of benzene adsorbed at the carbon–solution interface may still greatly exceed the number of ethyl alcohol molecules adsorbed, but the fact that a lowering of concentration of alcohol results in the bulk liquid means that a higher concentration of alcohol exists in the adsorbed layer than in the bulk liquid. This process must be classed as selective adsorption of ethyl alcohol, even though actually a greater number of benzene molecules is adsorbed. The plot of $H\Delta x/m$ against the concentration of alcohol $(1 - x)$ gives a curve similar to the curve for adsorption from very dilute solutions. The concavity of the log curve is more pronounced than that representing the adsorption of benzene from dilute solutions in ethyl alcohol. Thus, at about 0.2 mole fraction of ethyl alcohol ($x = 0.8$), carbon produces no change in the concentration of the solution (Fig. **3**). There probably is pronounced adsorption at this point, but the apparent adsorption of each component is zero because the concentration of the adsorbed layer is here the same as that of the bulk liquid.

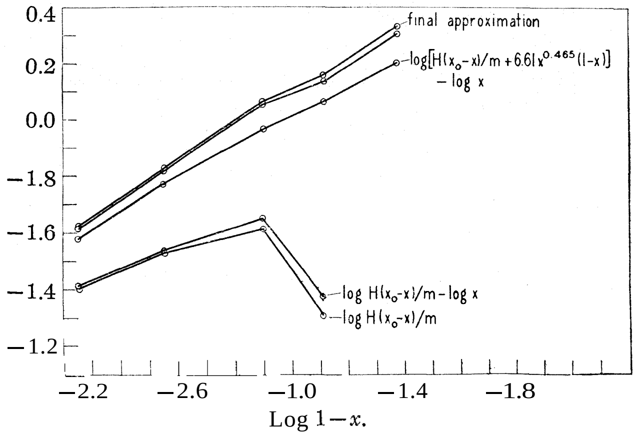

Fig. 3.—Ethyl alcohol from benzene by successive approximations.

Since the apparent adsorption of each component is in accordance with the Freundlich equation when that component is present in low concentration, it is reasonable to suppose that the Freundlich equation would be applicable for the adsorption of each component over a greater concentration range. The change in concentration due to adsorption of benzene can be represented by the following equation

$$H\Delta x_1/m = ax^n(1 - x)$$

Now let us represent the change in concentration due to adsorption of ethyl alcohol by a similar equation

$$H\Delta x_2/m = b(1 - x)^d x$$

The resultant change in concentration will be equal to the difference between these two terms. The decrease in mole fraction of benzene resulting from the simultaneous adsorption of both components is

$$H\Delta x/m = H(x_1 - x_2)/m = ax^n(1 - x) - b(1 - x)^d x$$

After this formula had been derived, it was found that such an equation had been used by Wo. Ostwald[5] to express the results of an experiment of Gustafson, who determined the adsorption from mixtures of acetic acid and phenol, concentrations being expressed in terms of weight rather than mole fraction.

Four points are necessary for the evaluation of the constants of this type of equation. The method of solution is one of successive approximations. Since the adsorption of benzene from dilute solution is governed largely by the first term of the equation, the first approximation for the constants a and n is made by plotting the difference between log $H\Delta x/m$ and log $(1 - x)$ as a function of log x. Since this plot approximates a straight line for small concentrations of benzene, two points are taken for calculation of the constants a and n, using the equation

$$\log H\Delta x/m - \log (1 - x) = \log a + n \log x$$

With this approximation the change in concentration due to adsorption can be represented by the equation

$$H\Delta x/m = 6.61x^{0.465}(1 - x)$$

This equation permits the calculation of the change in concentration due to benzene adsorption at those concentrations where ethyl alcohol is present in small amount. The measured adsorption of ethyl alcohol is then corrected by adding to it this calculated change in concentration due to benzene adsorption. The magnitude of the corrections is shown in Table II.

TABLE II

MAGNITUDE OF CORRECTIONS

EtOH concn.	$1 - x$	0.0180	0.0359	0.0806	0.1294	0.2370
App. ads. of alc.	$-(H\Delta x/m)$	.255	.337	.412	0.203	−0.164
Benzene, ads.	$6.61x^{0.465}(1-x)$	.118	.234	.451	0.802	1.382
EtOH ads., corr.	......	.373	.571	.863	1.005	1.218

These corrected values are now found to be represented fairly well by the Freundlich equation. The constants b and d of the term representing the adsorption of ethyl alcohol are obtained by plotting the difference between the logarithm of the corrected value of alcohol adsorption and log x against log $(1 - x)$. This plot is much nearer a straight line than the plot obtained with uncorrected values of $H\Delta x/m$ (see Fig. 3).

---

[5] Ostwald, *Kolloid-Z.*, **30**, 279 (1922); **32**, 57 (1923); **36**, 289 (1925).

The adsorption of alcohol from benzene can be represented, as a first approximation, by the equation

$$H\Delta x/m = 3.55(1 - x)^{0.550}x$$

This gives a measure of the adsorption of alcohol over all ranges of concentration. The original values for the adsorption of benzene from solutions containing small amounts of benzene can now be corrected. In this case the amount of correction is much smaller, but it does, however, tend to straighten the logarithm curve (see Fig. 2).

The difference in the successive values of the constants becomes so small after a few additional approximations that the accuracy of the experimentally determined values does not warrant further approximation. The successive series of approximations representing the change in concentration due to adsorption of each component is given in Table III. Four additional approximations result in very little change in the values of the four constants. The decrease in concentration of benzene due to adsorption from both dilute and concentrated solutions of benzene in ethyl alcohol, therefore, is obtained by combining the last two terms of the table into a single equation.

TABLE III

SUCCESSIVE SERIES OF APPROXIMATIONS

Adsorption of benzene, $ax^n(1 - x)$	Adsorption of ethyl alcohol, $b(1 - x)^dx$	Adsorption of benzene, $ax^n(1 - x)$	Adsorption of ethyl alcohol, $b(1 - x)^dx$
$6.61x^{0.465}(1-x)$	$3.55(1-x)^{0.55}x$	$8.83x^{0.514}(1-x)$	$5.69(1-x)^{0.648}x$
$8.24x^{0.508}(1-x)$	$4.89(1-x)^{0.615}x$	$9.39x^{0.526}(1-x)$	$6.31(1-x)^{0.668}x$
$8.72x^{0.512}(1-x)$	$5.19(1-x)^{0.627}x$	$9.76x^{0.532}(1-x)$	$6.26(1-x)^{0.662}x$

$$H\Delta x/m = 9.76x^{0.532}(1 - x) - 6.26(1 - x)^{0.662}x$$

The applicability of this equation to adsorption from moderately concentrated solutions is shown by comparison with data giving adsorption of benzene at three such concentrations.

TABLE IV

ADSORPTION OF BENZENE FROM ETHYL ALCOHOL

The curve representing adsorption over the entire concentration range has an S-shape (Fig. 5). Ethyl carbonate is preferentially adsorbed from solutions which are relatively dilute in ethyl carbonate; whereas ethyl alcohol is preferentially adsorbed from solutions which are relatively dilute

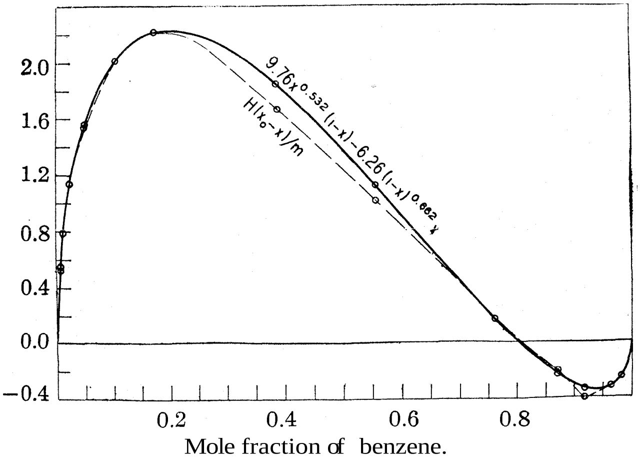

Fig. 4.—Benzene from ethyl alcohol.

in alcohol. The concave nature of the logarithm curve (see Fig. 6) shows how the change in concentration due to adsorption of ethyl carbonate is influenced by the simultaneous adsorption of solvent.

The accuracy in the determination of the change in concentration due to adsorption from this system is not so great as in the other systems investigated. This is due to the fact that there is very little difference between the refractive indices of the two components. This makes impossible an accurate calculation of the constants of the equation representing the adsorption from this system. The two parts of the S-curve are approximately the same. The exponent of the term representing the adsorption of ethyl carbonate is 0.7. The corresponding value for ethyl alcohol is 0.8.

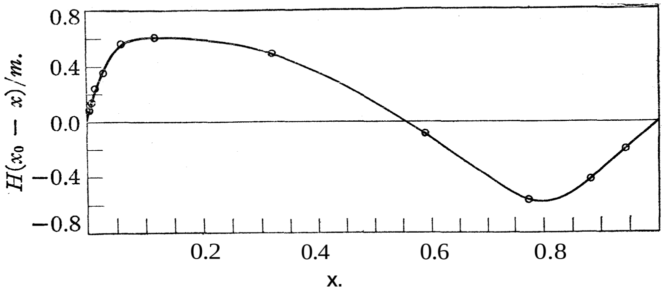

Fig. 5.—Ethyl carbonate from ethyl alcohol.

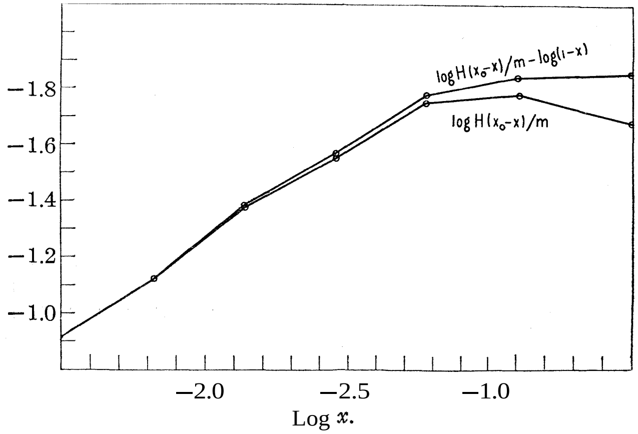

Fig. 6.—Ethyl carbonate from ethyl alcohol.

Adsorption from the System Benzene-Ethyl Carbonate.—The results of adsorption from this system are probably more striking than are those from other systems investigated. The adsorption of one of the components, benzene, conforms to the Freundlich equation up to a very high concentration of that component. This is shown by the fact that the plot

(Fig. 8) of the difference between the logarithms of $H\Delta x/m$ and x against $\log x$ is practically a straight line until x becomes 0.9. As the concentration of benzene is increased further, its adsorption is less than that indicated by the adsorption isotherm. At a molar concentration of 0.995, benzene is even slightly "negatively adsorbed." This statement does not mean that benzene is not adsorbed at this concentration. There is reason to believe that the adsorption of benzene is even greater at this concentration than it is when it is positively adsorbed at a lower concentration. The customary use of the term, negative adsorption, is an unfortunate one. A reader unacquainted with the accepted meaning of this term is led to believe that the other component (ethyl carbonate in this case) makes up the adsorbed layer exclusively. It would be better to speak of this as a preferential adsorption of ethyl carbonate rather than a negative adsorption of benzene. In this system the agreement of the experimentally determined points with the Freundlich equation indicates that the adsorption of ethyl carbonate is comparatively small. The straight portion of the logarithm curve permits

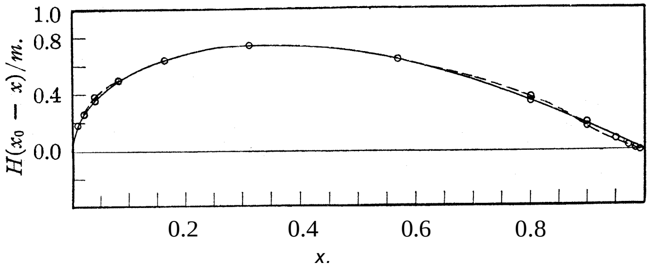

Fig. 7.—Benzene from ethyl carbonate.

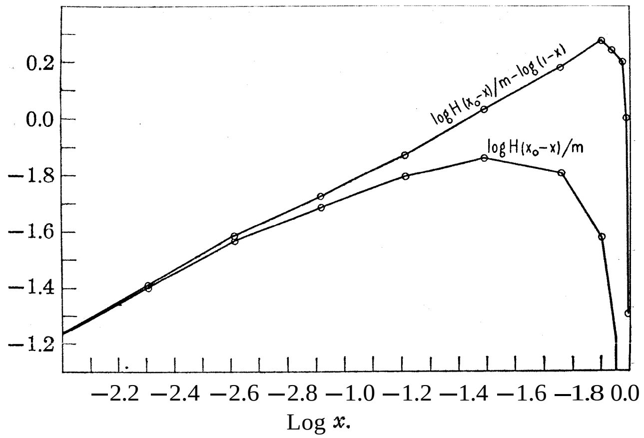

Fig. 8.—Benzene from ethyl carbonate.

a calculation of the constants of the equation representing the adsorption of benzene.

$$H\Delta x/m = 2.01x^{0.535}(1 - x)$$

The agreement between the values calculated using this equation and those experimentally determined is shown in Table VII.

having the higher adhesion tension will be the one which will be adsorbed to the greater extent. No one component of a binary system, however, is preferentially adsorbed over the entire concentration range. From each of the systems investigated, the substance of lower adhesion tension is adsorbed if it be present in sufficiently low concentration in solution. This gives rise to the so-called S-shaped adsorption curve. This is in agree-

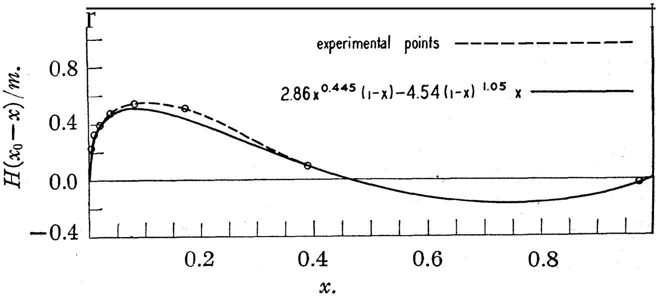

Fig. 9.—α-Bromonaphthalene from benzene.

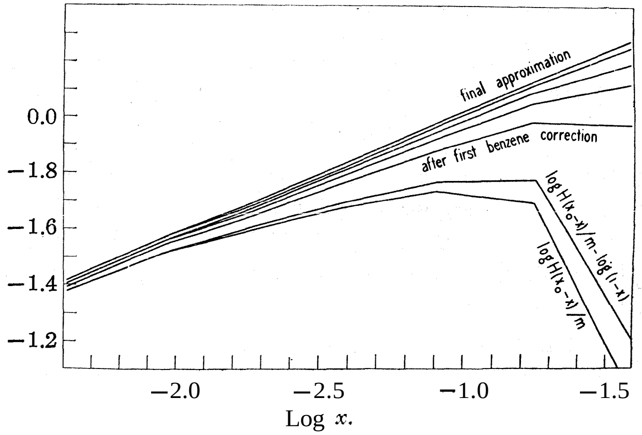

Fig. 10.—Adsorption of α-bromonaphthalene from benzene by successive approximations.

ment with the work of Williams,[6] who considered it justifiable to assume a minimum in the solid–liquid interfacial tension–concentration curve. Williams contended that the results obtained by Dora Schmidt-Walter[7] and Gustafson[8] indicating negative adsorption could be explained on the basis of the Gibbs adsorption equation[3] by considering that the addition of either component to the other which is in contact with a carbon surface will result in a lowering of the interfacial tension at the carbon–liquid interface. Although there is no method for a direct measurement of these interfacial values, the existence of such minimum points is not improbable. It has been shown that, for most binary systems, the surface tension-concentration curve does have a minimum point.[10] If the Gibbs adsorption formulation holds, the results of the experiments herein described point to a more pronounced minimum point in the interfacial tensions between a solution and carbon than between a solution and air. If the method of

[8] Gustafson, *Z. physik.* Chem., *91*, 385 (1916).

[9] Reference is here made to the rather generally used adsorption equation, $u = -(c/RT) \times dS/dc$, which has been developed from the thermodynamic rule of Gibbs relating change of concentration in the boundary layer and surface tension or interfacial tension. For lack of a better designation, this will be referred to as the Gibbs equation.

[10] Freundlich, "Colloid and Capillary Chemistry," p. 53.

Bartell and Osterhof[11] can be extended so as to measure the adhesion tension value of a binary liquid mixture against a solid, it is believed that a rigorous test can be made of the Gibbs formulation. Adhesion tension is defined by the following equation, $A_{12} = S_1 - S_{12}$. It follows that the sum of the value of the adhesion tension A_{12} and interfacial tension of a liquid against the same solid, S_{12}, must be equal to the surface tension of that solid S_1 (this latter value being constant). A change in the value of the interfacial tension with concentration at the solid–liquid interface is equal and opposite in sign to the corresponding change in adhesion tension.

$$\mathrm{d}A_{12}/\mathrm{d}c = -\mathrm{d}S_{12}/\mathrm{d}c$$

The Gibbs equation, $u = (-c/RT) \times dS_{12}/\mathrm{d}c$, then becomes

$$u = +\frac{c}{RT} \times \frac{\mathrm{d}A_{12}}{\mathrm{d}c}$$

Corresponding values of $\mathrm{d}A_{12}/\mathrm{d}c$ (adhesion measurements of solutions) and of u (interferometric measurement of change in concentration due to adsorption) should afford a test of the Gibbs formulation. Such a test has been lacking heretofore because no reliable data could be obtained for the values of both u and $\mathrm{d}S_{12}/\mathrm{d}c$ at a single interface. This correlation should establish the importance of certain factors which are disregarded by the usual formulation of the Gibbs principle. These factors include: the change of thermodynamic potential due to adsorption of solvent as well as that of solute, electrical properties of the boundary layer and the deviation of the osmotic pressure from the ideal state.

Determination of Total Adsorption.—Williams[6] realized that the measurement of the change in concentration gives only the apparent adsorption. He attempted, therefore, to obtain a second independent equation for the adsorption of each component by measuring the amount of each which is adsorbed by carbon from the vapor phase. The attainment of equilibrium in this latter procedure is not easy, as is shown by the recent work of Tryhorn and Wyatt[12] and Gustafson.[8]

Bakr and King,[13] working with a benzene-iodine-carbon system, and Bakr and McBain,[14] working with toluene and acetic acid, appear to have been successful in obtaining adsorption data for both solute and solvent for systems in equilibrium.

The fact that the change in concentration can be expressed quite accurately by a combination of two adsorption isotherms makes possible a calculation of the absolute adsorption of each component. If the equation $H\,\Delta x/m = ax^n(1-x) - b(1-x)^d x$ holds over the entire concentration

---

[14] Bakr and McBain, THIS JOURNAL, 46, 2718 (1924).

range, ax^n and $b(1-x)^d$ are the respective weights of the solute and solvent adsorbed; a is the weight of solute adsorbed from pure solute. The fact that the value of a for a given solute does vary somewhat for the given solute means that the solute adsorption may be cut down to some extent by the presence of solvent. The results of Gustafson and of Bakr and McBain also indicate this. As the concentration of solute becomes large, the term $(1-x)$ decreases and the change in concentration due to solute adsorption becomes small. Even though the value of a is lower than the weight taken up from pure solute, it may still be used to represent the adsorption from the more dilute solutions.

In this investigation adsorption is expressed in terms of $H\Delta x/m$. In order to express the apparent adsorption more accurately, the change in concentration should be multiplied by the number of millimoles of solution after adsorption rather than the number before (H). Measurements indicate that as much as 5% of the solution may be adsorbed. The change in the value of H may therefore be quite appreciable unless relatively constant amounts of carbon and solution are used. A series of adsorption curves could be obtained over a limited range of concentration (about 50%) by using different amounts of carbon. If, for a given value of x, the value of $H\Delta x/m$ varies with the amount of carbon added, it will permit a calculation of the change in the value of H. This change represents the true total molecular adsorption.

Adsorption by Silica.—The measurements of Bartell and Osterhof[11] indicate that the order of the adhesion tension of different liquids against silica is opposite to the order against carbon. Thus benzene has a high adhesion tension against carbon, whereas the corresponding value against silica is low. On the other hand, the adhesion tension of ethyl carbonate is relatively low against carbon and high against silica. Since the adsorption from a binary system by carbon has been found to be dependent on the adhesion tension of the components against carbon, it is reasonable to expect that the adsorption by silica would be dependent on the corresponding adhesion tension values against silica. Thus, ethyl carbonate should be adsorbed by silica to a greater extent than benzene from solutions containing these two substances, inasmuch as the adhesion tension of the ethyl carbonate against silica is greater than that of benzene. This has been found to be the case. The results of measurements of adsorption by silica from this and other systems will be reported in a future paper. In each of the systems investigated the adsorption curve is S-shaped and the carbon and silica curves are quite opposite in nature.

Summary

The interferometric method is used to measure the adsorption by carbon from a number of binary non-aqueous systems over the entire concentration

range. In each case the adsorption curve is S-shaped. The component having the higher adhesion tension against carbon is the one which is adsorbed to the greater extent. When the component of lower adhesion tension is present in very low concentration it is, however, preferentially adsorbed.

An equation

$$H\,\Delta x/m = ax^n(1 - \mathrm{X}) - b(1 - x)^d x$$

is used to represent the preferential adsorption over the entire concentration range. The derivation of this equation is made on the assumption that the adsorption of each component follows the Freundlich equation.

It is pointed out that the adsorption at a given interface must depend on the rate of change of that particular interfacial tension with the concentration of the bounding phases. The importance of the measurement of adhesion tension values of solutions is pointed out since the rate of change of adhesion tension is equal and opposite in sign to the rate of change of interfacial tension with concentration.

The Gibbs principle is restated in terms of adhesion tension rather than interfacial tension. *"There will be an excess in the concentration of the solute in the interfacial layer if the rate of change of the adhesion tension of the solution against the adsorbent is positive."* It is pointed out that the usual formulation of the principle of Gibbs does not take into consideration a number of existing factors. It is felt that a correlation of the data from adsorption and adhesion tension measurements will permit a more complete formulation of this principle.

A MODIFICATION OF THE MOVING BOUNDARY METHOD FOR THE DETERMINATION OF TRANSFERENCE NUMBERS

BY H. P. CADY AND L. G. LONGSWORTH

RECEIVED JANUARY 4, 1929 PUBLISHED JUNE 5, 1929

Introduction

An adaptation of the method of moving boundaries for the determination of transference numbers, involving two differences from recent procedure, has been developed and studied by the authors. The novel features are, first, a single ascending boundary only is observed and, second, a metal anode soluble under the action of the electric current is the source of indicator ions. For example, metallic silver was electrolyzed into a solution of potassium nitrate. Under the conditions of the experiment, this silver furnishes silver nitrate which serves as the indicating electrolyte for the potassium ion constituent of potassium nitrate. The necessity of previous adjustment of the concentration of the indicator electrolyte is thus avoided and no special mechanism is required in the initial formation of the boundary. It was the object of this research to determine the effect of the various factors involved on the stability and velocity of the boundary thus produced.

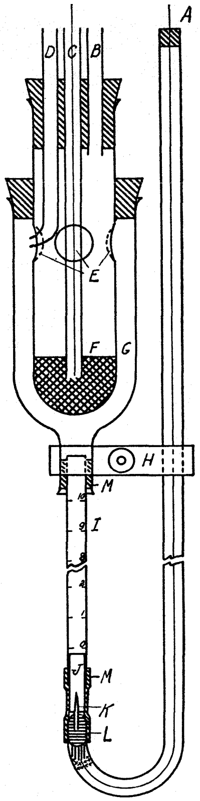

Fig. 1.—Moving boundary cell. *A*, Anode lead; B, vent tube; *C*, cathode lead; D, tube for filling cell; E, holes in cathode tube; F, cathode, lead dipping in paste of PbO_2 and H_3BO_3; G, cathode chamber; *H*, clamp; **I**, graduated tube in which boundary ascends; *J*, cylindrical metal anode; *K*, platinum tip sealed in tube leading anode connection out of thermostat; L, mercury globule making contact with platinum tip and anode held in place by de Khotinsky cement; ***M***, rubber connections.

Apparatus and Method

(a) The Cell.—The apparatus used is shown in Fig. 1. The cylindrical metal anode, J, is machined to fit the graduated and calibrated tube, I, in which the boundary is developed and moves. This anode fits the tube rather snugly and is wedged onto the platinum tip sealed into the glass tube leading the anode connection out of the thermostat. The general design of the cathode chamber is as described by MacInnes and Brighton,[1] and is arranged to have the cathode at some distance from the calibrated tube in which the boundary ascends. The cathode is designed so as to avoid influences which might disturb the progress of the boundary in the graduated tube.[2]

The assembled cell is then mounted in a thermostat furnished with parallel plate glass sides and equipped with the optical system whose profile is shown in Fig. 2. The microscope, F, contains a scale in the eyepiece and is of such depth of focus as to have the tube in which the boundary moves within its focal range.[3] The frosted glass background, H, was illuminated from behind and the narrow black screen, I, on this background, together

---

[1] MacInnes and Brighton, This journal, 47, 994 (1925).

[2] A cylinder of fused silver chloride with a helix of silver wire as core was used with equal success.

[3] In order to locate the boundary with respect to the graduations on the tube, the virtual image, K, of the dark-light margin, I, must be near enough to the graduated tube so that it also comes within the focal depth of the microscope. This may be accomplished by moving the screen and background, H, I, in closer to the moving boundary cell or by working with higher concentrations in the moving boundary cell. The first expedient, however, reduces the sensitivity of this means of detecting the boundary, and the second necessitates the use of solutions of such concentrations as are almost outside the range of the method as developed thus far. With certain solutions of the alkali acetates in anhydrous acetic acid as solvent, it has been found possible to use a microscope in this manner and to a very marked advantage, but for most of the work in water where the concentrations varied from 0.2 to 0.02 *N* it was found necessary to dispense with the microscope and this was replaced by a tube with rectangular openings at either end—merely to insure uniform line of sight in locating the boundary.

with the microscope carriage, E, were arranged on threaded rods, D, provided with bevel pinions, B, so that the two could be raised or lowered together.

The source of potential for these experiments has been four hundred volts of storage "B" batteries. The current in the circuit was maintained constant throughout any given experiment by hand regulation of a rheostat in series with the moving boundary cell and the source of potential. The value and constancy of this current was ascertained by means of a potentiometric determination of the potential drop across a standard resistance inserted in the circuit.

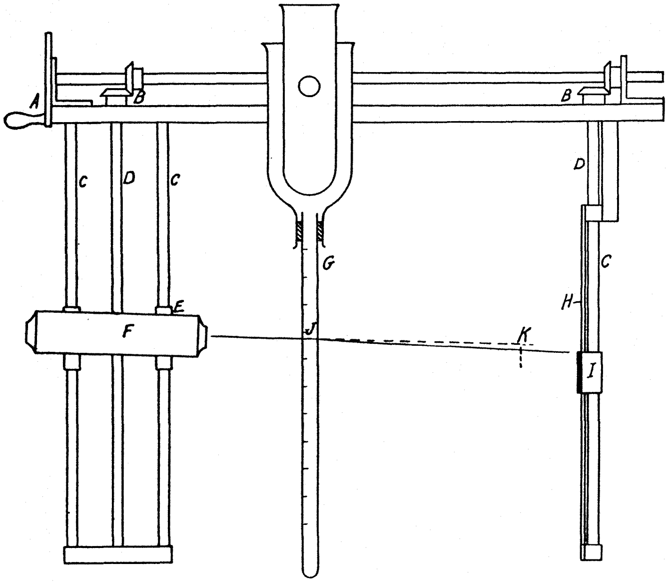

Fig. 2.—Profile of optical system. *A*, Crank; B, bevel pinions; *C*, guide rods; D, threaded rods; E, microscopic carriage; *F*, microscope; G, moving boundary cell and tube; *H*, ground glass background—illuminated from behind; *I*, movable opaque screen; *J*, position of margin; K, refraction (?) image of upper edge of I.

The tube was graduated as described by MacInnes, Cowperthwaite and Huang,[4] and is calibrated for total volume between the first and last marks only[5] by means of mercury and a dividing engine. The boundary is caused to sweep through the entire volume between these marks and the intermediate marks were used to ascertain the constancy of the boundary velocity under a constant potential gradient. Such constancy is one criterion of a properly functioning boundary.

(b) Location and **Visibility** of **the** Boundary.—The boundary we are dealing with in this research is the liquid junction between the solution of electrolyte originally placed in the cell and the ever-increasing column of heavier electrolyte having a common anion and an unlike cation formed from the metal anode. The characteristics which this in-

---

[5] The uniformity of bore was not determined directly but the boundary velocities indicated that all of the tubes employed, save one, were sufficiently uniform.

dicator cation must have are described in detail by Franklin and Cady[6] in their article on ion velocities in liquid ammonia.

A necessary condition for a visible boundary is a difference in refractive indices of the two solutions of electrolytes meeting at the boundary. Due to this difference of refractive index the upper edge of the movable opaque screen on the illuminated background (see Fig. 2) will appear distorted when in line with the boundary; this distortion serves as a means of locating the boundary. However, the visibility of a boundary seems to depend also on a sharpening[7] produced by the sudden change of the potential gradient at the boundary as well as on the difference in the refractive indices. Thus cadmium nitrate as indicator electrolyte formed by electrolysis of metallic cadmium into 0.1 N potassium nitrate gave more distinct boundaries than did either lead or silver nitrate—due to its relatively high specific resistance, though the difference in refractive index at the boundary would favor the other indicator electrolytes.

Consideration of Factors Affecting the Results

The expression, $T_c = (LCFA)/(1000IT)$, correlating the quantities determined in a single boundary experiment with the transference number of the given ion constituent has been derived by a number of investigators. In this expression the symbols have the following significance. The boundary travels L centimeters in T seconds in a tube whose (uniform) average cross-sectional area is A square centimeters. I is the current in amperes flowing in the tube. C is the number of equivalents per liter of solution of electrolyte originally placed in the tube and F is the Faraday in coulombs. The ratio L/T thus corresponds to the boundary velocity when the current, and hence the potential gradient, is maintained constant. The various quantities measured and the factors influencing the motion of the boundary are discussed in the following.

(a) The Concentration Range Studied.-Sharp and easily visible boundaries were obtained with potassium nitrate at 0.02, 0.1, 0.2 and 1.0 N with either lead or silver as indicator ion at the three lower concentrations and silver only at the higher concentration. In the 1.0 N solution the formation of ions at the silver anode could not be made to proceed smoothly for any great period of time and oxygen evolution would usually destroy the boundary after it had risen two or three centimeters from the face of the electrode. Also, convection currents in the indicator solution at this concentration are marked and their disturbing effect on the boundary velocity probably renders concentrations of this magnitude outside the range of the method in its present state of development—at least, in tubes of the size employed.

(b) Tube Area.—Boundaries with 0.1 N potassium nitrate were run in four sizes of tubes, their average cross-sectional areas being 0.1934, 0.1102, 0.06702 and 0.03909 sq. cm., respectively. Both silver and lead anodes were used as sources of indicator ions and a variety of potential gradients employed. In the two larger tubes the measured values of the transference numbers were found to be independent of the tube area whereas in the two smaller tubes these values decreased with the size of the tube—the measured transference number in the smallest tube being about 0.8% lower than the values obtained in the two largest tubes.

These results are recorded in Table I.

y

TABLE I

EFFECT OF TUBE AREA

Measured transference number of the potassium-ion constituent of 0.1 N potassium nitrate at 25°.

Anode	Ag	Pb	Pb	Ag	Pb	Ag
Tube area	0.1934	0.1934	0.1102	0.06702	0.03909	0.03909
Poten. grad., v./cm.	8.615	12.92	Table II	12.34	12.69	10.57
T_c	0.5122	0.5123	0.5121	0.5096	0.5089	0.5076

The possibility of electro-endosmotic forces affecting the boundaries in small-bore tubes has been suggested by Dr. D. A. MacInnes.

(c) Potential Gradient.—The simple theory requires the measured transference number to be independent of the potential gradient. This was tested by making several series of runs over a considerable range of potential gradients. The results of one such set of determinations are recorded in Table II.

TABLE II

EFFECT OF POTENTIAL GRADIENT

Measured transference number of the potassium-ion constituent of 0.1 N potassium nitrate at 25° with a lead anode as the source of indicator ions.

Tube area, sq. cm.	0.1102	0.1102	0.1102	0.1104	0.1102	0.1102	0.1102
Poten. grad., v./cm.	3.781	7.562	11.34	11.34	15.12	18.91	22.69
T_c	0.5119	0.5121	0.5120	0.5122	0.5151	0.5165	0.5228

All values for the transference numbers have been corrected for the volume changes at the electrodes as described by Lewis.[8] The constant value obtained at low potential gradients (T_c = 0.5120) is in good agreement with that of MacInnes, Cowperthwaite and Blanchard[9] (T_c = 0.5122) obtained from observations on descending boundaries.

Table II serves to illustrate a rather significant feature of the method, namely, the range of potential gradient over which the transference number is independent of that gradient. The range over which the measured transference number is independent of the potential gradient is greater the smaller the cross-sectional area of the tube.

(d) Metals Used as Indicators.—Cadmium, used as a source of indicator ions for the potassium ion constituent of potassium nitrate, did not electrolyze smoothly and values obtained by its use are somewhat inconsistent and persistently low, due probably to secondary electrode reactions producing faster ions that forged ahead of the ions under observation, thus slowing up the boundary. Cadmium, however, electrolyzed very smoothly in halide solutions and gave consistent values for the transference number of the potassium ion constituent of potassium chloride and bromide, respectively. The values obtained, while differing but slightly from the accepted values, will not be quoted here. They probably do not

---

[9] MacInnes, Cowperthwaite and Blanchard, *ibid.*, 48, 1909 (1926).

represent the accuracy of which the method is capable since two refinements, automatic current control and elimination of vibration, were not made in the prosecution of this research.

The value of the measured transference number quoted in Table II is that obtained from the time required for the boundary to travel the full ten centimeters. At high potential gradients, however, time readings per centimeter showed that the boundary was being accelerated, even when acted upon by a constant potential gradient. The initial velocity obtained by graphical methods gave a value of T_c much nearer the constant value obtained at low potential gradients. The lower limit of potential gradient seems to be determined by the sensitivity of the optical system employed and by the sharpening effect of the potential gradient change at the boundary. On the other hand, the upper limit is controlled almost entirely by the convection currents in the indicator solution due to the larger quantity of heat developed in this portion of the tube. It should be noted that long before convection currents become sufficiently vigorous to destroy the boundary entirely, it has become quite convex and its velocity is no longer an indication of the true velocity of the preceding ion constituent.

Automatic Concentration Adjustment

According to Kohlrausch[10] the concentration of the indicator ion will be automatically adjusted to the relation, $C/C' = T_c/T'_c$, where C and T_c are the concentration and cation transference numbers of the solution under observation and the primed symbols the corresponding quantities for the indicator solution.

Two methods of attack have been employed in ascertaining to what extent this concentration adjustment was automatically made. The first depends on the fact that the total resistance of the cell increases as the boundary ascends the tube, since the indicator ions have lower mobilities than the ions they are replacing. The rheostat resistance in the circuit must, therefore, be continually decreased in order to maintain the current constant. The rate of this decrease is a direct indication—except for the effect of the diffusion layer at the electrode—of the velocity of the indicator ion constituent and hence, indirectly, its transference number. If we take the anode as the origin, the length of the tube as L, and the position of the boundary as x, the total resistance of the tube is

$$R = \frac{L - x}{KA} + \frac{x}{K'A}$$

The dimensions of the cathode chamber permit the resistance of this portion to be neglected. The variation of the total resistance with the position of the boundary is

$$\frac{dR}{dx} = \frac{1}{K'A} - \frac{1}{KA}$$

---

[10] **Kohlrausch,** *Ann. Physik,* **62,209** (1897).

from which

$$K' = \frac{K}{1 + KA\dfrac{dR}{dx}}$$

where K is the specific conductance of the solution under observation and K' the corresponding quantity for the indicator solution. *A* is the cross-sectional area of the tube. Hence if we know K' as a function of C', we can determine C'. The values of C' were read directly from a plot of K' against C' and the error involved in this procedure may be rather large since conductance data on some of the electrolytes under consideration at 25° are not very concordant. The effects of the formation of a diffusion layer, to be discussed, and of convection, are both to reduce the measured value of dR/dx. We therefore use the highest value obtained in any given series of runs, this maximum occurring at fairly low potential gradients. According to the equation, C/C' should equal T_c/T'_c. By means of the values of C' obtained as just described, we can determine with the aid of the transference numbers in the literature whether adjustment to the conditions predicted by Kohlrausch has been made. These computations are made in Table III.

TABLE III

CONCENTRATION ADJUSTMENT

Solution	Indicator	C	C′	T_c	T_c	C/C'	T_c/T'_c
KNO_3	Pb	0.0997	0.0961	0.512	0.487	1.04	1.05
KNO_3	Ag	.0997	.0932	.512	.468	1.07	1.09
KCl	Cd	.1000	.0891	.492	.431	1.12	1.14
KBr	Cd	.1008	.0925	.485	.432	1.09	1.12

The ratios, C/C' and T_c/T'_c, given in the last two columns should be the same for each salt measured. The fact that they are nearly so indicates that automatic "adjustment" is attained by the method described in this article. The ratio C/C' is, however, consistently slightly lower than T_c/T'_c. This may arise from the fact that there is a diffusion layer next to the electrode which has the effect of making the concentration appear too high.

The second method consisted in directly measuring the conductance between two platinized platinum tips sealed in the side of the tube. Such measurements were made before and after the boundary had moved by them. The concentration, C', was then interpolated from existing con-

TABLE IV

CONCENTRATION ADJUSTMENT

Solution	Indicator	C	C′	T_c	T'_c	C/C'	T_c/T'_c
KNO_3	Pb	0.1004	0.0932	0.512	0.487	1.07	1.05
KNO_3	Ag	.1004	.0909	.512	.468	1.10	1.09
KCl	Cd	1000	.0873	.492	.431	1.14	1.14
KBr	Cd	.1008	.0912	.485	.432	1.10	1.12

ductance data as has been described in the previous paragraph, and used to test whether "adjustment" had been attained. The results of our measurements by this method are recorded in Table IV.

The values of T_c and T'_c employed in Tables III and IV are those of MacInnes and co-workers where available; otherwise they are taken from the compilation of Noyes and Falk. In all cases they are values at the nearest concentration and temperature to those of the experiment which are available.

This method, which is more nearly independent of errors due to the diffusion layer just mentioned, shows even better concordance between the ratios C/C' and T_c/T'_c.

The Diffusion Layer

For each Faraday of electricity passed through the cell, one gram equivalent of metallic ion is formed at the anode by the electrochemical reaction there. However, only T'_c equivalents are carried away from the electrode by electrolytic migration. Thus $(1 - T'_c)$ equivalents of indicator electrolyte is left in the neighborhood of the electrode. Hence, there is a diffusion layer of indicator electrolyte, of higher concentration than the adjusted value, C', formed at the anode. Our observations and computations[11] from existing theory both show that under the conditions of the experiment pure diffusion will at no time alter the adjusted concentration of the indicator solution immediately behind the boundary. If, however, the convection currents developed in the column of indicator electrolyte penetrate and disturb this diffusion layer, this excess electrolyte will be partially distributed throughout the region of the indicator column. If we can utilize the experience of Smith and MacInnes,[12] which tends to show that an indicator electrolyte concentration greater than C' causes the boundary to move too rapidly, this would explain the high values shown by T_c in Table II at high potential gradients.

In conclusion a word should be said as to the range of the method. With lead and silver as sources of indicator ions the electrolytes to be observed would be restricted to those whose anions give soluble salts with these two metals—which greatly restricts the field—but with cadmium as a source of indicator ions the halides and several other anions are possible but the cations must not be too heavy. Metallic thallium has been made to serve as indicator ion for one of the faster cations in some work in anhydrous acetic acid as solvent. Amalgam electrodes and electrodes of the second class, that is, reversible with respect to the anion, have been investigated to a certain extent and their use would still further extend the range of the method.

The authors wish to express their appreciation to Dr. D. A. MacInnes for many helpful suggestions and constructive criticisms in the preparation of this manuscript.

Summary

1. A modification of the moving boundary method for determining transference numbers, in which rising boundaries are used, has been studied. In this new method the boundary starts at the surface of the metal electrode, which furnishes the "indicator" ions by electrochemical solution of the metal.

2. When applicable the new method furnishes a simpler means of obtaining boundaries than has been so far proposed. The method also avoids the necessity of making measurements with indicator solutions of varying concentration, since it has been shown experimentally that there is, with this method, automatic adjustment to the condition, $C/C' = T_c/T'_c$. (C and C', and T_c and T'_c, are, respectively, the normality and cation transference number of the leading and indicator solution.)

A GRAVIMETRIC AND COLORIMETRIC METHOD FOR THE DIRECT DETERMINATION OF SODIUM

BY EARLE R. CALEY WITH C. W. FOULK

RECEIVED JANUARY 5, 1929 PUBLISHED JUNE 5, 1929

It is a curious and interesting fact that no satisfactory method for the direct determination of sodium had ever been produced before the recent appearance of the paper by Barber and Kolthoff,[1] and it is also interesting to note that the present independent experimental study of the same subject had just been completed when the above paper was published. Barber and Kolthoff precipitated the sodium with zinc uranyl acetate. The method described here is analogous but uses magnesium uranyl acetate.[2] The sodium is thrown down as magnesium sodium uranyl acetate, $NaC_2H_3O_2 \cdot Mg(C_2H_3O_2)_2 \cdot 3UO_2 \cdot (C_2H_3O_2)_2 \cdot 6^1/_2H_2O$, which can then either be dried and weighed or, if small in amount, dissolved in water and measured colorimetrically.

This method, which was first suggested by Streng[3] for the qualitative detection of sodium, was also studied by Miholic[4] and Blanchetière[5] and

later by Barber and Kolthoff, who rejected it partly because of the poor results obtained by other investigators (see paper of Barber and Kolthoff for references) and partly because of their own failure to obtain by its means a precipitate that was stable on prolonged drying. Our own preliminary experiments amply bore out the experience of the previous workers, but fortunately they also suggested the reasons why these early investigators failed to get the desired results. These causes of failure will be given in detail below but they can be summed up here by the general statement that it happened to be a method which required closer attention than is usually given to such details as temperature, stirring and concentration of precipitant. The early investigators failed to consider these points and consequently rarely obtained quantitative results.

A comparison of the Barber and Kolthoff method with the one offered here shows the former to be the more precise if limited to the precipitation of small amounts of sodium (0.008 g. or less) and the latter to be superior in handling larger amounts, up to 0.050 g.

Preparation of the Magnesium Uranyl Acetate.—The following was found to be the most satisfactory method of preparing the reagent.

SOLUTION A		SOLUTION B	
Crystallized uranyl acetate	85 g.	Crystallized magnesium acetate	500 g.
Glacial acetic acid	60 g.	Glacial acetic acid	60 g.
Distilled water	to 1000 cc.	Distilled water	to 1000 cc.

Each solution is separately heated to about 70° until all the salts are dissolved and then the two solutions are mixed at this temperature and allowed to cool to 20°. The large vessel containing the mixed reagent is next placed in water at 20°, and held at this temperature for an hour or two until the slight excess of salts is crystallized out. The reagent is finally filtered through a dry filter into a dry bottle. The solution thus prepared apparently suffers no alteration upon standing and is permanent for all practical purposes when kept away from direct sunlight. A separate portion of some of the first lot of reagent kept in a clear glass bottle exposed to diffused daylight for eight months showed no change in activity or appearance at the end of this time.

General Gravimetric Procedure

The neutral solution containing the sodium, preferably as the chloride, should be reduced to a volume of 5 cc. or less, if there is no separation of salts. A volume of reagent corresponding to the probable sodium content of the solution is then rapidly added and the two solutions are mixed. The flask containing the mixed solution is next partly immersed in a water-bath maintained at 20° and the solution vigorously stirred for thirty to forty-five minutes. The precipitate is then immediately filtered into a Gooch crucible using gentle suction, and after all of the solution has run through the precipitate is washed with successive 5-cc. portions of 95% alcohol. The crucible with its precipitate is finally dried in an air oven at 105 to 110° for thirty minutes and weighed.

The weight of the precipitate, plus one milligram for each 5 cc. of alcohol used in washing, times 0.0153, gives the sodium content of the original solution.

By reason of the large volume and weight of the precipitate formed, 25 mg. of sodium is the maximum amount that should be present, although with care 50 mg. may be determined. In case the amount of sodium present is very small (1 mg. or less) the volume of the solution should be 1 or 2 cc.; otherwise a volume of 5 cc. is used.

Not less than 100 cc. of reagent should be used when the probable amount of sodium is 10 mg. or less. For larger amounts the number of cubic centimeters of reagent should be ten times the number of milligrams of sodium present. An excess of reagent in any case does no harm. It is sometimes necessary to filter the reagent before use if the original filtration was not entirely effective.

A thermostatic control is unnecessary for regulating the temperature at 20°, since a variation of a degree either way does no harm. Indeed, it is only necessary to fill a large vessel with water brought to 19 or 20° and then pay no further attention to temperature control. There is no advantage in working at a lower temperature. The stirring or shaking should be vigorous, since gentle agitation leads to incomplete precipitation.

During filtration the solution should be stirred continually to prevent the crystalline precipitate from adhering to the sides of the flask. The alcohol is preferably delivered from a graduated wash bottle having a fine tip. The first portions should be used to remove the adhering precipitate from the sides of the flask with the aid of a rubber-tipped rod. The end of the washing process is indicated by the wash liquid going through colorless. Ordinarily 20 to 30 cc. of the alcohol is required. A phenomenon that attends the washing of these precipitates should be mentioned because of its deceptive appearance. There frequently appears in the filtrate a precipitate closely resembling that of the triple acetate, which makes it look as though the latter were running through the filter. This precipitation is due to salts thrown out of the concentrated solution by the alcohol.

It is preferable to dry the precipitate at 105° and in no case should the temperature be allowed to rise above 110°, since decomposition begins at a slightly higher temperature.

By reason of the small factor and the slight uncertainty involved in the washing correction, there is no advantage in weighing the precipitate closer than the third decimal place. The use of a washing correction may be eliminated by washing with 95% alcohol saturated with the triple acetate.

Experimental Basis of the Procedure

Causes of the Failure of Previous Investigators.—Preliminary experiments showed that variations of a few degrees in the temperature of the solution had such an effect on the solubility of the precipitate that concordant results could not be obtained without at least a rough temperature control, and, secondly, that above 20° the sodium was not completely precipitated. Since 20° is about the average temperature of a laboratory, low results would be obtained on warm days. The early investigators, evidently unaware of these points, did not control the temperature of their experiments and consequently obtained discordant results, which, as a rule, were too low.

Composition and Properties of the Precipitate.—Streng[3] stated that the triple acetate contained nine moelcules of crystal water, while Miholic[4] found only six. BlanchetiPre[B] on the other hand assumed, without experimental basis, that the precipitate dried at 110° was anhydrous and contained 1.65% of sodium. Our analyses soon showed that this assumption was wrong and that about six molecules of water were retained at 110°. This is in accord with the composition of the analogous and isomorphic sodium uranyl zinc acetate, as found by Barber and Kolthoff. Table I shows the composition of the precipitate formed at 20°.

TABLE I

SHOWING THE COMPOSITION OF A REPRESENTATIVE SAMPLE FROM A MIXTURE OF TWENTY-FIVE PRECIPITATES, ALL OF WHICH HAD BEEN DRIED AT 110°

No.	Uranyl UO_2, %	Magnesium, %	Sodium, %	Acetate radical, %	Water
1	53.77	1.65	1.58	35.79	..
2	53.67	1.65	1.53	35.42	..
3	53.64	1.63	1.58	...	..
4	53.74	1.61	..	...	..
Av.	53.71	1.63	1.56	35.60	7.50
Calcd. compn.[a]	53.79	1.61	1.53	35.26	7.78

[a] The calculated composition is based on the formula, $Mg(C_2H_3O_2)_2 \cdot NaC_2H_3O_2 \cdot 3UO_2(C_2H_3O_2)_2 \cdot 6^1/_2H_2O$.

The values for uranium in the above table were obtained by precipitating the element as ammonium uranate, dissolving and reprecipitating and finally igniting and weighing as U_3O_8. The magnesium was determined by evaporating the filtrate from the uranium precipitate with an excess of sulfuric acid and igniting the mixed sulfates of magnesium and sodium. The magnesium was then determined as the phosphate and after calculating it as sulfate it was subtracted from the mixed sulfates to get the amount of sodium. The acetate radical was obtained by distillation with phosphoric acid and titration of the acetic acid in the distillate with carbonate-free sodium hydroxide. Water was found by difference since the temperature necessary to drive it off caused the decomposition of the material.

These analytical results, it is seen, agree very well with the assumption that the triple acetate has 6.5 molecules of water (see Table I) and contains 1.53% of sodium. This is further confirmed by the numerous analyses made of samples containing known amounts of sodium.

The results in Table I, however, are from a composite sample and since Miholic[4] and Chamot and Bedient[6] have stated that the triple acetates of uranium are of variable composition, it is necessary to offer analyses of a number of individual precipitates. Determinations of uranium and magnesium alone were made since any serious variation in composition would be apparent in these values.

The results of Table II show that the composition of the precipitate is

---

[6] E. M. Chamot and H. A. Bedient, *Mikrochemie*, 6, 13 (1928).

not variable if the conditions of its formation are kept constant as described in the procedure above.

TABLE II

ANALYSES OF SEVERAL INDIVIDUAL PRECIPITATES

Weight of precipitate, g.	0.3212	0.6585	0.9686	1.3002	1.6351	
Uranyl (UO_2), %	53.71	53.60	53.67	53.77	53.57	Av. 53.66
Magnesium, %	1.62	1.58	1.63	1.60	1.64	Av. 1.61

Experiments to determine the proper temperature for drying the precipitate showed that it could be heated for thirty to forty-five minutes at 110° without loss, but a higher temperature or a longer period of heating resulted in decomposition. (Barber and Kolthoff,[1] who also experimented with this precipitate, report that it lost only 0.3% after drying for twenty hours at 110°.) Attempts to ignite the substance to a form suitable for weighing met with failure.

The solubility of the precipitate in 95% alcohol—the most satisfactory washing liquid—was found to be 0.001 g. for each 5 cc. of alcohol used. Since 25 to 35 cc. of alcohol is sufficient for the washing of even a large precipitate, it is seen that this solubility is almost negligible when calculated in terms of sodium. For example, the use of 35 cc. of alcohol corresponds to only 0.0001 g. of sodium.

Effect of Volume of Solution on Completeness of Precipitation.—In the early quantitative work[4] with this method 0.1 N sodium chloride solutions were used, that is, the concentration was kept constant but the volume of the solution varied. Since under practical analytical conditions the opposite is more likely to be true and since, further, a too high dilution of the solution for analysis also dilutes the reagent, the point was studied by making a series of precipitations with varying volumes of sodium chloride solution, all, however, containing the same amount of sodium. The results showed that the volume of the sodium salt[7] solution should not be more than 5 cc. unless between 25 and 50 mg. of sodium were to be precipitated, in which case the volume might be 10 cc., though even in this case 5 cc. would be better.

Amount of Reagent for Complete Precipitation.—Since the reagent is dilute, large volumes must be used for precipitation. The experimental results on this point are presented in Table III.

The above data indicate the importance of having a sufficiently large volume of reagent present to precipitate all of the sodium as triple acetate. The results show that a large volume is required to precipitate the higher amounts of sodium, so much so in fact that the determination of over fifty milligrams of the element renders the method inconvenient and expensive on this account. For practical purposes it would appear that the

---

[7] In these experiments as well as in all subsequent ones the sodium chloride used was purified by several precipitations with hydrogen chloride.

method is restricted to the determination of small amounts of sodium, which is fortunately the usual case in practice. The uncommonly large volume of reagent required for the complete precipitation of larger amounts of sodium explains in part the failure of previous workers to obtain other than very poor results when working with amounts of sodium in excess of a few milligrams.

Effect of Agitation on Completeness of Precipitation.—As might **be** expected from the complex nature of the triple acetate, its rate of formation is slow. The solutions should, therefore, stand for twenty-four hours or longer before filtering, or they should be stirred or shaken. The latter is obviously the more sensible procedure in these days of motor-driven laboratory equipment.

A series of experiments was made in which sets of 10-mg. portions of sodium as the chloride in 5 cc. of solution were treated with 125 cc. of the reagent. Without agitation, precipitation was far from complete on three hours' standing and even one hour of "gentle" shaking failed to give quantitative results. Thirty minutes of rapid shaking or stirring (motor-driven apparatus) in a flask, however, gave complete precipitation. These experiments disclose still another reason why previous workers had failed to get good results. They all recommend "gentle" stirring or "occasional agitation."

Test of **the** Procedure with Known Amounts of Sodium Chloride.—The results in Table IV were obtained by following the procedure given above.

TABLE IV

A TEST OF THE PROCEDURE WITH KNOWN AMOUNTS OF PURE SODIUM CHLORIDE

Corr. wt. ppt., g.	Sodium found, g.	Sodium present, g.	Diff., g.	Corr. wt. ppt., g.	Sodium found, g.	Sodium present, g.	Diff., g.
0.034	0.0005	0.0005	0.0000	0.966	0.0148	0.0150	—0.0002
.033	.0005	.0005	.0000	1.636	,0250	.0250	.0000
.129	.0020	.0020	.0000	1.660	.0253	.0250	.0003
.129	.0020	.0020	.0000	3.215	.0492	.0500	-.0008
.491	.0075	.0075	.0000	3.261	.0499	.0500	-.0001
.489	.0075	.0075	.0000	3.255	.0498	.0500	-.0002
.969	.0148	.0150	-.0002	3.243	.0496	.0500	-.0004

The results of Table IV show that as much as 50 mg. of sodium can be precipitated successfully. Even the worst case, the fourth from the bottom, would give a satisfactory analytical result on the basis of a one-gram sample (see also Table VII).

Influence of Other Ions.—The results in Table V below were obtained by adding the specified amount of reagent to 5-cc. portions of solution con-

taining the sodium and another element. The salts (chlorides) of the added elements had been purified until the flame test showed only traces of sodium.

An inspection of these results shows that the ammonium ion is practically without effect on the precipitation. The results for potassium show that under the conditions used no more than 0.25 g. should be present if 100 cc. or more of reagent is employed. With smaller amounts of sodium calling for only 50 cc. of reagent, not more than 0.1 g. is allowable. In such a case, however, more reagent can be used if much potassium is present. The separation from lithium is not good if more than one or two milligrams of that element is present.

The separation from the alkaline earths is presented in Table VI. The experiments were performed as described above for Table V. All of the alkaline earth salts (chlorides) were purified until only spectroscopic traces of sodium remained.

TABLE VI

EXPERIMENTS ON PRECIPITATING SODIUM IN THE PRESENCE OF THE ALKALINE EARTHS AND FERRIC IRON

Element present	Wt. of other element, g.	Reagent, cc.	Sodium present, g.	Sodium found, g.	Diff., g.
Ca	0.3000	100	0.0100	0.0100	0.0000
	.4000	100	.0100	.0101	+.0001
Mg	.3000	100	.0100	.0100	.0000
	.4000	100	.0100	.0101	+.0001
Sr	.3000	100	.0100	.0102	+.0002
	.4000	100	.0100	.0100	.0000
Ba	.3000	100	.0100	.0105	+.0005
	.4000	100	.0100	.0105	+.0005
Fe	.3000	100	.0100	.0101	+.0001
	.4000	100	.0100	.0100	.0000

It is seen that the presence of alkaline earths has no effect on the separation. The high results in the presence of barium were found to be due to traces of sulfate ion in the reagent, which precipitated barium sulfate.

No quantitative experiments were carried out in which sodium was precipitated in the presence of cations other than those recorded above, but this would hardly be necessary because these ions can be removed easily from the solution. Phosphoric acid would obviously interfere and should be removed before attempting to precipitate the sodium.

A Practical Analytical Test.—An important test of a new method is, of course, that of using it in the analysis of some commercial materials the composition of which has been obtained by other methods in competent hands. That test was applied to this method by using it in the determination of sodium in several samples obtained from the U. S. Bureau of Standards. These were Standard Samples No. 88, a Dolomite; No. 70, a Feldspar; and No. 80, a Lime-Soda Glass.

The dolomite was analyzed by treating a one-gram sample with hydrochloric acid and decomposing the insoluble residue by two evaporations with hydrofluoric and sulfuric acids. The two portions were united and evaporated to dryness. The residue was dissolved in hot water, evaporated to 50 cc. and the sodium precipitated as described in the procedure above. A half-gram sample of the feldspar was decomposed by the J. Lawrence Smith method, which was followed up to and including the extraction of the sintered mass with water. This water extract was then acidified with hydrochloric acid and evaporated to dryness. The residue was next dissolved in 5 cc. of water and the sodium precipitated.[8] The lime–soda glass was decomposed with hydrofluoric and sulfuric acids, 0.3000-g. to 0.0400-g. samples being used. The sulfates so obtained were extracted with water and the sodium was precipitated in the solution. The results of these determinations are given in Table VII.

TABLE VII

ANALYSES OF BUREAU OF STANDARDS SAMPLES BY THE DIRECT METHOD FOR SODIUM

No.	Sample	Method of solution	Na_2O, (B. of S.), %	Na_2O by new *method, %	
88	Dolomite	Dec. with HCl, H_2F_2 and H_2SO_4	0.08	0.09	0.09
70	Feldspar	J. Lawrence Smith method	2.38	2.32	2.33
80	Glass	Dec. with H_2F_2 and H_2SO_4	16.65	16.79	16.61

The values in Table VII compare favorably with the Bureau's results and were obtained in far less time than the standard methods require.

The Colorimetric Estimation of Sodium

The triple acetate precipitate is readily soluble in water and, since the resulting solution is colored yellow by the uranium compound present, a colorimetric method of measurement naturally suggests itself. The usual preliminary experiments were performed in order to learn the maximum amounts that could be measured in this way, the observational errors involved and the effect of temperature changes on the depth of color of the uranium solution. The results are embodied in the procedure and notes below.

Procedure for Colorimetric Measurement.—The precipitation is made in the manner given under the gravimetric method except that the volume of sodium solution should be only one or two cubic centimeters. The precipitate is collected in an unweighed Gooch crucible and washed with four successive portions of 95% alcohol. Air is then drawn through the crucible for five minutes to remove most of the alcohol, after which the precipitate is dissolved through the crucible into a colorimeter tube with warm water (60 to 70°), using it in 2- to 3-cc. portions. The solution is then cooled to room temperature and diluted to some definite volume,

---

[8] It is worth noting that the very large amount of calcium in this solution did not interfere with the precipitation.

between 15 and 25 cc., depending upon the volume of water used in dissolving the precipitate. The depth of color of this solution is next compared with that of a standard solution that has been prepared in the same way.

About 5 mg. of sodium is the maximum amount that can be determined colorimetrically because the amount of uranium compound associated with more than this gives too deep a yellow color for satisfactory comparison. The wash alcohol must be removed in order to avoid cloudy solutions. Good results are obtained only if a colorimeter is employed. Color-comparison tubes alone are not so satisfactory.

It is very important that the solution under analysis and the standard solution be at the same temperature, since the depth of color is strongly affected by the temperature.

The best results are obtained when the solutions show a fairly deep straw color in the colorimeter. At least five readings should be taken with each pair of tubes and the results averaged.

A standard solution of approximately the same concentration as the one under examination should be used. These standard solutions should be prepared by precipitating the sodium from measured portions of standard sodium chloride solution. A convenient strength is 2.542 g. of sodium chloride per liter. One cubic centimeter of this solution contains 1 mg. of sodium.

A peculiar advantage of the colorimetric procedure is that suspended matter need not be removed from the original sodium salt solution. It will be retained in the crucible when the precipitate is dissolved through.

TABLE VIII

EXPERIMENTS ON THE COLORIMETRIC ESTIMATION OF SMALL AMOUNTS OF SODIUM

0.0005	29	25	0.0005	0.0006	+0.0001
	24	22		.0005	.0000
	23	26		.0004	−.0001
.0010	19	43	.0005	.0004	−.0001
	16	38		.0004	−.0001
	20	42		.0005	.0000
.0020	28	22	.0025	.0025	.0000
	25	20		.0025	.0000
	37	31		.0024	−.0001
.0030	26	30	.0025	.0026	+.0001
	30	37		.0024	−.0001
	23	29		.0024	−.0001
.0040	35	30	.0050	.0046	−.0004
	42	35		.0048	−.0002
	28	24		.0047	−.0003
.0060	44	55	.0050	.0048	−.0002
	42	50		.0050	.0000
	36	41		.0052	+.0002

Some typical results obtained by the colorimetric method are given in Table VIII.

The results of Table VIII are seen to be entirely satisfactory except in the instance in which an attempt was made to compare the depths of color of a tube containing 5 mg. of sodium with a standard tube containing 4 mg. More experience with the method will undoubtedly remove such discrepancies.

Summary

1. A method for the direct determination of sodium by precipitating it as magnesium sodium uranyl acetate has been presented.
2. Both gravimetric and colorimetric measurements have been used.

EMULSIONS: STABILITY, AREA PER MOLECULE IN THE INTERFACIAL FILM, DISTRIBUTION OF SIZES AND THE ORIENTED WEDGE THEORY[1]

BY WILLIAM D. HARKINS AND NORVIL BEEMAN

RECEIVED JANUARY 7, 1929 PUBLISHED JUNE 5, 1929

1. Introduction

When this work was begun no accurate determination had been made of the distribution of sizes of the droplets in emulsions. If such determinations could be made they would give a basis for a decision with respect to three of the most important fundamental problems of this branch of colloid science. These are: (1) the number of molecules of the emulsifying agent per unit area of the oil–water interface, (2) the stability of emulsions and the effect of aging and (3) the oriented wedge theory of emulsions.

While the requirements of the last two problems might be met by large-scale methods, the demands of the first problem seemed to necessitate the use of a fine-scale, or microscopic method, since with large-scale methods there is considerable uncertainty in the theory which is used to translate the scattering of light or the speed of sedimentation into the sizes of the drop?.

2. Experimental Methods

1. Apparatus

1. Microscopic Equipment.—An image of the highly diluted emulsion was projected on a screen by the use of a microscope fitted with a 61x, 3-mm. apochromatic oil immersion objective, 1.40 N.A.; an aplanatic condenser 12-mm., 1.40 N.A.; and a 25x, compensating ocular.

---

[1] A preliminary version of this article was received August 31, 1925.

2. The Cell.—An important part of the equipment was the microscope slide, which was made of thin glass and contained a cell of 4-mm. diameter with a depth of 0.10 mm. which was covered by a thin cover glass. The bottom of this cell was ruled in squares and it was surrounded by a circular depression 0.5 mm. deep and 3 mm. wide. Two small grooves leading from this depression allow any excess of solution to flow away when the cover glass is put in place, The use of a drop of the emulsion suspended from the bottom of a cover glass gives poor results since the surface forces cause a considerable segregation of the droplets according to their sizes.

2. Preparation of Emulsions

1. Materials. Oils.—The octane was the synthetic substance obtained from the Eastman Laboratories, Rochester, N. Y. The "Stanolax" was a heavy paraffin oil sold by the Standard Oil Company of Indiana. Kahlbaum's benzol, thiophene-free, was also used.

Water.—The water used for making the emulsions and for cleaning the slide and cover glasses was distilled water examined periodically to assure freedom from suspended particles of microscopic size.

Soaps.—The oleate soaps were made from oleic acid, U. S. P., after extensive purification by both the lead salt and barium salt treatments[2] and finally by a vacuum distillation.

The sodium and potassium oleates were made by dissolving the solid alkali metal in absolute alcohol, filtering to remove any carbonate, adding oleic acid and evaporating to dryness. The residue was then dissolved in absolute alcohol and refluxed for a half hour. (The amount of oleic acid was arbitrarily determined according to the method used by Laing[3] in which the acid was added until the alcoholic solution after dilution with a recently boiled mixture of alcohol and water (3:1) was found by repeated tests to give a neutral reaction with neutral alcoholic solution of phenolphthalein.) The hot solution was now filtered through a hot-water funnel and the soap allowed to crystallize out. It was then drained, washed with absolute alcohol and ether and dried.

For the cesium oleate, cesium nitrate was converted into cesium carbonate by fusion with oxalic acid. An excess of the carbonate was dissolved in a small volume of water, the oleic acid dissolved in 95% alcohol, the two solutions were mixed and evaporated to dryness. The residue was dissolved in absolute alcohol, the exact amount of oleic acid being determined as before. The solution was filtered and again evaporated to dryness. After redissolving in absolute alcohol the procedure was the same as for sodium and potassium oleates. Cesium oleate is a fairly "soft" soap and does not crystallize out readily even in the cold.

The stearates and other soaps were made in much the same manner. Kahlbaum's best stearic acid was used for the stearate soaps. The chaulmoogric acid was obtained from Professor B. H. Nicolet and was a sample sent to this Laboratory for research purposes in connection with the chaulmoogra oil treatment for leprosy. The elaidic acid was purified by Mr. T. C. Poulter in this Laboratory.

Aluminum and magnesium oleates were made by the precipitation of these oleates from sodium oleate solutions followed by purification by recrystallization from absolute alcohol.

Through the kindness of Professor J. H. Hildebrand samples of the sodium and cesium stearates formerly used in work with emulsions at the University of California were also tried.

2. Procedure.—The general method followed for oil in water emulsions was to make a fresh soap solution of the concentration desired, add an equal quantity of oil and then beat or stir to form the emulsion. The beating was done by a motor-driven egg beater, the stirring by an Arnold drink mixer. For the former **7** to **10** cc. of soap solution and an equal volume of oil were most convenient; for the latter *5* cc. or more of each phase was put in a large flat-bottomed test-tube. The time of beating and stirring was varied according to purpose but more commonly emulsions were given twenty minutes' beating by the egg beater or, if stirring was the method, ten minutes' stirring with the drink mixer. **A** Briggs' homogenizer was used, except in special cases, and the emulsion after beating or stirring was drawn through about five times by suction. The homogenizer was especially of service in removing air bubbles formed during beating. *Unstable emulsions were easily broken by homogenization* and this treatment was omitted in such cases, the air bubbles if found present being removed by subjecting the emulsion to a vacuum treatment.

There seems to be ***a*** definite relation between foaming and efficiency of emulsification. This applies particularly to emulsification with dilute soaps. It was noticed that emulsions which did not foam up during the beating—and this was rather characteristic of emulsions made with very dilute soaps—separated more readily than those which did foam, though some very stable emulsions were made which did not foam. It was a common practice in such cases to beat the soap solution to a foam and then add the oil in a thin stream or in portions whiie beating.

3. Method of **Sampling.—The** emulsion—cream, aqueous phase and all—was mixed by running it back and forth from end to end of the test-tube which contained it. Care was taken to prevent formation of foam during this mixing. From this thoroughly mixed emulsion **3** or 4 drops were pipetted out and diluted in microscopically clear distilled water. The degree of dilution depended upon the emulsion, varying from 1 drop in **300** cc. of water in some octane emulsions, in which the particles were very small and more numerous, to 8 or 9 drops in **300** cc. of water for some Stanolax emulsions, in which the drops were much larger and less numerous. Immediately after dilution the sample was pipetted out, placed upon the slide and covered with a cover glass. Oil contacts between condenser and slide and between cover glass and objective were made with Stanolax since it was more easily cleaned off and does not harden after exposure to the air as cedar oil does.

4. Cleaning the Slide and Cover Glass.—The slide and cover glass must be thoroughly clean if good results are to be obtained. Sticking of drops to the cover glass was avoided entirely by the following method. The slide and cover glass were washed in soap solution. Just before use the cover glass and slide were removed from the soap solution and rinsed well with clear, distilled water. This rinse water was shaken off and the sample placed between the *wet* slide and a *wet* cover glass. For water in oil emulsions the slide and cover glass were cleaned as before, dried with alcohol and ether, and then dipped into some of the same oil as that of the continuous phase of the emulsion to be examined.

5. Measuring the Drops.—The sample was diluted so that there were about **10** or **12** drops in the field at one time. Measurements were taken upon every drop from the bottom of the cell to the cover glass in a strip across the cell from one edge to the other. This strip was definitely determined by lines drawn in a horizontal direction across the scale on the screen.

The smallest drops up to **1** micron in diameter were recorded and plotted as ***0.5*** micron, from 1 to ***2*** as 1.5 micron, from ***2*** to ***3*** as ***2.5*** microns, etc.

Exact measurements upon moving spheres of varied sizes are difficult because the sizes seem to change with the change of focus of the microscope, intensity of illumination, direction of the beam of light, condition of the eyes with respect to presence or absence of fatigue, etc. For this reason a finer scale was not used in the classification.

3. Effects of Various Monovalent Cations on the Distribution of Sizes

The distribution of sizes (diameters) of the oil droplets in emulsions produced by oleate soaps is found to be exactly the same, within the experimental limits of accuracy, for any of the three univalent cations, lithium, sodium and cesium. This is shown to be true in emulsions of a very viscous paraffin oil (Fig. 1) and in those in which the oil is extremely fluid, such as octane or hexane (Figs. 2 and 3). According to the method used in plotting, each point gives the number of drops per 100 counted of the size designated. Thus the maximum number found in these figures occurs at 1.5 microns, and for emulsions of Stanolax the number for this size is **30.** That is, in the Stanolax emulsion 30% of the droplets have diameters between 1 and 2 microns.

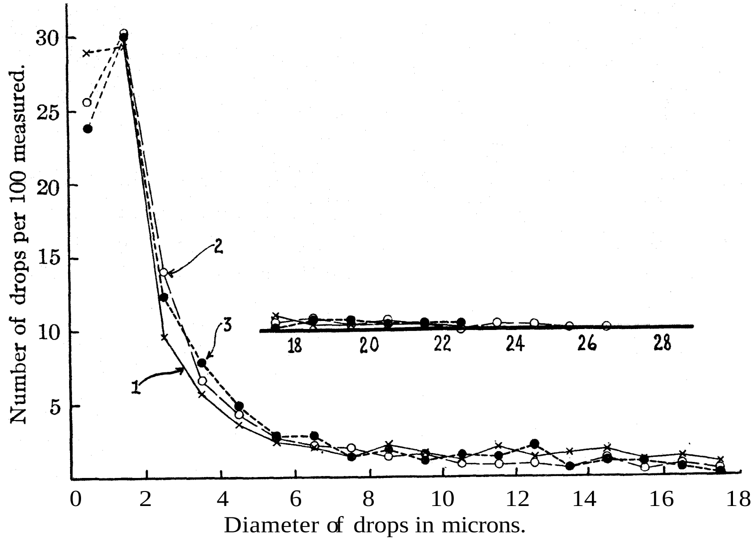

Fig. 1.—Stanolax emulsions beaten by egg beater. 1, $M/10$ sodium oleate, ×—×—×; 2, $M/10$ potassium oleate, ○--○--○; 3, $M/10$ cesium oleate, ●···●···●.

A forced variation from this general procedure occurs for the points at 0.5 micron, which represent the number of droplets between 1μ as the upper limit and about 0.1μ (the limit of visibility) as the lower limit. Obviously if ultramicroscopic droplets were counted, the number represented at 0.5μ would be greater, but it is improbable that the distribution of area of the interface is greatly affected by this omission.

The results described above have a bearing upon the extent of application of the oriented wedge theory. Langmuir considered that the form of colloidal particles of oleic acid is determined by the *adsorption of hydroxyl* groups: "If a film of closely packed oleic molecules covers the surface to which sodium hydroxide has been added, OH groups are adsorbed by the COOH radicals, causing an expansion of the lower side of the film without a corresponding expansion of the upper side. This results in the bulging of the film downward in spots so that it finally detaches itself in the form of particles, the outer surfaces of which consists of COOH groups together with adsorbed OH, while the interior consists of the long hydrocarbon chains.

"The size of the colloidal particles is determined by the difference in size between the two ends of the molecules, just as the size of the arch is dependent upon the relative sizes of the two ends of the stones of which the arch is constructed."[4]

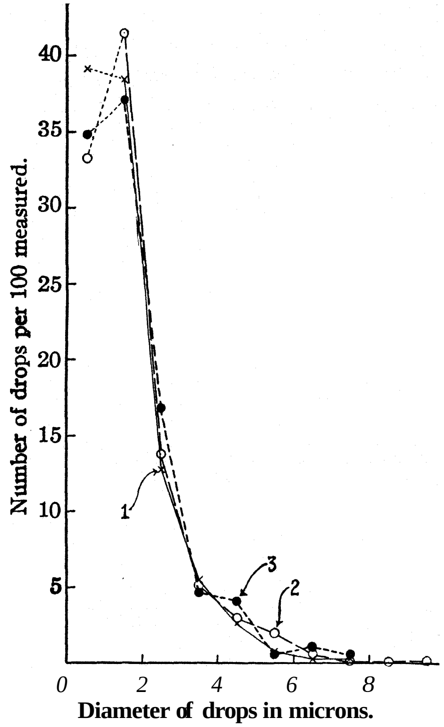

Fig. 2.—Octane emulsions beaten by egg beater: 1, $M/10$ sodium oleate, X—X—X; 2, $M/10$ cesium oleate, O—O—O; 3, $M/10$ cesium oleate, ●—●—●. Curves 2 and 3 show the effect of aging an emulsion produced by 0.1 molal cesium oleate. Curve 2 was obtained on the day of preparation and Curve 3 one month later.

The idea that the number of hydrocarbon groups associated with one ion of a metal determines whether the emulsion shall be one of oil in water (univalent cation) or of water in oil (polyvalent cation) was advanced by Harkins, Davies and Clark,[5] as shown in the following quotation.

"The molecules in the surfaces of liquids seem to be oriented, and in such a way that the least active or least polar groups are oriented toward the vapor phase. The general law for surfaces seem to be as follows: *if we suppose the structure of the surface of a liquid to be at first the same as that of the interior of the liquid, then the actual surface is always formed by the orientation of the least active portion of the molecule toward the vapor phase, and at any surface or interface the change which occurs is such as to make the*

[4] Langmuir, *Chem. Met. Eng.*, 15, 468 (1916); THIS JOURNAL, **39**, **1848 (1917)**.

[5] **Harkins, Brown and Davies,** *ibid.*, 39, 354–364 (1917); Harkins, **Davies and Clark,** *ibid.*, 39, 541–596 (1917); **and later papers.**

transition to the adjacent phase less abrupt. This last statement expresses a general law, of which the adsorption law is only a special case. If the molecules are monatomic and symmetrical, then the orientation will consist in a displacement of the electromagnetic fields of the atom. This molecular orientation sets up what is commonly called a "double electrical layer" at the surfaces of liquids and also of solids.

"This law if applied to special cases indicates for a few pure liquids the following orientation: In water the hydrogen atoms turn toward the vapor phase and the oxygen atoms toward the liquid. With organic paraffin derivatives the CH_3 groups turn outward, and the more active groups, such as NO_2, CN, COOH, COOM, COOR, NH_2, $NHCH_3$, NCS, COR, CHO, I, OH, or groups which contain N, S, O, I, or double bonds, turn toward the interior of the liquid.

"If any of these organic compounds are dissolved in water, their orientation in the water surface is the same as that just given, with the active groups inward.

"At interfaces between two pure liquids the molecules turn so that their *like* parts come together in conformity with the general law. With solutions, the solute molecules orient so that the ends of the molecules toward the liquid A are as much like A as possible and the ends toward B are as much like B as possible. So at interfaces between organic liquids and water, for example, the organic radical sets toward the organic liquid and the polar group toward the water. . . . .

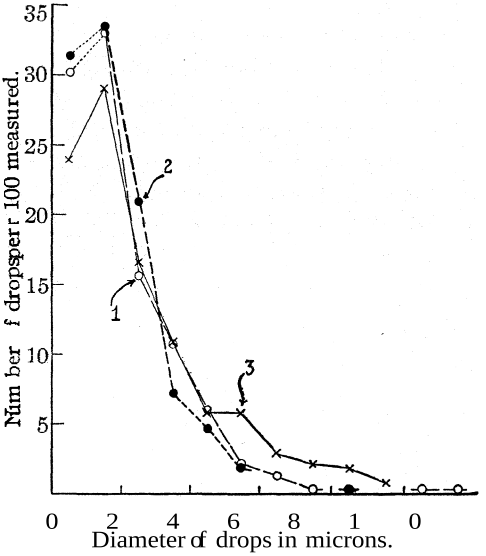

Fig. 3.—Octane emulsions stirred by drink mixer: 1, $M/200$ sodium stearate, O—O—O; 2, $M/200$ cesium stearate, ●—●—●. Stanolax emulsion beaten by egg beater and inverted: 3, $M/10$ sodium oleate, X—X—X, after inversion with aluminum nitrate. Curve 3 represents a water in oil emulsion.

"When Newman, working with Bancroft in 1914, found that while sodium oleate in solution will give emulsions of benzene in water, and the oleate salts of a metal with a valence higher than one will give emulsions of water in benzene, we were working experimentally in this Laboratory on the adsorption of these long hydrocarbon chains. Now while Bancroft seemed to think that this work indicated that the liquid with the higher surface tension forms the inner phase, it seemed to us that the only apparent relation was that to the *number of oleate radicals* in the molecule of the protective colloid (sodium oleate, or magnesium oleate). Therefore, it quite possibly may be the orientation and the form of the molecules together with adsorbed ions in the interface between the dispersoid particles (or small drops), and the dispersion medium which determine the surface energy relations; and, therefore, the size of the drop at which it becomes stable. In other words, this idea is that the drop would be stable whenever the molecules, together with adsorbed ions, etc., in the interface, fit the curvature of the drop. The molecules in the curved surface would not need to be all of the same kind. If the molecules do not fit in the curved surface, the drop will not be perfectly stable and will either decrease or increase in size if given time."

This "oriented wedge theory" of emulsions was, seemingly, given strong support by the experimental results of Finkle, Draper and Hildebrand,[6] who determined the distribution of the number of drops according to their diameters in solutions of sodium, potassium and cesium palmitate, which were used as emulsifying agents. Thus they kept the negative ion constant but varied the positive ion. The latter is, presumably, turned toward the outside of the drop, that is, toward the aqueous phase. Now it is known that the *atoms,* sodium, potassium and cesium, increase in diameter in the order given, so if the atoms are effective in the sense of the wedge theory, the outer part of the wedge increases in size in the same order and this would increase the curvature in just this order. Thus the droplets of oil should decrease in diameter as the emulsifying agent is changed from sodium to potassium and cesium oleate, and this is just what was found in the experiments of Finkle, Draper and Hildebrand. Preliminary results obtained by Harkins and Keith[7] also seemed to agree entirely with theirs, but later, upon the more careful elimination of all factors which might cause some type of segregation and the use of a more suitable optical system, the result presented above was obtained.

However, there is another more proper point of view according to which *the oriented wedge theory does not indicate any such decrease in size of the droplets in the change from sodium to cesium.* The negative oleate ions are adsorbed at the oil–water interface with the hydrocarbon radical toward the oil and the –COO– group toward the water. The Na^+ or Cs^+ ions are held to these by electrostatic attractions alone, so the alkali ions form a diffuse but extremely thin positively charged layer, in which the distribution may follow the Boltzmann e-theorem. A part of the soap in the film is present as oleic acid formed by hydrolysis. From this point of view it seems improbable that the sizes of the atoms will produce any marked influence upon the sizes of the droplets. It is known too that the smaller the alkali atom, the more highly hydrated is its ion.

---

[6] Finkle, Draper and Hildebrand, THIS JOURNAL, 45, 2780 **(1923).**

[7] Harkins and Keith, *Science,* 59, 463–467 *(1924).*

When, on the other hand, the ion of the metal is bi- or tri-valent, the electrostatic relations are such that in general two $RCOO^-$ ions are held by only one M^{++} ion. Such conditions are favorable to the expansion of that side of the film which is turned toward the oil by the spreading of the hydrocarbon chains. Thus the addition of aluminum nitrate to an emulsion produced by sodium oleate inverts the emulsion and changes it to the water in oil type.

It was found by Harkins and Keith that when a drop of the emulsion is suspended from a cover glass, there is a segregation of the microscopic droplets in the emulsion according to their sizes. This makes it extremely difficult to obtain a correct determination of the distribution of sizes, and is undoubtedly the cause of the discrepancy between the earlier work and that presented here.

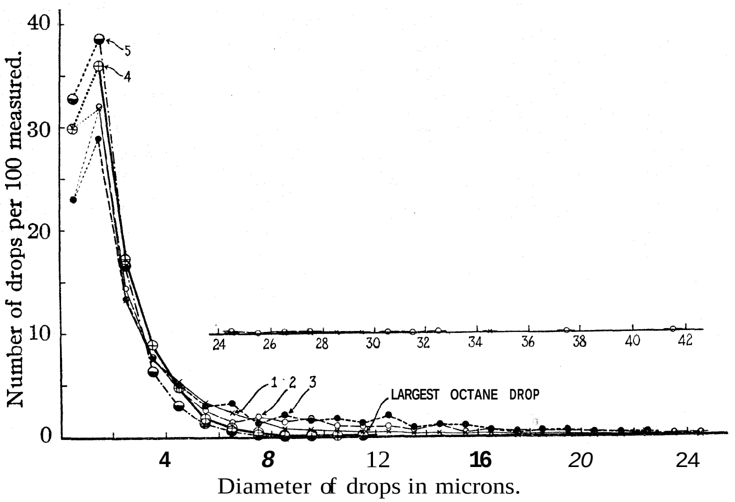

Fig. 4.—Distribution of diameters in emulsions of octane and Stanolax stabilized by sodium, potassium and cesium oleates. Stanolax emulsions: 1, sodium soaps, ×—×—×; 2, potassium soaps, O--O--O; 3, cesium soaps, ●--●--●. Octane emulsions: 4, sodium soaps, ⊕—⊕—⊕; 5, cesium soaps, ⊖-·-⊖-·-⊖.

4. Influence of the Viscosity of the Oil

Although the viscous paraffin oil (Stanolax) had a viscosity more than 150 times that of the octane, it is remarkable that with either oil the greatest number of droplets occurs between 1 and 2μ, that is, the peak in the distribution according to diameters occurs at the same place for either oil. The marked difference illustrated by Fig 4 is that of the larger drops. Thus the largest of the 5668 octane droplets represented by this figure had a diameter of about 10.5μ, while the diameters of those of Stanolax were as great as 41.5μ, or nearly four times as great. The effect of the viscosity of the oil is exhibited by Tables IA and IB, and by Figs. 4 and 5. Fig. 5 illustrates a Stanolax emulsion produced by 0.1 *M* sodium oleate.

The most regular results are given by emulsions prepared by the drink mixer (Fig. 6).

5. Influence of the Concentration of the Soap

No appreciable influence of change in soap concentration upon the distribution of diameters in freshly *made* emulsions was discovered. Isolated cases here and there might suggest such a relation but on the whole no positive conclusions could be drawn. With emulsions permanent enough to measure, the difference in soap concentration produced little or no detectable effect. On the other hand, as the emulsions aged, a decided effect was observed in the cases of dilute emulsions. This effect is discussed in the next paragraph.

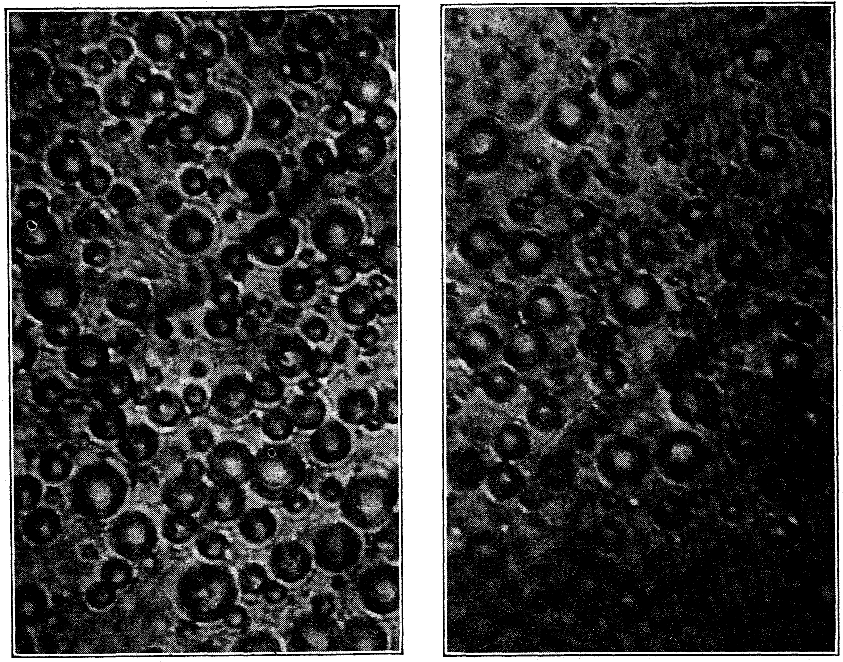

Fig. 5.—Stanolax emulsion (X 1000). Diluted 100 times. The emulsifying agent was 0.1 M sodium oleate. (Taken by R. S. Dean.)

6. Stability: Effect of Aging

The stability of certain emulsions has been ascertained by a determination of the variation of the distribution of sizes (diameters, areas and volumes) with the time. It is evident that this gives much information concerning the stability not indicated at all by the older method of merely observing the gross features of the emulsion such as the separation of oil in bulk (Tables II and III).

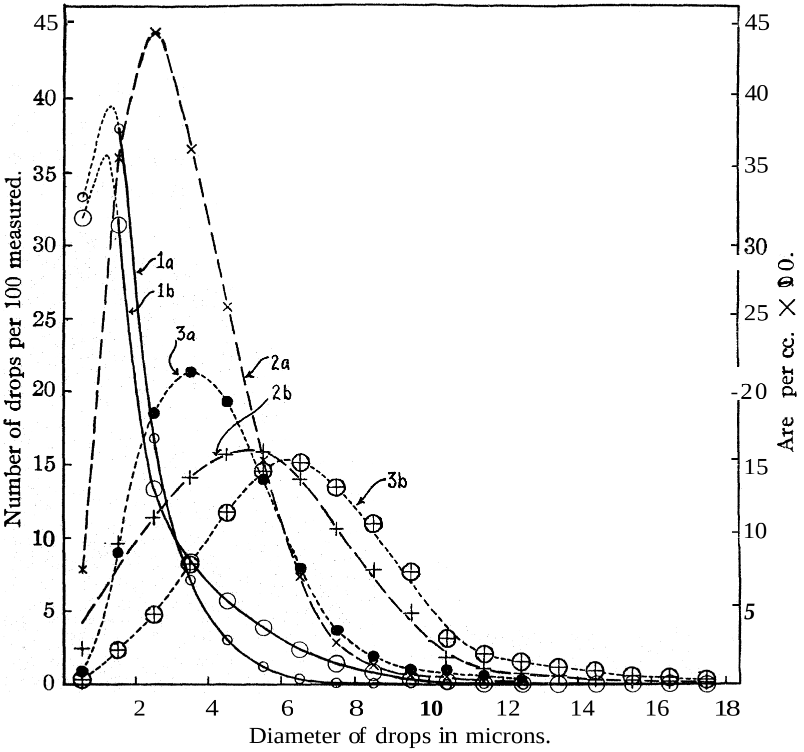

Fig. 6.—This figure represents measurements on about 2500 droplets of octane and 4000 of Stanolax, numbers so large as to give smooth curves. Comparison of octane and Stanolax emulsions made by drink mixer. Diameter distribution: 1a, octane, o—o—o; 1b, Stanolax, O—O—O. Area distribution (area/cc. X 10): 2a, octane, X—X—X; 2b, Stanolax, +—+—+. Volume distribution (vol. X 100): 3a, octane, ●--●--●; 3b, Stanolax, ⊕--⊕--⊕.

The more concentrated soap solutions seem to form emulsions which are very stable even over long periods of time. Emulsions made with 0.1 *M* soap solutions and with greater concentrations, where the soap is soluble enough to remain in solution, were not observed to change appreciably in the course of a year. One possible exception was 0.1 M potassium chaulmoograte and Stanolax (see under "Influence of Different Hydrocarbon Chains"). Curves 2 and **3,** Fig. 2, are fairly representative of the effect of aging emulsions produced by 0.1 M soaps. Curve 2 is for a 0.1 M cesium oleate and octane emulsion; Curve **3** is for the same emulsion more than a month later.

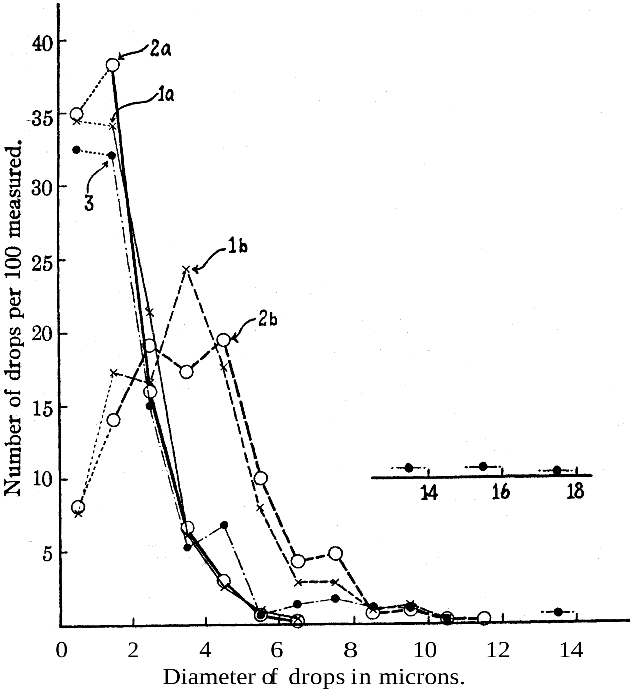

Fig. 7.—Changes in diameter distribution with aging. *M*/100 sodium oleate and octane (drink mixer): 1a, measured on first day; 1b, measured on tenth day. *M*/100 cesium oleate and octane (drink mixer): 2a, measured on first day; 2b, measured on tenth day. *M*/100 sodium oleate and octane (egg beater and different soap): 3, measured fifteen and one-half months later.

At the other extreme, emulsions' produced by very dilute soaps were found to change rapidly. Thus 0.0005 M, 0.0008 M and 0.008 M soaps gave unstable emulsions which showed signs of breaking within a few hours after making. The most dilute soap which produced an emulsion (Table IV) stable long enough to measure had a concentration of 0.0008 M.

(A measurement required from one to two hours.) Soaps of a concentration of 0.005 M gave emulsions which broke markedly within a few days in some cases, while in others they were stable to all appearances except to microscopic observation. In every case, whether they broke ultimately or not, the microscope showed unmistakable changes in all of the 0.005 *M* emulsions studied. Figs. 7 and 8 exhibit the changes produced by aging in the diameter distribution and Figs. 9 and 10 in the area and volume distributions for emulsions of octane made with 0.01 M and 0.005 M solutions of cesium and sodium oleates. An actual shift in maxima and a relative increase in the number of large drops accompany aging of all the emulsions made with 0.005 M sodium and cesium oleates.

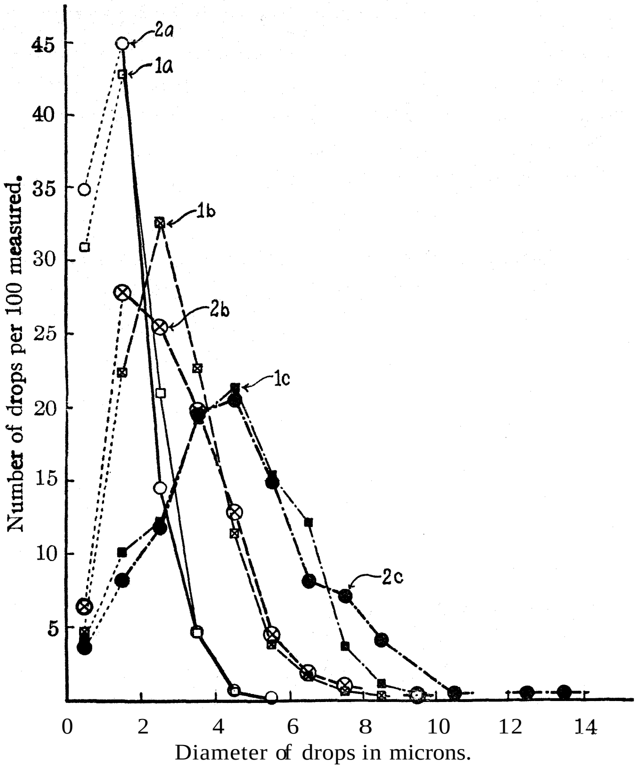

Fig. 8.—Changes in diameter distribution with aging. *M*/200 sodium oleate and octane (drink mixer): 1a, measured on first day, 1b, measured on third day; 1c, measured on seventh day. *M*/200 cesium oleate and octane (drink mixer): 2a, measured on first day; 2b, measured on third day; 2c, measured on seventh day.

Thus an emulsion produced from equal quantities of octane and a 0.005 M aqueous solution of *sodium oleate* gave an area of 25,466 sq. cm. per cc. of oil immediately after it was prepared, and 14,630 sq. cm. on the third day later. It is remarkable how closely these values were duplicated by an emulsion prepared with the same concentration of cesium oleate: 25,000 sq. cm. at first, and 13,813 sq. cm. on the third day.

Emulsions produced by 0.01 *M* soaps were much more stable (Fig. 7), and changed less in ten days than those with 0.005 M soap in seven days.

7. Influence of Different Methods of Preparation

It was found that twenty minutes' stirring with a motor-driven egg beater, or ten with a high-speed drink mixer gave the same distribution of sizes as double these periods. The drink mixer gave fewer large drops, but the remarkable feature was that either the beater or the mixer, or shaking by hand, gave the same position for the peak in the curve.

	817	99.9	12.227	9.593	127.434	1.000

8. Influence of the Addition of a Second Substance to the Soap

Surface tension work in this Laboratory has shown the marked effects of the addition of a substance like sodium hydroxide or oleic acid to a solution of sodium oleate. In contrast, the results obtained in this investigation when sodium hydroxide or oleic acid was added to the sodium oleate used as an emulsifying agent showed only slight effects upon the distribution curve. Various concentrations of sodium hydroxide were added to a 0.1 *M* sodium oleate solution and emulsions made by the use of each of these for the aqueous phase. Measurements were made on each emulsion but no markedly great effect was noticed until the concentration of the base had reached 1 M. At this concentration the diameter distribution was altered by a decrease in the number of large drops and an increase in the number of small drops. A similar change was obtained with the addition of 0.1 M oleic acid. The emulsion seemed to be more sensitive to the addition of oleic acid than of sodium hydroxide, though not sensitive to low concentrations of either.

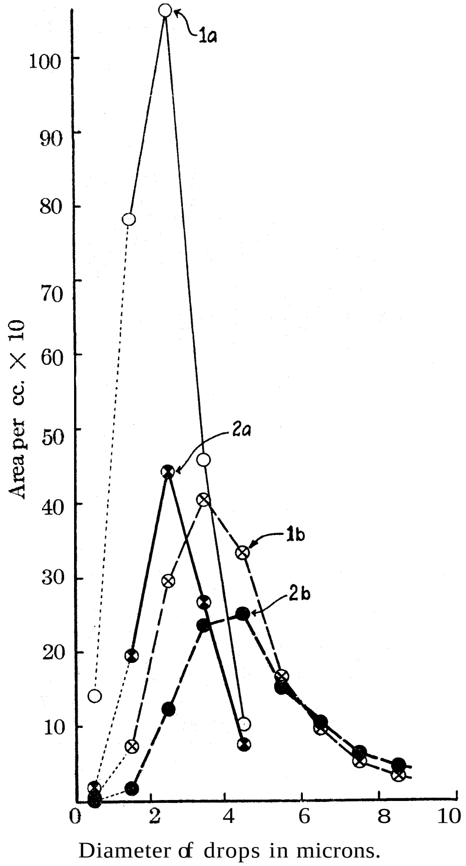

Fig. 9.—Changes with aging. $M/200$ sodium oleate and octane (same as in Fig. 8). Changes in area: 1a, measured on first day; 1b, measured on third day. Changes in volume: 2a, measured on first day; 2b, measured on third day.

9. Influence of Different Hydrocarbon Chains

Sodium stearate, elaidate and cerotate were used as stabilizing agents with the result that the same general distribution of sizes was obtained. Some other means of measuring particles smaller than one micron in diameter might indicate differences in the distribution of diameters of the smaller drops. In the case of the cerotate the emulsion which formed was very stiff and jelly-like and measurement was so difficult it could only be carried out roughly.

With 0.1 M potassium chaulmoograte and Stanolax, beaten by the egg beater, a surprisingly large number of the smaller drops was found. Thus the number of those of a mean diameter of 0.5 micron was almost twice the number of those of a diameter of 1.5 microns. Potassium chaulmoograte was found to be a very soluble soap but the emulsions made with it were not as stable as the emulsions made with potassium oleate. Very shortly after beating, whether the emulsion was run through the homogenizer or not, a thin layer of Stanolax separated out.

10. Water in Oil Emulsions: Influence of Metals Other Than Univalent

Magnesium and aluminum oleates were dissolved in Stanolax and equal volumes of this oil and water were emulsified. They gave water in oil emulsions which when measured were found to give diameter distributions of the same type as those found for oil in water emulsions.

A Stanolax emulsion with 0.1 M sodium oleate made in the usual manner was inverted by the addition of the required quantity of aluminum nitrate. The inversion was carried out while beating. When this emulsion was measured it was found to be of the same general type (Curve **3**, Fig. **3** and Table V). The same procedure was carried out with magnesium nitrate and again an inverted emulsion was the result, but in this case the drops were not spherical but irregular and gave the appearance of being inclosed in solid films. **A** careful set of measurements was impossible but a rough one was made and the usual distribution of sizes was indicated. These water-in-oil emulsions were not very stable and were almost entirely broken after a week or so.

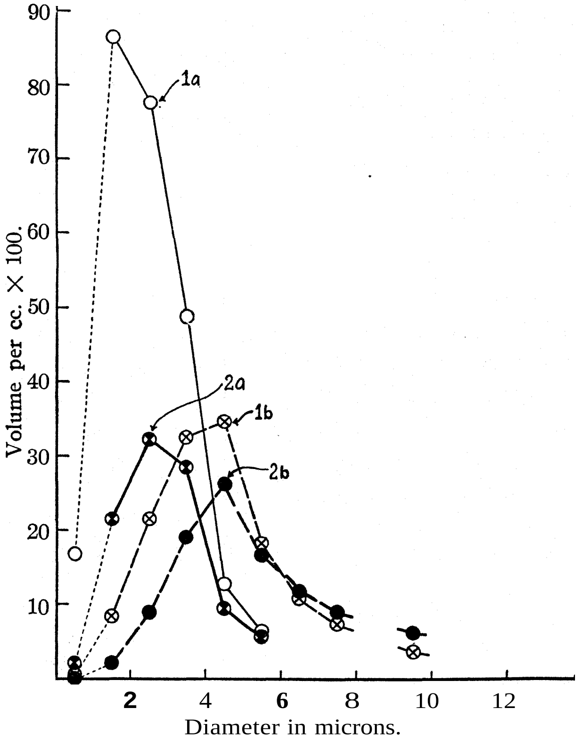

Fig. 10.—Changes with aging. $M/200$ cesium oleate and octane (same as in Fig. 8). Changes in area: 1a, measured on first day; 1b, measured on third day. Changes in volume: 2a, measured on first day; 2b, measured on third day.

A large quantity of sodium oleate dissolved in Stanolax by warming set to a jelly-like consistency upon cooling. To **this** solution of sodium oleate in oil was added water, while beating, and a water-in-oil emulsion was formed which broke within a few hours. This method was used by Harkins and Keith.'

TABLE V

DISTRIBUTION OF DIAMETERS IN A WATER-IN-OIL EMULSION OBTAINED BY INVERTING AN EMULSION OF STANOLAX PRODUCED WITH 0.1 M SODIUM OLEATE BY THE ADDITION OF ALUMINUM NITRATE

Diameter	0.5	1.5	2.5	3.5	4.5	5.5	6.5	7.5	8.5	9.5	Total

Per cent.	24.0	29.0	16.8	10.9	5.8	5.8	2.9	2.2	1.8	0.8	100.0

11. Emulsions Made .without a Stabilizing Agent

It was noticed in the emulsion made with magnesium and aluminum oleates, which were of the water-in-oil type, that the aqueous layers had a very cloudy appearance. When examined under the microscope they were found to contain oil drops, that is, these aqueous layers were dilute oil-in-water emulsions. This led to the examination of both layers of an emulsion formed by stirring together equal volumes of Stanolax and water without using a stabilizing agent. About two hours after stirring samples were taken from each layer. In the oil layer was found a water-in-oil emulsion, and in the water layer an oil-in-water emulsion, but in the latter the concentration of droplets was about ten times greater than in the former. Measurements taken on the drops in these two layers showed diameter–distribution curves of the usual type except that the curves extended distinctly upward from the 1.5 micron to the 0.5 micron points, there being about 5% more drops of 0.5μ than of the 1.5 micron mean diameter in each case.

12. Emulsions of Benzene in Aqueous Soap Solutions

Benzene in water emulsions were made with different soaps. The distribution of diameters was of the usual type, except that more drops were observed between 0 and 1μ in diameter than between 1 and 2μ. As compared with those of Stanolax and octane, emulsions of benzene contained many more small particles.

13. Area at the Interface

Area is of prime importance in a study of colloids because of its relation to the phenomenon of adsorption. For those octane emulsions which are very stable it is seen that the greatest area is furnished by drops of approximately 2.0 to 2.5 microns in diameter[8] (see Curve 2a, Fig. 6). This holds

---

[8] The first point in the area and volume curves is calculated upon the assumption that 0.75 micron is the mean diameter rather than 0.5 micron, though it is made to appear in the graphs as 0.5 micron. That is, it is felt that 0.75 micron rather than 0.5 micron represents more nearly the mean diameter of the very smallest drops visible by means of our optical system.

fairly well for the less stable emulsions also, but only if they are fresh (see Curves 1a, Fig. 9, and 1a, Fig. 10). Stanolax emulsions exhibit a different relation since the diameter which gives the maximum area is about 5 microns, since relatively fewer small drops are formed from the more viscous oil.

As indicated in Figs. 7 and 8 the aging of emulsions stabilized by rather dilute soaps is an important factor in the change of number, area and volume distributions. With a 0.005 M soap the shift of the maximum of the diameter-distribution curve for octane is about **3** microns in six days, or 0.5 micron per day. With 0.01 *M* soap the shift for the same oil, in two cases out of three, was about 2 microns in nine days, or 0.2 micron per day. This may be taken as a measure of the relative stability of these two emulsions. No shift in emulsions made with 0.1 M soaps was discovered, these apparently having more than enough soap to stabilize the interfacial film and, at the same time, enough soap in the aqueous phase to maintain equilibrium.

Table IV, fifth column, shows the area per cubic centimeter of oil calculated from the number distribution of drops measured in a Stanolax emulsion stabilized by 0.00083 M sodium oleate. This emulsion was not very stable and began to break shortly after measuring. The area per cubic centimeter of Stanolax in such an emulsion when fresh amounts to 9.6×10^3 sq. cm. Equal volumes of all and soap solution were used so, since 1 cc. of 0.00083 M soap solution would contain 0.505×10^{18} molecules, the area associated with one molecule of soap (if all of the soap were in the interface) would be 9.6×10^3 divided by 0.505×10^{18} or 190×10^{-16} sq. cm. This would be the minimum area which could be associated with one molecule of soap in the interfacial area of this emulsion. Since all the soap does not go into the interface the actual area is considerably larger. In comparison it may be noted that the area occupied by one molecule of oleic acid in a closely packed monomolecular film is 20.5×10^{-16} sq. cm.

In general only about 2% of paraffin oil is emulsified by pure water, but with soap as an emulsifying agent a highly concentrated emulsion, with about 75% of oil, is easily obtained by the formation of a highly dilute monomolecular film. The film gives such an emulsion even when it contains only one-tenth to one-fifth as many molecules of the soap as there are molecules of oleic or palmitic acid in a tightly packed monomolecular film. Such an emulsion is not stable, and on standing the area of its interface decreases and the area per molecule of soap in the film decreases, until the area becomes about that for a tightly-packed monomolecular film. Whether the film becomes thicker than this on long standing has not been determined but work on this problem is in progress.

Griffin[9] carried out careful analytical work on emulsions of kerosene

---

[9] Griffin, THIS JOURNAL, **45,** 1648 (1923); see also van der Meulen and Rieman, *ibid.*, **46,** 876 (1924).

and found that the soap film exhibited about half as many molecules (sodium oleate and oleic acid) as are present in a condensed film of oleic acid. His determinations would have been decisive if sufficient work had been done on the distribution of sizes of the droplets in the emulsions; but, since only about 200 droplets in each emulsion were measured, and these were observed in a drop of emulsion suspended from a cover glass, it is evident that the error in the interfacial area may have been very large. However, the areas per cubic centimeter of oil found by him are consistently lower than those obtained by us, so, unless the method of emulsification which he used was much less efficient, the areas which he obtained are probably too low. If this is true, the conclusion which he reaches, that the soap film is monomolecular and of a much lower concentration than a condensed film of the acid, would still be valid.

Table VI gives the area per molecule of soap (sodium oleate or oleic acid) for three emulsions, and minimum, not actual, areas for still others. The minimum areas given are those obtained on the basis of the (incorrect) assumption that all of the soap is in the interface.

TABLE VI

MOLECULAR AREAS POR THE SOAP AT THE INTERFACIAL FILM IN OIL-IN-WATER EMULSIONS (ACTUAL AND MINIMUM AREAS X 10^{16})

Emulsion	First day, min.	Third day, min.	Third day actual	Seventh day, min.	Tenth day, min.	15.5 months, min.
0.00083 M NaOl and Stanolax	190	..	..	..	..	..
0.005 M sodium oleate and octane	84	46"	61[a]	35 6	..	..
0.005 M cesium oleate and octane	82	48	64	30	..	..
0.01 M sodium oleate and octane	32.4	24	50	..	18.3	12.7
0.01 M cesium oleate and octane	32.7	..	..	..	..	..

[a] Determined on the second instead of the third day.

The evidence thus far obtained does not indicate that any of the soap films are thicker than monomolecular.

14. Summary

The distribution of sizes for the droplets in emulsions, both of the oil-in-water and the water-in-oil types, has been determined by a statistical method by the use of a projection apparatus used in conjunction with a microscope.

The following conclusions summarize the results of the work.

1. Within the range of microscopic observation there is no progressive shift in the maxima of the curves which show the distribution of diameter for emulsions made with soaps, as the cation is changed from sodium to potassium and to cesium.

2. In general, the greater the viscosity of the oil the greater the diameter of the largest drops in oil-in-water emulsion, but the peak in the diameter-distribution curve is not shifted.

3. A study of the changes in diameter-distribution, area-distribution and volume-distribution of emulsoid particles with aging gives a more exact method for determining stability than the older method of merely observing the gross features of the emulsion such as the separation of oil in bulk.

4. The method used in preparing an emulsion is one of the factors determining the distribution, but the striking feature of the present work is that the shift of the diameter at the maximum is so slight with the different methods of shaking or stirring employed.

5. The distribution of diameters of the particles of emulsions stabilized by soaps is changed only slightly by the addition of moderate concentrations of oleic acid or of the corresponding base (as of sodium hydroxide to sodium oleate). However, 0.1 M base increased considerably the number of small drops. The stability is, however, usually lessened considerably by the addition, for example, of 0.1 *M* oleic acid to the organic phase, or either 0.1 M sodium hydroxide or 0.1 M sodium chloride to the aqueous phase before the emulsion is formed.

It may be noted that the addition of either sodium hydroxide or sodium chloride to an aqueous-sodium oleate solution of low or moderate concentration greatly lowers the interfacial tension against an oil.

6. Such variations in the hydrocarbon chains of the soaps as were tried had little or no effect upon the distribution, except in the case of *potassium chaulmoograte in which the number of the smallest drops was greatly increased* above that for the oleate or stearate.

7. Magnesium and aluminum soaps gave emulsions of water in oil in which the distribution of sizes is the same, in general, as that found for those of the oil in water types.

8. Exceedingly dilute emulsions made *without* stabilizing agents also exhibit the usual type of distribution, but the drops are much smaller.

9. The area per molecule of sodium oleate in the interfacial film was 61×10^{-16} sq. cm. (61 Å.^{2}) for an emulsion made with 0.005 molar soap. At the time this area was determined, two days after the emulsion was made, the concentration of the soap in the aqueous phase was 0.00105 molar. For emulsions produced by 0.0008 sodium oleate and of Stanolax the molecular interfacial area was *greater* than 190 Å.^{2} according to measurements made within four hours of the time of preparation. It is evident that concentrated emulsions may be produced by means of an interfacial soap film in which the number of molecules of soap is *considerably less* than corresponds to a closely packed monomolecular film. However, the total interfacial area decreases with the time in such cases until finally the film becomes more tightly packed, but the evidence obtained thus far does not indicate that the film becomes thicker than monomolecular.

THE POTENTIOMETRIC DETERMINATION OF BROMINE, OCTAVALENT AND QUADRIVALENT OSMIUM IN HYDROBROMIC ACID SOLUTIONS

BY WILLIAM R. CROWELL AND H. DARWIN KIRSCHMAN

RECEIVED JANUARY 21, 1929 PUBLISHED JUNE 5, 1929

. Introduction

Among the problems engaging the attention of this Laboratory is that of a study of the rate of reaction between octavalent osmium and hydrobromic acid. Since the products of this reaction are quadrivalent osmium and bromine, it is apparent that its rate might be measured either by a determination at suitable time intervals of the remaining octavalent osmium, or of the bromine or quadrivalent osmium formed. Previous work on ruthenium[1] and octavalent osmium[2] and preliminary experiments on the potentiometric titration of hydrobromic acid solutions of bromine, octavalent and quadrivalent osmium indicated that trivalent titanium would be a satisfactory reducing agent for this purpose. In these last experiments the titration curve obtained by plotting voltage readings against cubic centimeters of reagent added showed three inflections. The first inflection corresponded to the reduction of the bromine to bromide ion, the second to the reduction of the octavalent osmium to the quadrivalent state and the third to the reduction of the quadrivalent osmium to the trivalent form.

The present paper deals with an investigation of the suitability of trivalent titanium as a reagent for determining one or more of these constituents with sufficient accuracy to warrant its use in the rate experiments. It describes the conditions employed and the results obtained in the potentiometric titration of hydrobromic acid solutions of (1) octavalent osmium, (2) bromine, (3) bromine in the presence of octavalent osmium, (4) bromine in the presence of quadrivalent osmium and (5) bromine, octavalent and quadrivalent osmium when present together.

Apparatus and Materials

The apparatus used was that employed in the potentiometric determination of octavalent osmium with hydrazine sulfate[2] except that provision was made for keeping the reducing agent as well as the titration vessel in an atmosphere of nitrogen.

Hydrobromic acid free of bromine was obtained by distilling the 42-48% acid and retaining the middle portion.

---

[1] Crowell and Yost, THIS JOURNAL, 50,374 (1928).

[2] Crowell and Kirschman, *ibid.*, 51,175 (1929).

The bromine solution was prepared by distilling the c. P. reagent from potassium bromide and sulfuric acid into distilled water.

The stock solutions of osmium tetroxide were prepared as described in the above mentioned article,[2] and were about 0.5 N in potassium hydroxide.

The thiosulfate solution was frequently checked against a potassium permanganate solution which had been standardized by means of sodium oxalate from the Bureau of Standards.

The titanium solutions were prepared from 1 *N* titanous chloride or sulfate. These were made 0.005–0.01 *N* in trivalent titanium and 0.3 *N* in hydrochloric, hydrobromic, or sulfuric acid. In order to remove traces of hydrogen sulfide, the undiluted acid and reagent were boiled together for one minute before making up to volume. The concentration of these solutions was determined by means of a solution of ferric sulfate which had been standardized against the permanganate solution. Standardizations were made before and after each set of three or four potentiometric titrations and the concentration was usually found constant within 0.1–0.2%. If the change was much greater than this the results obtained were rejected.

Titration of Octavalent Osmium with Titanous Chloride

Definite volumes of the standardized osmium tetroxide solution were titrated with a titanous solution in the presence of sulfuric, hydrochloric or hydrobromic acid. The procedure was as follows: the osmium solution was pipetted into the titration beaker containing about 50 cc. of the acid solution at room temperature, the cover of the beaker placed in position, a volume of titanous solution within 1–2 cc. of that required to reduce the osmium to the quadrivalent state added immediately and nitrogen then admitted slowly (one bubble every two seconds). This procedure was found necessary for accurate work on account of the volatility of the tetroxide. After the octavalent osmium had been reduced to quadrivalent, the nitrogen was bubbled through the solution more rapidly (1–2 bubbles per second). An amount of titanous solution was then added whose volume was within about 1 cc. of that necessary to effect reduction to the trivalent form and the titration continued until well past the inflection point.

The effect of different acids and of variations in the concentrations of these acids upon the color of the osmium solutions is an interesting feature of these titrations. The neutral or slightly acid solutions of octavalent osmium are colorless. When the reduction with titanous ion took place in a sulfuric acid solution, an amber color developed which persisted even after sufficient reagent had been added to reduce the osmium to the trivalent state. With this acid it was possible to obtain only one recognizable inflection in the titration curve, *viz.*, that corresponding to the reduction from the octavalent to the quadrivalent state. On addition of titanium reagent in the presence of hydrochloric acid the solution at first became light yellow, but when five equivalents of reducing agent per gram atom of osmium had been added, the solution became practically colorless. However, only one marked inflection in the titration curve was obtained, that corresponding to the octa–quadrivalent change. With hydrobromic acid (Curve B, Fig. 1) the solution became a deep orange-red as soon as reduction to the quadrivalent form was complete. Further addition of titanous solution produced a gradual change in color to a light yellow and when five equivalents of trivalent titanium per gram atom of osmium had been added, the solution became almost colorless. Two easily recognizable inflections were obtained: one when reduction to the quadrivalent state was complete; the other when reduction to the trivalent form had taken place. Since the most satisfactory drops in potential were obtained in solutions containing the hydrobromic acid, a more detailed study of the influence of the temperature and concentration changes was made with solutions containing this acid.

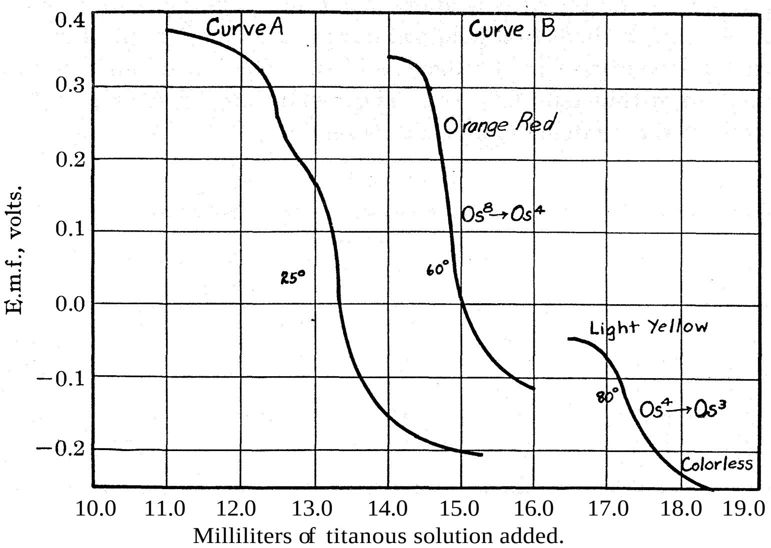

Fig. 1.—Potentiometric titration of hydrobromic acid solutions of octavalent osmium.

The concentration of hydrobromic acid which gave the largest drop in potential at the octa-quadrivalent end-point was found to be about 0.2–0.3 N. At acid concentrations below 0.1 N the solution became amber colored due probably to hydrolysis. At concentrations of acid higher than 0.3 N the drop in potential at this end-point was noticeably smaller and less abrupt. At room temperature a double inflection in the titration curve was obtained (Curve A, Fig. 1), while at 60° a single large drop in potential was obtained (Curve B, Fig. 1). Except in the immediate vicinity of the inflection point the voltage was considered constant when the rate of change was less than 3 millivolts per minute. In the reduction from the quadrivalent to the trivalent state the best inflections were obtained at a temperature of about 80° and at an acid concentration of about

1 *N* (Curve B, Fig. 1). A decided drift upward in the voltage readings was noticed at acidities below 1 *N*. The best results were obtained when the tetroxide solutions were first heated with strong hydrobromic acid in sealed tubes at the temperature of the steam-bath. On diluting these heated solutions to an acidity of about 1 *N* and titrating the quadrivalent osmium at 80°, sharper and greater drops of potential were obtained than when the titrations were carried out at the same temperature and acid concentration but without previous continued heating at 98°. Moreover, there was very little drift in the voltage readings. Results obtained in this manner will be described in more detail in the last section.

Table I contains the results of four typical titrations of a stock solution of octavalent osmium with titanous chloride. The end-points were determined from the inflection points of a curve obtained by plotting voltage against cubic centimeters of reagent added. The inflections could be determined to within 0.02–0.05 cc. The results are compared with those obtained by the modified iodimetric method.[2]

TABLE I

POTENTIOMETRIC TITRATION OF OCTAVALENT OSMIUM SOLUTIONS WITH TITANOUS CHLORIDE

Initial volume = 52–55 cc.

Normality of HBr	OsO_4 soln., cc.	Cc of $TiCl_3$ used		OsO_4 found, millimoles/liter		
		$Os^8 \rightarrow Os^4$ infl.	$Os^4 \rightarrow Os^3$ infl.	$Os^8 \rightarrow Os^4$ infl.	$Os^4 \rightarrow Os^3$ infl.	Iodide method
0.2	4.96	18.30	23.70	6.33	6.56	6.35
.2	4.96	18.28	...	6.30	..	6.35
.3	2.005	9.80	12.25	6.26	6.26	6.35
.4	2.005	10.20	12.90	6.26	6.33	6.35

In the second experiment no satisfactory inflection corresponding to the reduction from quadrivalent to trivalent osmium was obtained. While the third and fourth experiments indicate that the quadri–trivalent break gives as good results as the octa–quadrivalent break, probably the data of the first experiment are more typical, since the general tendency is for the second inflection to give decidedly high results. The results determined from the first inflection point are usually lower than those obtained by the modified iodide method, due probably to loss of the volatile tetroxide during the titration and to the fact that the volatility of tetroxide even from an alkaline solution causes such a rapid decrease in concentration that it is important to make the potentiometric and iodimetric determinations simultaneously. In the later experiments improved technique made this difference much smaller as shown by the results given in Table III.

The Potentiometric Titration of Bromine with Titanous Sulfate

To determine the feasibility of estimating bromine in the presence of hydrobromic acid, octavalent and quadrivalent osmium, four series of experiments were conducted. Since Hendrixson[3] has shown that it is possible to determine bromine potentiometrically in its sulfuric acid solution by means of trivalent titanium, the first series was merely to confirm his results and consisted in the potentiometric titration of sulfuric acid solutions of bromine with the titanous sulfate. The second series was conducted in the presence of hydrobromic acid, the third series in the presence of this acid and 2 cc. of osmium tetroxide solution and the fourth series in the presence of this acid and 2 cc. of quadrivalent osmium solution.

In the first three series the samples of stock bromine solution were pipetted into 50–80 cc. of ice-cold distilled water containing the other constituents. A volume of titanous solution within 1 cc. of that required in a preliminary titration was added immediately and the titration rapidly completed below 5° while nitrogen was bubbled through the solution at the rate of one bubble every two to three seconds. Unless the bromine solution was run into a fairly large volume of cold solution the loss was incredibly high. It was found that if the contents of a 50-cc. pipet was allowed to drain into the empty titration vessel at room temperature and the titration conducted in this solution, the loss was over 10%.

The fourth series of experiments was carried out as follows: a 2-cc. sample of the stock tetroxide solution and 5 cc. of 8 N hydrobromic acid were heated for several hours at 98° in a closed tube. The tube was cooled in an ice-bath, opened under about 40 cc. of ice water, washed into the titration vessel with an additional 40 cc. of ice water and the liberated bromine titrated with the titanous solution. To this quadrivalent osmium solution, which now contained no free bromine, was added a known volume of the stock bromine solution and the titration carried out as before. In these solutions there was always present a small amount of octavalent osmium.[4] During a titration of the bromine the voltage readings became constant to within a millivolt in less than two minutes.

Results of the four series of titrations together with those obtained by the iodide method of bromine determination are recorded in Table II.

The results with sulfuric acid confirm those of Hendrixson. The results also show that bromine can be determined potentiometrically with trivalent titanium in the presence of hydrobromic acid. The average difference between the potentiometric and iodimetric methods in Series 1 and 2 where these acids were present is 0.3–0.4%. In Series 3 where osmium tetroxide was present the percentage difference between the titanous sulfate and iodide–thiosulfate methods varies from about 3% for the highest concentrations of osmium tetroxide and hydrobromic acid to about 0.5%

---

[3] Hendrixson, THIS JOURNAL, 45, 2013 (1923).

[4] This seems to indicate that the osmium is not completely reduced even on protracted heating in concentrated hydrobromic acid but that an equilibrium is reached in which the concentration of octavalent osmium is very small but measurable.

	0.27 N HBr		.5	,00896	28.95	10.38	10.39

for the lowest concentrations of these substances. In the latter case the concentration of the octavalent osmium is approximately 0.1 millimole per liter, while the concentration of the hydrobromic acid is 0.1 N. The experiments of Series 4 indicate that bromine can be determined without appreciable error in the presence of quadrivalent osmium as high in concentration as 0.5 millimole per liter when the hydrobromic acid is as high in concentration as 0.3 N.

Potentiometric Titration of Bromine, Octavalent and Quadrivalent Osmium in Hydrobromic Acid Solutions Containing All Three Constituents

The next step in the investigation was the determination of bromine, octavalent and quadrivalent osmium in hydrobromic acid solutions containing the three constituents in such proportions as to require on titration suitably large volumes of the reducing agent. These solutions were prepared as follows. Samples of 1.996 cc. of stock tetroxide solution which contained approximately 23 millimoles per liter and 5 cc. of 2.4 N hydrobromic acid were sealed into glass tubes of about 20-cc. capacity and heated at 98° for about three hours. The tubes were then cooled in an ice-bath, broken under about 40 cc. of the ice-cold water, rinsed into the titration vessel with an additional 40 cc. of the cold water and the titrations carried out immediately. As soon as the bromine–bromide ion inflection had been determined, an amount of titanous solution within 1–2 cc. of that necessary to reach the octa–quadrivalent end-point was added immediately. The temperature was then raised to 60° and the titration continued until the $Os^8 \longrightarrow Os^4$ break had been passed. Next, 2.5–8.0 cc. of 8 N hydrobromic acid was added, the temperature was raised to 80° and the quadrivalent–trivalent inflection point was determined. During the titration the nitrogen was bubbled through the solution in the same manner as in the titration of osmium tetroxide. A typical titration curve showing the three inflections is shown in Fig. 2.

The concentration of the stock osmium tetroxide was determined by the modified iodimetric method, care being taken to conduct the potentiometric and iodimetric determinations simultaneously.

The results obtained by the two methods are shown in Table III. For convenience the final results have been expressed in terms of milliequivalents of bromine. On this basis, if amounts of tetroxide are expressed as equivalent bromine, the titration of the 1.996 cc. of tetroxide solution before heating should be equal to the liberated bromine plus the undecomposed tetroxide after heating.

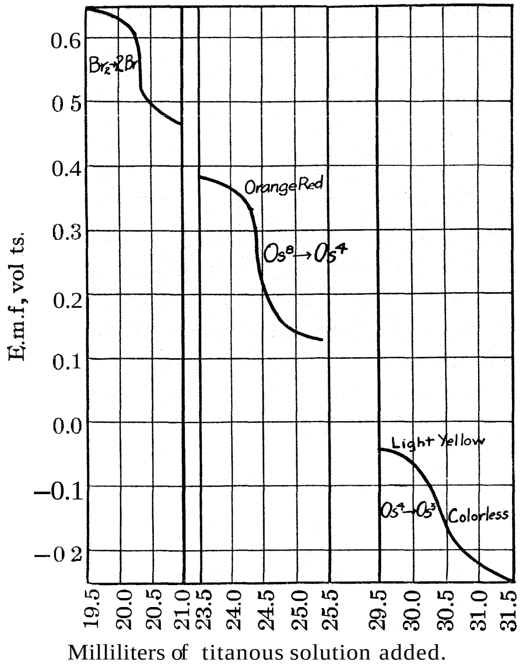

Fig. 2.—Potentiometric titration curve for solution containing bromine, hydrobromic acid, octa- and quadrivalent osmium.

TABLE III

POTENTIOMETRIC DETERMINATION OF BROMINE, OCTAVALENT AND QUADRIVALENT OSMIUM IN HYDROBROMIC ACID SOLUTIONS

Volume of OsO_4 solution used = 1.996 cc. Initial volume = 90–100 cc. Initial concentration of HBr in bromine titration = 0.17 *N*. Initial concentration of HBr in OsO_4 titration = 0.15 N. Initial concentration of HBr in Os^4 titration = 0.4–0.8 *N*

Titanous soln., *N*	Titanous solution used $Br_2 \longrightarrow Br^-$, cc.	$Os^8 \longrightarrow Os^4$, cc.	$Os^4 \longrightarrow Os^3$, cc.	Bromine found $Br_2 \longrightarrow Br^-$ Infl., milli-equivalents	Milliequivalents of total bromine calcd. $Os^8 \longrightarrow Os^4$ infl.	$Os^4 \longrightarrow Os^3$ infl.	Iodide method
0.00909	10.00	...	...	0.0909	....	....	0.1837
.00907	9.95	20.24	25.80	0.0903	0.1836	0.1872	.1837
.00906	10.15	20.40	25.95	.0919	.1849	.1882	.1837
.00906	...	20.12	...	....	.1822	....	.1837
.00905	10.20	20.40	...	.0923	.1845	....	.1837

An inspection of Table III shows that for the last four tubes the average deviation of the results of the bromine titrations from the mean is about 0.6%. The general tendency of this bromine value is to increase somewhat. However, the total bromine values (*i. e.*, the free bromine plus the undecomposed tetroxide) are of more significance and are in satisfactory agreement with those obtained by the iodimetric method, the average difference between the latter and the individual potentiometric values being about 0.5%.

It seems evident that it is possible by this method to conduct analyses of solutions in reaction tubes containing the four constituents and obtain results of determinations of bromine and of bromine plus octavalent osmium reliable to within 0.6%. In the rate experiments for which this method is primarily intended, this reliability is quite sufficient. The accuracy can be somewhat increased, if desired, by determining the concentration of the tetroxide solution added to the tubes before heating by potentiometric titration with hydrazine sulfate,[2] titrating only the liberated bromine with the titanous solution, and obtaining the undecomposed tetroxide by difference.

In the experiments where it was possible to obtain fairly good inflections in the curve corresponding to the reduction of the quadrivalent osmium to the trivalent, it will be seen that the values obtained are 2.0–2.5% higher than those obtained by the iodimetric method.

Summary

A method is described for the potentiometric determination of bromine and octavalent osmium in hydrobromic acid solutions containing bromine, octavalent and quadrivalent osmium by titration with solutions of titanous salts. The voltage–cubic centimeter curves obtained show three inflections—the first corresponding to the reduction of the bromine to bromine ion, the second to the reduction of the osmium from octavalent to quadrivalent and the third to the reduction of the quadrivalent osmium to trivalent.

Results reliable to 0.6% were obtained using the first two inflections. The third inflection was not found to be satisfactory for quantitative work.

The potentiometric titration of acid solutions of osmium tetroxide is described and some interesting color changes are noted.

THE SOLUBILITY OF GOLD IN MERCURY

BY ARTHUR A. SUNIER AND BRUCE E. GRAMKEE

RECEIVED JANUARY 21, 1929 PUBLISHED JUNE 5, 1929

Although three rather extensive researches on the system gold-mercury have been published[1] within the last ten years, the disagreement in the various results is most remarkable, particularly at lower temperatures. Quite recently rather precise results on the system silver-mercury, using a new type of solubility tube, have been published by Sunier and Hess;[2] it has therefore been thought advisable to redetermine the solubility of gold in mercury using the apparatus just referred to. This paper will present the results obtained on this system between the temperatures 80 and 200".

Materials.—Mercury which had been run through a five foot Meyer column containing mercurous nitrate and distilled in an all-glass apparatus at reduced pressure according to the method of Hulett and Minchin[3] was used in the first three determinations. The mercury collected in the evaporation of amalgams was used for the remaining determinations. Thousand-fine gold foil obtained from the Philadelphia Mint was used in preparing the amalgams of known concentration and in the first few determinations. The gold residues were used to make up the samples for the later determinations.

Apparatus.—The solubility tube, Fig. 1, a modification of the one used by Sunier and Hess, was made of pyrex glass and consisted of the sample tube, A, a capillary filter finely constricted at B, a glass wool filter, C, the upper tube, D, in which the amalgams were prepared and the capillary, E, which is used in the sampling of amalgams. This capillary had a diameter of one-half millimeter.[4]

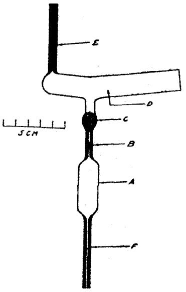

Fig. 1.—Solubility tube.

The solubility tubes were fastened to a rack made of square brass rod and built in a figure H; a side view of the rack is shown in Fig. 2. The tubes in this position are ready for sampling; when turned 180 degrees about the point P the tubes are in the shaking position. The rack (holding four tubes) pivots about the point P and is held in either position by the lock L. The amalgams were shaken by pivoting the vertical rod R in the center and imparting a pendulum-like motion to the tubes on the lower end of the rod of such an amplitude as to completely transfer the amalgams from

[2] Sunier and Hesq THIS JOURNAL, 50, 662 (1928).

[3] Hulett and Minchin, *Phys. Rev.*, 21, 388 (1905).

[4] There was, of course, the *possibility* that the mercury in the capillary did not become saturated with gold (since diffusion processes alone must be relied upon to accomplish this); then, on breaking the capillary for sampling, this mercury would drop into the main body of the amalgam, causing a dilution effect. Because of this possibility the bore of the capillary was made so small that no appreciable error would be caused if no gold at all was to be found in the small portion of mercury. The excellent agreement of the determinations from both the low and high sides gave added proof that no error arose from this cause.

one end of the tubes to the other. The motion imparted to the rod was obtained by a motor-driven eccentric.

The thermostat, a ten-gallon copper tank heavily lagged, containing heavy cylinder oil, was heated by four 500-watt immersion heaters and agitated by four double paddle stirrers (1000 r.p.m.). Thermal balance was obtained at each temperature by two grid heaters of variable resistance placed on opposite sides of the bath. The mercury thermoregulator operating a 40-watt elongated bulb kept the temperature constant to less than 0.05" over a three-hour period.

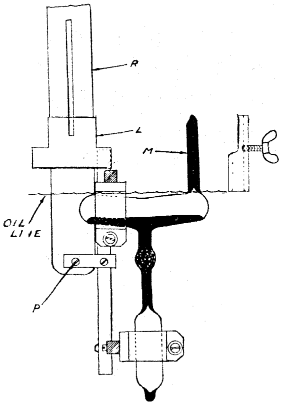

Fig. 2.—Sampling devices.

All temperatures were read from two mercury thermometers graduated in degrees, one standardized by the Physical Laboratory of Taylor Instrument Companies and the other recently standardized by the Bureau of Standards.

Experimental Procedure

The fine capillary, E (Fig. 1), was sealed off and file marked. About 4 cc. of mercury and a 300% excess of gold (using Britton and McBain's data as a guide) were put into the tube, D, which was then sealed off. Capillary F was attached to a Cenco pump, the air evacuated to about 5 mm. and sealed off near the lower end of Tube A.

For a determination of the solubility at a certain temperature, eight tubes were made up and saturation was attained from the low and then from the high temperature side, four tubes being used in each. In the first case the bath was raised to the desired temperature as quickly as possible (requiring at least an hour), the materials were shaken for three hours after thermal balance was obtained and then sampled.

For the corresponding high-side determination the bath was held for three hours at least 5° (sometimes 10 to 15°) above the desired temperature and then allowed to drop back to the determination temperature. This was succeeded by the usual three-hour shaking at constant temperature and sampling. The good agreement is sufficient evidence that equilibrium was attained.

When the tubes were ready to be sampled, the shaker was stopped, the lock L raised and the tubes inverted (with the aid of a brass rod not shown) to the position shown in Fig. 2. The fine capillary was broken at the file mark, M, by means of the apparatus, shown separately in Fig. 2, which is a square brass rod drilled to fit the capillary and fitted with a thumb screw. The capillary is broken by tightening the thumb screw. Both the tipping and breaking devices have greatly facilitated the sampling procedure and have been proved to be very reliable. After filtration the tubes were removed from the bath, wiped clean and cooled. The sample tubes were cut off and the amalgam samples transferred to weighed crucibles.

The evaporation method of analysis for gold was employed, the amalgams being heated in porcelain crucibles placed on iron supports in a large pyrex tube heated by gas. A stream of dry hydrogen was passed through the tube, which was held at about 200" (higher temperatures increase the danger of loss of samples through bumping) until no mercury could be detected with the eye; then the temperature was raised to 500–550° and held there for twelve to sixteen hours in the final runs. The apparatus used is apparently similar to that of Britton and McBain in their Series

III, the percentage of gold running from about 7 to 55% in this series; at lower temperatures and percentages of gold, they used the ferrous ammonium sulfate method of analysis; in neither case is any mention made of the precision of analysis, no blank determinations being recorded. This being the case, considerable preliminary work was done before adopting the evaporation method of analysis; a few of the results obtained will now be presented.

This method of analysis was checked as follows: weighed samples of gold foil heated at 500° for four hours in the stream of hydrogen showed no change in weight; samples of mercury slowly evaporated at 200° and then heated to 500° yielded no weighable residue; lastly, four mixtures of gold and mercury were prepared and the mercury was slowly evaporated at 200°; then the samples were heated to 300° for four hours. Additional heating periods are indicated in Table I. The pieces of gold foil weighed 0.4082, 0.3673, 0.4199, 0.3517 g., respectively; the mercury weighed about 50 g. in each case. The results of this experiment are given in Table I.

TABLE I

EVAPORATION OF MERCURY FROM GOLD–MERCURY MIXTURES

Temp., °C.	Heating period, hours	Percentage of mercury still present in gold			
300	4	6.77	7.14	14.5	6.74
300	4	3.27	3.48	8 38	2 84
400	4	0.76	0.70	2.26	0.43
450	4	0.17	0.23	1.14	0.17

This procedure yielded results 0.2% high, hence in later work (Table II and following) higher temperatures were used with much better results. Merz and Weith[5] found that gold retained about 0.33% of mercury after heating gold amalgams at the temperature of sulfur vapor (445°) for sixty hours.

To test the whole experimental arrangement, four tubes were made up containing weighed amounts of gold and mercury and carried through the entire procedure. Table II shows the excellent results obtained, especially for such a low percentage of gold.

TABLE IV

SOLUBILITY OF GOLD IN MERCURY (SUMMARY OF EXPERIMENTAL DATA)

No. of detns.	8	8	8	4	8	7	7
Temp., °C.	80.8	101.2	121.7	142.1	159.2	182.3	201.1
At. % sol.	0.467	0.697	1.021	1.482	1.847	2.434	2.875[a]
Av. dev., p.p.t.	12.8	6.4	12.1	1.3	3.4	2.5	24.7

[a] This value is a result of seven determinations made by Mr. O. Fitzsimmons, working in this Laboratory, using the tube developed by Sunier and Hess and evaporating amalgams in a vacuum of 0.003 mm. and flaming the residues. A run at 100.1° using this method of analysis gave results in substantial agreement with those presented here. Both methods of analysis are thus quite satisfactory.

TABLE V

SOLUBILITY OF GOLD IN MERCURY AT ROUNDED TEMPERATURES (FROM LOG N vs. $1/T$ PLOT)

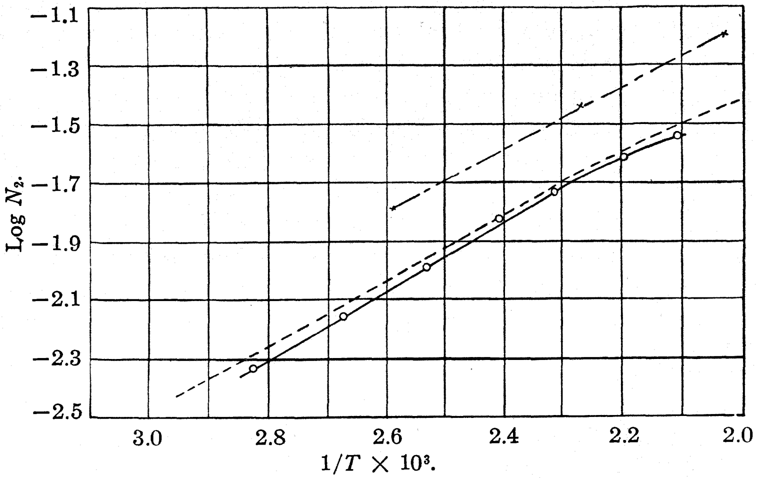
Temp., °C.	80.0	100.0	120.0	140.0	160.0	180.0	200.0
100 N (from curve)	0.459	0.684	0.996	1.385	1.871	2.380	2.849
100 N (calcd.)	0.457	0.688	0.994	1.380	1.864	[a]	[a]
Error, p.p.t.	4	6	2	4	4	[a]	[a]

[a] Equation not valid above 160°.

Of the 48 final determinations only five have been omitted. Of these one was rejected because the deviation was greater than four times the average deviation from the mean for that temperature; the other four constituted the high side at 140° and were rejected because the gold spattered during evaporation; considering the remarkable agreement of the determination from the low side (1.3 p.p.t.) the high-side determination was not repeated. All solubilities are given in atomic per cent. (atoms of gold per 100 total atoms).

Discussion of Results

In Fig. **3** the results are plotted as log N *vs.* $1/T$. It is seen that the values obtained by Parravano and Britton and McBain are greater than those obtained by the authors. The dashed line represents the best line obtained from a plot of Britton and McBain's data, which are on the average 5–10% higher than those presented here. Their analytical procedure, discussed earlier, may account for the high results. The data of Parravano are on the average about 75% high, as compared with those presented here. A fusion method was used by Parravano, so it is difficult to judge where error may have crept in, unless it be due to supercooling which is so likely to give trouble in such cases. Braley and Schneider's results are so very different (and are not plotted in Fig. 3) from the others just mentioned and those presented here, that it seems probable that some serious error was made during the conduct of the research. Kasanzeff's results, obtained so long ago, are indeed remarkable for their probable accuracy; his results are in substantial agreement with those presented in this paper. Kasanzeff pressed his amalgams through chamois skin and also filtered them through a fine capillary; analytical details are rather scanty—indeed the whole article is really an abstract only three paragraphs long.



×——–, Parravano; - - - -, Britton and McBain; —○—, Authors.

Fig. 3.—Solubility of gold in mercury.

A large plot was carefully constructed and used in determining the equation of the straight line, which can be used for temperatures up to 160° only. The equation found is $\log_{10} N = -1167.4(1/T) + 0.966$. The solubility values in Table V were obtained from the large plot and by means of this equation.

It will be noted that when $\log N$ is plotted against $1/T$, the resulting line is not straight at higher temperature. This, it appears, may be true for one or more of three reasons (even though ideal solutions may be in question): (1) the latent heat of fusion of the solid phase is a function of the temperature; (2) the solid phase may not be the one indicated; (3) an actual transition in the solid phase may take place at the temperature where the break occurs. These possibilities will not be discussed at present. If gold amalgams are not ideal solutions the significance of the slope of the $\log N$ vs. $1/T$ curve is rather complicated. Studies along these lines are also under way, not only for amalgams, but other systems. It may be mentioned that some years ago Hildebrand,[6] after a rather thorough research on the vapor pressures of gold and some other amalgams, concluded that the rather large positive deviations from Raoult's law which were encountered might be explained on the assumption of compound formation; more recently,[7] however, the same investigator has said that the gradual accumulation of evidence tends to cast doubt upon this explanation and confirm the theory that internal pressure differences may be largely responsible for such deviations.

Summary

1. A method of preparing and analyzing gold amalgams has been described which yields results 2 parts per thousand high.

2. The solubility tube described earlier has been found suitable (with only slight modification) for the investigation of the system gold-mercury. Fifty-six determinations have been made in the range of temperature 80 to 200°; the present results are considerably lower and the precision of measurement is considerably higher than those previously reported by most other workers.

3. The empirical equation $\log_{10} N = -1167.4(1/T) + 0.966$ expresses the experimental results to 160°, but not above this temperature.

THE CRYSTAL STRUCTURE OF BARIUM

BY A. J. KING[1] AND G. L. CLARK

RECEIVED JANUARY 26, 1929 PUBLISHED JUNE 5, 1929

In 1921 Hull[2] determined the crystal structure of calcium, for which he reported a face-centered cubic lattice with a parameter of 5.56 Å. at room temperature. Prior to the beginning of the investigation here reported the structure of barium and strontium had not been determined, but recently a paper has appeared by Simon and Vohsen[3] presenting the results of their measurement of the lattice structure of strontium, to which they assign a farce-centered cubic structure having a unit edge of 6.03 Å.

Optical measurements of calcium and strontium at room temperature indicate that these metals do not crystallize with cubic symmetry, but with hexagonal symmetry. Since x-ray data do not confirm this, it is possible that a polymorphic transformation occurs above room temperature, leaving the external appearance of the crystals unchanged.

Barium with a purity of 99.9% was used for the x-ray study of this metal. This was prepared by a method described elsewhere.* The samples for x-ray analysis were prepared by pressing the metal into a cylindrical bar in a steel die, then rolling this into a thin foil under dry oil in order to protect the foil from oxidation as far as possible. The foil was cut into narrow ribbons and carefully sealed in pyrex tubes with pure sodium chloride, which served as a standard for the measurement of the diffraction pattern. The sodium chloride and the metal were separated so that their spectrograms were adjacent along the center of the film. Although soft metals are known to recrystallize at room temperature, random orientation of the crystallites was assured by annealing the sample at 120°. Since the spectrograms show no lines which could be ascribed to barium oxide, it is evident that this method of procedure is satisfactory and that oxidation is at most but superficial.

The powder spectrograms were taken with the General Electric x-ray diffraction apparatus. This is provided with a Coolidge x-ray tube containing a molybdenum target and with quadrant cassettes which contain zirconium dioxide filters, so that only the Mo-K, radiation is effective.

The x-ray data agree very well with those for a body-centered lattice with two atoms in the unit cell, the unit edge of which is 5.015 ± 0.003 Å. The relative intensities of the lines compare favorably with those calcu-

$a_0 = 5.015 \pm 0.003$ Å.

lated for this type of lattice. The density, 3.58, calculated from x-ray data further corroborates this assumption and is in harmony with the values 3.66 and 3.64 obtained by actual measurement.[5] The atomic radius of barium is found to be 2.171 Å., whereas the closest approach of the ions of barium in barium fluoride is only 2.684 Å. This is not in conformity with the hypothesis of constant atomic radii, but is of the same magnitude as that of calcium, 1.963 Å., as determined by Hull, and of strontium, 2.131 Å., calculated from the data of Simon and Vohsen.

In view of the disagreement between optical data and x-ray measurements, further studies are being undertaken to ascertain the possible existence of other modifications of the alkaline earth metals at higher temperatures. The work of Simon and Vohsen shows that but one form of strontium exists between room temperature and 100° absolute.

Ebert and Hartmann[6] have recently published the results of their study of the crystal structure of barium. Their results verify those of the authors. A preliminary paper on this subject[7] has apparently escaped their attention.

An investigation of the binary systems calcium–barium, calcium–strontium and barium–strontium is at present under way and will be published in a subsequent paper.

Summary

1. The crystal structure of very pure barium has been found to be body-centered cubic with a parameter of 5.015 ± 0.003 Å.

PARTIAL MOLAL HEAT CAPACITIES AND RELATIVE PARTIAL MOLAL HEAT FUNCTIONS IN SOLUTIONS OF MOLTEN METALS

BY ALBERT N. GUTHRIE AND EARL E. LIBMAN

RECEIVED FEBRUARY 8, 1929 PUBLISHED JUNE 5, 1929

There exist in the literature no data on the partial molal properties of solutions of molten metals. There is likewise a great dearth of experimental work from which such data may be calculated. It seems worth while, therefore, to put on record the following results for the partial molal heat capacities and relative partial molal heat functions of Pb–Sb and Bi–Cd solutions calculated from the work of Wüst and Durrer.[1] By direct calorimetric measurements these investigators have determined the values of the specific heats of the above solutions at different concentrations from which the partial molal heat capacities may be determined. They have also obtained the heats absorbed per gram in going from the pure solid components to the liquid solution at the eutectic temperature, for different concentrations. From these data the relative partial molal heat functions may be calculated.

Relative Partial Molal Heat Functions

Consider a solution made up of components a and b. Let $H = E + PV$ be the total heat function of the solution. Then the partial molal heat function h_a of component a in the solution is defined as $(\mathrm{d}H/\mathrm{d}n_a)_{PTn_b}$ where the n's are the number of moles of the respective components in the solution. If h_a^0 is the value of h_a in some arbitrarily chosen reference state, $\bar{h}_a = h_a - h_a^0$ is called the relative partial molal heat function. It is convenient to choose for the reference state the infinitely dilute solution of a in b.[2]

Consider a system composed of some pure a and some solution. Let some of the a go from the pure phase into the solution. If Q is the heat absorbed by the system, then the molal heat of solution of a is defined as $l_a = (\mathrm{d}Q/\mathrm{d}n_a)_{PTn_b}$. Knowing l_a we may calculate $\bar{h}_a$ from the relation

$$\bar{h}_a = l_a - [l_a]_{n_a = 0} \tag{1}$$

Finally, when $\bar{h}_a$ is known, $\bar{h}_b$ can be calculated from

$$\int_{n_a = 0}^{n_a} \mathrm{d}\bar{h}_b = - \int_{n_a = 0}^{n_a} \frac{n_a}{n_b}\, \mathrm{d}\bar{h}_a \tag{2}$$

---

[1] "Forschungsarbeiten auf dem Gebiete des Ingenieurwesens," Heft 241 (1922).

[2] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, pp. 87–95.

Let us now fix ow attention upon a system of two components completely miscible in the liquid state, completely immiscible in the solid state. Such a system has a definite eutectic temperature. Let L be the heat absorbed when one mole of b and n, moles of a go from the pure solid state at atmospheric pressure and eutectic temperature into the liquid state to form a solution. Then if λ_a and λ_b are the molal heats of fusion, at the eutectic temperature, of *a* and b

$$L = \lambda_b + \lambda_a n_a + \int_{n_a = 0}^{n_a} l_a \mathrm{d}n_a \qquad (3)$$

and

$$\left(\frac{\mathrm{d}L}{\mathrm{d}n_a}\right)_{PTn_b} = \lambda_a + l_a \qquad (4)$$

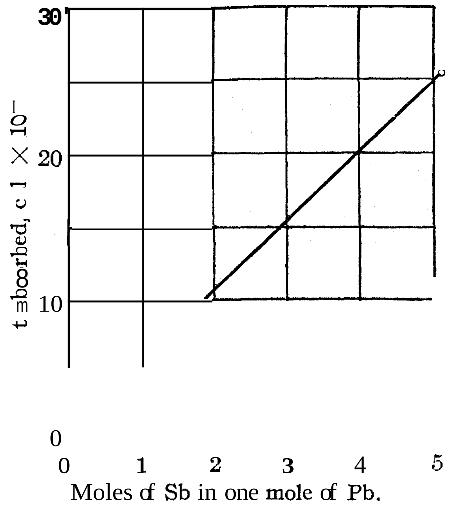

Fig. 1.—Relative partial molal heat functions in Pb–Sb solutions at eutectic temperature.

Values of L are given by Wiist and Durrer in the article mentioned, for different concentrations. Plotting L against n_a and drawing tangents, values of l_a may be determined by (4). As shown in Figs. 1 and 2, the L-n, curves for the systems Pb-Sb and Bi-Cd are straight lines. Thus $(\mathrm{d}L/\mathrm{d}n_a)_{PTn_b}$ is, in each case, a constant, independent of the concentration, and by (4) the heats of solution for these systems are likewise constant, independent of the concentration. Then by (1) and (2) the relative partial molal heat functions at the eutectic temperature are strangely enough zero for these solutions at all concentrations (Tables I and 11).

Partial Molal Heat Capacities

Let C_p he the total heat capacity of a solution of components a and *b*. Then the partial molal heat capacity of *a* is defined as $c_{pa} = (\mathrm{d}c_p/\mathrm{d}n_a)_{PTn_b}$. The data of Wüst and Durrer give the specific heats for the solutions Pb–Sb and Bi–Cd

[b] In the original article some error was made in the calculation of this value and it has been recalculated from the experimental data.

for different weight per cents. These are plotted in Figs. 3 and 4. The tangents to these curves at any concentration intersect the axes at points representing the partial specific heats of the components.[3] For the systems considered the curves are straight lines and so the partial specific heats, and also the partial molal heat capacities, are constant, independent of the concentration and equal to the molal heat capacities of the pure components in the liquid state. This circumstance affords a means of checking the results by comparison with data obtained by Wüst, Meuthen and Durrer[4] from the pure components (Table III).

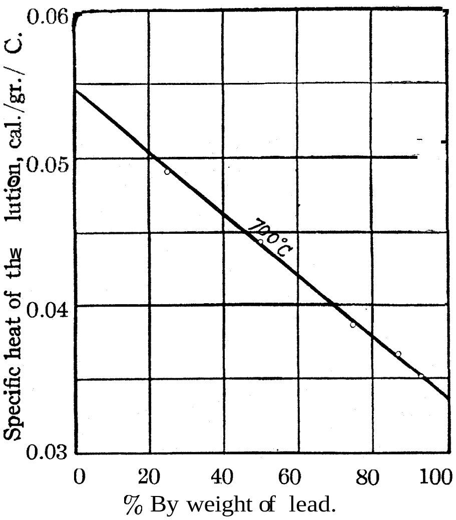

Fig. 3.—Partial molal heat capacities in Pb–Sb solutions.

In making use of the valuable data obtained by these investigators, it is to be noted that some errors have been made in the calculations. Thus Table 29 on the true specific heats of lead, above the melting point, is in error and should be recalculated directly from the experimental data given in the article. Unfortunately the errors noted have been reproduced in the "Handbook of Chemistry and Physics"[7] published by the Chemical Rubber Publishing Co., the Smithsonian Physical Tables (7th edition), and perhaps elsewhere.

We have seen that the partial molal heat capacities of Bi–Cd are constant and equal to the molal heat capacities of the pure liquid components both at 300 and 1000°. It is reasonable to assume that this is true for all temperatures. If we do so we may readily calculate the relative partial molal heat functions at temperatures other than that of the eutectic.

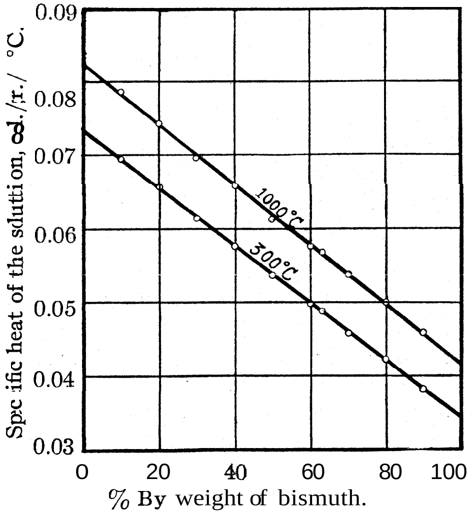

Fig. 4.—Partial molal heat capacities in Bi–Cd solutions.

We have $(\mathrm{d}h_a/\mathrm{d}T)_p = c_{pa}$ and $(\mathrm{d}h^0_a/\mathrm{d}T)_p = c^0_{pa}$, so that $(\mathrm{d}h_a/\mathrm{d}T)_p = [\mathrm{d}(h_a - h^0_a)/\mathrm{d}T]_p =$

	1000 °C.	.0823

		Partial molal heat capacity, all concentrations
Bi	300 °C.	7.20
	1000 °C.	8.69
Cd	300 °C.	8.24
	1000 °C.	9.25

[a] Wüst and Durrer.

$c_{pa} - c^0_{pa}$. But on the assumption just made $c_{pa} - c^0_{ap} = 0$, and we have $(d\bar{h}_a/dT) = 0$. From this we see that $\bar{h}_a$ is independent of the temperature. Thus not only at the eutectic temperature but at all temperatures the relative partial molal heat functions of the components are zero at all concentrations.

Conclusions

1. The relative partial molal heat functions of the components of the systems Pb–Sb and Bi–Cd have been calculated for the eutectic temperatures. They are found to be equal to zero independent of the concentrations.

2. The partial molal heat capacities of the components of the system Pb–Sb have been calculated at 700° and have been found to be constant and equal to the molal heat capacities of the pure liquid components. The same calculation has been performed for the system Bi–Cd at the temperatures 300 and 1000° and in each case the partial molal heat capacities have been found to be constant, independent of concentration and equal to the molal heat capacities of the pure components.

3. Assuming that the partial molal heat capacities are the same as the molal heat capacities of the pure liquid components, not only at the temperatures for which this has been verified but at all others, it is shown that the relative partial molal heat functions are zero not only at the eutectic temperature but at all others.

THE THERMAL REACTION BETWEEN POTASSIUM OXALATE AND MERCURIC CHLORIDE

BY W. E. ROSEVEARE AND A. R. OLSON

RECEIVED FEBRUARY 11, 1929 PUBLISHED JUNE 5, 1929

The oxidation of oxalates by mercuric chloride as expressed by the following equation

$$2HgCl_2 + C_2O_4^{--} = Hg_2Cl_2 + 2Cl^- + 2CO_2$$

has been studied by a large number of investigators during the past seventy-five years. It is not surprising that the conclusions drawn by the various investigators should be lacking in agreement, since the reaction is influenced by both positive and negative catalysts. The reaction is sensitive not only to heat, but also to light of a frequency range extending all the way from the visible to the very hard x-rays. The present investigation, which deals with the thermal reaction in neutral aqueous solutions, is the first section of a more general investigation of this reaction.

Methods **of** Measuring the Rates of Reaction.—Two methods were used for making the kinetic measurements. The first consisted in sealing the reacting solutions in pyrex flasks, which were kept in a thermostat at the desired temperature for definite lengths of time, after which they were removed from the thermostat and quickly plunged into cold water. The bulbs were broken open and the amount of mercurous chloride formed was determined gravimetrically. In some cases, however, the amount of mercury remaining in solution was determined by precipitating as sulfide.

A second method was used where samples for analysis were drawn at different times from the same solution. This method involved the use of the apparatus shown in Fig. 1, which consists of a one and one-half liter pyrex bulb with a 1-mm. capillary sealed in through the top and extending to 0.5 cm. from the bottom. A is an all-glass condenser about 12 cm. long, through which the capillary passes to the capillary stopcock. Inside the condenser the capillary is thin walled to facilitate the rapid cooling of the contents while a sample is being taken. The tube B was used to introduce the reaction mixture, after which it was sealed off at the constriction. The bulb was immersed in a thermostat up to the point C. Water was passed through the condenser jacket and through a coil of copper tubing which was placed around the stopcock to keep the stopcock grease from melting and blowing out, but which could be removed when a sample was to be withdrawn. The vapor pressure of the water and carbon dioxide in the bulb gave a total pressure of about two atmospheres, which forced the solution out through the capillary when the stopcock was opened.

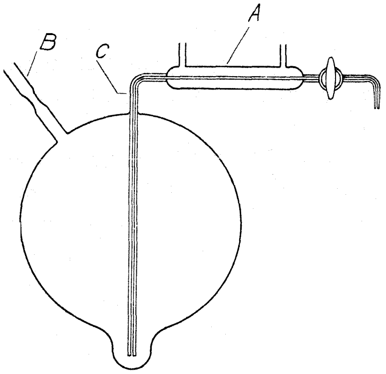

Fig. 1.

Before taking a sample, sufficient solution was run out to wash out the capillary and then the sample was taken in a test-tube, which was cooled to room temperature in a water-bath A five or ten-cc. portion was measured out with a pipet, filtered free of mercurous chloride and acidified with hydrochloric acid to prevent any further reaction. The solutions were analyzed for mercury by precipitating with hydrogen sulfide and weighing as sulfide. The reaction vessels were always cleaned with hot chromic acid which was followed by hot concentrated hydrochloric acid to insure the removal of traces of iron. It was found that the results were more reproducible when the hydrochloric acid was used. The potassium oxalate, potassium chloride and mercuric chloride used were all twice recrystallized from the C. P. materials, whose analyses were given as containing **0.001%** iron. The solutions were made up with ordinary distilled water.

The "zero" of time, in this method of measuring the rate, was not taken as the time when the apparatus was placed in the thermostat, but was taken as the time when the first sample was withdrawn, which was about half an hour after placing it in the thermostat. In this way the effect of the lag in coming to the temperature of the thermostat was avoided. Measurements by both methods were carried out in a paraffin thermostat regulated to within 0.1° at 100° and **0.15**" at 120°. The solutions were mixed and analyzed in dim artificial light but at other times were kept in the dark.

The Reaction in the Absence of Oxygen.—The reaction is sensitive to very small traces of oxygen and so it was necessary to use great care to insure its removal. The oxygen was removed by saturating the solutions with pure carbon dioxide at atmospheric pressure and then the carbon dioxide was boiled out of the solutions under reduced pressure, carrying the oxygen with it. This process was repeated six times, giving solutions with much less oxygen than could be obtained by passing oxygen-free carbon dioxide through the solutions for six hours. The bulbs were then filled with purified carbon dioxide to atmospheric pressure at *25*° and sealed off. The carbon dioxide was freed from oxygen by passing it through copper turnings heated to 400°. In spite of these precautions, there appeared to be sufficient oxygen left to affect the rate. This was the principal cause of the difficulty in obtaining reproducible results.

The Effect of the Mercuric Chloride.—The order of the reaction with respect to mercuric chloride was determined by using a solution where the amount of potassium oxalate was equivalent to about ten times the quantity of mercuric chloride present. Under these conditions the total observed order of the reaction would be that of the mercuric chloride. Table I shows the results of such an experiment made by the second method where samples were drawn from the same solution.

TABLE I

100°; ATM. **PRESSURE OF** CO_2; KCl, **0.0909** *M;* $K_2C_2O_4$, **0.405** *M;* $HgCl_2$, **0.0836** M

Minutes	0	65	143	262	428	549	
HgS (5 cc.)	0.0819	0.0751	0.0672	0.0567	0.0466	0.0374	
−Log HgS	1.087	1.124	1.173	1.246	1.351	1.427	
K (1st order) × 10^5		57	60.2	60.7	61.7	61.9	Mean, 61

This shows that the velocity of the reaction is very nearly proportional to the first power of the total mercury in solution. No correction was made for the retarding effect of chloride ion formed in the reaction. If such a correction were made it would give an upward trend to the constants, making it appear less than first order. Such a trend may be explained as due to the increased dissociation of Hg_2Cl_4[1] which would occur when the $HgCl_2$ is used up in the reaction.

The Effect of Chloride Ion.—When chloride ion is added to the solution the rate of reaction is decreased. Tables II and III give results when the chloride-ion concentration is large compared to the concentration of the mercuric chloride. The two parts of each table represent duplicate experiments using the large bulb.

TABLE II

100°; ATM. PRESSURE OF CO_2; KCl, 0.3636 *M*; $K_2C_2O_4$, 0.405 *M*; $HgCl_2$, 0.0836 *M*

		Mean,	24.1 × 10^{-5}

TABLE III

SAME AS TABLE II EXCEPT KCl, 0.7272 *M*

Minutes	0	346	1030	1752	0	1030	2595	
HgS	0.1929	0.1816	0.1662	0.1535	0.1910	0.1659	0.1447	
−Log HgS	0.7147	0.7409	0.7794	0.8139	0.7190	0.7801	0.8395	
K (1st order) × 10^5	....	7.6	6.3	5.7	....	5.9	4.6	Mean, 6

It will be observed that the mean rate in Table II is almost exactly four times that in Table III. Since the chloride ion is in large excess and the concentration is doubled in the latter, it is evident that the rate varies as the inverse second power of the chloride-ion concentration when the latter is large. The mercury, under these conditions, is nearly all present as $HgCl_4^{--}$ as shown by the equilibrium $(HgCl_2) = k(HgCl_4^{--})/(Cl^-)_2$. Therefore, the rate is proportional to the concentration of the $HgCl_2$ molecules under all conditions, the chloride-ion concentration only affecting the concentration of the $HgCl_2$.

There is a marked downward trend in Tables II and III which can be accounted for by the retarding action of the chloride ion formed during the reaction. The retarding effect of the chloride ion formed during the reaction is greater, the larger the initial chloride-ion concentration. This

---

[1] G. A. Linhart, THIS JOURNAL, 37, 271 (1915).

is because there are, for each atom of mercury reduced, three times as many chloride ions formed when the chloride-ion concentration is large as when it is small. The main reaction for very large and very small ion concentrations may be represented as $HgCl_4^{--} + (-) = {}^1/_2Hg_2Cl_2 + 3Cl^-$ and $HgCl_2 + (-) = {}^1/_2Hg_2Cl_2 + Cl^-$. We do not know the dissociation constant of $HgCl_4^{--}$ at 100°; therefore we cannot make an accurate correction for the retarding effect of the chloride ion formed. However, a calculation was made assuming a negligible dissociation and this fully accounted for the trend in Table II and for half the trend in Table III.

The Effect of the Oxalate.—The effect of the oxalate concentration was determined using an excess of oxalate with a solution similar in every respect to the solution in Table I except that the oxalate concentration was made exactly one-half as large. The results for this solution listed in Table IV give a mean of 14×10^{-5}. The mean of Table I is 61×10^{-5}.

TABLE IV

AT 100°; ATM. PRESSURE OF CO_2; KCl, 0.0909 *M;* $K_2C_2O_4$, 0.2025 *M;* $HgCl_2$, 0.0836 M

Minutes	0	118	353	702	1293	
HgS	0.0924	0.0893	0.0831	0.0754	0.0574

K (1st order) $\times 10^5$	....	13	13	13	16	Mean, 14

This value is equal to four times the mean value in Table IV. Since the oxalate concentration in Table I is twice that of the oxalate in Table IV, the rate varies as the second power of the oxalate concentration.

The power of the oxalate in the kinetic equation was also determined under conditions where the mercuric chloride was in excess, by the method of sealed bulbs. In this case the total observed order of the reaction will be that of the oxalate since there will be only a negligible change in the mercury concentration.

TABLE V

120"; CO_2 PUMPED OFF BEFORE SEALING; KCl, 0.05 M; $K_2C_2O_4$, 0.0100 *M;* $HgCl_2$, 0.0989 M

K (2d order)	.....	0.049	0.053	0.050

TABLE VI

120°; CO_2 PUMPED OFF BEFORE SEALING; $HgCl_2$, 0.0989 *M;* $K_2C_2O_4$, 0.00997 *M*

Minutes	0	405	606	2140
Hg_2Cl_2	.....	0.0396	0.0493	0.0855
$(a - x)$ mole/liter	0.00997	0.00664	0.00576	0.002758
$1/(a - x)$	100.3	150.6	173.6	363.0
K (2d order)	.....	0.124	0.121	0.123

These results are given in Tables V and VI. Potassium chloride was added to the former but not to the latter. In both cases, however, the rate obeys a second-order law, showing that the rate is proportional to the second power of the oxalate concentration when the mercuric chloride is large as well as when the oxalate is in excess.

The Reaction in the Presence of Oxygen.—Oxygen not only retards the reaction but changes the order of the reaction with respect to the oxalate. This change depends on the pressure of oxygen and upon the concentration of the reactants. It was necessary to measure the rates in short enough time intervals so that we could neglect the change of concentration of the reaction materials. In Table VII the quantity of oxygen is stated in terms of millimoles of oxygen admitted to the flasks.

TABLE VII

100°; $K_2C_2O_4$, 0.200 M; $HgCl_2$, 0.12 M; KCl, 0.100 M

Oxygen	0.223	0.446	0.892	1.784	3.568
Minutes	60	60	255	255	255
Hg_2Cl_2, g.	0.1318	0.0798	0.1516	0.1085	0.0847
Rate, Hg_2Cl_2/min.	0.00220	0.00133	0.00059	0.00043	0.00033
Rate, calcd.	0.00222	0.00120	0.00069	0.00043	0.00031

The concentration of oxygen in solution would be proportional to this quantity, since the volume of each flask was 152 cc. After 50 cc. of the solution was placed in each flask the air was pumped out and the stated amount of oxygen admitted before sealing off. For the lower concentrations of oxygen the rate is nearly inversely proportional to the oxygen concentration, but at higher concentrations of oxygen its effect is much less. Analyses of the gas remaining in the flasks as well as of the resulting solutions showed that the oxygen did not oxidize determinable amounts of the oxalate.

The rate here may be best expressed by the equation

$$\frac{dx}{dt} = \frac{1}{k'(O_2)} + k'' \tag{1}$$

If k' is assumed to be 22×10^2 and k'' to be 18×10^{-5}, one obtains the calculated values of the rate given in the last column of Table VII. In Fig. 2 the experimental rates are given by the circles while the calculated values fall identically on the curve. This shows that the calculated values obtained from the above equation lie on the best smooth curve drawn through the experimental points.

The Effect of the Mercuric Chloride with Oxygen Present.—The order of the reaction was determined using an excess of oxalate so that the total observed order was that of the mercuric chloride.

The results obtained by the method of small flasks are given in Table VIII, which shows that the rate of the reaction is proportional to the first power of the concentration of the mercuric chloride. The retarding effect

Table VIII

100°; Atm. Pressure of O_2 when at 25°; Trace of CO_2; $K_2C_2O_4$, 1.796 *M;* $HgCl_2$ 0.0968 M

Minutes	0	206	450	974	1464	1890
HgS	0.2255	0.1794	0.1414	0 0904	0.0554	0 0394
−Log HgS	0.6468	0.7462	0.8495	1.0438	1 2565	1.4045
K (1st **order**) × 10^5		48	45	41	42	40

of the chloride ion formed in the reaction is sufficient to account for the downward trend in the rate constants. With oxygen present it is impossible to determine the effect of chloride ion when the latter is in excess, since then the rezction is immeasurably slow.

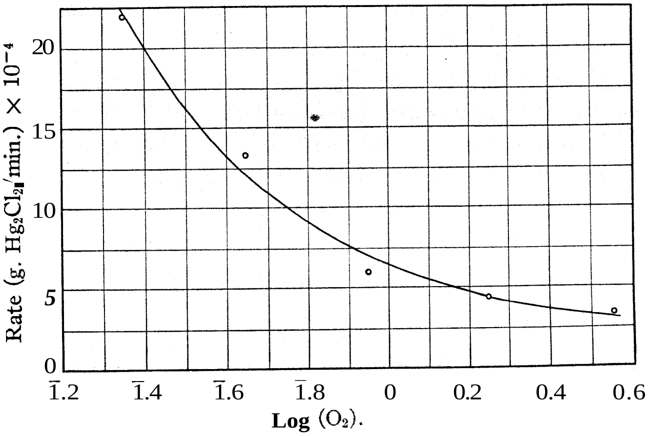

Fig. 2.

The Effect of the **Oxalate with** Oxygen Present.—The order of the reaction with respect to the oxalate was determined by using a solution similar to that in Table VIII in every way except that the concentration of the oxalate was one-half as great.

Table IX

Same as Table VIII except $K_2C_2O_4$, 0.898 *M*

Minutes	0	1149	1460	2997
HgS	0.2255	0.1155	0.0985	0 0533
−Log HgS	0.6468	0.9374	1.0066	1.2733
K (1st **order**) X 10^5	....	25.3	24.6	20.9

The results given in Table IX show a rate that is one-half the rate in Table VIII; therefore the rate is proportional to the first power of the concentration of the oxalate.

The Effect of Iron Salts.—The effect of oxygen depends on the amount of iron salts present in the solution. The addition of one part of ferrous salt to 100,000 parts of mercuric chloride will change the order of the reaction with respect to the oxalate from second to first when an appropriate concentration of oxygen is present. This accounts for the results of Dahr,[2] who found that the rate varied as the first power of the oxalate concentration in solutions made from C. P. materials when saturated with carbon dioxide. Table X shows that the reaction is first order with respect to the oxalate when a small amount of iron salt is added, even when the pressure of the oxygen was too small to measure with an ordinary manometer.

TABLE X

120°; TRACE OF O_2; $HgCl_2$, 0.100 *M*; $K_2C_2O_4$, 0.0100 M; $FeCl_3$, 0.004 M

Minutes	0	360	653	1448
Hg_2Cl_2	....	0.0363	0.0583	0.0900
(a − x), mole/liter	0.0100	0.00693	0.00506	0.00238
−Log (a − x)	2.000	2.159	2.296	2.623
K (1st order) X 10^5	....	44	45	43

Ordinary C. P. mercuric chloride and potassium oxalate, in which the analysis as stated on the container admitted 0.001% iron, also were found to give a rate proportional to the first power of the oxalate concentration. This appears to be due to the iron salts contained in them since the recrystallized chemicals react with a rate proportional to the second power of the oxalate concentration under the same conditions.

Discussion and Summary

The experimental results may be summarized by the equation

$$\frac{dx}{dt} = \frac{k_1(HgCl_2)(C_2O_4^{--})^2}{k_2(O_2) + k_3} + \frac{k_4(HgCl_2)(C_2O_4^{--})(Fe^{++})^x(O_2)^z}{k_5(O_2)^z + k_6}$$

k_3 is necessary in order that the rate does not approach infinity as the concentration of oxygen is continually decreased. It is so small, however, that it could be neglected in all experiments where oxygen was admitted. Under all conditions the rate is proportional to the concentration of the $HgCl_2$ molecules. Chloride ion does not occur in the equation since it changes only the concentration of the $HgCl_2$ by forming $HgCl_4^{--}$. When the concentration either of oxygen or ferrous ion is large the first term can be neglected and the rate will be proportional to the first power of the oxalate concentration. On the other hand, when the concentration of the oxygen is very small, the first term is large and the second term can be neglected, making the rate proportional to the second power of the oxalate concentration. When the concentration of the mercuric chloride, oxalate and ferrous ion is constant the rate will be given by

$$\frac{dx}{dt} = \frac{1}{k_2'(O_2) + k_3'} + \frac{k_4'(O_2)^z}{k_5(O_2)^z + k_6}$$

However, k_3 and k_6 are so small that they may be neglected in all the experiments where oxygen was present. Then the equation reduces to

$$\frac{dx}{dt} = \frac{1}{k_2'(O_2)} + k_4''$$

---

[2] N. R. Dahr, J. *Chem. Soc.*, 111, p. 752 (1917)

which was found to be true experimentally. The presence of two terms in the kinetic equation indicates that there are two reactions proceeding simultaneously, the total rate being the sum of the two separate rates. Winther[3] studied the effect of ferrous salts on the reduction of mercuric chloride by ammonium oxalate in the presence of oxygen at room temperature. He found that the oxidation of ferrous oxalate by oxygen induced the reaction to take place, giving as many as 4000 molecules of mercurous chloride per molecule of ferrous oxalate oxidized by oxygen, but this number decreased with increasing oxygen concentration. However, there was no reaction when oxygen was absent. It is evident that the reaction observed by Winther must take place at 100° when oxygen and iron are present, even though in very small amounts. In the present investigation it was found that ferric oxalate decomposes into ferrous oxalate and carbon dioxide at 100" at a moderate rate, so that there will be repeated oxidation of the ferrous iron by oxygen and reduction of ferric iron by oxalate. The first part of each cycle would cause a chain of some 4000 molecules of mercuric chloride to react with oxalate. The repetition of this cycle would account for the catalytic effect of such small quantities of iron. The quantity of oxygen consumed would be equivalent to less than one-thousandth of the oxalate or mercuric chloride reacting, which agrees with the experimental fact that practically no oxygen was used up in the reaction. The effect of iron is too complex to be expressed analytically at the present time as the fraction of the iron present in the ferrous form depends on the concentrations of oxygen and oxalate in the solution, even when one assumes that the steady state is quickly attained.

In the investigation of the photochemical reaction now in progress, the quantum efficiency has been found to be 3000 molecules reacting per quantum of light absorbed. It also is inhibited by oxygen. Dahr[4] has found that the reaction is induced by many oxidizing agents in the dark, giving as many as several thousand molecules of mercurous chloride per molecule of inductor transformed.

The effect of oxygen, therefore, must be three-fold: (a) the inhibiting effect in the first term as shown by the equation, (b) the oxidation of ferrous oxalate to ferric oxalate, thus increasing the number of chains in the second term, and (c) the shortening of the average length of the chain in the second term corresponding to a similar effect in the first term. From these considerations and the fact that the rate becomes independent of the oxygen concentration as the later is increased (see Equation 1), it seems evident that oxygen must occur in both numerator and denominator of the second term to the same power. At the low concentrations of oxygen which would be necessary to determine k_6, the value of the first term

---

[3] Chr. Winther, *Z. Wiss. Phot.*, 7, 411 (1908).

[4] N. R. Dahr, *Ann. chim.*, 11, 197 (1919).

of the rate equation is so great as to make such a determination impossible. On the other hand, if the concentration of the ferrous salt is made large, the retarding effect of the resulting ferric ion, which was observed by Winther, will be large in comparison to k_6. When the concentration of oxygen is large, k_6 and the first term of the equation may be neglected. Under these conditions the oxygen cancels out of the second term and the rate is independent of the oxygen concentrations.

The discussion of the mechanism of the chains occurring in these reactions will be postponed until more work has been done on the reaction in acid solution and on the photochemical reaction.

THE CHEMICAL EFFECTS OF HIGH FREQUENCY SOUND WAVES
II. A STUDY OF EMULSIFYING ACTION

BY WILLIAM T. RICHARDS

RECEIVED FEBRUARY 16, 1929 PUBLISHED JUNE 5, 1929

One of the most spectacular manifestations of the effects of the high frequency sound waves produced by Wood and Loomis[1] is their emulsifying action on benzene, paraffin and even mercury in contact with water. Since this action promises to be of some practical value and since, moreover, it gives important indications of the nature of sound wave effects, it has been briefly investigated.

1. The Mutual Emulsification of Two **Liquids.**—When benzene and water are placed in a test-tube which has been previously wet with water and the tube is irradiated with intense sound waves of 300 K.C., the benzene layer at once becomes cloudy, the water layer more slowly so and, finally, the boundary between the two disappears. A similar action may be observed between water and any other liquid of similar physical properties; even medicinal paraffin follows the same course. With high intensities of sound the agitation of the interface is, however, so intense that reliable observation of the locality at which emulsification occurs is impossible.

In order to verify the suspicion that emulsifying action occurs primarily at the wall in contact with benzene and not at the liquid–liquid interface, very low intensities of sound (roughly one-tenth of those employed by Wood and Loomis, and the author and Loomis,[2] and designated by the latter 100%) were used, and the following results obtained.

In water-wet tubes containing a benzene–water interface the white

---

[1] R. W. Wood and A. L. Loomis, *Phil.* Mag., [vii] 4, 417 (1927).

[2] W. T. Richards and A. L. Loomis, THIS JOURNAL, 49, 3086 (1927).

cloud of emulsion came off the walls of the tube slowly into the benzene layer only. There was little agitation of the interface, and the water layer remained clear until, after two minutes, when the benzene layer was extremely milky, a thin but gradually increasing haze of emulsion drifted down from the interface.

In dried test-tubes into which water was pipetted with great care to avoid wetting the upper part of the tube, and benzene then similarly added, no emulsification whatever took place unless the sound wave intensity was sufficient to agitate the interface considerably. Then emulsion formed at the wall-layer so produced, and was slowly driven through the liquid by radiation pressure. If drops of water were attached to the wall opposite the benzene layer they became milky and gradually emulsified completely. The converse was also true.

These results were verified with many immiscible liquids, a uniform indication being obtained with all. At low intensities of sound, emulsification evidently takes place almost wholly at the wall in contact with the dispersion medium when wetted with the liquid dispersed.

An attempt was made to study the action of sound waves on a benzene–water interface when confusing wall action was eliminated by damping out as far as possible vibrations in the glass. For this purpose a vessel was made consisting of a wide glass tube to the bottom of which was cemented a brass collar and a very thin brass membrane. Further lo damp vibrations in the glass it was wound with heavy layers of rubber bands immediately above and below the benzene–water interface. When radiated with sound care was taken to immerse only the brass collar in the oil transmitting sound waves from the vibrating crystal since, brass being a poor conductor of transverse waves, the greater part of the sound energy present in the tube must then enter the liquid through the metal membrane. Under these conditions no visible action took place at the interface, although with very high intensities of sound slow emulsifying action at the walls was noted. This is a further indication that the major part of the emulsifying process occurs at the wall.

The type of emulsion produced when mercury is dispersed in water demands another explanation, since mercury does not wet the glass tube. It has never been found possible, moreover, to cause the mutual solution of the mercury and water layers. In this case the action, if studied under varying conditions, takes place somewhat differently. It is dependent, in the first place, on the amount of mercury in the tube. If 1 cc. is present in a pyrex combustion tube with 10 cc. of water, emulsifying action proceeds rapidly. If 2 cc. of mercury is present it proceeds more slowly, and with 5 cc. of mercury it is almost completely arrested even with the highest sound wave intensity. This may safely be attributed to the damping action of the mercury on waves in the glass. When under the, best conditions for observation the emulsifying action may be seen to take place only in a small ring where the mercury, water and glass are in contact. Then white ribbons of emulsion are driven out slowly into the water from this circle. The action is accelerated by ammonium chloride, which is a pronounced emulsifying agent. Mercury withdrawn from sound action in water-wetted tubes and quickly strained through filter paper has an abnormally high water content, which it soon loses; it is therefore probable that water is emulsified in mercury, although the emulsion soon stratifies.

A picture of the mechanism of this emulsification may readily be formed on the basis of these results. It evidently is closely parallel to that described by Nordlund,[3] who obtained similar emulsions by bubbling water through a mercury layer.

2. Emulsification as a Measure of Sound Wave Intensity.—When this investigation was undertaken it was hoped that an absolute measure of local forces in the sound waves producing emulsification could be obtained. There remains, however, a certain usefulness for the emulsification process as a measure of relative sound intensities.

The following method makes this possible and gives, moreover, certain other valuable indications. Uniform test-tubes were coated internally with a mixture of celluloid and medicinal paraffin dissolved in acetone of such composition that, on the evaporation of the acetone and after drying for two hours at 70°, a coherent mixed film was formed which did not either peel or release paraffin on the introduction of water into the tube. By raying these tubes and measuring nephelometrically their turbidity, a standard of radiation intensity was obtained which was reproducible to about 20%.

The emulsification in these tubes, since it proceeded under almost optimal conditions, made possible the detection of exceedingly small intensities of sound. Only certain isolated spots on the glass surface were active in the process and ribbons of emulsified oil were shot from them across the tube. More emulsification took place at the top of the tube, which was open and hence relatively undamped, than at the bottom, which was necessarily immersed in oil.

3. The Emulsification of Glass in Water.—The intense emulsifying action at the wall of a glass vessel raises the question whether glass itself is emulsified on prolonged radiation. In more general investigations in progress with sound waves it is important to answer this and to ascertain with some precision the alteration of the properties of water if any occurs.

To this end pyrex tubes were washed with soap and water, heated with chromic acid and nitric acid and finally boiled repeatedly with distilled water. They were then filled by distillation without ebullition, being

---

[3] Nordlund, "Dissertation," Upsala, 1918.

washed with the water so distilled repeatedly until no further dust particles could be observed in the liquid. They were then sealed off without admission of air. In this way water was obtained showing only a faint uniform blue cone, due probably to the molecular scattering of water, with intense illumination and a black background.

One of these tubes was rayed with maximum intensity for sixty minutes. It showed a distinct increase in turbidity in an intense Tyndall beam, indicating that a small amount of glass had been torn from the sides, but the change in turbidity was not detectible with a precision nephelometer. By a dielectric loss method to be described elsewhere it was demonstrated that the electrolyte concentration was less than 10^{-6} N. The PH, as measured by bromthymol blue, was about 0.2 units more basic than that in an unrayed tube, but this was not considered significant in unbuffered water. Five cc. of the liquid from the rayed and from an unrayed tube evaporated on a watch glass showed that the former had a slightly greater non-xolatile content, but the difference was too small to be detectible on a precision analytical balance.

Since the result was clearly negative, except in so far as slight fragmentation of the sides of the tube was concerned, and since raying for an hour is a tedious matter, no further experiments of a similar nature were carried out.

These results make it appear unlikely that sound waves should in a liquid fracture small glass particles. This supposition was confirmed by experiment. Uniform glass particles which would pass an 80 to the inch but not pass a 100 to the inch sieve were selected, washed with chromic acid, and violently agitated many times with distilled water. Particles of this size were too small, if in low concentration, readily to undergo flocculation by the sound waves, and yet not small enough to be held in standing waves at the glass surface and thus suffer possible mechanical fracture. A standard weight of glass in water was rayed for unit intervals of time and an identical weight was simultaneously given violent mechanical agitation in another portion of water of the same volume. After raying, the water from the two was poured off and compared nephelometrically. The turbidity of both converged toward the same limit within error of measurement, indicating that, although patently more effective in detaching adhering smaller particles of glass, the sound waves were causing no more actual breakage of the larger particles than that which mechanical agitation produced.

Discussion

The observations recorded above indicate clearly that emulsification in a liquid takes place largely at the walls of the containing vessel when they are wetted with the liquid dispersed, This makes it improbable that compressional waves in the liquid produce the action; more probably the transverse waves in glass, noted by Wood and Loomis, are the effective agents. As described by these authors the transverse waves in a glass rod 0.1 mm. in thickness at a frequency of 300 K.C. have a wave length of about 6 mm., which gives an index to the general characteristics of similar waves in a test-tube of equal thickness. Their amplitude, as judged by their physical effects, must be far larger than that of the compressional waves in the same medium; measured under somewhat different conditions it was of the order of 6000 Å.

This conclusion makes it appear probable that many destructive phenomena, which have formerly been attributed to direct action of the sound waves in liquids, are, in fact, of a secondary nature. The rupture of blood cells, small unicellular organisms, and the like cannot now necessarily be supposed to take place in the liquid proper, but may evidently occur primarily in the neighborhood of the walls.[4] Any small body perceptibly adsorbed by the glass surface would, of course, be even more subject to this destructive action. Indeed, in all cases where sound is transmitted through a glass vessel into a liquid, transverse waves must be considered as a possible primary explanation for any effects observed. Action on dry explosives and liquid-in-air cloud production may safely be attributed to the same cause in most cases.

These data, furthermore, indicate clearly the method by which emulsification may be most effectively produced in any desired case. It is evidently unnecessary to have a liquid–liquid interface in the containing vessel except as an envelop for the dispersion medium. The same considerations, with obvious modification, apply equally to solid-liquid systems.

Finally, it follows that no measurements valuable for the estimation of the absolute radiation pressure in a liquid can be obtained from a study of emulsification. The effects of transverse wall waves must inevitably be confused with the effects of compressional waves in the liquid. Furthermore, even if, at high intensities, emulsification occurred at a plane liquid–liquid interface, it would not be amenable to quantitative treatment. The process of emulsification is, in such a case, a matter essentially of velocity and not of equilibrium: in order to be perceptible a definite amount of liquid must be dispersed in a given time. The radia-

---

[4] This statement must not be considered categorical. Turtle's blood is laked, although slowly, in a rubber bag in which transverse waves connot exist. Certain phenomena encountered in the capillary of a funnel gage [W. T. Richards, *Proc. Nat. Acad. Sci.*, 15,310 (1929)], where the sound energy is concentrated by reflection, indicate that fracture of a liquid–liquid surface may take place in the absence of transverse waves. The fracture of a gas–liquid interface by compressional waves in the liquid is evidently far easier. This is demonstrated strikingly at high sound intensities by the emergence from the capillary opening of a funnel gage of a fine spray, even when the capillary tube is tightly encased in rubber.

tion pressure of sound and the amount of energy necessary to convert a gram of substance from infinite radius to a small finite radius are both easy to estimate, but no specific mechanism can be formulated for the emulsification process and without this the two cannot be usefully equated. Since, moreover, the standing waves in liquids are shifting constantly both in intensity and in position, it seems certain that, even if it occurred, emulsification would under these conditions lead to no useful conclusions.

Summary

It has been demonstrated that emulsions produced by sound waves are due largely to action at the walls of the vessel. A method has been devised whereby the process of emulsification may be used as a fairly reliable measure of relative intensities of sound. An argument is advanced which makes it appear unlikely that absolute radiation pressures can be calculated from any similar process. It has been demonstrated that the walls of a glass vessel are slightly emulsified and that small uniform glass particles in liquids are not fractured by intense sound waves.

A COMPARISON OF THE ATOMIC WEIGHTS OF TERRESTRIAL AND METEORIC NICKEL. III. THE ANALYSIS OF NICKELOUS BROMIDE

BY GREGORY PAUL BAXTER AND SABURO ISHIMARU

RECEIVED FEBRUARY 18, 1929 PUBLISHED JUNE 5, 1929

In two recent investigations comparisons of terrestrial and meteoric nickel have been made by the quantitative determination of nickel in nickelous oxide[1] and of chlorine in nickelous chloride.[2] In both series of experiments the meteoric nickel was obtained from the same source, the Cumpas meteorite found in 1903, near Cumpas, Sonora, Mexico. In neither case could any difference be detected between the atomic weights of terrestrial and meteoric nickel larger than the error of the experiments. Since the origin of any meteorite must necessarily be largely a matter of conjecture, the possibility of a difference in the isotopic composition of nickel from different meteorites, although remote, is not negligible. Therefore, the availability of a considerable quantity of meteoric nickel from another source has led us to a new comparison of this material with that of terrestrial origin. In order to vary the method somewhat from those outlined above and in order to take advantage of the very great suitability of silver bromide for precision work, in this case nickelous

---

[1] Baxter and Parsons, THIS JOURNAL, 43,507 (1921).

[2] Baxter and Hilton, *ibid.*, 45,694 (1923).

bromide was selected for analysis. As before, we have been unable to establish any difference between terrestrial and extra terrestrial material.

Purification of Materials

The preparation of reagents followed lines already proved to be adequate in numerous earlier investigations. Water, nitric acid, hydrochloric acid, formic acid, ammonium carbonate and ammonia were purified by distillation. Silver was especially important as being the standard of comparison. The processes employed were double precipitation of the chloride followed in each case by reduction with sugar solution made alkaline with electrolytically purified sodium hydroxide, fusion of the metal on a lime boat in a blast flame, solution in nitric acid and repeated crystallization of silver nitrate, precipitation of the metal with ammonium formate, fusion on pure lime in an electrically heated muffle, electrolytic transport through a concentrated silver nitrate solution made from the same silver, fusion on pure lime in an atmosphere of pure dry electrolytic hydrogen, etching with nitric acid and drying in a vacuum at 500°.[3]

Pure lime was made from calcium nitrate which had been recrystallized until free from iron and then precipitated as carbonate. To prepare receptacles for the fusion of silver, the carbonate was ignited and a mixture of the product with a small proportion of nitrate was used to line either porcelain crucibles or porcelain boats.

Bromine was first distilled from aqueous potassium bromide to remove the bulk of the chlorine. Next one-fourth of the product was converted to potassium bromide by means of recrystallized potassium oxalate and the remaining three-fourths of the bromine was distilled from solution in the potassium bromide. All the product was then converted to potassium bromide by means of potassium oxalate and the potassium bromide was fused in a platinum dish with enough recrystallized potassium permanganate to oxidize all organic matter. In order to obtain bromine, the purified potassium bromide was dissolved in a solution of pure sulfuric acid and the potassium sulfate which separated was removed. The excess of permanganate in the bromide caused a small quantity of bromine, to be liberated. This bromine was removed by distillation, since it might have contained a trace of iodine. Enough pure permanganate to liberate the greater portion of the bromine was then added and the bromine was distilled into a receiver cooled with ice. In this last step the bromine received a third distillation from a bromide. After separation from the aqueous layer, the pure bromine was redistilled. In all the above operations cork and rubber' were rigidly excluded from the apparatus.

Hydrogen bromide was prepared from the bromine by catalytic synthesis

---

[3] See especially Richards and Wells, *Pub. Car. Inst.*, No. 28, p. 16 (1905); Baxter, THIS JOURNAL, 44,591 (1922).

with hydrogen. Electrolytic hydrogen dried by fused potassium hydroxide was charged with bromine at about 44° and the mixture passed over hot platinized asbestos in a hard glass tube. To prepare an aqueous solution the product was collected in water and the solution distilled through a quartz condenser with rejection of the extreme portions. To obtain the pure, dry gas a slight excess of bromine was used and the product freed from bromine by being passed through an aqueous solution containing pure ferrous bromide. The comparatively small amount of water which evaporated from the saturated hydrogen bromide solution was removed by fused calcium bromide since phosphorus pentoxide reacts with the gas. Calcium bromide leaves 0.2 mg. of water per liter of gas. There was no evidence, however, that this small quantity of moisture reacted with nickelous bromide in the presence of a high concentration of hydrogen bromide.

Nitrogen was prepared from air with an excess of ammonia by the Wanklyn catalytic process and the hydrogen produced catalytically was oxidized by hot copper oxide. After drying the gas thoroughly, oxygen liberated from the cupric oxide was removed by hot nickel.

Air was passed over aqueous silver nitrate and potassium hydroxide, concentrated sulfuric acid and phosphorus pentoxide and through a sintered glass filter.

All the apparatus for purifying gases was constructed of glass with fused or well ground joints. No lubricant whatever was used on the ground joints since past experience has shown that organic greases evaporate sufficiently to introduce carbonaceous residues into substances otherwise free from organic material, while inorganic lubricants are likely to carry moisture to the interior.

Purified terrestrial nickel chloride and metal remaining from earlier work were converted to nitrate by treatment with nitric acid, and nickel ammonia nitrate was produced by saturating the solution with distilled ammonia. This salt was recrystallized four times by solution in hot water kept saturated with ammonia, followed by cooling. Centrifugal separation of crystals from mother liquor was carried out in platinum Gooch crucibles. From the nickel ammonia nitrate the hydroxide was prepared by hydrolysis. The salt was treated with a considerable amount of water in platinum dishes and kept at boiling temperature until ammonia ceased to be evolved. The precipitate was washed, dried and ignited. The product was then dissolved in nitric acid and the nitrate crystallized three times from concentrated nitric acid. Decomposition of the nitrate at a high temperature in a platinum boat yielded the oxide a second time. This was dissolved in pure aqueous hydrogen bromide, in a quartz vessel to avoid the action of bromine liberated by the higher oxides of nickel. The bromide was then crystallized four times in platinum vessels with centrifugal drainage.

The meteoric nickel was obtained in the course of the extraction of cobalt for the earlier investigation. The source was a meteorite probably found in the western part of the United States, and possibly was a portion of the Cañon Diablo meteorite. Professor Emeritus J. E. Wolff, of Harvard University, very generously donated this material. Originally about 7 kilograms of the meteorite was dissolved in nitric acid and the iron largely separated by crystallization as ferric nitrate. Nearly all the remaining iron was removed by precipitating the sulfides and extracting with dilute hydrochloric acid. The cobalt was then separated by treatment with a large excess of potassium nitrite in the presence of acetate. The remaining salts were converted to chlorides by evaporation with hydrochloric acid and those metals forming less soluble sulfides were removed by fractionation with hydrogen sulfide in slightly acid solution. Conversion of the salts to nitrates by evaporation with an excess of nitric acid was followed by precipitation of the iron with a large excess of ammonia in dilute solution. After evaporation of the solution, nickel ammonia nitrate was prepared as with the terrestrial material. The subsequent steps in the preparation of nickelous bromide were identical with those outlined above.

To prepare anhydrous nickelous bromide for analysis the hydrated salt was first partially dehydrated over fused potassium hydroxide at room temperature. The residual water was then removed by heating the salt, contained in a quartz boat, in a quartz tube through which a mixture of nitrogen and hydrogen bromide was passed at about **360"**. Sublimation of the anhydrous material from the boat to the tube in the same atmosphere then followed and the product was twice resublimed to adjacent portions of the tube. As in the case of nickelous and cobaltous chlorides which had been similarly prepared, a slight siliceous residue remained, diminishing with each sublimation. In a second triple sublimation no evidence of silica could be detected. The final product was preserved over fused potassium hydroxide for analysis.

Before being weighed the dehydrated bromide was again heated to the sublimation point in a current of dry nitrogen and hydrogen bromide. The salt, contained in a weighed platinum boat, was placed in a transparent quartz tube which formed part of a Richards and Parker[4] bottling apparatus. After the air had been displaced the tube was electrically heated at gradually increasing temperatures until finally the bromide began to sublime. After the tube had been allowed to cool, the hydrogen bromide was displaced by dry nitrogen and this in turn by dry air before the boat was transferred to the weighing bottle in which it had been originally weighed. A second weighing of the bottle and boat followed.

The boat and contents were next covered with about **1000** ml. of pure water in a precipitating flask, and allowed to stand for several days until

---

[4] Richards and Parker, *Proc Am. Acad.*, **32,** 59 (1896).

solution was complete. There was never the slightest evidence of insoluble matter. The boat was then carefully removed and at the same time was thoroughly rinsed. Pure silver nearly equivalent to the bromide was weighed out, dissolved in nitric acid and diluted to approximately 0.1 N concentration. The silver solution was then added to the bromide solution in small portions with frequent shaking and the flask was allowed to stand at room temperature for some days with occasional agitation. The clear supernatant solution was next tested in a nephelometer for excess of bromide or silver, and the estimated deficiency of either was added in the form of 0.01 N solution. The solution was then shaken, allowed to clarify and tested as before and the process was repeated until exactly equivalent quantities of silver and bromide had been used. A period of six to eight weeks in every case elapsed between the precipitation and the final adjustment of equilibrium, since long experience has shown that this is necessary for the leaching out of material initially occluded by the precipitate.

In all but two analyses, after the end-point of the comparison had been reached, an excess of silver nitrate (from 0.002 to 0.02 g.) was added and the analyses were allowed to stand for some time longer. Then after the silver bromide had been washed many times with pure water it was collected on a weighed platinum sponge Gooch crucible and dried in an electrically heated porcelain air-bath at a temperature not far from 400° before being weighed. In Analyses 10, 11 and 13, the main bulk of the precipitate was transferred to a porcelain crucible and the loss on fusion, presumably due to retained moisture, was determined.

In Analysis 9 the silver bromide was accidentally fused in the Gooch crucible during the initial drying. Since no apparent deterioration of the bromide resulted, in Analysis 12 the bromide was first dried at 370° and weighed and then was fused for a short time in the Gooch crucible. A loss in weight of 0.12 mg. resulted. Three repetitions of the fusion for periods of two, two and four hours resulted in changes in weight of -0.05, $+0.03$, and -0.11 mg. In Analysis 14, also, the silver bromide was once fused in the Gooch crucible after having been dried at 360° and weighed. These experiments so far as they go indicate that a short period of fusion in the platinum sponge crucible introduces little danger from decomposition of the silver bromide, although prolonged fusion is doubtless objectionable. This method has the great advantage of avoiding the transfer of the dried precipitate to a porcelain crucible for the fusion. Further experiments in this direction are obviously desirable. The small proportion of moisture found in these precipitates, 0.0005%, is in accordance with the observation by Hönigschmid and Birckenbach[5] that silver chloride dried at 300° is nearly if not quite anhydrous.

[5] Honigschmid and Birckenbach, *Z. anorg. allgem. Chem.*, **163**, 332 *(1927)*.

Slight corrections were .applied to the weight of silver bromide for solubility in the mother liquors and wash waters,[6] for silver bromide found in an ammoniacal solution with which the precipitating flask was finally rinsed, and for bromide introduced during the nephelometric comparison of the nickelous bromide with silver.

All objects were weighed by substitution for similar counterpoises. Weights were standardized to hundredths of a milligram by the Richards substitution method.[7] Vacuum corrections were applied on the basis of the air density observed at the time of weighing, and the following densities: weights, 8.3; $NiBr_2$, 4.64; AgBr, 6.47; Ag, 10.49.

[6] Calculated on the basis of a solubility of silver bromide in water of 0.1 mg. per liter.

[7] Richards, THIS JOURNAL, 22,144 (1900).

Within the experimental error the terrestrial and meteoric samples are identical in isotopic composition. The combined average result, 58.694, would be raised only 0.002 unit by the omission of the two most discordant determinations, Analyses 7 and 11.

Modern determinations of the atomic weight of nickel are given in chronological order in the following table.

Richards and Cushman	$NiBr_2:2Ag$	58.680	**Baxter and Parsons**	$NiO:Ni$	58.702
	$NiBr_2:2AgBr$	58.683	**Baxter and Hilton**	$NiCl_2:2Ag$	58.6998
				$NiCl_2:2AgCl$	58.701[8]
	$NiBr_2:Ni$	58.682	**Baxter and Ishimaru**	$NiBr_2:2Ag$	58.695
				$NiBr_2:2AgBr$	58.693
	Average	58.682		Average	58.698

As has been pointed out before, the material analyzed by Richards and Cushman was not ideal for the purpose since it contained impurity extracted from the porcelain tube during sublimation. The average of the more modern values is almost 0.02 unit higher than the older one of Richards and Cushman and probably is nearer the truth.

During a temporary absence of the senior author, for a portion of the time, oversight of this work was undertaken by the late Professor T. W. Richards. We gratefully acknowledge our indebtedness for his kind advice.

Summary

1. Nickel extracted from a new meteorite has been found to have the same isotopic composition as terrestrial nickel.
2. The atomic weight of nickel has been found to be 58.694.
3. The average of the most recent determinations of this constant is 58.697.

CAMBRIDGE, MASSACHUSETTS

THE DIELECTRIC POLARIZATION OF LIQUIDS. IV. THE DEPENDENCE OF MOLAR REFRACTION UPON CONCENTRATION IN MIXTURES

BY C. P. SMYTH, E. W. ENGEL AND E. BRIGHT WILSON, JR.

RECEIVED FEBRUARY 23, 1929 PUBLISHED JUNE 5, 1929

In considering the dependence of the polarization of a binary mixture upon composition, it has been customary to attribute all deviations from a linear relation to variation in the polarization due to orientation of the dipoles. The molar polarization, P_{12}, of a mixture of two liquids 1 and 2 is represented by the expression

$$P_{12} = c_1P_1 + c_2P_2 = P_1 + c_2(P_2 - P_1)$$

in which P_1 and P_2 are the polarizations and c_1 and c_2 the mole fractions of Components 1 and 2, respectively. From this it follows that P_{12} is a linear function of c_2 if P_1 and P_2 are constant. The polarization of a pure substance is regarded as the sum of three quantities, the polarization P_E caused by electronic shifts induced in the molecules, the small polarization P_A attributed mainly to shifts of atoms or radicals induced in the molecules, and P_M caused by orientation of the molecular dipoles. P_A is difficult to determine accurately, but is usually small in comparison with P_E and sometimes very small in comparison with P_M. The possible variation with concentration of P_A for a substance in solution need not, therefore, be considered as a serious factor in our present methods of obtaining polarization. The assumption of the independence of P_E of concentration has appeared warranted by the approximate constancy found in a number of mixtures for the Lorentz–Lorenz expression for the molar refraction,[1] which is equivalent to P_E, that is, $P_E = (n^2 - 1)/(n^2 + 2)M/d$, in which n is the refractive index, M is the molecular weight and d is the density. The electronic polarization of a mixture of two components 1 and 2 is

$$P_{E,1,2} = \frac{n^2 - 1}{n^2 + 2} \times \frac{c_1M_1 + c_2M_2}{d} = P_{E,1} + c_2(P_{E,2} - P_{E,1})$$

in which M_1 and M_2 are the molecular weights of 1 and 2 and $P_{E,1}$ and $P_{E,2}$ are the electronic polarizations or molar refractions of the two components.[2] Not only the approximate constancy found for the molar refractions in a number of mixtures but also the additivity of the refractions of radicals give ground for the belief that $P_{E,1}$ and $P_{E,2}$ are usually approximately independent of c_2. However, the refraction calculated

for an isolated ion has been found to be different from that possessed by the ion when attached to other ions because the forces acting on the outer electrons are different.[3] It would appear possible, therefore, that the occurrence of pronounced molecular association in a liquid might affect the forces acting on the outer electrons of the molecules. Change in the degree of association of the molecules brought about by change of temperature or change in the concentration of a mixture might alter the forces acting upon some of the outer electrons and thus alter the polarization. It has been shown for a number of substances that the molar refraction does not change much with temperature or even with change of state, but it has seemed desirable to use a series of refractive index measurements carried out upon fifteen pairs of liquids to examine further the constancy of $P_{E,1}$ and $P_{E,2}$. Unfortunately, the densities are not available for a number of these mixtures, but all the refractive indices are, nevertheless, reported. The liquids used were carefully purified but, as the same materials were used for vapor pressure measurements, the methods of purification and the criteria of purity are given elsewhere.[4] The excellent agreement of the indices of the pure components with the values contained in the literature is evidence of their purity.

The indices of refraction for the sodium D line were measured with a Pulfrich refractometer, a temperature of 20° constant within 0.01" being obtained by a flow of water from carefully adjusted thermostats. The probable error in a value of the index was 0.00007. The results are given in Table I, in which the first column under each pair of substances gives the mole fraction of one component and the second the refractive index. In order to show the deviation of the refractive indices from a linear dependence upon composition, the third column gives the composition calculated from the observed refractive index on the assumption that the latter is a linear function of composition. For example, a refractive index half way between the values for the pure components of a mixture would give a calculated mole fraction of 0.5000. The difference between the known value of the mole fraction and that calculated in this manner is given in the fourth column as a measure of the departure from a linear relation between refractive index and composition.

The densities of the mixtures of several of these pairs of substances have been determined by Mr. W. N. Stoops and Mr. H. E. Rogers and will be published in another connection. The values of the refractive indices for the concentrations at which the densities were determined were obtained by interpolation. Additional refractive indices for the sodium D line and densities were selected from the measurements of Williams and Krchma, who determined these quantities at 25° for a few mixtures of a

considerable number of pairs of substances.[5] Some of the latter data were eliminated because of apparent small discrepancies, while a few pairs were omitted as being of less interest than the others. Table II gives the results of the calculations from the data in Table I combined with the densities mentioned. The first column gives the mole fraction of one of the two components, the second column gives the value of $(n^2 - 1)/(n^2 + 2)(c_1M_1 + c_2M_2)/d$, which is the observed $P_{E,1,2}$, the third column gives the value of $c_1P_{E,1} + c_2P_{E,2} = P_{E,1} + c_2(P_{E,2} - P_{E,1})$, where $P_{E,1}$ and $P_{E,2}$ are taken as the values of the pure components, and the fourth column gives the difference between the observed and calculated. As the

---

[5] Williams and Krchma, THIS JOURNAL, 49, 1678, 2408 (1927).

probable error in the density determinations was 0.0002 and in the refractive indices 0.00007, the probable error in the observed value of $P_{E,1,2}$ should usually be about 0.014. The results calculated from the data of Williams and Krchma are shown in Table III, in which the error is probably somewhat greater than in Table II, although the less certain results have been eliminated.

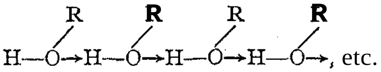
less than 0.1%, between the observed and calculated values of $P_{E,1,2}$ is no larger than the experimental error. In other words, $P_{E,1}$ and $P_{E,2}$ are constant as far as can be measured throughout the mixtures, which means that in these liquids the contribution to the polarization of the electronic shifts induced in a molecule is practically independent of the surrounding molecules. The differences are about one-tenth as large as those found by Falk[6] between the molar refractions of several substances at 20 and at 80°.

These results have an interesting bearing upon the problem of molecular association. Sidgwick[7] states that "the great majority of associated substances contain a hydroxyl group," polymerization arising through the hydroxyl "hydrogen acting as acceptor and the oxygen as donor," that is, the hydrogen of one hydroxyl group becomes attached to the oxygen of the hydroxyl of another molecule and, as a result, shares electrons with both oxygens. Alcohol molecules would associate thus



$$H{-}\overset{R}{O}{\rightarrow}H{-}\overset{R}{O}{\rightarrow}H{-}\overset{R}{O}{\rightarrow}H{-}\overset{R}{O}{\rightarrow}, \text{ etc.}$$

---

[6] Falk, THIS JOURNAL, 31, 86, 807 (1909); *Z. physik. Chem.*, 82, 504 (1913).

[7] Sidgwick, "The Electronic Theory of Valency," Oxford University Press, Oxford, England, 1927, p. 134.

It has been shown that an oxygen atom with a completed octet of electrons to which two hydrogen nuclei are attached to form a water molecule has a refraction of 3.76. When one of the linkages to hydrogen is replaced by a linkage to carbon, the refraction is reduced to 3.23, and when both hydrogen linkages are replaced by carbon linkages the refraction is reduced to 2.85.[3] Fajans and Joos[3] have calculated the following refractions: O^{--}, 7; OH^-, 5.10; OH_2, 3.75; OH_3^+, 3.04. Evidently, the attachment of a hydrogen nucleus to oxygen brings about a considerable reduction in the refraction. A somewhat smaller reduction would probably be effected by attaching a hydrogen to an hydroxyl already linked to carbon, since the electrons are here more tightly bound, as evidenced by the lower refraction 3.23. Also, if the hydrogen were already attached to another oxygen, as pictured by Sidgwick for the alcohols, the forces which it exerted on the electrons of this oxygen would probably be weakened by its sharing with a second oxygen. This weakening would raise the refraction and thus tend to compensate for the reduction in the refraction of the other oxygen. An exact compensation, however, would be a very improbable coincidence. There is good reason then to believe that an association like that supposed by Sidgwick would bring about a reduction of 0.2 to 0.5 in the molar refraction of the alcohols. As the degree of association would be altered by mixing with another liquid and would vary with the concentration of the mixtures, the refraction of the alcohol should vary to an extent readily detectible in the results in Table II. The absence of such a variation provides evidence against the hypothesis of Sidgwick. If, however, the association is merely an orientation brought about by the powerful forces between the dipoles in the alcohol molecules, as discussed by two of the authors[4] in another connection, the forces of the electrons may not be sufficiently affected by change of concentration in the mixtures to alter the refraction by a detectible amount.

It has been found that the molar refraction of a pure substance in the vapor state at 100° is often from 1 to 3% higher than the refraction of the liquid at room temperature,[8] although for some liquids a decrease of about the same magnitude accompanies the rise in temperature and vaporization. The changes observed are of the same order of magnitude as the increases found by Falk to result from raising the temperature from 20 to 80°. Moreover, these changes are no greater for substances containing an hydroxyl group than for those supposed to be unassociated. For example, water vapor at 100° has a refraction 0.4 to 1.3% higher than the liquid at 10°, the values of different investigators varying; ethyl alcohol vapor at 100° is 0.7% higher than the liquid at 10°, the

[8] Lorenz, *Ann. Physik,* 11, 70 (1880); Prytz, *ibid.,* 11, 109 (1880); Brühl, *Z. physik. Chem*, **7**, 4 (1891).

supposedly unassociated ethyl ether is 1.4% higher in the vapor state at 100° and ethyl iodide is 0.9% higher, while methyl alcohol vapor at 100° is 0.3% lower than the liquid at 10°. The refraction of liquid n-heptyl alcohol increases 0.7% between 10 and 80" and that of the hydrocarbon, di-*iso*-amyl, increases by a similar amount. It is interesting to note that these increases are, in proportion to the temperature rise of 70°, of the same size as the increases, 1.6 to 1.9%, found by Smyth and Stoops[9] in the total polarizations of three isomers of heptane and an octane for a temperature increase of 180". As these substances have no electric moments, the total polarization is $P_E + P_A$ and P_A is found to have a value only about 3% of that of P_E for these isomers. It is evident that the alcohols fail to show a change of refraction greater than that shown by supposedly unassociated substances when not only the temperature but even the state is changed, although the association must decrease with rise of temperature and, for most of the substances, become negligible on vaporization. Just as the change in the degree of association almost certain to accompany change in the concentration of mixtures leaves the refraction unaffected within the limit of accuracy of the measurements, so the change produced by change of temperature has no distinguishable effect. Further evidence is thus brought to bear against the hypothesis of an actual sharing of electrons between molecules when association occurs in the alcohols and water.

Summary

The refractive indices for the sodium D line at 20° are measured for a large number of mixtures of fifteen different pairs of liquids.

The data are used to calculate the molar refractions of the liquids. It is found that the molar refractions of the components of the mixtures are independent of the concentration to within 0.07%. This proves that the contribution of induced electronic shifts to the polarization of a molecule of one of these substances is practically unaffected by the surrounding molecules.

The independence of composition shown by the molar refraction of the alcohols is used as evidence against the sharing of electrons between their molecules to bring about molecular association.

THE ATOMIC WEIGHT OF ANTIMONY FROM DIFFERENT SOURCES

BY R. K. MCALPINE

RECEIVED FEBRUARY 27, 1929 PUBLISHED JUNE 5, 1929

In 1923 Muzaffar[1] published a preliminary note under the above title in which he claimed that four samples of antimony, derived from rtibnites from Hungary, Borneo, Peru and Bolivia, gave by titration against potassium bromate atomic weights as follows: 121.14, 121.56, 121.72 and 122.37. In 1027 Krishnaswami[2] reported the results of comparisons of Kahlbaum's antimony with the metal obtained from four ores of Indian and Burmese origin. "A few trials were made of Muzaffar's method, but in spite of its apparent simplicity certain disadvantages became evident in practice and it was abandoned." Instead, the metal was converted to bromide and comparisons made of the bromide with silver and with silver bromide, copying the procedure that had been employed in this Laboratory.[3] A sentence from the conclusion tells the story: "The results are in good agreement with the best previous determinations; there is no indication that the variation is due to a change in atomic weight, and in any case such variation does not exceed 0.01 unit for the samples examined."

The present work was undertaken to review the work of Muzaffar using samples of antimony from the same sources and comparing them by density and by titration with potassium bromate. The materials used by Muzaffar had been exhausted, but through the kindness of Mr. C. T. Heycock under whose direction the work had been done it was possible to obtain some of the same ores from the supply house that had furnished the original materials. Since the extreme values were reported for the antimony obtained from Hungary and Bolivia, respectively, the ores from these countries were selected as sources of metal for detailed study.

Preparation of Materials

Antimony.—The metal was recovered by the same process that was used by the other workers. Following extraction with concentrated hydrochloric acid, the antimony was precipitated as oxychloride, dissolved in hydrochloric acid, oxidized with chlorine and several times recrystallized as metachloro-antimonic acid. This material was then hydrolyzed with water, the precipitate evaporated with nitric acid to remove chloride, ignited to oxide and reduced to metal by fusion with recrystallized potassium cyanide. The buttons thus obtained were cleaned mechanically and then alternately etched with nitric acid and fused in hydrogen until the latter process gave clear-surfaced globules which on solidifying formed crystalline masses with the highest luster on all surfaces.

[3] Willard and McAlpine, THIS JOURNAL, **43,797 (1921).**

Throughout all these operations all reagents were specially purified and all utensils scrupulously cleaned, employing the technique used in the previous work in this Laboratory.[3]

Potassium Bromate.—Some of Kahlbaum's special reagent was recrystallized several times from redistilled water, using centrifugal drainage of the crystals and conducting the operations in quartz and platinum ware. The material thus obtained was dried in a desiccator over potassium hydroxide sticks. Qualitative tests for halide and chlorate were negative. A portion of this material was further dried by heating for three hours at 130° for use as a standard. A very small amount of water was still present, probably several hundredths of one per cent. A small portion of the stock has been reserved for a moisture determination which it is hoped to carry out before long.

Experimental

The experimental work may be divided into two parts: I, the determination of the density of antimony from different sources and II, the determination of the ratio of antimony to potassium bromate.

I. The Density of Antimony from Different Sources.—According to the theory of isotopic mixtures, if the atomic weight of an element varies with different specimens, the density of these specimens should also vary, and in direct proportion to the atomic weight. Since the values in question differ by slightly more than 1% in their extremes, a determination of the density should give an immediate check on variations of that magnitude.

Experimentally the method finally employed for this determination consisted in weighing the buttons of antimony in air and then in water and calculating their volumes from the differences in weights and the density of the water at the temperature used. A small platinum wire basket was constructed to hold the antimony. This was then suspended from the hook on the balance and weighed carefully. Then it was immersed in water to a fine knot on the suspension wire and weighed again. Next, after the basket had been carefully dried, an antimony button was placed in it and the system weighed as before, first in air, then in water. From these weights and the density of the water at the temperature of the experiment the density of the metal was then calculated.

Preliminary experiments showed that the ordinary round buttons of antimony gave erratic results. It appeared as if spaces were formed inside the buttons when they solidified, causing the apparent density to vary and to be lower than the true density. This difficulty was overcome in the following manner. A 20-centimeter hard glass tube was heated in an oxy-gas flame until the closed end was perceptibly cone-shaped for a length of three or four centimeters. The test-tube was then cleaned thoroughly. Next, the antimony was placed in the tube and a clean two-holed rubber stopper inserted bearing an inlet and an outlet tube for hydrogen. The antimony was then fused in hydrogen and after removing the flame the tube was rotated in such a way as to cause the metal to solidify as a shell in the cone-shaped part of the test-tube. With this manipulation it was found possible to get reasonably concordant results on repeated fusions followed by density determinations. The specimens of antimony were therefore prepared in this way and the densities determined, using redistilled water that was freshly boiled and cooled. In each case, after immersion in water, the surface of the shell was searched carefully for air bubbles. Only occasionally was one found. In such a case it was effectively removed by careful manipulation with a fine glass rod. Boiling to displace air was considered of doubtful value, because of *(a)* the chance for action of boiling water on the antimony and (b) the decrease in density noted by Cohen[4] when antimony was maintained for some time at 102–105°. Since the average value obtained here is slightly higher than that of Cohen[4] and still higher than that recommended by "International Critical Tables" (Vol. I, p. 104), the error due to trapped air must be very small. The results are given in Table I.

TABLE I

THE DENSITY OF ANTIMONY PROM DIFFERENT SOURCES

Source of antimony	Wt. of Sb in air, g.	Wt. of Sb in water. g.	Temp. of water, °C.	Density of Sb
Kahlbaum's	**15.3981**	**13.1024**	**22.3**	**6.694**
Hungarian stibnite	**14.9260**	**12.7342**	**22.3**	**6.703**
Bolivian stibnite (a)	**13.5033**	**11.4907**	**22.3**	**6.696**
(b)	**12.9599**	**11.0275**	**22.3**	**6.695**

The inherent limitation of this method lies in the sluggish action of the balance when weighing in water. It was found possible, however, to determine the resting point of the balance to within one milligram; therefore the error in weighing, with two weighings in water involved, should not exceed two milligrams at the maximum. Since the weight of displaced water is approximately two grams, the density values should check within 0.1%.

The figures in Table I give no evidence of variation in the density of antimony from different sources. The variations from the average, +0.006 and −0.003, are within the limits of the method used. Even if the attempt were made to attach significance to these variations it would be noted that their indications are at variance with the work of Muzaffar, not only as regards magnitude, but also in direction. He reported 121.14 for the atomic weight of antimony from Hungary and 122.37 for that from Bolivia. On that basis the density of the antimony from Bolivia should be highest, Kahlbaum's antimony intermediate, corresponding to the atomic weight 121.77, and that from Hungary lowest.

II. The Ratio of Antimony to Potassium Bromate.—In analytical work the bromate method for antimony is recognized as one capable of distinct accuracy, but the size of the sample is commonly limited to two or three-tenths of a gram of metallic antimony. Since it was desirable to

---

[4] Cohen and van den Bosch, *Z. physik. Chem.*, 89, 757 (1915).

use larger samples to increase the accuracy of the determination, some preliminary experimentation was necessary to work out a satisfactory procedure. In these studies it was found that a sample as large as three grams could be converted to sulfate readily by digesting at near the boiling point with fifty milliliters of concentrated sulfuric acid. On cooling a considerable amount of antimony sulfate crystallized out, but this dissolved readily in dilute hydrochloric acid. The usual procedure recommends that the final solution contain approximately 20% by volume of concentrated hydrochloric acid, and be titrated with methyl orange as indicator at not less than 60°. With the large amount of sulfuric acid already present it was found that a lower concentration of hydrochloric acid gave better results, both in sharpness of end-point and in completeness of oxidation of the antimony by the bromate. It was also found that the reaction proceeds readily at room temperature, making it possible to add the bromate in solid form, swirl to dissolve the bromate, then heat to the proper temperature to obtain a sharp end-point and complete the titration. To avoid error in the transfer of the bromate it was found convenient to weigh the salt into a small shell vial, ten by thirty centimeters in size, and then drop vial and all into the solution, taking care to avoid spattering. This operation was carried out in a flask that could be stoppered until all of the bromine fumes were absorbed by the solution, thus avoiding error from loss of bromine. In the final determinations the following method was used.

A sample of 2 to 3 g. of antimony was weighed out, transferred to a half-liter glass-stoppered Erlenmeyer flask and treated with 50 ml. of concentrated sulfuric acid; the flask was covered with a watch glass and heat applied with a small flame until the metal was dissolved. This required one-half to three-quarters of an hour. As soon as the reaction was complete the flame was removed and when cool enough to permit it the flask was placed in running water for a few minutes. Then there was added 350 ml. of dilute hydrochloric acid containing 10% by volume of the concentrated acid, the cover glass and walls of the flask being rinsed with acid of the same strength. The solution was boiled for several minutes to remove sulfur dioxide, using a current of carbon dioxide to prevent access of oxygen from the air and continuing the process for two or three minutes after the odor had disappeared. The solution was then cooled in running water, with the atmosphere of carbon dioxide maintained, and when cold the glass stopper was inserted. Meanwhile an amount of potassium bromate was weighed out 3 to 5 mg. less than sufficient to oxidize the antimony. The stopper was then removed and the vial containing the bromate dropped in, the stopper reinserted and the solution swirled until the salt was completely dissolved and the solution again colorless. This required only two or three minutes. The cold solution was allowed to stand for about five minutes longer for complete absorption of any bromine fumes, then the stopper was removed, the solution heated to 60–70° under an atmosphere of carbon dioxide, three drops of methyl orange solution added and the titration completed with a standard solution of potassium bromate containing one milligram of the salt per milliliter. In some cases duplicate titrations were carried out by reducing with sulfur dioxide and repeating the above operations, starting with the removal of excess sulfur dioxide by boiling in a current of carbon dioxide. The blank to determine the correction to be applied for the end-point showed that one-tenth of a milligram of potassium bromate was sufficient to destroy the color of the indicator under the conditions used.

Table II gives the results of comparison of the different specimens of antimony with each other by titration with potassium bromate.

[a] Pieces of shell from density determination.

[b] In this determination, through error in calculation, an excess of potassium bromate was added as solid so the first titration was lost.

In examining the data in Table II two points are to be noted: first, that with repeated titrations the ratio of potassium bromate to antimony falls off slightly; second, that comparisons of the ratios for first titrations show a concordance indicating the essential identity of the different specimens of antimony. The average ratio for first titrations is 0.4580 and the maximum variation from this—0.0003—is shown between the two samples of antimony from Bolivia. This shows that the atomic weights of the different specimens of antimony studied are identical within 0.05 unit of each other in contrast to a difference of 1.23 reported.

Concerning the true ratio of potassium bromate to antimony, the value calculated from the accepted atomic weights is 0.4571. The average ratio for first titrations, 0.4580, is obviously too high because of the presence of a slight amount of moisture in the potassium bromate. It is doubtful, however, if the moisture alone would be sufficient to account for this difference. Further, the decrease in ratio with successive titrations suggests the possibility that the reaction of antimonous chloride with potassium bromate is not quite so simple as represented by the ordinary equation. This reaction is capable of experimental investigation, but since it does not affect materially the question of the atomic weights of antimony from different sources it has been set aside for the moment.

It is hardly worth while to speculate on the errors of Muzaffar's work. The paper as originally presented for publication contained density determinations indicating variations corresponding to the atomic weights reported. These were omitted in the published article, as well as several of the crudities noted in other parts of the work. In the paper as published the experimental details are lacking that should be considered if critical comment were to be made. The most charitable view, however, would be that he attempted the application of procedures to unknown material before he had tested them sufficiently to understand their behavior on known material, a not uncommon mistake in analytical work.

Summary

1. Muzaffar reported atomic weights of **121.14** and 122.37, respectively, for specimens of antimony derived from stibnites from Hungary and from Bolivia.
2. Specimens of metallic antimony have been prepared from stibnites from Hungary and Bolivia, the ores being obtained from the supply house that furnished the material for Muzaffar.
3. These specimens have been compared with each other and with Kahlbaum's antimony by density determinations and by titration with potassium bromate.
4. The densities of the three specimens lie within one-tenth of one per cent. of one another.
5. The ratios of potassium bromate to antimony lie within five-hundredths of one per cent. of each other.
6. There is no evidence of variation in the atomic weight of antimony from different sources.

THE SHIFT IN THE 1.14μ ABSORPTION BAND OF SOME BENZENE DERIVATIVES

BY JAMES BARNES AND W. H. FULWEILER

RECEIVED FEBRUARY 28, 1929 PUBLISHED JUNE 5, 1323

In an earlier paper[1] by the authors it was shown that the frequencies of the absorption bands (at approximately 0.87μ) of benzene and some of its derivatives are shifted progressively toward lower values as methyl and ethyl groups are added to the benzene ring. This note is to report that a similar effect has been observed in benzene, toluene, p-xylene and mesitylene in their next outstanding absorption band toward the infra-red, which has a wave length of approximately 1.14μ. The amount of the shift is the same within the limit of error as that observed in the 0.87μ band.

The apparatus used, namely, source of continuous radiation, six-foot

[1] **Barnes** and **Fulweiler,** THIS JOURNAL, **49,2034 (1927).**

Rowland concave grating and thalofide cell, as well as the method of measurement, were the same as those described in the *Physical* **Review,** 32, 618 (1928). In addition, **a** No. 87 Wratten filter was placed in front of the slit of the grating spectrometer.

The results obtained with an absorption cell **30** mm. in length are recorded by small circles on the curves of Fig. 1. These curves show the variation in the transmission ratio with wave length for the hydrocarbons used. In order clearly to separate the curves the zeros of the transmission ratio for the different liquids are uniformly raised along the ordinate axis. The wave-length scale is, however, in the same position for each liquid.

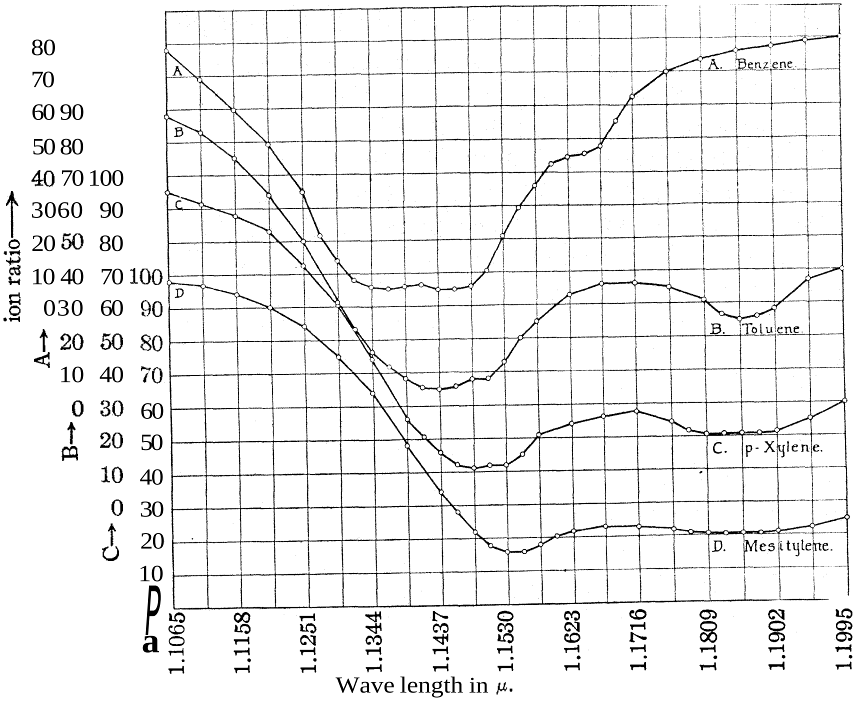

Fig. 1.—Variation of transmission ratio with wave length for benzene derivatives.

Inspection of these curves shows that the wave length of the center of the outstanding absorption band is shifted toward the region of longer wave length and hence the frequency of the oscillator is decreased as methyl groups are added to the benzene ring. They also show that the addition of this group appreciably lowers the transmission in the region from 1.16μ to 1.20μ, with a broad and weak absorption band at approximately 1.185,~.

The following table gives the wave length, λ(μ), of the center of this outstanding absorption band for each of the liquids investigated. The values are believed to be accurate within ±0.001μ.

TABLE I

WAVE LENGTHS OF ABSORPTION BANDS OF BENZENE DERIVATIVES

Derivative	Benzene	Toluene	p-Xylene	Mesitylene

THE EFFECT OF AIR ON THE POTENTIAL OF THE MERCURY–MERCUROUS SULFATE ELECTRODE

BY MERLE RANDALL AND HENRY A. STONE

RECEIVED MARCH 13, 1929 PUBLISHED JUNE 5, 1929

Vosburgh[1] has shown that the potential of Weston standard cells with slight additions of basic mercuric sulfate to the mercury–mercurous sulfate electrode in neutral or slightly acid saturated cadmium sulfate solutions or prepared with the materials in contact with air is about 0.03 mv. higher than that of cells prepared out of contact with the air. Randall and Young[2] found relatively large errors of the order of 1.5 mv. in acid calomel electrodes prepared in the presence of air. We shall here study the effect of air on the hydrogen–mercurous sulfate–mercury cell.

The Reaction between Dilute Sulfuric Acid and Mercury.—Redistilled mercury and 0.1 *M* sulfuric acid were sealed in pyrex flasks[2] and rotated for twenty-four hours in a thermostat at 25°. In some of the flasks the air was displaced with a current of pure nitrogen and acid which had been freed from air by boiling in a current of pure nitrogen was used. There was no evidence of the formation of a precipitate but upon the addition of air-free dilute hydrochloric acid a precipitate of mercurous chloride appeared in the acid from the flasks in which no precautions had been taken to exclude air.

Materials.—The sulfuric acid was prepared and analyzed as described by Randall and Scott.[3] Nitrogen was prepared by passing commercial nitrogen over three feet of reduced copper turnings at a bright red heat, or by adding a small amount of hydrogen and passing the mixed gas over white-hot platinum wire. The dilute acids were prepared from the stock acid by dilution with conductivity water (weight burets, concentration in moles per 1000 g. of water in vacuum) and traces of air were removed by bubbling through pure nitrogen for eight hours. The acids were stored in quartz flasks.

Mercurous sulfate was prepared by precipitation in the dark from mercurous nitrate.[4] It was washed six to eight times with air-free acid in an atmosphere of nitrogen in the pipet (Fig. 1) and introduced into the cell by a slight adaptation of the method of Vosburgh.[1] Considerable care was taken to shield the mercurous sulfate from the light. We found that mercurous sulfate in contact with 0.1 M sulfuric acid

had turned yellowish-brown after two months' contact with mercury in the half-cells which had been submerged in the oil thermostat at 25° in a moderately lighted room.[5] In the experiment quoted here the outside of the half-cells was coated with black "Duco" lacquer.

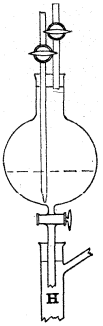

Fig. 1.—Pipet.

Cells.—The hydrogen electrode was the usual type.[2] The essential parts of the mercury–mercurous sulfate half-cell are shown in Pig. 2. To insure the absence of air a current of pure nitrogen was used to displace the sir in the apparatus assembled as shown, with stopcocks A, B and C open and D and E closed. The stopper F of the half-cell H was then quickly withdrawn (with an increased current of nitrogen), the mercury introduced and then the pipet (Fig. 1) containing the air-free suspension of mercurous sulfate in the sulfuric acid replaced the stopper. The mixture of paste and acid then filled the cell to the level of the side arm, and while the current of nitrogen was continued the pipet was withdrawn and the cell again quickly sealed by the stopper F. (The pipet could have been left in the cell.) The stopcock A was now closed and acid introduced into the reservoir I and bubbled with pure nitrogen, the cell painted with black "Duco" and then transferred to the thermostat with the oil level as indicated by the dotted line. The current of nitrogen was replaced by a current of electrolytic hydrogen which had passed over a white-hot filament to remove traces of oxygen. After three days the sulfuric acid in the cell was replaced by flushing the cell by opening stopcock A. The intermediate vessel J was filled, stopcock C closed, the tube leading to D filled and this stopcock closed. The acid was then removed through C until flushing was complete. Contact with the hydrogen electrode was made through the greaseless stopcock E, the tube leading to J being filled with acid brought from the hydrogen electrode vessel. The stopcock B also connected to a second mercury–mercurous sulfate half-cell. The flushing was usually done in the evening and reading commenced on the following morning. The cells came to equilibrium in from twenty-four to forty-eight hours and were constant to less than a maximum difference of 0.03 mv.

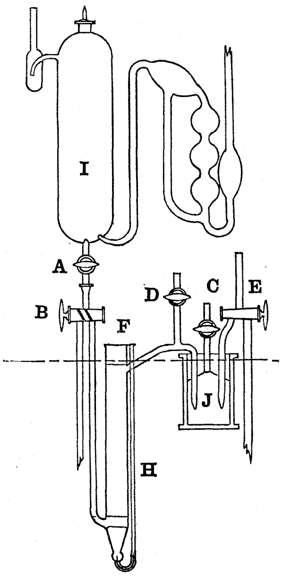

Fig. 2.—Half-cell.

---

[5] Similar discolorations have been noted by (a) Hulett, *Phys. Rev.*, 32, *262* (1911); (b) Obata, *Proc. Phys. Math. Soc., Japan,* **(3)** *2*, 79, 223 (1920) and (c) Horsch, THIS JOURNAL, 41, 1787 (1919), who stated that the discoloration (in the presence of zinc sulfate) would not take place if a small concentration of hydrogen ion was present.

Potential Measurements.—After three days moist air was introduced at the surface of the mercury, at first only a few bubbles and later as much as a liter. Initial values from 0.2 mv. to 0.4 mv. lower were obtained but in fifteen minutes the cells would be back to their normal voltage and remained constant as before for thirty days. Replacing the electrolyte produced no change in the potential.

The following values of the hydrogen–mercury–mercuroussulfate cell are shown in Table I.

TABLE I

VALUES OF THE HYDROGEN–MERCURY–MERCUROUS SULFATE CELL

Molality of sulfuric acid	0.1000	0.2101
Exptl. e.m f., volts	0.73694	0.71858
Interp. e.m f. (R. and C.)[6]	0.73697	0.71852

Summary

Mercury is dissolved by dilute sulfuric acid containing air.

The effect of air upon the potential of the mercury–mercurous sulfate electrode in moderately concentrated acid solution is negligible when the electrodes are prepared in the usual manner.

BERKELEY, CALIFORNIA

NOTE

Sodium Maleate—A Buffer for the PH Region of 5.2 to 6.8.—In the course of a research on autoxidation the author has found that the buffering range of sodium hydrogen maleatesodium hydroxide mixtures extends from a PH of 5.2 to 6.8, giving maximum buffering power in the region where phthalate and phosphate buffers have the least. The lower valence of the ions results in a smaller salt effect than is the case with citrate buffers.

Sodium hydrogen maleate is easily prepared in pure form as $NaHC_4H_2O_4 \cdot 3H_2O$.[1] The following method was found convenient. A liter of aqueous solution containing 250 g. of maleic acid was exactly halved. To the first half was added 6 N sodium hydroxide until the precipitate first formed had redissolved, then normal sodium hydroxide to the neutral point. The two halves were mixed, cooled in an ice-bath and the crystallized salt was filtered off. Recrystallization is very easy. One recrystallization was found sufficient for a product made from Kahlbaum acid. When dried in a warm place in the open room, the salt conforms exactly to the trihydrate formula and may be weighed as such. Preliminary tests indicated that it might even be used as a primary standard in acidimetry.

[1] Biichner, *Ann.*, 49, 64 (1844); Weiss and Downs, THIS JOURNAL, 45, 2342 (1923).

The following table gives the composition of mixtures for P_H values from 5.2 to 6.8, as taken from a curve constructed from several titrations with a quinhydrone electrode against a saturated calomel cell at 25°.

TABLE I

COMPOSITIONS OF MIXTURES (TAKEN FROM CURVE)

Fifty cc. of $N/5$ sodium hydrogen maleate in each case; diluted to 200 cc.

P_H	5.2	5.4	5.6	5.8	6.0	6.2	6.4	6.6	6.8
$N/5$ NaOH, cc.	7.2	10.5	15.3	20.8	26.9	33.0	38.0	41.6	44.4

The base was added from a buret to a maleate solution containing 0.109 g. of quinhydrone. The region of each titration was small, so that the total volume could be kept within limits of 100 ± 3 cc. Potentiometric measurements of the cell

Au | buffer–quinhydrone | sat. KCl | sat. calomel cell

were used for calculation of P_H according to the usual method,[2] ignoring salt effect and contact potentials. Results from several titrations over different regions, comprising twenty-five measurements, were united into a single curve, from which the above figures were interpolated.

THE ABSORPTION SPECTRA OF SOME PHTHALEINS OF THE TRIHYDROXYPHENOLS[1]

BY R. C. GIBBS AND C. V. SHAPIRO[2]

RECEIVED AUGUST 27, 1928 PUBLISHED JUNE 5, 1929

In several previous papers data have been presented on the absorption spectra of the benzeins and phthaleins derived from some of the mono- and dihydroxybenzenes, for example, phenol,[3] *o*-cresol,[3] resorcinol[4] and hydroquinol.[5] The present study of the trihydroxy derivatives includes

the benzein,[6] phthalein and sulfonephthalein[7] of pyrogallol, the phthalein and sulfonephthalein[8] of hydroxyhydroquinol and the sulfonephthalein of phloroglucinol.[9]

With the extensive data now available a number of significant generalizations have become evident, which clearly indicate that definite conclusions may be drawn from absorption spectra both regarding the structure of these triphenylmethane compounds and their chemical properties, but these will be elaborated in greater detail in a later paper. The effect produced on the chemical properties and on the nature of the absorption by the introduction of hydroxyl groups in the phthaleins is a function both of their number and position. Thus the acidic properties of the sulfonic acid radical in the sulfonephthaleins are greatly influenced by the nature of the substitution in the two phenolic residues. The tendency to form an inner salt may be taken as a qualitative measure of the dissociation constant of the acid group, and a reliable indication of the existence and stability of such a salt is furnished by the similarity of the absorption spectra of the neutral and acid solutions. Thus hydroquinolsulfonephthalein appears as a stronger acid than either phenol- or o-cresolsulfonephthalein, for it shows the same type of absorption in aqueous, alcoholic and sulfuric acid solutions,[5] while the two latter compounds exhibit the inner salt structure in alcoholic solution but the quinoid hydrate configuration in aqueous solution.[3e] The addition of a molecule of water to form the hydrate necessitates the rupture of the inner salt bond and hence points to a lesser stability of the latter structure in the phenol and o-cresol compounds than in the hydroquinol derivative. By an independent method, B. Cohen[10] has demonstrated the weakening of the acidic properties of the sulfonephthaleins due to alkyl substitution in the meta position to the phenolic hydroxyl and it is hoped to check these conclusions by the spectroscopic method outlined above. If it is granted that the introduction of hydroxyl groups serves to enhance the acid properties, it is to be anticipated that the carboxyl radical, ordinarily a very weakly dissociable acid group, will have its dissociation constant so increased in a sufficiently hydroxylated phthalein as to render the formation of an inner salt possible. This has now been realized with hydroxyhydroquinolphthalein, whose solutions in absolute alcohol and in concd. sulfuric acid exhibit closely analogous absorption spectra, which in turn closely resemble those obtained for the corresponding solution of hydroxyhydroquinol*sulfone*phthalein, as pointed out below. The effect of the position of the hydroxyl groups on these

properties is clearly demonstrated by pyrogallolphthalein, or gallein, which is isomeric with hydroxyhydroquinolphthalein but whose absorption spectrum in absolute ethanol is typical of the lactone structure, indicating that its carboxyl radical has the usual weakly acid function that occurs in the other lactoid phthaleins.

Discussion of the Absorption Spectra

The curves for the absorption spectra of the pyrogallol derivatives in absolute ethanol solution are shown in Fig. 1. Curve A for pyrogallolbenzein, Curve B for pyrogallolphthalein (gallein) and Curve C for pyrogallolsulfonephthalein (sulfonegallein) represent three distinct types of absorption and hence indicate that each of these related compounds possesses a different internal structure. The absorption curve of pyrogallolbenzein bears a general resemblance to the curve obtained for resorcinolbenzein[4a] and is regarded as evidence for the existence of these compounds in the quinoid state and not as quinoid hydrates. In such cases where hydrate formation is definitely known to take place, as previously observed with benzaurin[3c] (phenolbenzein) and *o*-cresolbenzein,[3d] fading of the solution occurs due to the setting up of an equilibrium between the colored hydrate and the colorless carbinol, and the absorption in the ultraviolet region is characterized by the presence of several weak bands, of which two have been found to be typical of the benzenoid state in triphenylmethane derivatives.[11] Neither fading nor the development of the above typical bands has been observed with pyrogallol- or resorcinolbenzein.

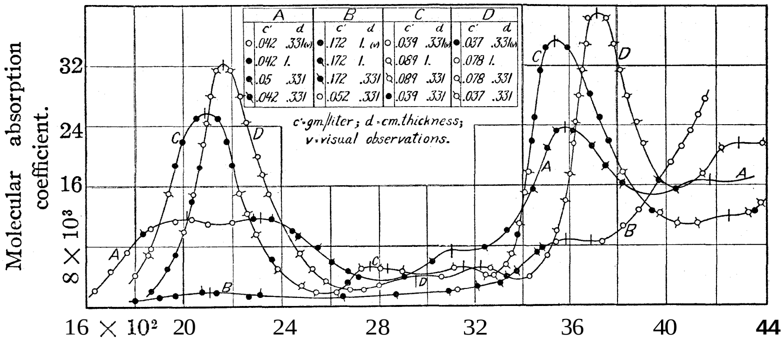

Fig. 1.—Neutral absolute ethanol solutions: A, pyrogallolbenzein; B, gallein; C, sulfonegallein; D, dimethyl ether of sulfonegallein.

The absorption spectrum of gallein in absolute ethanol, Curve B, is marked by a weak band in the visual region and by two weak bands of nearly equal intensity in the ultraviolet at frequency numbers 3583 and 3693, having a separation of 110 mm.$^{-1}$. In position, separation and in-

[11] Gibbs and Shapiro, Proc. *Nat.* Acad. *Sci.*, 14, 251 (1928).

tensity these two bands correspond closely with the characteristic pair of bands found for numerous other lactoid phthalein derivatives.[11] It therefore appears certain that gallein, despite its color in the solid state and in neutral solution, is present primarily as the lactone. The band at 2107 responsible for the color of the solution may be related to the near ultraviolet band found in the colorless neutral solutions of hydroquinolphthalein[5] and of phenol- and *o*-cresoltetrachlorophthaleins,[3e] but shifted into the visual region because of the addition of hydroxyl groups or, what is more likely, it may be due to the presence of a small amount of the quinoid form, in equilibrium with the lactone. The closely related tetrachlorogallein is an almost colorless compound and has been considered by Orndorff and Delbridge[12] as being primarily lactoid, but containing a small percentage of the quinoid modification.

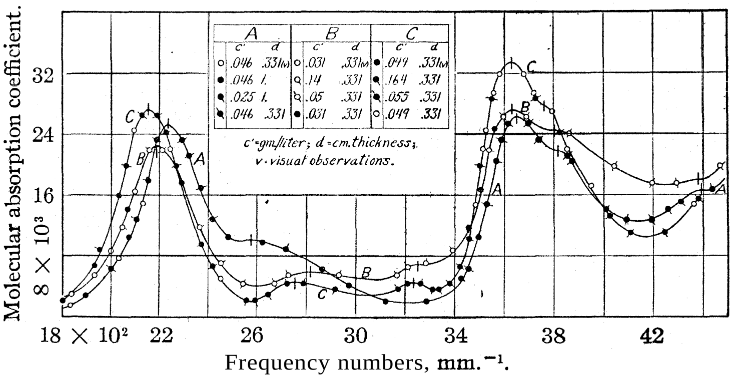

Fig. 2.—Concd. sulfuric acid solutions: A, pyrogallolbenzein; B, gallein; C, sulfonegallein.

Sulfonegallein exhibits absorption, Curve C, which is very similar to that of its sulfuric acid solution, Fig. 2, Curve C. Since in the latter solvent salt formation occurs on the basic, quinoid oxygen atom, this type of absorption is evidently characteristic of a salt structure and hence is the basis for assigning the inner salt configuration to sulfonegallein in neutral ethanol solution. Orndorff and Fuchs[13] arrived at the same conclusion from the fact that sulfonegallein does not react with hydrogen chloride gas, which indicates that the basic properties have already been neutralized. Sulfonegallein takes on a molecule of water at the oxygen atom of the pyrone ring, giving rise to pyrogallolsulfonephthalein, but the latter compound shows exactly the same absorption as the former in all solvents. The existence of the pyrone ring thus plays no part in determining the optical properties of the compound, a conclusion which was reached previously on comparison

---

[12] Orndorff and Delbridge, *Am. Chem. J.*, **42**, 183 (1909).

[13] Ref. 7, p. 1943.

of phenolphthalein and fluoran.[4b] Curve D of Fig. 1 shows the absorption of the dimethyl ether of sulfonegallein in absolute ethanol and is of the same type as Curve C for sulfonegallein but is shifted bodily toward the ultraviolet. As this evidence indicates that the dimethyl ether must likewise be considered as an inner salt, it follows that methylation of two of the hydroxyl groups has no radical effect on the nature of the molecule.

Figure 2 presents the absorption spectra of the sulfuric acid solutions of the pyrogallol derivatives. The general similarity of the curves is striking and affords sufficient basis for postulating identical quinoid salt structures for the three compounds in this solvent. Attention is called to the characteristic double band, in the region of frequency numbers 3600–3800, which has been found for the sulfuric acid solutions of nearly all phthaleins containing the pyrone ring, such as fluorescein,[4b] sulfonefluorescein[4c] and the hydroxyhydroquinol derivatives described below. The hydroquinol and phloroglucinol compounds have proved exceptional in this respect.

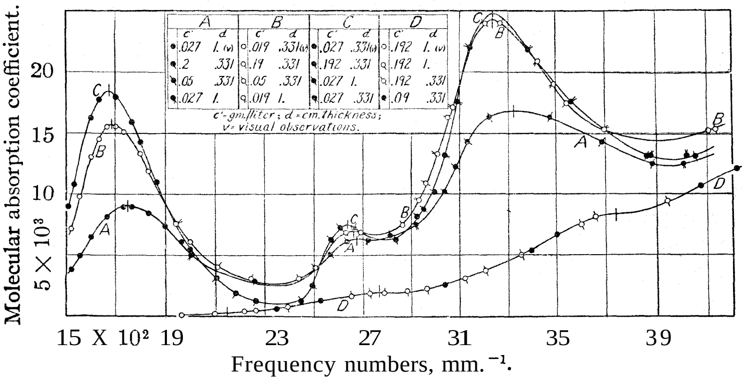

Fig. 3.—Aqueous alkaline solutions. A, pyrogallolbenzein in 5% KOH; B, gallein in 33% KOH; C, sulfonegallein in 33% KOH; D, sulfonegallein—faded.

The freshly prepared aqueous alkaline solutions, pyrogallolbenzein in 5% potassium hydroxide and gallein and sulfonegallein in 33%, also exhibit closely related absorption spectra, as shown in Fig. 3. It is noted in passing that pyrogallolbenzein, like resorcinolbenzein,[4a] is not soluble in solutions of potassium hydroxide greater than 5%. Unlike resorcinolbenzein and in common with the other pyrogallol compounds, its alkaline solution is not fluorescent and rapidly fades to a very pale yellow in the course of a few days. It is probable that the lesser intensity of the absorption of its freshly prepared solution, Curve A, as compared with Curves B and C for gallein and sulfonegallein, respectively, is due to a somewhat greater incipient fading. However, the similarity in form and position of the bands indicates the existence of basic salts of identical structure in alkaline solution, even though pyrogallolbenzein, lacking an acidic radical, forms only a *tri*basic salt, while the others are converted into tetrabasic salts. The fading of these solutions, which was complete in three to four days, is due to the formation of salts of the colorless, benzenoid carbinol, in a manner entirely analogous to the behavior of phenolphthalein in strongly alkaline solution. The absorption spectra of the faded solutions are fairly similar and are characterized by the presence of three shallow bands superimposed on a background of weak general absorption, as illustrated by Curve D for the solution of sulfonegallein measured five days after its preparation. Owing to the difficulty of accurately locating shallow bands of this type, their positions are given only approximately in round numbers. Table I summarizes the locations of all the bands for the above pyrogallol compounds in the various solvents employed.

Figure 4 presents the absorption spectra of absolute ethanol solutions of hydroxyhydroquinolphthalein, Curve A, hydroxyhydroquinolsulfonephthalein, Curve B, and phloroglucinolsulfonephthalein, Curve C. The two hydroxyhydroquinol derivatives have almost identical absorption, the phthalein showing slightly greater intensity and having its bands shifted slightly toward the ultraviolet with the exception of the one at 3055, which is to the red side of the corresponding band for the sulfonephthalein. This is the first instance in the course of our study of the phthaleins, where a phthalein and sulfonephthalein of a given phenol have shown the same type of absorption in ethanol solution. Taking into account the fact that their sulfuric acid solutions, Fig. 5, Curves A and B, also have absorption of this type, it is evident on the basis of the criterion already established and verified, that hydroxyhydroquinolphthalein must possess the structure of an inner salt and hence that its carboxyl group has acidic properties equivalent to those of the sulfonic acid radical. Such a marked increase in the dissociation constant of the carboxyl group as the result of substitution in the molecule is, of course, not without precedent, as note, for example, acetic and trichloro-acetic acids. The objection that the active substituents are far removed from the affected carboxyl group, since they are located in different phenyl nuclei, is met by

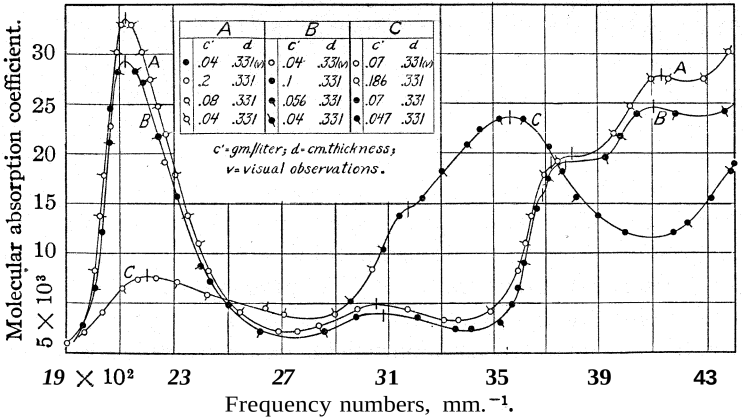

Fig. 4.—Neutral absolute ethanol solutions: A, hydroxyhydroquinolphthalein; B, hydroxyhydroquinolsulfonephthalein; C, phloroglucinolsulfonephthalein.

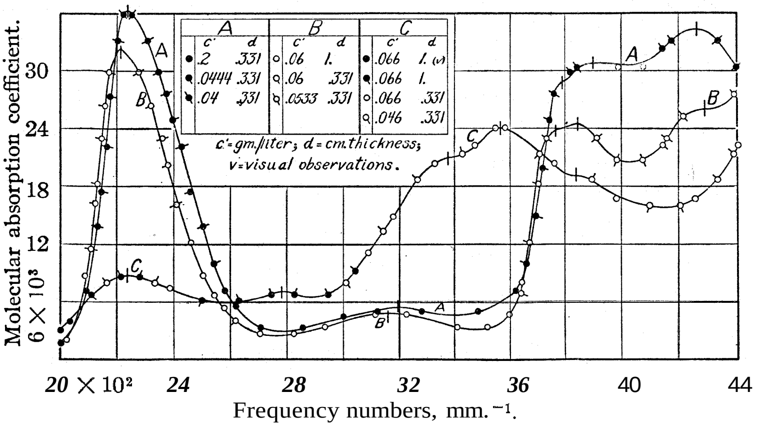

Fig. 5.—Concd. sulfuric acid solutions: A, hydroxyhydroquinolphthalein; B, hydroxyhydroquinolsulfonephthalein; C, phloroglucinolsulfonephthalein.

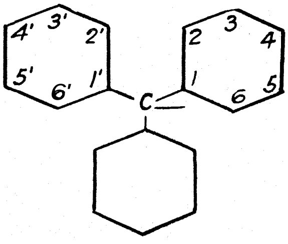
considering that any change in the distribution of chemical forces in a given benzene ring is transmitted to the rest of the molecule through its point of linkage, which in this case is the methane carbon atom and this in turn is in the ortho position to the acid radical.

The absorption spectra of phloroglucinol in absolute ethanol, Curve C, Fig. 4, and in concd. sulfuric acid, Curve C, Fig. 5, while alike in type, are entirely different in character from those of the hydroxyhydroquinol derivatives. In general it has been noted that those quinoid phthaleins which have a different number or arrangement of phenolic hydroxyls, have quite different absorption spectra. Thus each of the sulfonephthaleins derived from the following phenols has its own peculiar absorption: phenol (or 4,4′-dihydroxydiphenylsulfonephthalide), hydroquinol (anyhydro-2,2′,5,5′-), resorcinol (anhydro-2,2′,4,4′-), pyrogallol (2,2′,3,3′,4,4′), hydroxyhydroquinol (anhydro-2,2′,4,4′,5,5′-), and phloroglucinol (anhydro-2,2′,4,4′,6,6′-).[14] *o*-Cresolsulfonephthalein, however, which is a dimethyl derivative of phenolsulfonephthalein and which has its phenolic hydroxyls in the same relative position, 4,4′-, as phenolsulfonephthaiein, shows the same type of absorption spectrum as that compound.[3e] Similarly the dimethyl ether of sulfonegallein, in which two of the phenolic hydrogen atoms are replaced by methyl groups, absorbs in the same manner as its parent substance (see above). On the other hand, all the lactoid phthaleins, as well as lactoid derivatives of the quinoid phthaleins, have been shown to possess related absorption spectral[1] regardless of the number and position of the hydroxyl groups. A possible explanation of this difference in optical behavior on the part of the quinoid and lactoid phthaleins may be that with the former the molecule is in a much less stable condition, as indicated by the generally greater reactivity of such compounds, and that the introduction of active groups, such as hydroxyl, can therefore produce a marked effect on the distribution of interatomic forces with a corresponding effect on the absorption spectrum.

Figure 6 exhibits the absorption spectra of freshly prepared solutions of hydroxyhydroquinolphthalein and -sulfonephthalein and of phloroglucinolsulfonephthalein in 33% aqueous potassium hydroxide. Curves A and B for the two hydroxyhydroquinol derivatives, respectively, are fairly parallel and are characterized by a relatively complex set of six bands. Both



---

[14] The numbering of the positions of the hydroxyl groups is based on the schematic structure indicated. Where hydroxyl groups are present in the 2,2′-positions and water is split off to form the pyrone ring, the word anhydro- is prefixed.

solutions fade in a few days to a very pale yellow and their absorption spectra, represented here by that of hydroxyhydroquinolphthalein, Curve C, are found to have practically the same bands, except for the disappearance of the one in the visual region, as curves for the fresh solutions. Owing to the general flattening out of the absorption curve it is much more difficult to locate these bands precisely, This type of behavior is, however, different from that of the other phthaleins on which measurements have been obtainable before fading occurred, since in these cases the absorption spectrum was different for the fresh and faded solutions. Phloroglucinolsulfonephthalein in strong alkali yields a solution of an orange-yellow color, quite unlike the well-known red or bluish-red of alkaline solutions of the other phthaleins, and is also exceptional in that no fading was observed over a period of several months. Its absorption, Curve D, is marked by three broad bands.

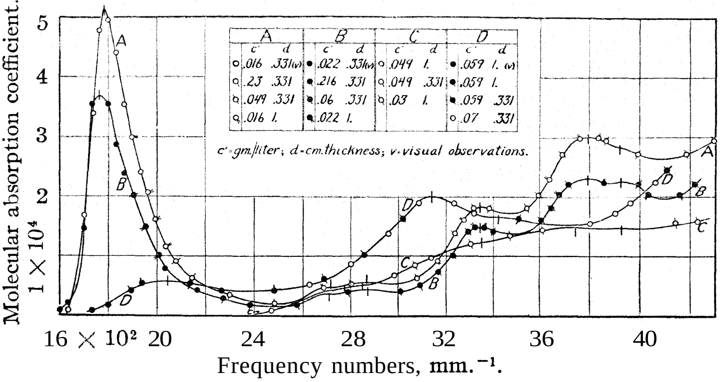


Fig. 6.—33% aqueous potassium hydroxide solutions. A, hydroxyhydroquinolphthalein; B, hydroxyhydroquinolsulfonephthalein; C, hydroxyhydroquinolphthalein—faded; D, phloroglucinolsulfonephthalein.

The positions of the absorption bands for the various solutions of the hydroxyhydroquinol and phloroglucinol compounds are listed in Table II.

Concd. KOH, fresh	2047	3137	3425		

Both hydroxyhydroquinolphthalein and hydroxyhydroquinolsulfonephthalein behave in an unusual manner, when gradually increasing amounts of potassium hydroxide are added to their neutral absolute ethanol solutions. With most of the colored phthaleins and sulfonephthaleins, it has been observed that over a certain range of alkali concentrations there is a more or less rapid disappearance of the visual band of the neutral solution and a corresponding growth of the band characteristic of the alkaline solution.[15] The wave-length positions of the neutral and alkaline bands remain fixed, since they are due to the presence of two different substances, the neutral form and the basic form, and the relative intensities are a measure of their relative concentrations and therefore of the state of equilibrium between them.[16] In the case of the hydroxyhydroquinol derivatives, as illustrated in Fig. 7 by the set of curves covering the visual region for alkaline solutions of hydroxyhydroquinolphthalein, there is, however, an almost continuous shift of the bands toward the red, while the intensities pass through a maximum for an intermediate concentration of alkali. Curve A is a reproduction of the visual portion of the absorption

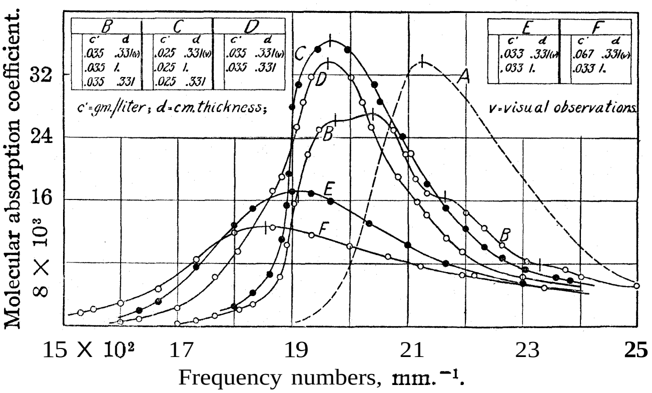

Fig. 7.—Hydroxyhydroquinolphthalein in alcoholic potassium hydroxide: A, neutral solution; B, 1 molecule:2 molecules of KOH; C, 1 molecule:4 molecules of KOH; D, 1 molecule:23 molecules of KOH; E, 1 molecule:87 molecules of KOH; F, 1 molecule:100 molecules of KOH.

curve for the neutral solution. Curve B for two molecules of potassium hydroxide to one of the phthalein has a lesser intensity and there are present a prominent double band and two weak shoulders in place of the single band of the neutral solution. For four and twenty-three molecules of alkali, Curves C and D, there are now present again only single bands but shifted to the region of frequency number 1990 while the maximum of intensity has been reached at Curve C. Thereafter further additions of alkali, 87 molecules for Curve E and 100 molecules for Curve F, produce a rapid shifting of the band toward the red together with a marked decrease of intensity. Coincident with these changes in absorption, there is first an increase and then a disappearance of fluorescence. The neutral solution shows faint fluorescence, but with the addition of alkali up to twenty-three molecules, this becomes quite intense, corresponding to the increased absorption at this concentration. Abruptly with the shift of the band from its position on Curve D to that of Curve E, the fluorescence completely disappears. If there are assumed several changes in molecular configuration during the addition of the potassium hydroxide and therefore a correspondingly complex set of equilibrium conditions, it is possible at least qualitatively to interpret the above data. It was demonstrated above that hydroxyhydroquinolphthalein in neutral ethanol solution possesses the structure of an inner salt. In the presence of an amount of alkali insufficient to form the tetrabasic salt, it is conceivable that the molecule would revert to the condition of the free acid, which would have a different type of absorption from that of the inner salt. It is therefore significant, inasmuch as hydroxyhydroquinolphthalein may be regarded as dihydroxyfluorescein, that Curve B for two molecules of potassium hydroxide, half the theoretical amount, closely resembles the curves for neutral solutions of resorcinolbenzein[4a] and fluorescein,[4b] both quinoid compounds and the latter a free acid. With four and twenty-three molecules, salt formation is completed and the fluorescence is at a maximum, but with more alkali a decisive change must be produced in the molecule, corresponding to the creation of a new type of absorption and the loss of the fluorescence. Since the hydroxyhydroquinolphthalein can be reprecipitated from the non-fluorescent solution by the addition of acid, this last change is reversible and hence must be in equilibrium with the other two processes—the rupture of the inner salt bond and the formation of the tetrabasic salt. The ultraviolet spectrum, which consists of three well-defined bands for the solution containing four molecules of potassium hydroxide, undergoes no unique changes such as are found in the visual region, but with increasing alkali concentrations the bands become shallower until in the presence of 100 molecules it is difficult to locate them with accuracy. For completeness all of the bands for the various alkaline solutions are listed in Table III.

TABLE III

FREQUENCY NUMBERS OF BANDS IN ALCOHOLIC ALKALINE SOLUTIONS OF HYDROXYHYDROQUINOLPHTHALEIN

Ratio to KOH							
1:2	1975	2039	2105	2330	3018	3657	4125
1:4	1965				2911	3612	4093
1:23	1962				2950	3600	4092
1:87	1911				2995	3558	3987
1:100	1855				2900	3450	3950

Summary

1. Data and curves are presented on the absorption spectra of various phthalein derivatives of pyrogallol, hydroxyhydroquinol and phloroglucinol. Correlations are drawn with data previously obtained for phthaleins of the mono- and dihydroxybenzenes.

2. The effect on the chemical properties and absorption spectra of the phthaleins, due to the introduction of hydroxyl groups, is discussed.

3. Gallein, which is colored in both the solid state and in neutral solution, is shown to be primarily lactoid in structure, but probably in equilibrium with a small amount of the quinoid modification.

4. The unusual behavior of hydroxyhydroquinolphthalein in weakly alkaline solutions both as regards its absorption and fluorescence is described and a possible explanation is advanced.

THE PREPARATION OF AMINONAPHTHOLS

BY WILSON F. BROWN, JOHN C. HEBDEN AND JAMES R. WITHROW

RECEIVED SEPTEMBER 4, 1928 PUBLISHED JUNE 5, 1929

1-Amino-7-naphthol and 1-amino-6-naphthol were needed for work in progress. An investigation was therefore conducted for the preparation of these compounds by caustic fusion of the respective α-naphthylaminesulfonic acids.

Among other things, the results indicated that 1-amino-6-naphthol could be prepared from α-naphthylamine-6-sulfonic acid by caustic soda fusion. The melting point of the picrate of 1-amino-6-naphthol was not the same as that given in the literature. Further, 1-amino-7-naphthol was prepared in good yield (average of 58%) by caustic soda fusion of α-naphthylamine-7-sulfonic acid.

Literature

The Cassella Company[1] gave an example of the preparation of 1-amino-7-naphthol by caustic fusion from α-naphthylamine-7-sulfonic acid In

---

[1] German patent 69,458; *Friedländer*, 3, 476 (1890).

the first part an autoclave is used and in the second part an open kettle. They do not mention the 1-amino-6-naphthol.

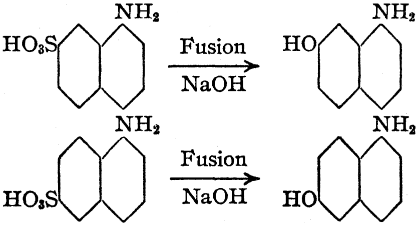
Kehrmann and Engelke[2] described the purification of crude 1-amino-7-naphthol and gave the melting point of the purified product as 205–207°. They also described the preparation of the mono-acetyl compound of 1-amino-7-naphthol.

1-Amino-6-naphthol was prepared by nitration of naphthalene, according to Friedländer,[3] and subsequent partial reduction.

Franz Sachs[4] gave a method for the production of 1-amino-6-naphthol in his patent on the preparation of aminonaphthols by the action of sodamide on naphthol sulfonic acids. He stated that the melting point of the 1-amino-&naphthol was 185°.

Nowhere in the literature was there found a process for the preparation of 1-amino-6-naphthol by fusion of a-naphthylamine-6-sulfonic acid with caustic soda. A method was devised, therefore, based on the illustration of the Cassella patent for the 1,7-compound.

The reactions involved in the preparation of the 1-amino-7-naphthol and 1-amino-6-naphthol were anticipated to be the following



Experimental

Preparation of **Aminonaphthols.**—The Cassella illustration for the 1,7-compound was investigated but failed to work. When the temperature of the fusion was raised from 265 to 305°, however, good results were obtained. The method finally adopted consisted in melting caustic soda, with the addition of a small quantity of water, and then adding the a-naphthylaminesulfonic acid gradually to avoid foaming. When all of the α-naphthylaminesulfonic acid was in, the melt was heated to 265–275° for one hour, then to 305° for five minutes and finally cooled to 200°. The aminonaphthol was isolated by diluting the melt with water, neutralizing with hydrochloric acid, boiling, filtering and adding soda solution until no more precipitation could be obtained.

Preparation of 1-Amino-6-Naphthol.—In preparing to make the 1-amino-6-naphthol the method selected was that given by the Cassella Company[1] for making 1-amino-7-naphthol. This method was followed as to proportions but here also it was found necessary to heat to approximately 305° in order to complete the reaction when an open pot was used. The isolation of the final product presented no difficulties. The yield of 1-amino-6-naphthol was consistently good and even better than the 1,7. There was some loss of aminonaphthol, however, by volatilization.

Acetylation of 1-Amino-6-naphthol.—The method of Kehrmann and Engelke[5] for the preparation of the acetyl compound of 1-amino-7-naphthol was followed in attempting to prepare the acetyl compound of 1-amino-6-naphthol. One part of 1-amino-6-naphthol was mixed with three parts of acetic anhydride, the mixture becoming slightly warm. It was warmed on the hot-plate for a few minutes, filtered and the mass washed with water. The residue was extracted with boiling dilute ethyl alcohol (1:1) and filtered. The filtrate was allowed to cool and the precipitate that came out was filtered and dried in air. On testing, the substance melted gradually, starting at 195" and continuing up to 220°. The mono-acetyl and di-acetyl compounds are said to melt at 218 and 186°, respectively.[6]

Yield based on sulfonic, g.	85.6	70.8	79.6	84.0	32.3	53.4	23.4	84.2	82.0

Variation in yield due mainly to volatilization of aminonaphthol from open pot.

Purification of 1-Amino-6-Naphthol.—The 1-amino-6-naphthol was purified in two ways. (A) The 1-amino-6-naphthol was extracted with 7.5% hydrochloric acid, filtered and ammonium hydroxide added to the filtrate just to alkalinity. Three crops of precipitates were obtained, the third of which was crystalline and gave a melting point of 186.8°, corrected. (B) The 1-amino-6-naphthol was purified by repeated recrystallization from boiling water. The melting point of the purified product was found to be 190.6" corrected. As previously mentioned, Sachs gave the melting point as 185" but did not state whether it was corrected or not.

Identification of 1-Amino-6-Naphthol.—The picrate of 1-amino-6-naphthol was prepared several times and a melting point of 170°, corrected, obtained. This is not in accord with the value given by Sachs,[4] who states that the picrate of 5,2-aminonaphthol (1-amino-6-naphthol) melts at 185° (as he states for the parent substance also). The hydrochloride was prepared by adding an excess of hydrochloric acid to the melt during neutralization and cooling the solution to room temperature. The 1-amino-6-naphthol hydrochloride separated in glistening, dark red crystals, whereas the hydrochloride of 1-amino-7-naphthol is gray. References to these two hydrochlorides are not found in the literature.

[6] German patent 173,522; *Friedländer*, 8, 172 (1905–1907).

Conclusions

1. The I-amino-7-naphthol was prepared in good yield and of good quality from α-naphthylamine-7-sulfonic acid by caustic soda fusion, at much higher temperatures than were given by Cassella and was isolated both as the base and as the hydrochloride.

2. The 1-amino-6-naphthol was prepared in good yield and of good quality from α-naphthylamine-6-sulfonic acid, by caustic soda fusion, and was isolated both as the base and as the hydrochloride.

3. Acetylation of the I-amino-6-naphthol was unsuccessful.

4. The melting point of the picrate of 1-amino-6-naphthol was found to be 170°, corrected, as against 185° as given by Sachs.

THE ABSORPTION SPECTRA OF SOME HALOGENATED FLUORESCEINS[1]

BY R. C. GIBBS AND C. V. SHAPIRO[2]

RECEIVED SEPTEMBER 6, 1928 PUBLISHED JUNE 5, 1929

In previous investigations on the absorption spectra of resorcinolbenzein,[3a] fluorescein[3b] and sulfonefluorescein[3'] in various solvents, the effect of introducing acid groups, carboxyl and sulfoxyl, into the benzein was studied. It was shown that in the presence of the highly dissociated sulfonic acid group an inner salt was formed with the basic, quinoid oxygen atom. Dibromosulfonefluorescein[3'] also exhibited the inner salt configuration, but the bands in its absorption spectra were shifted toward longer wave lengths relative to those of sulfonefluorescein, as the result of the addition of two bromine atoms.

Data are now presented for di- and tetrabromofluorescein (eosin), in which the bromine atoms are attached to the phenol residues, and for tetrachlorofluorescein, in which the chlorine replaces the hydrogen atoms of the phthalic acid residue. It is known from the work of B. Cohen[4] on indicators of the sulfonephthalein class that halogen substitution in the phenolic residues results in an increase in the apparent dissociation constant of the phenolic hydrions. Although his data on the halogen derivatives give

no indication of a similar effect on the dissociation of the acid group, carboxyl or sulfoxyl, such an effect is nevertheless to be expected, since it has been shown that the properties of the acid group, as well as the hydroxyl, are modified by alkyl[4] and hydroxyl[5] substitutions. In order that a change in the acid properties shall be recognizable from a study of absorption spectra, it is necessary in the case of fluorescein, which exists as a free acid in the quinoid state, that substitution shall either increase the acid properties to such an extent that an inner salt is formed, or decrease them to a point where the lactone becomes stable. In the first case the absorption spectra of the neutral and acid solutions will be found to be similar;[5] in the second case, the neutral solutions will show the characteristic absorption bands of the benzenoid phthaleins.[6] The results of the present investigation bring out, however, a complete similarity between the absorption spectra of fluorescein and its halogen derivatives and indicate that any changes in the acid properties are relatively slight and are negligible compared with the effects produced by the introduction of hydroxyl groups. In other words, whatever effect there may be upon the acidity, it is not sufficient to produce marked changes in the absorption spectra. The result of halogen substitution is primarily to shift the absorption bands toward longer wave lengths, with the most pronounced changes occurring for eosin and the least usually for tetrachlorofluorescein. Dibromofluorescein, which has about the same molecular weight as the tetrachloro compound but differs from it in having the bromine atoms on the phenol residues, shows shifts in its absorption bands intermediate between those of eosin and tetrachlorofluorescein. It thus appears that substitution in the phenol residues is more effective than substitution in the phthalic acid portion of the molecule in modifying the absorption of fluorescein.

The compounds used in the present investigation were all of analytical purity.[7] The sample of eosin[7b] was almost white in color but its solution in absolute ethanol did not differ from that of another pure sample which was a deep pink in the solid state. It must therefore be assumed, as with the red and yellow varieties of fluorescein,[3b] that if any differences in structure exist in the solid state they disappear when in solution, probably by giving rise to an equilibrium mixture of the lactoid and quinoid forms, in which the latter predominates.

Figure 1 presents the absorption curves for absolute ethanol solutions of dibromo-, Curve A,A′, tetrabromo-, Curve B,B′ and tetrachlorofluorescein, Curve C,C′. The absorption curve for fluorescein, Curve D,D′, is repeated from our previous paper,[3b] where data on the concentrations em-

ployed will be found. The positional effect of the halogen atoms is most marked in the visual and near ultraviolet regions, where the absorption of eosin is nearly eight times as intense as that of tetrachlorofluorescein or of fluorescein itself and its bands are shifted to the greatest extent. In the ultraviolet region eosin again exhibits the greatest intensity, but tetrachlorofluorescein now lies intermediate between it and dibromofluorescein.

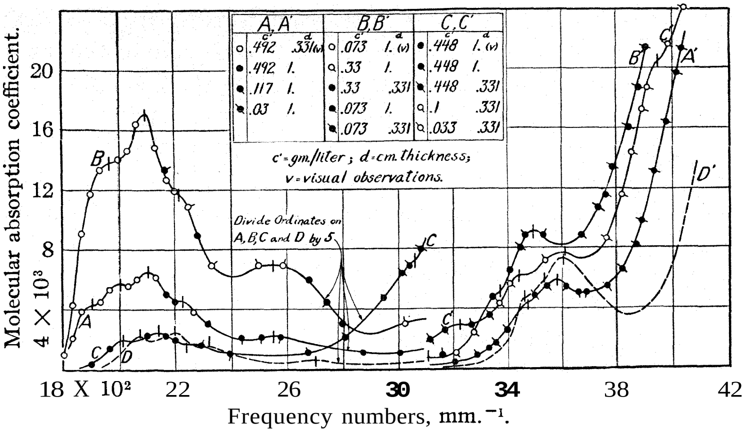

Fig. 1.—Neutral ethanol solutions: A,A', dibromofluorescein; B,B', tetrabromofluorescein–eosin; C,C', tetrachlorofluorescein; D,D', fluorescein.

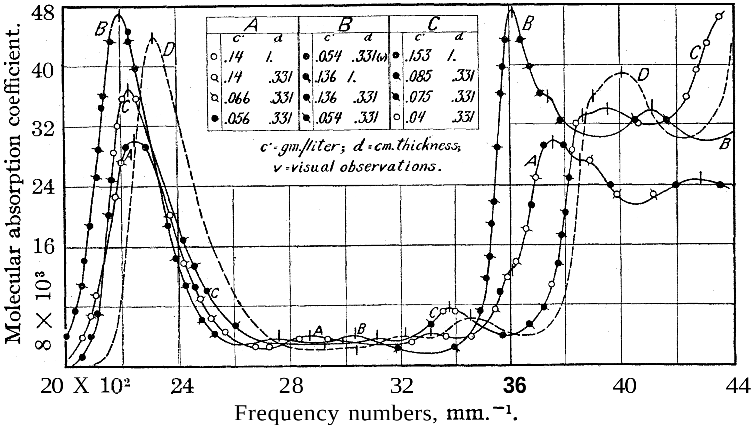

Fig. 2.—Concd. sulfuric acid solutions: **A**, dibromofluorescein; B, tetrabromofluorescein–eosin; ***C***, tetrachlorofluorescein; D, fluorescein.

The mass effect of halogens is brought out in the extreme ultraviolet range by the fact that the rapid increase of absorption occurs at relatively longer wave lengths for Curves A' and B' as compared with Curve D'.

The absorption curves of the sulfuric acid solutions are given in Fig. 2.

The lack of any resemblance of these curves to those obtained for the neutral solutions, Fig. 1, is evidence for the non-existence of an inner salt structure for the halogenated fluoresceins. This is confirmed by the finding that fluorescein and dibromofluorescein form hydrochlorides; eosin also adds on dry hydrogen chloride but less readily than the above compounds.[7b] According to Orndorff and Hitch,[7a] tetrachlorofluorescein does not form a hydrochloride under any circumstances, but in this respect it is probably similar to phenolphthalein, whose hydrochloride is stable only at −30°.[8] Orndorff and Hitch ascribe the failure to obtain a hydrochloride to the weakly basic properties of the quinoid oxygen atom but it is evident by analogy with fluorescein that a sulfate is formed in concd. sulfuric acid. The visual band for the halogenated compounds is shifted markedly toward the red from that of fluorescein in the following order: tetrabromo > tetrachloro > dibromo. The order of these shifts, as well as their magnitude, agrees closely with the results obtained by Holmes[9] for the same compounds in weakly alkaline solutions. In the ultraviolet, however, tetrachlorofluorescein is relatively close to fluorescein, while the two dibromo derivatives exhibit a large shift toward the red. Another striking difference between these two groups is in the relative intensities of the two components of the complex ultraviolet band. For the first pair of compounds the short wave-length component is slightly the more intense, while for the second pair the long wave-length component is very much more intense. This complex band has been found to be characteristic of the sulfuric acid solutions of almost all phthaleins containing the pyrone ring and in the majority of cases its contour is of the second type. In the following list, Col. A represents those compounds for which the short wave-length component is the stronger and Col. B those for which it is the weaker.

A	B	
Fluorescein	Dibromofluorescein	Tetrabromofluorescein
Tetrachlorofluorescein	Sulfonefluorescein[3c]	Sulfonegallein[6]
Hydroxyhydroquinolphthalein[5]	Dibromosulfonefluorescein[3c]	Gallein[5]
Hydroxyhydroquinolsulfonephthalein[5]	Resorcinolbenzein[5]	Pyrogallolbenzein[5]

In ethanol solutions of these fluorescein compounds involving complex equilibrium conditions between several forms, it is not possible to isolate completely the effect of halogen substitution, whereas in concd. sulfuric acid solution we may safely assume the existence of these several compounds in analogous states and may therefore ascribe the differences in their absorption more definitely to halogen substitution. Halogenation of the phenolic groups thus appears to bring two opposing forces into action: (1) a tendency to decrease the intensity which can be ascribed to the intrinsic nature of the halogen; (2) a tendency to increase the intensity,

---

[8] Meyer and Hantzsch, *Ber.*, 40, 3479 (1907).

[9] Holmes, THIS JOURNAL, 46, 2770 (1924).

which may be ascribed to the mass action of the halogen. It should be possible to judge the relative importance of these two factors by a study of derivatives of fluorescein in which bromine is replaced by chlorine or iodine.

The positions of the absorption bands for the neutral and acid solutions of fluorescein and its halogenated derivatives are listed in Table I.

ETHYL- AND HEXYLFLUORESCEIN. THEIR DIBROMO AND MONOMERCURY DERIVATIVES

BY REUBEN B. SANDIN AND JOHN W. SUTHERLAND

RECEIVED DECEMBER 26, 1928 PUBLISHED JUNE 5, 1929

A great number of mercury derivatives of phenolphthalein and related compounds has been prepared. Many of these have been reported in the patent literature.[1] White[2] has prepared mercury derivatives of phenolphthalein, o-cresolphthalein, fluorescein, dibromofluorescein and phenolsulfonephthalein, containing from one to four atoms of the metal. Very recently Harden[3] has reported salicylsulfonephthalein, its tetrabromo and monomercury derivatives. The latter compound shows marked germicidal power.

[1] Pauly and Traumann, German Patent 201,903 (1909); Fahlberg, List and Co., German Patent, 308,335 (1918); White, U. S. Patent 1,535,003 (1925); 1,549,942 (1925).

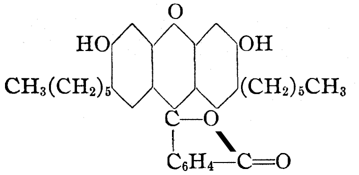
[2] White, THIS JOURNAL, 42, 2355 (1920).

[3] Harden, *ibid.*, 49, 3139 (1927).

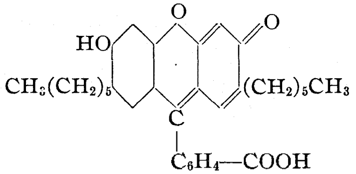
In connection with a study of the mercuration of the alkylresorcinols,[4] the authors have prepared the monomercury and dibromo derivatives of ethyl- and hexylfluorescein. At present work is proceeding on a study of the bactericidal value of the mercury derivatives.

The ethyl- and hexylfluoresceins were prepared by the action of phthalic anhydride on ethyl- and hexylresorcinol,[5] respectively. This was done in a manner similar to Gatterman's[6] preparation of fluorescein, with the exception that the cold melt was extracted with a solution of sodium hydroxide and the dye then precipitated by the addition of hydrochloric acid or acetic acid.

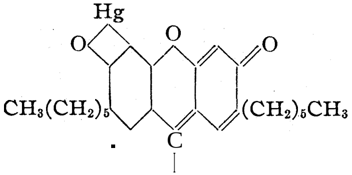
In the preparation of the ethyl- and hexylfluorescein, some observations have been made which are similar to the observations made by Orndorff and Hemmer[7] in connection with fluorescein. When an alkaline solution of ethyl- or hexylfluorescein, as obtained in the original preparation, was treated with acetic acid in the cold, the yellow dye was precipitated. However, when a boiling alkaline solution of either phthalein was treated with concentrated hydrochloric acid, the dye in each case was precipitated as a dark brown amorphous mass. In accordance with the views of Orndorff and Hemmer, a suggested structure for the yellow modification is Formula I, and for the brown modification, Formula II.



I. Yellow hexylfluorescein (lactoid)



II. Brown hexylfluorescein (p-quinoid)



III. Anhydromonomercurihexylfluorescein

The dibromo compounds were prepared in the usual way by the addition of a slight excess over the required two moles of bromine to a suspension or solution of one mole of the phthalein in glacial acetic acid. The mono-

PROPERTIES AND ANALYSES OF THE MONOMERCURY DERIVATIVES OF ETHYL- AND HEXYLFLUORESCEIN

Anhydromonomercuri-( )-fluorescein	Formula	Color of powder	Calcd., % Hg	Acetic acid	Found, % Hg			Acetic acid
Ethyl	$C_{24}H_{18}O_5Hg$	Red	34.19	0	33.60	34.09	33.90	0
Hexyl	$C_{32}H_{34}O_5Hg$	Red-brown	28.71	0	28.27	28.44	28.34	0

Summary

1. The preparation of ethyl- and hexylfluorescein and their dibromo and monomercury derivatives has been described.

2. Ethyl- and hexylfluorescein each exists in two isomeric forms, a yellow and a brown. The formula of the two isomeric ethylfluoresceins is $C_{24}H_{20}O_5$, and of the two isomeric hexylfluoresceins is $C_{32}H_{36}O_5$. The yellow form is prepared by adding acetic acid to a cold alkaline solution of the dye, and according to Orndorff and Hemmer is given the lactoid structure. The brown modification is obtained by adding hydrochloric acid to a boiling alkaline solution of the dye. It is given the p-quinoid structure.

[Contribution from the Laboratory of Organic Chemistry of the State University of Iowa]

THE ACTION OF BROMINE ON CERTAIN MIXED ETHERS

By L. Chas. Raiford and D. M. Birosel

Received December 29, 1928 Published June 5, 1929

Henry[1] obtained phenyl allyl ether by the action of allyl bromide on sodium phenolate, but gave no details regarding the method and recorded no yield. He noted that when bromine was brought in contact with the ether, both the allyl and the phenyl radicals reacted. However, nothing was said about the character of the product. 2,4,6-Tribromophenyl allyl ether was obtained by Varda[2] by the alkylation of the bromophenol, and Claisen and Eisleb[3] obtained 4-bromophenyl allyl ether by synthesis from *p*-bromophenol, not by bromination of the ether. Fairbourne and Toms[4] brominated 2,4-dinitrophenyl allyl ether and, as might have been predicted,[5] found that the halogen entered the allyl radical only. Colbert,[6] working in this Laboratory, noted similar behavior with 2-nitro-4-chlorophenyl allyl ether, though the amount of material available and the difficulty of purification prevented absolute identification of the product. In view of these facts, it was proposed to test the action of bromine on phenyl allyl ether under conditions where both radicals might react.

When phenyl allyl ether was treated with excess[7] of bromine it gave some 2,4,6-tribromophenol and a tetrabromo ether. The identity of the ether was established by preparing it in a different way. 2,4-Dibromophenol was converted into the corresponding allyl ether and the latter was treated with excess of bromine. The tetrabromo ether isolated in the first experiment was obtained here.

The failure to introduce more than two atoms of bromine into the phenyl radical of phenyl allyl ether under the conditions stated suggested the examination of ethers containing alkyl radicals. The methyl, ethyl and propyl ethers of 2,4,6-tribromophenol are on record, but only the

[4] Fairbourne and Toms, *J. Chem. Soc.*, **119**, 1038 (1921).

[5] It is well known that the difficulty of introducing substituents into the phenyl radical increases as the number of groups present increases, and that the ether or ester is less reactive than the corresponding phenol. This relation was emphasized in the preparation of the bromine addition product of *o*-allyl phenol by Adams and Rindfusz, This Journal, **41**, 654 (1919), who found it necessary to protect the hydroxyl group by acetyl, to use only the calculated amount of bromine to saturate the allyl radical and to conduct the experiment at 0°.

[6] Colbert, unpublished report.

[7] More than that required to saturate the allyl radical and to substitute positions 2,4 and 6 in the phenyl group.

first was made by bromination of the ether. In the present work, in which the ethers were allowed to remain in contact with excess of bromine for several days, it was found that, in addition to bromination of the phenyl radical, certain ethers were split by the hydrogen bromide formed. With phenyl methyl, ethyl, n-propyl and isobutyl ethers, the 2,4,6-tribromo ether[8] resulted; with 2,4,6-tribromophenyl n-propyl and isopropyl, no changes occurred, while with phenyl isopropyl, *sec.*-butyl[9] and *tert.*-butyl, and with 2,4-dibromophenyl isopropyl and to the extent of 10 and 20%, respectively, with phenyl methyl and ethyl, the 2,4,6-tribromophenol[10] was formed.

Experimental Part

A. Phenyl Allyl Ether and Substitution Products

2,4-Dibromophenyl-β,γ-dibromopropyl Ether.—Twelve g. of phenyl allyl ether[11] dissolved in 10 cc. of chloroform was treated gradually with an excess of bromine in chloroform, with cooling, the mixture allowed to stand for four days and then the solvent and excess of bromine were distilled off. Distillation under reduced pressure gave one fraction that boiled just below 190° at 5 mm. and which solidified upon standing. Crystallization from petroleum ether gave nearly colorless needles that melted at 93°[12] A second fraction distilled at 220–223° at 10 mm., apparently with slight decomposition. This did not solidify on standing. Analysis is given in Table I.

2,4-Dibromophenyl Allyl Ether.—This was obtained in 54% yield by converting 25 g. of the corresponding dibromophenol into the ether by Claisen's general method. The product distilled between 165 and 170° at 20–22 mm and was nearly colorless. It did not solidify upon cooling. When a chloroform solution of this product was treated with an excess of bromine, it gave the tetrabromo compound described above.

2,4,6-Tribromophenyl-β,γ-dibromopropyl Ether.—Twenty-eight g. of *s*-tribromophenyl allyl ether, m. p.[13] 75°, was dissolved in 100 cc. of chloroform, 15 g. of bromine was added slowly with cooling and the mixture allowed to stand for three days, after which the solvent and excess of bromine were distilled off under reduced pressure.

---

[8] The ethyl derivative melted at 69° and is probably identical with that obtained by Purgotti [*Gazz. chim. ital.*, 16,528 (1886)] by treatment of the silver salt of the bromophenol with ethyl iodide, and who reported 69°, but did not analyze the product. Varda [*ibid.*, [II]23, 494 (1893)] used the potassium salt of the phenol and reported 72–73" for a substance that analyzed well, The product here in question was nearly pure. *Anal.* Subs., 0.1173: AgBr, 0.1840. Calcd. for $C_8H_7OBr_3$: Br, 66.83. Found: Br, 66.68.

[9] The product boiling between 100 and 108° under 40-mm. pressure, and obtained in 23% yield from phenol and secondary butyl bromide by Claisen's method, was used.

[10] Sodium acetate in the reaction mixture prevents splitting except in the case of phenyl *tert.*-butyl ether.

[11] Claisen and Eisleb, *Ann.*, 401, 29 (1913).

[12] Repetition of this experiment showed that this fraction consisted mainly of 2,4,6-tribromophenol. The hydrogen bromide evolved in the conversion of a portion of this ether into a bromine substitution product decomposed some of it to give phenol, which was then brominated. If the bromination is conducted in the presence of sodium acetate, the splitting and consequent formation of tribromophenol can be avoided.

[13] Varda, ref. 2, recorded 77°.

Recrystallization from ligroin (40–60°) by cooling in a freezing mixture gave nearly colorless needles.

2-Nitro-4-chlorophenyl-8,r-dibromopropyl Ether.--One g. of the corresponding **nitrochlorophenyl** allyl ether'' was treated with excess of bromine in chloroform solution and allowed to stand for a few days After removal of solvent and excess of bromine, the oily residue was held at about 98° and 20 mm. for several hours and then allowed to cool and solidify. Crystallization from petroleum ether gave colorless needles.

2,4,6-Trinitrophenyl-β,γ-dibromopropyl Ether.—Five g. of picryl allyl ether[15] was dissolved in chloroform, an excess of bromine in the same solvent added and the mixture allowed to stand for twenty-four hours. Evaporation of solvent and unchanged bromine left a colored solid which after repeated crystallization from petroleum ether gave nearly colorless prisms.

B. Phenyl Alkyl Ethers

2,4-Dibromophenyl Isopropyl Ether.—This was prepared by Claisen's method from the dibromophenol and isopropyl iodide, and was obtained as an oil that distilled at 156° and 18 mm.

2,4,6-Tribromophenyl Isopropyl Ether.—This was obtained in 74% yield from tribromophenol with a slight excess of isopropyl bromide. At 190° and 30 mm. it distilled as a faintly colored oil that solidified on standing.

TABLE I

PHYSICAL CONSTANTS AND ANALYTICAL DATA

Compound β,γ-Dibromopropyl ethers	Formula	M. p., °C.	Analyses, %		
				Calcd.	Found
2,4-Dibromophenyl-	$C_9H_8OBr_4$	Liq.	Br	70 75	70.80
2,4,6-Tribromophenyl-	$C_9H_7OBr_5$	42.5–435	Br	75.32	75.23
2-Nitro-4-chlorophenyl-	$C_9H_8O_3NClBr_2$	55	Hal	52 32	52.31
2,4,6-Trinitrophenyl-	$C_9H_7O_7N_3Br_2$	102[a]	Br	37 27	37 23
Isopropyl ethers					
2,4-Dibromophenyl-	$C_9H_{10}OBr_2$	Liq.	Br	54.42	54.37
2,4,6-Tribromophenyl-	$C_9H_9OBr_3$	40	Br	64.34	64.26

[a] After this work had been completed Fairbourne and Foster [J. *Chem. Soc.*, 3148 (1926)], published a report in which this product was assigned a melting point of 106–107°, while the allyl ether from which it was obtained melted at 90°.

Summary

1. Under the conditions of these experiments only two bromine atoms were introduced into the phenyl radical of phenyl allyl ether.

2. The hydrogen bromide evolved in 'the bromination of the ethers tested may split them unless sodium acetate is present. The splitting is most pronounced when the alkyl is connected through a secondary or tertiary carbon atom.

3. Further work on these derivatives is in progress.

RESEARCHES ON PYRIMIDINES. CVII. THE EXAMINATION OF YEAST 'NUCLEIC ACID FOR 5-METHYLCYTOSINE[1]

BY TREAT B. JOHNSON AND HENRY H. HARKINS[2]

RECEIVED JANUARY 5, 1929 PUBLISHED JUNE 5, 1929

In a paper from this Laboratory on pyrimidines (CV) the authors[3] described the acetol test for thymine and 5-methylcytosine, II, which is applicable in the presence of the pyrimidines, uracil and cytosine, I. A technique was described which permits of the identification of any one of these four pyrimidines in the presence of another. The specific color test (acetol test) recommended for identifying thymine is so delicate that quantities of this pyrimidine as small as one milligram can be detected with ease. The successful application of this acetol test for thymine and methylcytosine adds a new and practical procedure to our present technique for analysis of the pyrimidine content of a nucleic acid molecule.

The program outlined for research in this Laboratory on the "Chemistry of Bacteria" includes a study of the nature of the sugars linked in the nucleic acid of this bacterial cell. This work calls for a large supply of bacteria, but it is finally becoming possible through cooperation with commercial organizations to obtain bacteria, grown on synthetic media, in sufficient quantity to inaugurate an exhaustive study of the respective nucleic acids functioning in different types of bacterial cells. In the present stage of development of nucleic acid chemistry we have practically no knowledge of the composition of nucleic acids of bacterial origin. What accurate data we have regarding nucleic acid has been obtained by a study of a limited number of nucleic acids of animal origin and the nucleic acid of the yeast cell. The recent: results of biological experiments organized to include the study of the fundamental organic fractions of bacterial cells, as human, bovine and avian tubercle bacilli, indicate that the nucleic acid units of these cells play a significant and very important part in the life history of these lower organisms.

In the thymus nucleic acid molecule, and also in the nucleic acid of yeast, there is now no doubt as to the nature of the purine groupings which function as primary constituents. With reference to the pyrimidine constituents some doubt has been raised as to whether thymine and uracil are primary products, or whether they are hydrolytic products of methylcytosine, II, and cytosine, I, respectively. Present experimental evidence

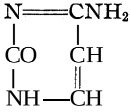
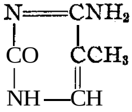
points to the conclusion that both uracil and cytosine function independently in the yeast nucleic acid molecule.

Of the nucleic acids of bacterial origin the one present in human tubercle bacilli—*tuberculinic* acid—has received the most attention. Johnson and Brown[4] made a careful examination of this substance, and they came to the conclusion that it is of the type of animal nucleic acids, that is, it contains a hexose sugar, cytosine and thymine, but no uracil. Later Johnson and Coghill continued the study of this interesting acid and obtained experimental evidence indicating that the cytosine fraction of tuberculinic acid contains a small amount of the pyrimidine 5-methylcytosine,[5] II. This was the first time that the natural occurrence of this aminopyrimidine has been observed. Johnson and Coghill identified the pyrimidine, II, as its picrate, by means of the characteristic crystallographic properties of this salt. The occurrence of this pyrimidine base in nature suggests again the possibility that the primary group in the thymine series may be 5-methylcytosine, and not thymine, in tuberculinic acid and also thymus nucleic acid. It is also possible that, while thymine is a primary constituent, 5-methylcytosine may be present in small amounts, and actually in an organic combination not to be accounted for by the present, proposed structure of thymus nucleic acid. If this last postulation be true, it might be expected that yeast nucleic acid may also actually contain a small amount of 5-methylcytosine.

I



II



In the light of this speculation, it seemed very desirable, therefore, to apply the most delicate tests available for detecting small amounts of 5-methylcytosine, II, in the presence of relatively large amounts of cytosine obtained from natural sources. The test for thymine and 5-methylcytosine which we have described in our previous paper (acetol test) can be applied successfully for detecting 5-methylcytosine under such conditions. Its application has also enabled us to decide in a new way quite conclusively whether 5-methylcytosine occurs mixed with cytosine in the nucleic acid of yeast.

When tuberculinic acids are available from new growths of tubercle bacilli of human, bovine and avian types, an exhaustive examination for all pyrimidines occurring in these bacteria will be made in this Laboratory.

The Preparation of Yeast Nucleic Acid.—Although there are many methods described in the literature for the preparation and purification of

yeast nucleic acid, it is very difficult to obtain a product which does not give a biuret reaction. Nearly all of these methods are modifications of one proposed by Altmann in 1889.[6] The most important improvements in technique have been recommended by Baumann,[7] Levene and La Forge[8] and also Steudel.[9] The latter investigator examined carefully the action of alkali on yeast nucleic acid and he pointed out the fact that 5% sodium hydroxide solution at room temperature causes nucleic acid to split off guanine-nucleotide. If the temperature is hold at 0°, however, no decomposition results. Steudel, therefore, extracted the yeast cell with 5% sodium hydroxide and kept the temperature at or below 0°. In this way he obtained a product which was protein free and which gave good values for nitrogen and phosphorus content. From Steudel's experiments, it may be concluded that a sufficient standard for the purity of a yeast nucleic acid prepared by alkali extraction is a negative biuret test and a theoretical content of guanine. As both of these requirements are easily determined, it becomes a simple matter to decide whether a given nucleic acid is pure.

The method which we used in preparing yeast nucleic acid is closely analogous to Steudel's procedure, although it is not an exact duplicate of his method. After many unsuccessful attempts to prepare a protein-free nucleic acid, the following procedure was adopted and was found to give a biuret-free product in every case.

Three hundred grams of starch-free yeast, containing about 70% of moisture, was suspended in water and cooled to 0° in the ice box. To this cooled suspension was added 322 cc. of sodium hydroxide solution which contained 0.31 g. of sodium hydroxide per cubic centimeter and which also had been cooled to 0°. The suspension was then diluted to a volume of 2 liters. The temperature was kept at 0° for two hours. Acetic acid was then added until the solution was just acid to litmus. (The PH of the solution was about 6.5.) When the solution had been neutralized its temperature was 15°. The suspension was centrifuged and a slightly turbid liquid resulted. To this was added enough alcohol to produce a solution containing 4% of alcohol. When this solution was filtered a sparkling clear filtrate was obtained. Enough concentrated hydrochloric acid was added to make the filtrate just acid to congo red paper, and finally an equal volume of 95% alcohol. A colorless, flocculent precipitate formed immediately. This was centrifuged, washed twice with 95% alcohol, then with ether three times. The product thus obtained was entirely biuret free, was perfectly white and contained the theoretical quantity of guanine as determined by the method described by Jones in his monograph on nucleic acids.[10] Several preparations of nucleic acid were made in this manner and a protein-free product was obtained in every case. The weight of the air-dried nucleic acid from 300 g. of moist yeast was usually between 4 and 5 g.

The Separation of Cytosine from Thymine.—If the acetol test for 5-methylcytosine is to be applied to the cytosine fraction of any nucleic acid molecule, it becomes absolutely necessary to know whether cytosine can be separated from thymine and the acetol test made negative on the cytosine so obtained. In case this specific test cannot be made negative in the cytosine unit when this pyrimidine is separated from mixtures known to contain only cytosine and thymine, it is obvious that the acetol test would be of no value in ascertaining the presence of 5-methylcytosine in the basic aminopyrimidine fraction of a nucleic acid, which is known to contain thymine. The following experiment was, therefore, carried out.

To 0.5 g. of pure cytosine and 2.0 g. of thymine (both of synthetic origin) dissolved in one liter of water, enough concentrated sulfuric acid was added to make the solution 5% in strength (50 g.). A 10% solution of phosphotungstic acid was then added until a precipitate ceased to form. This precipitate was removed by means of the centrifuge and decomposed in the usual manner by trituration with barium hydroxide solution. The barium phosphotungstate was separated by centrifugation and the excess of barium then removed by precipitation with carbon dioxide. The clear and practically colorless solution was diluted to a volume of one liter, the acidity adjusted to 5.0% and the phosphotungstic acid precipitation repeated and carried out as in the first case. The neutral solution containing the cytosine was evaporated to a volume of 50 cc. and tested for thymine in the usual way. A negative result was obtained. In other words, the aminopyrimidine cytosine can be freed from all traces of thymine by means of phosphotungstic acid. Since it is known that 5-methylcytosine and cytosine behave in a similar manner when treated with phosphotungstic acid, it can be concluded from the result of this experiment that it will be possible to apply the acetol test for determination of the presence of 5-methylcytosinc in any nucleic acid after preliminary hydrolysis of the nucleic acid molecule.

The Hydrolysis of Yeast Nucleic Acid.—Part of the nucleic acid used in this research was a special product obtained from the firm of Merck and Company. It was found to be protein-free and to contain the theoretical quantity of guanine. The pyrimidine fraction was isolated according to the following procedure.

To 50 g. of nucleic acid was added 300 cc. of water and 100 cc. of concentrated sulfuric acid. The mixture was heated in an oil-bath at 125° for twenty-five hours. The operation was conducted in a one-liter round-bottomed flask connected to a reflux condenser. At the end of this time the mixture was cooled and to it was added 3.6 liters of water. Finely-powdered barium hydroxide was then added until the solution was distinctly alkaline to litmus. The barium sulfate was centrifuged out, the precipitate suspended in two liters of hot water and again centrifuged. The two solutions were combined and concentrated *in vacuo* to a volume of 2 liters. Sulfuric acid was added to this solution until it was distinctly acid, the solution heated to its boiling point and filtered. To the filtrate was added a hot aqueous solution of silver sulfate (36 g.). A voluminous chocolate-colored precipitate came down immediately (the silver salts of the purines). This was filtered off and the solution made alkaline with barium hydroxide to precipitate the silver salts of the pyrimidines. Addition of barium hydroxide was continued until a precipitate no longer formed. The solution was thoroughly cooled and the silver salts of the pyrimidines were centrifuged out. After washing the precipitate with water, it was suspended in 2 liters of water, stirred thoroughly to break up any lumps, heated to 60°, made acid with 30 cc. of concentrated sulfuric acid and hydrogen sulfide passed into the solution for several hours. The silver sulfide was filtered off, suspended in hot acid solution and hydrogen sulfide passed in for another two hours to insure complete decomposition of silver salts. The silver sulfide was then removed by means of the centrifuge and the liquid added to the solution obtained from the first centrifugation. The sulfuric acid was removed from this solution with barium hydroxide and the excess of barium removed with carbon dioxide. The clear solution so obtained was concentrated in *vacuo* to a volume of 100 cc. Fifty cc. of this solution was treated with bromine and then made alkaline with barium hydroxide. The purple barium salt of dialuric acid was filtered off and to the filtrate was added 2 g of barium hydroxide crystals. This mixture was heated under a reflux condenser for fifteen minutes and then distilled to remove acetol. When the distillate so obtained was tested for acetol, a faint but distinct fluorescence could be observed. This would seem to indicate the presence of a small amount of either thymine or 5-methylcytosine. This assumption was not true. The fluorescence was found to be due to acetol arising from a small quantity of nucleosides contained in the pyrimidine fraction. Baudisch has shown that all the simpler carbohydrates, including pentoses, give rise to acetol when distilled with alkali.[11] Hence, an acetol test is not conclusive evidence as to whether either thymine or 5-methylcytosine is present in the pyrimidine fraction until it has been shown that distillation with alkali alone gives a negative acetol reaction.

The following experiment, therefore, was carried out to prove that the acetol test did not come from either thymine or 5-methylcytosine: 50 g. of nucleic acid was hydrolyzed for twenty-five hours with 33% sulfuric acid as described above. The solution containing the pyrimidine was concentrated to a volume of 100 cc., 33 cc. of concentrated sulfuric acid added and the mixture refluxed for twelve hours at 135". The mixture was then cooled and diluted with 2 liters of water and the sulfuric acid and barium removed in the usual way. The neutral solution was concentrated over a free flame to a volume of 100 cc. To 20 cc. of this solution was added 2 g. of barium hydroxide and the mixture refluxed for fifteen minutes. The distillate from this mixture gave a negative test for acetol, no fluorescence being observed even with the mercury arc light. It may be concluded from this experiment that the pyrimidine fraction tested was completely free of nucleosides. A second experiment was carried out with 20 cc. of the mixture. Bromine was added in excess, the excess removed by boiling and the solution made alkaline with barium hydroxide. The purple precipitate was removed by filtration. Two grams of barium hydroxide was added to the filtrate and the mixture refluxed for fifteen minutes as in the preceding experiment. The distillate from this mixture also gave a negative acetol test. It may be concluded, therefore, that the pyrimidine fraction of yeast nucleic acid, if it contains either thymine or 5-methylcytosine at all, contains these two pyrimidines in a quantity less than 1 mg. per 10 g. of nucleic acid.

Summary

1. A method for preparing a protein-free nucleic acid from yeast has been described. This is based on the original method of Altmann modified as recommended by Steudel.

2. The acetol test for thymine and 5-methylcytosine has been applied to the pyrimidine fraction of yeast nucleic acid, and has been found to be

negative. It may be concluded, therefore, that neither of these pyrimidines is present in yeast nucleic acid.

3. By application of the acetol test for 5-methylcytosine to the aminopyrimidine fraction of any nucleic acid, it is now possible to detect this substance when present in very minute quantities.

RESEARCHES ON HYDANTOINS. XLVIII. SYNTHESIS OF POLYPEPTIDE-HYDANTOINS FROM HYDANTOIN-1-ACETIC ACID[1]

BY ALICE G. RENFREW[2] AND TREAT B. JOHNSON

RECEIVED JANUARY 5, 1929 PUBLISHED JUNE 5, 1929

It is a growing belief that heterocyclic combinations containing active methylene groups (—CH_2—) occur in the structure of normal proteins; therefore, any information which increases the present knowledge of the chemistry of such cyclic groupings is of immediate value in the present period of intense interest in protein chemistry. Any consideration of cyclic amide groupings brings up at once the importance of the ureide structure, and the possible presence of polypeptide-hydantoin combinations in protein molecules. As a result of our chemical study of special bacteria like tubercle bacilli, we have learned that organic combinations are present in these unicellular organisms, some of which may function as inhibitors and some as accelerators of cell growth and development. These facts are important and lead one to ask whether there may not be some truth in the recent query of Prentiss,[3] who writes as follows: "Do chemicals exist in the tissues that are poisonous to infecting organisms and can such be isolated and made in sufficient quantities so that they could be used not only in the treatment of these infections, but possibly also in prevention in special instances? The presence of such substances is only hypothetical but the same may be said of numerous others commonly referred to in medical work as vitamines and whose presence we do not doubt." In fact, H. Kossel[4] studied the action of nucleic acid, a common constituent of cellular tissue, on bacteria and actually found that cholera germs and streptococci are readily killed

---

[1] This investigation was supported in part by a grant from the Therapeutic Research Committee of the Council on Chemistry and Pharmacy of the American Medical Association.

[2] Constructed from a dissertation presented by Alice Gertrude Renfrew to the Faculty of the Graduate School of Yale University, in June, 1927, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

by small quantities of the acid. Anthrax germs were more resistant. He considers that the bactericidal action of lymph cells is due in part at least to the action of nucleic acids. Thus in the consideration of medicinals there may be particular value in the study of structures resembling those functioning in characteristic biochemical products, and it is for such reasons that we emphasize the importance of both acyclic and cyclic peptide linkages.

In our last paper on the chemistry of hydantoins[5] we recorded the behavior toward aldehydes of 2-thiohydantoin-3-acetic acid and its oxygen analog and showed that only one methylene grcup in this combination is characterized by its pronounced reactivity toward aldehydes. In no case thus far studied have we observed an aldehyde condensation involving the methylene group of the substituent acetic acid radical. In other words, the methylene group $—CH_2—$ is activated by linkage in cyclic combinations as represented by hydantoin and diacipiperazine cycles. Whether corresponding side-chain substitutions in diacipiperazines will interact with aldehydes remains to be determined.

Instances of condensations in which an N-1-substituted hydantoin has been used with an aliphatic group joined to nitrogen adjacent to the methylene carbon are fairly numerous but scattered. In working with such substitution products very inconsistent results have been obtained and the reactivity of the cyclic methylene groups in these combinations has been a debatable question. Since both groupings $—NHCH_2CO—$ and $=NCH_2CO—$ may actually function in amino acids and polypeptides, there is, therefore, a general interest in any reaction that may contribute to a better understanding of the properties inherent in these structures.

According to our present knowledge we are justified in claiming that the methylene group of the hydantoin or thiohydantoin ring is more reactive toward aldehydes than is the methylene radical in acyclic combinations like hippuric acid. This reactivity is decidedly influenced, however, by substitution of aliphatic groups on nitrogen of the hydantoin cycle. Biltz[6] reported practically complete recovery of 1,3-dimethylhydantoin after heating this hydantoin with benzaldehyde in the presence of sodium acetate, acetic acid and acetic anhydride. Working with ethyl hydantoin-1-acetate Johnson and Bates[7] did not succeed in bringing about a condensation with benzaldehyde. No difficulty was encountered in accomplishing condensations by the use of N-1 acyl derivatives like 1-acetylhydantoin[8] and 1-benzoyl-2-thiohydantoin.[9] Erlenmeyer, Jr., also succeeded in condensing creatinine with benzaldehyde in the presence of acetic anhydride, giving

benzalacetylcreatinine.[10] By simple changes in experimental conditions Nicolet and Campbell[11] obtained better yields than those reported by Erlenmeyer, Jr. That creatinine interacts so favorably with aldehydes in acetic anhydride solution is possibly due to the fact that acetylation occurs before condensation, thereby leading to activation of the cyclic methylene group. With substituted glycocyamidine or methylcreatinine like I and II,[12] all attempts by Nicolet and Campbell to bring about condensation

I  or  II

were unsuccessful. Consequently they were unable to obtain any direct evidence as to the structure of the methylation products of creatinine by this method of attack. With 1-methylhydantoin they did succeed in effecting a condensation with benzaldehyde, but only with a yield of 32% of the theoretical. In all the work of Nicolet and Campbell no record is made of the identification of any geometric isomers.

Since the ultimate object of the present research was to develop methods for preparing specific compounds which might exhibit favorable properties as antiseptics, it was important that both N-1 and N-3 acetic acid derivatives of phenolic hydantoins be studied. As stated in our previous paper[6] the introduction of the acetic acid group was expected to increase solubility and lower toxicity of such combinations.

The reactivity of hydantoin-1-acetic acid, IV, toward an aldehyde has now been investigated by us, and a description of the different condensation products resulting from the action of anisaldehyde is given in the Experimental Part of this paper. The reactions that we desire to report at this time are recorded below.

In our research the acid, IV, was used in the form of its ethyl ester, V.[13] When this is condensed with anisaldehyde in the presence of sodium acetate and in acetic acid, the product of reaction is the sodium salt of anisalhydantoin-1-acetic acid, VII. The yield, however, is only 34% of the theoretical and thus far no geometric isomer has been identified. Alkylation of the hydantoin (V) with methyl iodide gives the methylhydantoin represented by Formula VI. When the latter is condensed with anisaldehyde under the usual conditions, two products of reaction result in small yields,[14] namely, the sodium salts of the two geometric isomers of 3-methylanisalhydantoin-1-acetic acid melting at 203–205° and 168–169°, respectively.[15] The results obtained by alkylation with methyl iodide were of special value as they enabled us to decide conclusively that the methylene radical in the N-1-acetic acid group is not the reactive position in ethyl hydantoin-1-acetate, V. Alkylation of anisalhydantoin-1-acetic acid, VII, gave the hydantoin, VIII, which underwent reduction with hydriodic acid, forming 3-methyl-5-hydroxybenzylhydantoin-1-aceticacid, X.[15] This same hydantoin, X, is also formed by the action of hydriodic acid on the two geometric isomers represented by Formula VIII and resulting by condensation of anisaldehyde with the hydantoin, VI. In other words, the reactive methylene group —CH_2— in both N-1- and N-3-hydantoin-acetic acids is the one in cyclic combination. In neither case did we observe any evidence of any other type of condensation reaction.

Experimental Part

Ethyl Hydantoin-1-acetate, V.—The imino-acetonitrile from which this compound was synthesized was prepared according to the method used by Bailey and Snyder[16] and later applied successfully by Johnson and Rinehart.[17] Bailey and Snyder report a 44% yield of the hydantoin ester. In several repetitions of this preparation we have consistently obtained yields varying from 35 to 45%. The ester melts at 85°.

5-p-Anisalhydantoin-1-acetic Acid, VII.—The reagents utilized for the preparation of this compound were applied in the following proportions: ethyl hydantoin-1-acetate, 7 g.; anisaldehyde, 6.3 g.; anhydrous sodium acetate, 8 g.; glacial acetic acid, 12 cc., and acetic anhydride, 3 cc. After refluxing this mixture for six hours the resulting solution was diluted with water and the reaction product separated by filtration. This was identified as the sodium salt of anisalhydantoin-1-acetic acid. It was colorless and had no definite melting point, charring badly when heated above 300". The yield of this salt was about 34% of the theoretical. Apparently all of the hydantoin-1-acetate that reacted with aldehyde underwent saponification in the proccss, as we obtained no

---

[13] Bailey and Snyder, THIS JOURNAL, 37, 940 (1915); Jongkess, *Rec. trav. chim.*, **27**, 287 (1908).

[14] It may be predicted from our past experience that the sulfur analog, ethyl 3-methylhydantoin-1-acetate [Bailey and Snyder, THIS JOURNAL, **37**, 940 (1915)], will be found to condense more easily with anisaldehyde.

[15] Hahn and Renfrew, *ibid.*, **47**, 147 (1925).

[17] Johnson and Rinehart, *ibid.*, 46, 768 (1924).

evidence of the formation of ethyl anisalhydantoin-acetate. Allowing for the fact that 55% of anisaldehyde was recovered, the yield of condensation product was 54% of the theoretical.

When this salt was dissolved in water and the solution was acidified with hydrochloric acid, the hydantoin-1-acetic acid separated. This acid is difficultly soluble in alcohol and water and moderately soluble in glacial acetic acid. It melts at 215–216° (uncorr.). The acid crystallizes from ethyl alcohol with one molecule of alcohol of crystallization which it loses at 110°.

Anal. Calcd. for $C_{13}H_{12}O_5N_2 \cdot C_2H_5OH$: N, 8.70. Found: N, 8.88, 9.00.

Anal. (after drying at 110°). Calcd. for $C_{13}H_{12}O_5N_2$: N, 10.14. Found: N, 9.85, 9.90.

In order to increase the yield of this condensation product, we incorporated other condensing agents besides sodium acetate as acetic anhydride and piperidine. With acetic anhydride the unchanged ethyl hydantoin-1-acetate was nearly all recovered after digesting with anisaldehyde for four hours. The ethyl hydantoin-1-acetate was also recovered unaltered when piperidine was employed as a condensing agent.

5-p-Hydroxybenzylhydantoin-1-acetic Acid, **IX.**—This hydantoin was formed when the preceding unsaturated hydantoin was reduced with hydriodic acid. The following proportions were used in the reaction: anisalhydantoin-1-acetic acid, 1.3 g.; hydriodic acid (sp. gr. 1.7) 6.5 cc., and red phosphorus, 0.4 g. The reduction was carried out at 105° for three hours, when methyl iodide was evolved in quantitative yield. After diluting with about 20 cc. of water and filtering from phosphorus, the excess of hydriodic acid was expelled by evaporation; the reduced hydantoin finally separated in a crystalline condition. The hydantoin was purified by crystallization from water and melted at 201°.

Anal. Calcd. for $C_{12}H_{12}O_5N_2$: N, 10.60. Found: N, 10.54, 10.50.

3-Methyl-5-p-hydroxybenzylhydantoin-1-acetic Acid, X.—The structure of 5-*p*-hydroxybenzylhydantoin-1-acetic acid and the corresponding anisal precursor was established conclusively as follows. The anisalhydantoin-1-acetic acid was first methylated by the action of methyl iodide in methyl alcohol in the presence of the required proportion of potassium hydroxide. The products of reaction were the methyl ester of 3-methylanisalhydantoin-acetate and the corresponding methylhydantoin-acetic acid. Both of the compounds were reduced by hydriodic acid and red phosphorus to the above methylated hydantoin, 3-methyl-5-p-hydroxybenzyl-hydantoin-1-acetic acid. This hydantoin proved to be identical with the methyl-p-hydroxybenzylhydantoin-1-acetic acid previously described by Hahn and Renfrew,[15] and there was no lowering of the melting point when a mixture of the two was heated in a capillary tube (167°). The formation of this methylated compound proves conclusively that ethyl hydantoin-1-acetate does not condense with anisaldehyde to form a hydantoin having the constitution XI represented below.

$$\text{XI}\quad CH_3OC_6H_4CH=C(COOH)\text{—}\overline{NCH_2CONHCO}$$

In other words, the methylene group in the hydantoin cycle is the reactive complex when brought into reaction with aldehydes.

Ethyl 3-Methyl-hydantoin-1-acetate, $CH_3\overline{NCON(CH_2COOC_2H_5)CH_2CO}$.—Three grams of ethyl hydantoin-1-acetate dissolved in 15 cc. of methyl alcohol was combined with a solution containing 2.4 equivalents of sodium methylate. This solution, from which an organic salt crystallized as it formed, was refluxed for eight hours and then digested with an excess of methyl iodide. When the reaction was complete, as indicated by the neutrality of the solution, sodium chloride was separated by filtration and the solution concentrated under diminished pressure. On diluting the concentrated alcohol solution with water and again evaporating to remove alcohol, the ethyl 3-methyl-hydantoin-1-acetate was finally separated by extraction with chloroform. After removing the chloroform the ester was finally purified by crystallization from alcohol. It separated in small, glistening plates melting at 91–92°. The sulfur analog of this ester **has** been described by Bailey and Snyder.[16]

Anal. Calcd. for $C_8H_{12}O_4N_2$: N, 14.0. Found: N, 14.11, 13.96.

3-Methyl-5-p-anisalhydantoin-1-acetic Acid, VIII.—This compound was prepared by condensing 3-methylhydantoin-1-acetic acid with *p*-anisaldehyde in the presence of sodium acetate in glacial acetic acid solution Here again the product of reaction was a sodium salt which gave the above acid when treated with hydrochloric acid. The high-melting modification of this acid was the first product obtained (melting point 203–205°).[15]

When the crude condensation mixture was extracted with ether in a Soxhlet and the solvent concentrated, a solid residue containing sodium remained behind. This was dissolved in water and on the addition of hydrochloric acid to this salt solution an immediate precipitate was produced. On recrystallization from dilute alcohol it melted at 168–169° and was identified as the labile modification of 3-methyl-5-p-anisalhydantoin-1-acetic acid.[15] The yield of either isomer was small.

Interesting results were obtained when the picric acid reaction[18] for a carbonyl group was tried on the above hydantoins. Ethyl hydantoin-1-acetate failed to give the red-brown color characteristic of hydantoin-3-acetic acid, but did give an intense orange-red coloration. On the other hand, both hydroxybenzylhydantoin-1-acetic acid and 3-methyl-p-hydroxybenzylhydantoin-1-acetic acid gave negative reactions.

Summary

1. Hydantoin-1-acetic acid condenses with aldehydes with formation of substituted derivatives. These condensations involve a reaction of the cyclic methylene group —CH_2— of the hydantoin cycle.
2. Hydantoin-1-acetic acid is less reactive than its isomer, hydantoin-3-acetic acid.
3. Thus far no evidence has been obtained of the formation of geometric isomers.
4. The biological importance of hydantoin-acetic acids is emphasized, and also their possible structural relationship to proteins.

THE DEARRANGEMENT OF NITROUREA AND ITS APPLICATION IN SYNTHESIS

BY TENNEY L. DAVIS AND KENNETH C. BLANCHARD

RECEIVED JANUARY 5, 1929 PUBLISHED JUNE 5, 1929

Nitrourea might be expected to dearrange[1] in two modes to form on the one hand (1) nitroamide and cyanic acid, and on the other (2) ammonia and nitrocyanic acid. The nitro group would promote the dearrangement and the molecule would fall apart more readily than does the molecule of urea. We have found abundant proof of dearrangement of the first sort," but only meager evidence for that of the second. We have isolated nitroamide and cyanic acid from solutions of nitrourea and have prepared nitrourea by the combination of nitroamide with cyanic acid. Since nitrourea dissolved in water dearranges in part into nitroamide and cyanic acid, and since nitroamide decomposes into nitrous oxide and water, it follows that an aqueous solution of one equivalent of nitrourea may be used, with great advantage, for purposes of synthesis as if it were a solution of one equivalent of cyanic acid itself.

Nitrourea decomposes on melting with the evolution of gas and yields a sublimate and a solid residue. The gases consist of water, nitrous oxide, cyanic acid, carbon dioxide and ammonia, and the solid materials of monoammonium cyanurate along with small quantities of ammelide, urea and biuret. These are the products which would be expected from the predicted dearrangements. The nitroamide breaks down into water and nitrous oxide. The cyanic acid in part escapes as such, in part combines with ammonia to form urea and in part polymerizes to form cyanuric acid, which combines with a portion of the ammonia to form ammonium cyanurate—and the latter substance by loss of water yields ammelide. Although nitrocyanic acid, $O_2N\text{-}NCO$, is not a known substance, it would, from analogy with known nitramines, be expected to decompose into nitrous oxide and carbon dioxide. The presence of ammonia and of carbon dioxide in the products of the decomposition of nitrourea by heat suggests strongly that this substance does dearrange into nitrocyanic acid and ammonia, but constitutes the only real evidence which we have found on that point. The presence of biuret might perhaps be explained by supposing that it is formed, as Werner[2] supposes it to be formed in aqueous solution, by the combination of cyanic acid with urea. We have found that

[2] Werner, "The Chemistry of Urea," Longmans, Green and Co., London, 1923, p. 25.

urea and cyanic acid do not combine in aqueous solution to form biuret, and prefer the more likely explanation that the cyanic acid combines with itself to form a dimer, dicyanic acid, NH_2–CO–NCO, which then combines with ammonia to form biuret—but wish to reserve a fuller discussion of the matter for a later paper.

When nitrourea is boiled with water, the nitroamide which results from its dearrangement breaks down completely, and nitrous oxide is given off quantitatively. Experiments in which nitrourea was heated with water in a sealed tube until gas was no longer produced, and in which silver nitrate was then introduced into the solution without opening the tube, showed that the production of cyanic acid is also quantitative.

A freshly prepared aqueous solution of nitrourea does not give the biuret test. After boiling it gives the biuret test, but contains no biuret. On evaporation to dryness, it yields a residue of practically pure urea, evidently formed by the combination of cyanic acid with ammonia produced by the hydrolysis of another portion of the cyanic acid.

The great ease with which nitrourea dearranges in aqueous solution may be shown by several striking experiments. A freshly prepared cold aqueous solution of nitrourea gives with silver nitrate a white crystalline precipitate of silver nitrourea. When the liquid is warmed, the precipitate dissolves; when this clear liquid is boiled for a minute or two, it deposits an insoluble precipitate of silver cyanate. If the freshly prepared solution is boiled, cyanic acid may be detected by its vinegar-like odor in the gases which are evolved. A freshly prepared cold solution gives, with copper sulfate and pyridine, a lilac-colored crystalline precipitate of copper pyridine nitrourea, insoluble in chloroform. The boiled solution with these reagents gives no precipitate, but the liquid yields a blue chloroform extract which contains copper pyridine cyanate. When copper pyridine nitrourea is allowed to stand in contact with water and chloroform at laboratory temperature, the chloroform turns blue after only a few hours, and if the mixture is allowed to stand overnight the copper pyridine nitrourea disappears entirely. Nitrourea recrystallized from warm, not boiling, water, under conditions where no gas is evolved, has an indefinite melting point between 135 and 150°. It may be obtained perfectly pure by recrystallization from ether, benzene or chloroform, in which solvents it does not dearrange, and melts sharply at 158.4–158.8° with decomposition.

We have obtained nitroamide from the dearrangement of nitrourea by dissolving the latter substance in water, warming until active gassing had commenced, freezing in liquid air, drying out the ice by triturating it with anhydrous sodium sulfate, extracting with ether, and finally by concentrating the ether extract and precipitating with petroleum ether. The resulting nitroamide, identified by its properties and by analysis, was found on heating to break down quantitatively into water and nitrous oxide.

We have also isolated nitroamide from a solution of urea nitrate in concd. sulfuric acid. We have shown that the dearrangement is reversible by producing nitrourea by the direct combination of nitroamide and cyanic acid, by stirring together silver cyanate and an aqueous solution of nitroamide to which dilute hydrochloric acid had been added.

Nitrourea dissolves in cold concd. sulfuric acid to form a solution which contains cyanic acid and nitroamide. On standing the sulfuric acid dehydrates the nitroamide slowly, nitrous oxide comes off, the mixture warms up, the cyanic acid is hydrated in part to form carbon dioxide and the effervescence becomes vigorous. Such a solution after effervescing actively for about an hour exploded with a distinctly audible puff and visible flash but without any damage to the beaker in which it was contained. The nitroamide which is present in a cold solution of nitrourea in concd. sulfuric acid may also combine with water under the hydrating action of the sulfuric acid to form nitric acid, and does this if the environment is such that the nitric acid may enter into other reactions. Such a solution in the nitrometer gives up quantitatively the nitrogen corresponding to the nitro group of its nitrourea.[3] We have used such a solution for the nitration of aniline, phenol, acet-*p*-toluide and cinnamic acid, in a manner similar to that in which a sulfuric acid solution of nitroguanidine has been used.[1d] No gas is given off if the nitration mixtures are kept below 0°. If they are allowed to warm up, effervescence becomes violent.

The spontaneous decomposition of nitrourea in aqueous solution is influenced by acids and by bases in the same way as the spontaneous decomposition of nitroamide.[4] The substance may be recrystallized without change from boiling water or from boiling alcohol if the solvent contains a small amount of sulfuric acid. Inorganic and organic bases promote the decomposition. We have noted in a number of cases that pure air-dried nitrourea stored in soft glass bottles decomposes after a few months, blowing out the stopper, giving off ammonia and leaving a pasty residue which contains water, urea and ammonium cyanurate, and have been able to show that the effect is due to the alkali of the glass which is dissolved by the water retained in the air-dried nitrourea. The decomposition does not occur in hard glass even if moisture is present, but does occur in hard glass if the sample is moistened with an aqueous extract of soft glass. It does not occur in an atmosphere dried with phosphorus pentoxide, even when sodium bicarbonate is in contact with the nitrourea.

Strong ammonia water dropped upon nitrourea hisses like water on phosphorus pentoxide. When an excess is used and the solution is evaporated to dryness, pure urea is obtained quantitatively. When one molecular equivalent of aniline is dissolved in a saturated aqueous solution of

---

Tope and Barab, THIS JOURNAL, 38,2552 (1916).

[4] Brönsted and Pedersen, *Z. physik.* Chem., 108, 189 (1924).

nitrourea and the liquid is allowed to stand at laboratory temperature, crystals of phenylurea are found to have separated after twenty-four hours, and after forty-eight hours the yield is nearly quantitative. When nitrourea is added to an aqueous solution of a primary aliphatic amine, such as methylamine, the reaction is very vigorous and requires cooling to moderate it. With less basic amines the reaction is correspondingly slower. Since the mono-substituted aliphatic ureas dearrange but little in boiling water, the reaction mixtures may be evaporated hot and give excellent yields of pure products. With suitable variations of procedure, we have prepared, from the corresponding primary amines, methylurea, ethylurea, n-butylurea, benzene-azo-phenylurea, ethylene-diurea, *m*- and *p*-uraminobenzoic acid, sodium *p*-uraminobenzene-sulfonate, hydantoic acid, a-uramino-a-isobutylacetic acid and ethyl hydantoate. The advantages of the method are especially apparent in the cases of methyl- and ethylurea. Nitrourea yields nothing but gases and a principal product which is practically pure at once and not deliquescent, while the older method with potassium cyanate and the hydrochloride of the amine yields a product which is contaminated with mineral salts and is deliquescent and difficult to purify.

By the same general method we have prepared, from nitrourea and the corresponding secondary amines, α,α-dimethylurea, α,α-diethylurea, α,α-di-n-propylurea and its picrate, α,α-di-*n*-butylurea (new) and its picrate (new), α,α-di-*iso*-amylurea and its oxalate and picrate (new), and 2,3,4-trihydroquinolylurea.

Derivatives of urea in which one aromatic and one aliphatic group are attached to the same nitrogen atom dearrange so readily in water solution that any attempt to purify them by recrystallization from that solvent only results in making them less pure. If they are boiled in water solution, they dearrange in part, the cyanic acid is hydrolyzed to ammonium carbonate, the secondary amine escapes with the steam and part of the material is lost. By allowing the amine to stand at laboratory temperature in contact with water and a slight excess of nitrourea until crystals had separated and could be removed, or until the mixture had spontaneously evaporated to dryness, in which case the whole residue was worked up with a non-dearranging solvent like benzene or petroleum ***ether,*** we have obtained α-methyl-α-phenylurea, a-ethyl-a-phenylurea, α-*n*-propyl-α-phenylurea (new), its picrate (new) and oxalate (new), and α-*n*-butyl-α-phenylurea (new) in excellent yields.

In the experiments with di-n-propylamine and n-propylaniline, in addition to the expected urea derivatives, there were obtained, respectively, ω,ω-di-*n*-propylbiuret (new) and ω-*n*-propyl-ω-phenylbiuret (new). No ω,ω-disubstituted biurets have heretofore been described. We have identified our substances by analysis and by comparison with the materials produced by a new method which has been found to be a general one for the preparation of ω,ω-disubstituted biurets, namely, the interaction of nitrobiuret with secondary amines, as described in the next paper of this series. In the present cases the cyanic acid from the dearrangément of nitrourea evidently combines with itself to form dicyanic acid, which then combines with the secondary amine to form the ω,ω-disubstituted biuret.

Nitrourea is but little affected by refluxing with dry alcohols and may be recovered unchanged. When refluxed with moist alcohols, it dearranges; the cyanic acid in part combines with the alcohol to form carbamic ester and in part apparently combines with itself to form dicyanic acid, which then combines with the alcohol to form allophanic ester. We reserve a fuller discussion of dicyanic acid for another paper. Allophanic esters are converted to carbamic esters by refluxing with alcohols. Nitrourea dearranges much more rapidly than urea, and in practice yields more allophanic ester because the solution is not subjected to so long a refluxing. Otherwise the reaction of nitrourea with alcohols has no more interest for purposes of synthesis than the reaction of urea itself.

Experiments

Experiments which are indicated in the foregoing with sufficient clearness are not again discussed in this section.

Preparation of **Nitrourea.**—Nitrourea was prepared by a modification of the original method of Thiele and Lachman.[5] Two hundred grams of carefully dried urea nitrate was added in small portions at a time with stirring to 300 cc. of concd. sulfuric acid[6] (1.84) while the temperature of the mixture was kept below 0°. After the last portion had been added, the cold milky mixture was allowed to stand for one minute and was then poured into a liter of ice and water. The finely-divided white precipitate was collected on the filter, sucked as dry as might be, and, without washing, was immediately dissolved while still wet in boiling alcohol.[7] The liquid deposited pearly leaflets on cooling. It was chilled in ice water before filtering and the crystals were rinsed with cold alcohol. The alcoholic mother liquors were used for the crystallization of several successive hatches. The air-dried product was sufficiently pure without another crystallization. Samples of it have remained unchanged in hard glass bottles for several years; yield, 90% or better.

Decomposition by Heat.—Nitrourea (0.6148 g.) was decomposed by heating at 170° in the vacuum of a mercury pump. The gases were allowed to stand overnight in order that the cyanic acid might polymerize on the walls of the apparatus. There resulted 0.2520 g. of residue (41%) which gave tests for biuret and cyanuric acid but which gave no color with the diphenylamine reagent, and 55.4 cc. of gas (at 761 mm. and

---

[5] Thiele and Lachman, *Ann.*, 288,281 (1895).

[6] Instead of 700 cc. as recommended by Thiele and Lachmann and by Ingersoll and Armendt, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1925, Vol. V, p. 85.

[7] The precipitate still contained enough acid to prevent the dearrangement of the nitrourea in boiling alcohol. For a second recrystallization it was found to be unsafe to heat the alcohol above 60°.

26°) which consisted of 9.8 cc. (17.8%) of CO_2 and HNCO (absorbed by caustic), 20.96 cc (37.8%) of NH_3 and 24.29 cc. (43.9%) of N_2O.

Twenty-one grams of nitrourea was heated at atmospheric pressure at 158–160° until decomposition commenced. After two or three minutes, when the reaction had subsided, the pasty sublimate was scraped from the condenser and added to the residue from the decomposition, total weight, 12.5 g. (59.9%). The material was entirely soluble in boiling water except for a few milligrams of amorphous matter which was identified as ammelide. The solution on evaporation gave off ammonia and yielded 4.95 g. of mono-ammonium cyanurate, identified hy the fact that it gave off ammonia on warming with sodium hydroxide solution, by the properties of the cyanuric acid obtained from it and by analysis.

Anal. Calcd. for $C_3H_6O_3N_4$: C, 24.66, H, 4.11; N, 38.36. Found: C, 25.4, 25.5; H, 3.6, 3.5; N, 38.3, 38.6.

When dissolved in boiling water, acidified, chilled and filtered, 1.135 g. yielded 0.9943 g. of cyanuric acid (99.2% of the calcd. amount). The mother liquors yielded more cyanuric acid on acidification, and, after chilling, filtration and evaporation to dryness, a residue from which butyl alcohol extracted the urea, 0.07 g., identified by mixed melting point and by its xanthydrol derivative. The final residue yielded a small quantity of biuret, identified by mixed melting point and by the biuret test.

Decomposition in Hot Water.—Samples of nitrourea were dissolved in 10 cc. of water and decomposed by warming until active gas evolution had commenced. The gases were allowed to mix at atmospheric pressure with a confined quantity of air whose temperature, volume and pressure could be measured. Analysis showed that the mixture after the experiment contained only nitrous oxide and the gases normally present in atmospheric air. The results, corrected for the vapor pressure of water and calculated to 0° and 760 mm. (but not corrected for the solubility of N_2O in water), were as follows: nitrourea, 0.1177, 0.1860; N_2O found, 24.85, 39.10 cc.; calcd., 25.09, 39.64 cc.

For the determination of the cyanic acid produced by the decomposition of nitrourea, experiments were first tried in which solutions were decomposed in stoppered flasks and then precipitated with silver nitrate, but the results were low, evidently because of the loss of cyanic acid with the gases which escaped when the stopper was removed. Precipitation was therefore accomplished before the gases were allowed to escape. Samples of nitrourea were weighed into Carius tubes, 10 cc. of water was added, then a thin glass ampoule containing 15 cc. of $N/10$ silver nitrate solution and the tubes were sealed. They were then wrapped in wire gauze and warmed in the water-bath until gas production had ceased. After cooling, they were shaken to break the ampoule and the contents were mixed. If the tubes were then opened, the outrushing gas was found to carry away a portion of the liquid. The contents were therefore frozen and loss of solution was avoided when the tubes were opened. The solids were filtered off and washed thoroughly, and unconsumed silver in the filtrate was determined by titration with ammonium thiocyanate: nitrourea, 0.1455, 0.1004; $N/10$ $AgNO_3$ consumed, 13.7, 9.5 cc.; HNCO found, 0.05892, 0.04086; calcd., 0.05954, 0.04108.

Ten grams of nitrourea was dissolved in 100 cc. of water, warmed until gas evolution had ceased and evaporated to dryness. Ammonia was given off. The residue weighed 1.9 g. and consisted of practically pure urea. In another experiment with the same quantities the cyanic acid was removed, after gassing had ceased, by the addition of an excess of silver nitrate solution. The liquid on evaporation to dryness yielded a residue (containing silver nitrate) from which hot butyl alcohol extracted only 0.08 g. of urea.

Effect of Certain Other Solvents.—Half-gram samples of nitrourea were boiled with 50 cc. of benzene, ether and chloroform, respectively, under a condenser the upper end of which was sealed to a gas buret containing mercury. No gas was produced in either experiment. Nitrourea recrystallized once from alcohol melted with decomposition at temperatures between 146 and 153°. Recrystallization from glacial acetic acid raised the melting point to 158.3–158.6°, while one crystallization from benzene, ether or chloroform, in which solvents it is sparingly soluble, yielded material melting at 158.4–158.8°. Several recrystallizations from water at 50° yielded material of great purity, melting at 158.1–158.3°, only slightly lower than crystals from ether.

Nitroamide from **Nitrourea.**—Ten grams of nitrourea was dissolved in 100 cc. of water in a large test-tube and warmed in a water-bath at 75° until gas evolution was active. Five cc. of 6 *N* sulfuric acid was added and the liquid was frozen suddenly by immersion in liquid air. The solid mass was broken up in a mortar and extracted with ether previously cooled to −10°. The ice was then allowed to melt and was triturated with anhydrous sodium sulfate until a dry mass was obtained. This was extracted with ten 50-cc. portions of ether. The ether extracts were evaporated separately in a stream of dry air. The first yielded only a very small amount of nitrourea. The second gave crystals of nitrourea which were removed, and the liquid portion when poured into petroleum ether produced a precipitate of shiny flakes of nitroamide. This was purified by dissolving in ether and precipitating with petroleum ether and finally yielded 0.43 g. of nitroamide, pearly white glistening flakes, melting at 72–73° with decomposition into volatile products. Nitrogen by combustion: found, 45.30; calcd. for NH_2NO_2, 45.16.

Nitroamide from Urea Nitrate.—Two hundred and fifty grams of urea nitrate was added in small portions at a time to 800 cc. of concd. sulfuric acid, as if for the preparation of nitrourea. The solution was removed from the freezing mixture and allowed to stand at room temperature until vigorous gassing had commenced, when it was poured onto 1 kilo of cracked ice and filtered through an asbestos filter (50 g. of nitrourea was obtained). Anhydrous sodium sulfate (about 1500 g.) was added to the filtrate until a thick mush was obtained and this was extracted repeatedly by triturating it with 100-cc. portions of ether. The combined ether extracts, dried with anhydrous sodium sulfate and worked up as described above, yielded 0.21 g. of nitroamide. Two repetitions of the experiment gave, respectively, 0.7 and 0.05 g. of nitroamide. The three yields were combined and, after four treatments with ether and petroleum ether, gave 0.51 g. of nitroamide, m. p. 71.5–75°; nitrogen by combustion: found, 46.49, 46.21; calcd., 45.16.

Nitrourea from **Nitroamide.**—Three grams of silver cyanate was suspended in 20 cc. of ice water, and 1.24 g. of nitroamide (from potassium nitrocarbamate) was added. Five cc. of 6 N hydrochloric acid was added drop by drop while the mixture was stirred with a mechanical stirrer. The stirring was continued for half an hour after the acid had been added. The precipitated silver chloride was removed and the clear liquid was evaporated to dryness at room temperature in a stream of dry air. The residue was extracted with ether and the ether on evaporation yielded 0.13 g. of material melting with decomposition at 146–147° and identified as nitrourea by the facts that it gave a blue color with the diphenylamine reagent and yielded phenylurea when warmed with aniline water. Several experiments in which smaller relative amounts of nitroamide were used were unsuccessful. A similar experiment with nitroamide and silver cyanamide failed to yield any nitroguanidine.

Effect of Impurities on the Stability of **Nitrourea.**—Samples of nitrourea were recrystallized from water (at 50°) which contained in solution ferrous sulfate, ferric nitrate, sulfuric acid, urea, urea nitrate and copper nitrate. The several samples, after drying in the air, were placed in corked test-tubes each in the dark and each in an eastern window. None showed any decomposition after six months.

A sample of nitrourea was recrystallized from water which had been previously refluxed for some time with finely-powdered soft glass. Another sample was washed with sodium bicarbonate solution. One half of each was dried quickly in vacuum over phosphorus pentoxide and put away in sealed glass tubes. The other half of each was dried in the air and placed in corked vials. Of the air-dried samples, that which had been washed with sodium bicarbonate decomposed in two days and that which had been recrystallized from the glass extract in nine days. The pentoxide-dried samples in the sealed tubes showed no signs of decomposition after four months. The tubes were then opened and the contents were emptied onto watch glasses which were allowed to stand in the laboratory under inverted beakers. The sample containing sodium bicarbonate decomposed after three weeks, and that containing glass extract after nine weeks.

Preparation of Mono-substituted Ureas.—The primary amine and slightly more than one molecular equivalent of nitrourea were brought together in water, the mixture was warmed to start the reaction or cooled to moderate it and the product was isolated either by filtration or by evaporating the reaction mixture to dryness. Yields are indicated below.

TABLE I

MONO-SUBSTITUTED UREAS

Product	Yield, %	M. p., °C.	Remarks
Methylurea	85	102	Stout needles from dry acetone
Ethylurea	80	92.1–92.4	Crystals from benzene
n-Butylurea[a]	91	96	Fine needles from benzene
Benzene-azophenylurea[b]	3	222–223	Crystals from alcohol
Ethylene-diurea[c]	78	193–194	Crystals from water; decomposes at 200°
m-Uraminobenzoic acid[d]	90	269.5–270.2	Very fine needles from water
p-Uraminobenzoic acid	Not determined		Microscopic needles from water; does not melt at 275°
Sodium p-uraminobenzenesulfonate[e]	Not determined		
Hydantoic acid[f]	60	160–161	Crystals from 50% alcohol
α-Uramino-α-*iso*butylacetic acid[g]	Not determined		
		186–187	Crystals from 90% alcohol
Ethyl hydantoate	62	134–135	Crystals from 50% alcohol
Phenylurea	98	147	Thick needles from water

[a] Werner, J. Chem. *Soc.*, 115, 1101 (1919), has erroneously reported the melting point as 86°. Butylurea is very readily soluble in water, from which it crystallizes on slow evaporation in thin laminated plates. We have obtained plates 11–12 mm. wide and 50–60 mm. in length.

[b] Benzene-azophenylurea has been prepared by Sonn, *Ber.*, 47, 2443 (1914), by the action of potassium cyanate on amino-azobenzene in acetic acid solution and by boiling an acetic acid solution of amino-azobenzene and urea. The low yield in our experiment is due to the fact that amino-azobenzene is very sparingly soluble in water.

[c] Previously prepared by Volhard, *Ann.*, 119, 394 (1861), by the interaction of silver cyanate with ethylenediamine hydrochloride. He reported it as colorless needles, m. p. 192°.

[d] Previously prepared by Menschutkin, Ann., 153, 84 (1870), by fusing together urea and m-aminobenzoic acid. He reported, m. p. 269–270°.

[e] Sodium *p*-uraminobenzenesulfonate has been prepared by Pellizzari and Matteucci, Ann., 248, 156 (1888), by heating together urea and sodium sulfanilate, and the potassium salt by evaporating to dryness a solution of sulfanilic acid and potassium cyanate. We find that nitrourea warmed with an aqueous solution of sulfanilic acid decomposes and gives off gas, but the cyanic acid so produced does not combine with the sulfanilic acid—and we have recovered the unchanged sulfanilic acid quantitatively. By warming nitrourea with an aqueous solution of sodium sulfanilate, concentrating and pouring into alcohol, we have obtained white crystals of sodium *p*-uraminobenzenesulfonate, identical with those described by Pellizzari and Matteucci.

[f] Lippich, Ber., 41, 2959 (1908), reports a melting point of 153–156° in an open tube and 163° in a closed tube. We find m. p. 160–161° in an open melting-point tube.

[g] Lippich reports, m. p. 188–189° in a closed tube. We find, m. p. 186–187" in an open tube.

We have not been able to secure any urea derivatives from the interaction of nitrourea with *p*-aminoacetophenone and with acetamide.

Preparation of α,α-Dialkylureas.—The preparation of these substances was carried out in essentially the same way as the preparation of the monosubstituted ureas.

TABLE II

α,α-DIALKYLUREAS

Product	Yield, %	M. p., °C.	Remarks
α,α-Dimethylurea	88	182	Crystals from alcohol
α,α-Diethylurea[a]	65	75.0–75.3	Pearly oblong plates from absolute ether
α,α-Di-*n*-propylurea	57	75.8–76.1	Waxy needles from petroleum ether
Picrate[b]	..	136	Recrystallized from water
α,α-Di-*n*-butylurea	86	...	Colorless oil at ordinary temp. Nitrogen: Found, 16.13; calcd. for $C_9H_{20}ON_2$, 16.27
Picrate[e]	..	82–83	Small plates from water–alc. Nitrogen: Found, 17 29; calcd. for $C_{15}H_{23}O_8N_5$, 17 45
α,α-Di-*iso*-amylurea	92	...	Colorless oil at ordinary temp.
Oxalate[d]	..	101.5–102	
Picrate[e]	..	72.8–73.9	Small prisms from water–alc. Nitrogen: found, 16.26; calcd. for $C_{17}H_{27}O_8N_5$, 16.34
2,3,4-Trihydroquinolylurea[f]	85	146.2–146.6	Colorless needles from water

[a] Franchimont, Rec. *trav. chim.*, 2, 122 (1883), reported m. p. 70°, and van der Zande, *ibid.*, 8, 226 (1889), m. p. 74". Ordinary laboratory ether is not a suitable solvent for the recrystallization of α,α-diethylurea.

[b] Melting point in agreement with McKee, Am. Chem. J., 42, 16 (1909).

[c] Dibutylurea and picric acid were dissolved together in alcohol, water was added and the oil which separated crystallized quickly on scratching.

[d] The oxalate precipitated when an alcohol solution of di-*iso*-amylurea was mixed with an aqueous solution of oxalic acid.

[e] Prepared by mixing an alcohol solution of di-iso-amylurea with an alcohol solution

of picric acid, diluting with water to precipitate the oil, dissolving the oil in alcohol, adding water to turbidity and allowing to stand. Melts at 72.8–73.9° with previous softening at 66.5–68°.

[f] The preparation was carried out in 50% alcohol because of the slight solubility of tetrahydroquinoline in water alone.

Purification of **α,α-Di-*n*-butylurea.**—The product separated as a yellow oil which floated upon the reaction mixture. The mixture was extracted with ether, and the ether extract was washed with dilute sulfuric acid for the removal of amine, then with water, dried with anhydrous sodium sulfate and concentrated in a vacuum over sulfuric acid. Attempts to distil the substance at ordinary pressure resulted in almost complete decomposition. It was distilled at a pressure of 2–3 mm. at 118–119°, and the distillate, although a water-white viscous oil of good appearance, smelled strongly of dibutylamine and was plainly less pure than before it had been distilled. The material was finally obtained pure by distilling it in the high vacuum (about 0.001 mm.) of a mercury diffusion pump. The tube containing the crude dibutylurea was sealed to two slender U-tubes (in series) each with a small bulb at the bottom of the U. The second U-tube was sealed to the pump. The tube containing the material and the U-tube nearest to it were then both warmed in an oil-bath at 50°, while the U-tube nearest the pump was cooled with liquid air. Dibutylamine distilled out and collected in white crystals in the cold tube. When no more amine could be collected, the tube containing the substance was heated in the oil-bath at 100–105°, and the U-tube directly connected to this was cooled in liquid air. The dibutylurea condensed in white needles which melted below room temperature to a colorless oil.

ω,ω-Di-*n*-propylbiuret.—In the preparation of dipropylurea, 30 g. of the amine and 40 g. of nitrourea were used. After the reaction was over, the mixture was extracted with ether and the ether extract was dried with solid caustic potash and concentrated. It yielded a residue which failed to crystallize after two weeks. On treating this with chloroform, 1.2 g. of insoluble material remained which was found to consist largely of urea along with a small amount of inorganic material. The chloroform solution desiccated in high vacuum gave 23.2 g. of white waxy needles of crude α,α-di-*n*-propylurea, and these extracted with petroleum ether yielded 0.5 g. of material insoluble in that solvent. Three recrystallizations from hot water made this material practically pure, m. p. 129°. It gave no biuret test or nitramine reaction and analyzed 22.28% of nitrogen; calcd. for $C_8H_{17}O_2N_3$, 22.46%. A mixed melting point showed it to be identical with the (slightly better) material, m. p. 129–129.4°, prepared from di-*n*-propylamine and nitrobiuret, and discussed more fully in the next paper of this series.

Preparation **of a-Alkyl-a-phenylureas.—The** reactions between nitrourea and mono-alkyl-anilines were carried out in the manner described in the first section of this paper.

TABLE III

α-ALKYL-α-PHENYLUREAS

Product	Yield, %	M. p., °C.	Remarks
a-Methyl-a-phenylurea	72	81.8–82.0	Thick prisms from benzene–ligroin
a-Ethyl-a-phenylurea	76	62.3–62.5	Thin plates from petroleum ether
a-n-Propyl-a-phenylurea	80	89.4–89.8	Thick plates and pyramids from benzene–ligroin. Nitrogen: found, 15.60; calcd. for $C_{10}H_{14}ON_2$, 15.73
Picrate	..	118–118.5	Needles from 50% alcohol. Nitrogen: found, 17.32; calcd. for $C_{16}H_{17}O_8N_5$, 17.19
Oxalate[a]	..	71–72	Recrystallized from 50% alcohol. Nitrogen: found, 12.37; calcd. for $(C_{10}H_{14}ON_2)_2 \cdot C_2H_2O_4$, 12.56
α-*n*-Butyl-α-phenylurea[b]	50	50.5–51.1	Waxy needles, very readily soluble in alcohol, ether and benzene. Nitrogen: found, 14.39; calcd. for $C_{11}H_{16}ON_2$, 14.58

[a] Softens at 65–66" and melts with decomposition at 71–72".

[b] a-n-Butyl-a-phenylurea separated from the reaction mixture as a dark-colored oil which did not respond to the usual devices for provoking crystallization but which crystallized spontaneously after standing for several months. The material was purified by treatment with decolorizing carbon and by repeatedly dissolving in alcohol and precipitating with water. The resulting pale yellow oil, dried in vacuum over sulfuric acid, was induced to crystallize by scratching. The substance is insoluble in water but very readily soluble in alcohol, benzene and ether, from all of which it is obtained as an oil.

The easy dearrangement of the a-alkyl-a-phenylureas may be demonstrated by heating a sample in a melting-point tube at 160–180°. The melt gradually deposits needles of cyanuric acid. The liquid portion consists of the free amine and does not solidify on cooling.

Effect of Heat on a-n-Propyl-a-phenylurea.—Three grams of the substance, heated in a distilling flask in the oil-bath, melted but showed no other change until a temperature of 210–215" was reached, when a sudden solidification took place. After a few minutes a liquid phase appeared above the solid one. The mixture, distilled in vacuum, yielded 2.15 g. of propylaniline, 94.3% of the theoretical. The residue in the flask weighed 0.78 g. and proved to consist of cyanuric acid.

ω-*n*-Propyl-ω-phenylbiuret.—The aqueous mother liquors from the preparation of propylphenylurea (from 50 g. of propylaniline) on evaporation to dryness yielded 2.8 g. of residue. All of this dissolved in 5 cc. of water, except 0.12 g. of material which was identified as cyanuric acid. The aqueous solution on dilution with alcohol deposited a small amount of inorganic matter and the liquid, concentrated and chilled, yielded 1.1 g. of small colorless glistening plates, m. p. 150–151°. Two recrystallizations from alcohol raised the melting point to 151°. The material gave no biuret test or nitramine reaction and analyzed 19.14% of nitrogen; calcd. for $C_{11}H_{15}O_2N_3$, 19.00. A mixed melting point showed it to be identical with the (slightly better) material, m. p. 151–151.5°, prepared from propylaniline and nitrobiuret.

Summary

Nitrourea dearranges into cyanic acid and nitroamide. It has been prepared from these two substances, and they have been prepared from it.

The products from the decomposition of nitrourea by heat are those which would be expected from the two possible modes of its dearrangement.

Nitrous oxide and cyanic acid are produced quantitatively when nitrourea is heated with water.

A solution of nitrourea in concd. sulfuric acid contains nitroamide and may be used as a reagent for nitrations.

Alkalies promote the decomposition of nitrourea; acids hinder it. A very slight alkalinity in the presence of a trace of moisture is sufficient to cause its spontaneous decomposition.

An aqueous solution of nitrourea, being a source of cyanic acid, reacts with ammonia and with primary and secondary amines to form urea and substituted ureas. The yields are excellent, the manipulation is simple and the other products of the reaction are gaseous. The method is especially advantageous for the preparation of those substituted ureas which cannot be heated in water without decomposition. A number of urea derivatives, a few of them new, have been prepared by this method.

ω,ω-Di-*n*-propylbiuret and ω-*n*-propyl-ω-phenylbiuret have been obtained as by-products in the preparation of urea derivatives from nitrourea and the corresponding amines.

Moist alcohols react with nitrourea to produce carbamic and allophanic esters.

THE DEARRANGEMENT OF NITROBIURET AND ITS APPLICATION IN SYNTHESIS

BY TENNEY L. DAVIS AND KENNETH C. BLANCHARD

RECEIVED JANUARY 5, 1929 PUBLISHED JUNE 5, 1929

A study of the dearrangement of nitrobiuret is especially interesting for the reason that it might be expected to produce the unknown dimer of cyanic acid, dicyanic acid, NH_2CONCO (or HOC(NH)-NCO). Nitrobiuret might be expected to dearrange in four modes, as indicated below. The known or expected decompositions of the nitro-amines from the four modes of dearrangement are also shown.

$$NH_2CONHCONHNO_2 \rightleftharpoons NH_2CONCO + NH_2NO_2 \longrightarrow N_2O + H_2O \quad (1)$$

$$NH_2CONHCONHNO_2 \rightleftharpoons NH_2CONH_2 + OCNNO_2 \longrightarrow N_2O + CO_2 \quad (2)$$

$$NH_2CONHCONHNO_2 \rightleftharpoons NH_3 + OCNCONHNO_2 \longrightarrow N_2O + CO_2 + HNCO \quad (3)$$

$$NH_2CONHCONHNO_2 \rightleftharpoons HNCO + NH_2CONHNO_2 \longrightarrow N_2O + H_2O + HNCO \quad (4)$$

We find that a freshly prepared cold aqueous solution of nitrobiuret does not give the biuret test. If the solution is boiled, nitrous oxide and carbon dioxide come off, and the liquid now gives a strong biuret test but shows no evidence of cyanic acid by Werner's sensitive test with copper sulfate, pyridine and chloroform. The solution, however, contains no biuret, for it yields a residue of urea along with some cyanuric acid when it is evaporated to dryness. Although the boiled solution at the beginning does not contain cyanic acid, it develops cyanic acid during the evaporation—but this is normal behavior of urea solutions. Since the solution immediately after dearrangement does not contain cyanic acid, we conclude at once that dearrangements of the third and fourth sorts (as indicated above) do not occur.

The evolution of nitrous oxide and carbon dioxide from the hot solution and the production of urea, as originally observed by Thiele and Uhlfelder,[1] suggest strongly that dearrangement occurs in the second of the above-indicated modes. The biuret test in the absence of biuret indicates some other reaction—and is, we believe, evidence of the presence of dicyanic acid in the solution. Moreover, solutions of nitrobiuret act with ammonia, amines and alcohols as if they contained dicyanic acid and yield with those reagents the products which that substance would be expected to yield. We conclude, therefore, that dearrangement occurs in the first two modes, namely, to form nitroamide and dicyanic acid, and urea and nitrocyanic acid.

A solution of nitrobiuret in concd. sulfuric acid gives up its nitro group quantitatively in the nitrometer and is a suitable reagent for the nitration of substances such as aniline and acet-p-toluide which are not injured by contact with strong sulfuric acid.

Nitrobiuret with alcoholic potash yields potassium allophanate. By boiling with alcohols and a little water, it produces allophanic and carbamic esters.

With ammonia it yields biuret along with some cyanuric acid and urea. With primary and secondary amines it gives ω-substituted biurets, substances which are evidently produced by the direct combination of the amine with dicyanic acid, thus

$$R_2NH + NH_2CONCO \longrightarrow NH_2CONHCONR_2$$

In this manner we have prepared ω-methyl-, ω-ethyl-, ω-n-propylbiuret (new), ω-*n*-butylbiuret (new), ω-benzylbiuret (new), ω-phenyl-, ω-*p*-tolyl-, and ω-α-naphthylbiuret (new), and from secondary amines a number (all new) of ω,ω-disubstituted biurets, namely, ω,ω-dimethyl-, ω,ω-diethyl-, ω,ω-di-n-propyl-, ω,ω-di-*n*-butyl-, ω-ethyl-ω-phenyl- and ω-*n*-propyl-ω-phenylbiuret.

The dicyanic acid from the dearrangement of nitrobiuret in water solu-

---

[1] Thiele and **Uhlfelder,** *Ann.,* **303, 93** (1898).

tion does not combine with urea to form carbonyldiurea or triuret,[2] but does combine with biuret to form tetruret.

Experiments

Preparation of Nitrobiuret.—Nitrobiuret was prepared by a method essentially that of Thiele and Uhlfelder.[1] Our first crude product from the drowning of the nitration mixture, purified by dissolving it in water with the addition of sodium hydroxide and precipitating with hydrochloric acid, yielded, from 100 g. of biuret with water of crystallization, 95 g., 70% of the theoretical, of very small white crystals which decomposed at 175–180°. Thiele and Uhlfelder report a decomposition temperature of 165". Two recrystallizations from water (52 cc. per gram) at 65–67° raised the decomposition temperature to 223". It was found necessary to carry out the crystallization below 70°, for at that temperature the solution begins to decompose with the evolution of gas. The nitrobiuret was identified by conversion to benzalaminobiuret and by analysis with the nitrometer; nitro group nitrogen: found, 9.50, 9.37; calcd. for $C_2H_4O_2N_3NO_2$, 9.42.

Tests for Nitrobiuret.—Nitrobiuret gives no color with ferrous sulfate and sodium hydroxide solution, in which respect it differs from nitroguanidine.8 One-tenth of a gram of nitrobiuret in 5 cc. of water, treated with 1 *g.* of zinc dust and 1 cc. of 50% acetic acid, allowed to stand for fifteen minutes, and filtered, yielded a solution which did not reduce silver acetate in the cold (as does the corresponding solution from nitroguanidine) but reduced ammoniacal silver nitrate instantly. When a small drop of benzaldehyde was added to such a solution, a crystalline precipitate of benzalaminobiuret was formed within a few minutes.

Decomposition of Nitrobiuret in Aqueous Solution.—Portions of about 1 g. each of nitrobiuret were dissolved in 10 cc. of water, warmed until gassing ceased and evaporated to dryness on the water-bath. The weight of residue in several experiments varied between 44.8 and 47.2% of the weight of the nitrobiuret which was taken. About 80% of the residue consisted of urea; about 20% of cyanuric acid. No other substance was found.

Nitrations with Nitrobiuret.—A solution of 3 g. of nitrobiuret in 30 cc. of concd. sulfuric acid at 2–3° was added slowly and with stirring to a cold solution of 1.96 g. of aniline in 7 cc. of concd. sulfuric acid. The mixture was stirred continuously for six hours while cooled with ice, then poured onto cracked ice, made alkaline with ammonia and extracted with chloroform. The chloroform solution yielded 2.34 g. of mixed nitranilines, 85% of the theoretical. This was analyzed by the melting-point method of Holleman, Hartogs and van der Linden[4] and found to consist of 30.3% *p*-, 42.0% o- and 27.7% m-nitraniline.

Three grams of nitrobiuret in 30 cc. of concd. sulfuric acid and 3 g. of acet-*p*-toluide in 10 cc. were mixed and warmed in the boiling water-bath for fifteen minutes. The mixture was drowned in ice water and the product, recrystallized from water, gave 1.5 g. of m-nitro-acet-p-toluide as pale yellow needles, m. p. 94–94.3°.

Potassium Allophanate from Nitrobiuret.—Five and six-tenths grams of nitrobiuret and 2 g. of potassium hydroxide were refluxed together for two hours in 60 cc. of 80% alcohol. Small plates of potassium allophanate separated from the cold liquid. These, after washing with alcohol and ether, weighed 0.95 g., 32% of the theoretical.

---

[2] Cyanic acid from nitrourea in water solution does not combine with urea to form biuret. A solution of urea and nitrourea on evaporation to dryness yields only urea along with some cyanuric acid and ammonium cyanurate.

[3] Davis, Ashdown and Couch, THIS JOURNAL, 47,1063 (1925).

[4] Holleman, Hartogs and van der Linden, *Ber.*, 44, 704 (1911).

The material was recrystallized from alcohol and a portion of it was converted to potassium sulfate by evaporation with sulfuric acid; 0.4632 g. yielded 0.5637 g. of K_2SO_4; calcd. for $C_2H_3O_3N_2K$, 0.5676.

In a similar experiment with absolute alcohol, no potassium allophanate was obtained. The fact that no gas was given off showed that dearrangement did not take place in the anhydrous solution.

In an experiment with 50% alcohol, urea was produced but no potassium allophanate could be isolated. The dicyanic acid was apparently hydrolyzed.

Reaction with Alcohols.—Portions of nitrobiuret were refluxed, respectively, with absolute ethyl, absolute n-propyl, absolute n-butyl and absolute *tert.*-butyl alcohols. The nitrobiuret was recovered unchanged and no evidence was found of carbamic or allophanic ester.

When nitrobiuret was refluxed with a 1% solution of water in the various alcohols, dearrangement evidently occurred, for nitrous oxide was evolved. The solutions were evaporated to dryness and the residues were extracted with boiling aviation gasoline and with boiling benzene, but neither of the extracts contained any dissolved substance—and we conclude that no carbamate or allophanate was formed. The material insoluble in gasoline and benzene was found in each case to be urea and cyanuric acid.

Five cc. of the alcohol and 1.4 g. of nitrobiuret in a small flask under reflux were heated in the boiling water-bath until no more air was driven out of the apparatus. Water was then admitted through a dropping funnel until the evolution of nitrous oxide commenced. The heating was continued for fifteen or twenty minutes until gas production had ceased. The solutions were evaporated to dryness; the residues were dried in vacuum and extracted with hot gasoline and hot benzene. The resulting carbamates and allophanates were identified, after recrystallization, by mixed melting points with samples of known purity. The yields are tabulated below.

TABLE I

PRODUCTS (GRAMS) FROM 1.4 GRAMS OF NITROBIURET AND 5 CC. OF ALCOHOL

Alcohol	Ethyl	n-Propyl	n-Butyl	*Tert.*-butyl	*Iso*-amyl
Carbamate	0.05	0.10	0.13	0.16	None
Allophanate	0.23	0.12	0.30	None	0.25

The carbamates are not formed first, for nitrobiuret does not dearrange to produce cyanic acid which could form them directly by combination with the alcohols. Undoubtedly the dicyanic acid from the dearrangement first combines with the alcohols to form allophanates, and these react with the alcohols to produce carbamates. We have found in fact that allophanates are converted to carbamates by reflaxing with alcohols.

Reaction with Ammonia.—Twenty-five cc. of strong ammonia water and 1.4 g. of nitrobiuret, heated together in a sealed tube at 100° for four hours, yielded 0.7 g. of biuret, 60% of the theoretical, and small amounts of cyanuric acid and urea.

Substituted Biurets.—Nitrobiuret and an equivalent quantity of the amine were brought together in water, generally enough to dissolve both reagents, and the mixture. was warmed gently until gas evolution had ceased. The liquid was then refluxed for fifteen or twenty minutes and allowed to cool for crystals—or concentrated and cooled—or evaporated to dryness, in which case the substituted biuret was extracted with an organic solvent which did not dissolve the cyanuric acid. All of the products were recrystallized to constancy of melting point; yields, etc., are shown in Table II.

The low yields in the cases of methyl- and ethylbiuret are evidently due to loss of the amines by volatilization. An experiment in which nitrobiuret, methylamine and water

TABLE II

SUBSTITUTED BIURETS

Substance, -biuret	Yield, %	% Nitrogen, Found	% Nitrogen, Calcd.	M. p., °C.	Habit
ω-Methyl	12.5	...	...	166.5–167	Prisms from alcohol

were heated in a sealed tube at 100° for half an hour gave a yield of 50% of the theoretical amount of ω-methylbiuret.

Nitrobiuret and Urea.—Two and eight-tenths grams of nitrobiuret and 1.2 g. of urea were dissolved in 25 cc. of water, allowed to stand for several days, diluted to 50 cc. and heated to boiling. On evaporation to 10 cc. and cooling, the mixture deposited crystals which did not melt at 260° and were identified as cyanuric acid. Schiff[5] reports that carbonyldiurea melts at 231–232° and is only sparingly soluble in water.

Nitrobiuret and Biuret. Tetruret.—One and four-tenths grams of nitrobiuret and 1 2 g. of biuret were dissolved in 50 cc. of warm water. After gassing had ceased, the mixture was evaporated to 10 cc. Six-tenths of a gram of crystals separated, m. p. 178–180°. Two recrystallizations from water raised the melting point to 186 2–187.1°. When treated with the reagents for the ordinary biuret test, the substance gave a beautiful blue-violet color such as Thiele and Uhlfelder[1] had found to be characteristic of tetruret. Those workers had prepared the substance by the action of ammonia on allophanic acid azide and reported the melting point as 186°.

Summary

Nitrobiuret appears to dearrange in two modes, to form nitroamide and dicyanic acid, and nitrocyanic acid and urea. When an aqueous solution is warmed, the nitroamide evidently breaks down into nitrous oxide and water, the nitrocyanic acid into nitrous oxide and carbon dioxide, and the liquid acts toward various reagents as if it contained dicyanic acid.

---

[5] Schiff, Ann., 291,374 (1896).

With moist alcoholic potash nitrobiuret yields potassium allophanate.

With moist alcohols it gives allophanic esters which react with the alcohols on refluxing to produce carbamic esters.

With aqueous ammonia it yields biuret; with biuret, tetruret; with primary and secondary amines, w-substituted biurets.

A number of w-mono-substituted biurets (several new) and of ω,ω-di-substituted biurets (all new) have been prepared and are described.

A solution of nitrobiuret in concd. sulfuric acid gives up its nitro group quantitatively in the nitrometer and is a suitable reagent for nitrations.

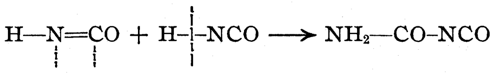
DICYANIC ACID

BY TENNEY L. DAVIS AND KENNETH C. BLANCHARD

RECEIVED JANUARY 5, 1929 PUBLISHED JUNE 5, 1929

Cyanamide, which differs from cyanic acid in having an NH group in place of an oxygen atom, combines with itself in warm water solution, one molecule functioning as a derivative of cyanic acid and one as a derivative of ammonia, to form a dimer which is a urea derivative, namely, dicyandiamide or cyanoguanidine. When heated in the dry state cyanamide trimerizes to form melamine, a white crystalline solid, sparingly soluble in cold water, which sublimes without melting. Cyanic acid yields a similar trimer, cyanuric acid, of about the same physical properties as melamine. We have found evidence which shows that cyanic acid in solution dimerizes in part, one molecule evidently functioning in the usual manner of cyanic acid in urea formation and one as an ammonia derivative, namely, as carbonyl-ammonia, to form a urea derivative, carbonylurea or dicyanic acid.



$$\mathrm{H{-}N{=}CO + H{-}NCO \longrightarrow NH_2{-}CO{-}NCO}$$

Dicyanic acid gives the biuret test; cyanic acid does not. Cyanic acid combines with amines to yield urea derivatives; dicyanic acid with amines to form biuret derivatives. An aqueous solution of cyanic acid in which some dimerization has occurred gives with aniline both phenylurea and phenylbiuret. With alcohols it yields both carbamic and allophanic esters.

Cyanic acid behaves in several different ways in aqueous solution. (1) It ionizes as a weak acid. (2) It trimerizes to cyanuric acid, which may precipitate out or may appear as a residue when the liquid is evaporated. (3) It undergoes hydrolysis to produce ammonia and carbon dioxide, and the ammonia combines with unchanged cyanic acid to form urea and ammonium cyanate in the ratio corresponding to the equilibrium between these substances. (4) It dimerizes to form dicyanic acid.[1] Dicyanic acid either depolymerizes during the evaporation of the solution or undergoes hydrolysis—for an aqueous solution of cyanic acid yields only urea and a little cyanuric acid when it is evaporated to dryness.

The dimerization of cyanic acid is obviously due to the affinity of one molecule of cyanic acid for another molecule of the same kind. Different solvents would probably have different effects upon it, some causing more dimerization or association, some less. The affinity of cyanic acid for the solvent itself would also come into play. Thus, cyanic acid gas passed into a solvent which has a great affinity for it would react with the solvent and might not dimerize at all. Passed into a solvent for which it has little or no affinity, it would be more likely to dimerize. When cyanic acid gas is passed into an alcohol, one portion may combine with the alcohol to form a carbamic ester, another portion may dimerize to form dicyanic acid which then combines with the alcohol to form an allophanic ester. Evidently the associating action of the solvent and the relative affinities of cyanic acid for cyanic acid and of cyanic acid for the solvent are both to be considered. These matters are now under investigation in this Laboratory.

The formation of allophanic ester from cyanic acid and alcohol was long ago explained by Hofmann[2] as being due to the direct combination of one molecule of cyanic acid with one of alcohol to produce carbamic ester and to the subsequent addition of a second molecule of cyanic acid to this substance. He claimed indeed to have prepared allophanic ester by the action of cyanic acid on urethan. Béhal[3] more recently was unable to obtain any allophanic ester by this method. He prepared an extensive series of aliphatic and aromatic allophanates by passing into the corresponding alcohols cyanic acid gas from the thermal depolymerization of cyanuric acid.[4] Carbamates were formed at the same time. He supposed that the allophanates probably resulted from the combination of the alcohols with dicyanic acid produced during the depolymerization. We think it more likely that the dicyanic acid is produced by dimerization in the liquid phase—and have found that the cyanic acid which results from the acidification of a solution of potassium cyanate dimerizes in part and yields both carbamic and allophanic esters with alcohols.

Lane[5] refluxed urea with n-butyl alcohol for three hours and obtained both allophanate and carbamate. After six hours' boiling he found only carbamate. He heated n-butyl carbamate with urea and with nitrourea,

[5] Lane, Bachelor's "Thesis," Massachusetts Institute of Technology, 1925.

and failed to produce any allophanate. Bishop[6] obtained both allophanate and carbamate by refluxing n-butyl alcohol with biuret for a short time, and on longer refluxing less of the allophanate. We conclude that the allophanate is formed directly and independently of the carbamate, and hence that dicyanic acid is present in the solution.

Carbamic ester when heated in alcohol solution evidently dissociates in part, reversing its formation from cyanic acid and alcohol. The cyanic acid which results associates in part to form dicyanic acid, which then combines with the alcohol to form allophanic ester. By heating ethyl carbamate with alcohol in a sealed tube at 100° we have converted a portion of it into ethyl allophanate.

An aqueous solution of potassium cyanate in a warm room hydrolyzes rapidly and contains both cyanic acid and urea. We have isolated urea from such a solution. The liquid however fails to give a biuret test, even after standing for several hours. It is evident that cyanic acid and urea do not combine to form biuret under these conditions.

When a concentrated aqueous solution of potassium cyanate is acidified with acetic acid and allowed to stand for a few minutes, the resulting liquid gives a biuret reaction. Werner[7] supposes that a portion of the cyanic acid undergoes hydrolysis, that urea is formed and that this combines with cyanic acid to form biuret. We find that the solution contains no biuret. By a colorimetric method the amount of biuret necessary to give a biuret reaction of the observed intensity was determined. The solution was worked up for biuret and none was found. An amount of actual biuret corresponding to the colorimetric determination was added to a similar solution; the liquid was worked up for biuret and four-fifths of that which had been added was recovered. An acidified solution of potassium cyanate, after standing for a short time, gave with aniline both phenylurea and ω-phenylbiuret.

The aqueous solutions which result, respectively, from the passage of cyanic acid (from the depolymerization of cyanuric acid) into water, and from warming a solution of nitrourea until gas evolution ceases, both give the biuret test. They contain cyanic acid and dicyanic acid—and, after standing, urea—but contain no biuret and yield on evaporation residues which consist of urea along with a little cyanuric acid. The liquid which results from warming an aqueous solution of nitrobiuret contains at first dicyanic acid but no cyanic acid; it gives the biuret test and yields a similar residue on evaporation.

Experiments

Allophanates and Carbamates from Potassium Cyanate.—Thirty cc. of ethyl alcohol was added to a solution of 16.2 g. of potassium cyanate in 30 cc. of water; the mixture

---

[7] Werner, "The Chemistry of Urea," London, 1923, p. 26.

was acidified with hydrochloric acid, allowed to stand for an hour and evaporated to dryness. The residue was extracted first with aviation gasoline and then with benzene, and the extracts yielded, respectively, 0.3 g. of ethyl carbamate, m. p. 49–50" after sublimation, and 1.4 g. of ethyl allophanate. m. p. 197–198° after recrystallization from benzene, both further identified by mixed melting points with known samples.

Similar experiments with 0.2 mole of potassium cyanate, 25 cc. of water and 0.1 mole of n-butyl and of iso-amyl alcohol yielded, respectively, 0 2 g. of n-butyl carbamate, m. p. 51–52", and 0.4 g. of n-butyl allophanate, m. p. 149–149.5°; and 0.3 g. of *iso*-amyl carbamate, m. p. 64–65° after sublimation and 0.1 g. of *iso*-amyl allophanate, m. p. 161.8–162.5°.

Ethyl Allophanate from Ethyl Carbamate.—Several experiments were tried in which urethan was refluxed for different intervals of time with different amounts of alcohol, but no allophanate was found in the residues when the liquids were evaporated to dryness. It was believed that whatever cyanic acid may have been produced escaped through the condenser. Ten cc. of alcohol was therefore heated with 8.9 g. of urethan in a sealed tube at 100° for half an hour. The residue from the evaporation of the liquid yielded 0.4 g. of material insoluble in gasoline which was identified as ethyl allophanate by mixed melting point.

The Biuret Test in an Acidified Solution of Potassium Cyanate.--Six cc. of glacial acetic acid was added very slowly to a well-stirred solution of 8.1 g. of potassium cyanate in 20 cc. of water. The mixture was brought to neutrality with barium carbonate, filtered and diluted to 50 cc. The intensity of color in the biuret reaction of a 5-cc. portion of this liquid was found to be equal to that produced by 0.03 g. of actual biuret—which would correspond to 0.27 g. of biuret in the remaining 45 cc. of solution. The remaining solution was evaporated to dryness and the residue was refluxed with 5 cc. of alcoholic potash (in which biuret is soluble while cyanuric acid is almost insoluble). The filtrate, acidified with hydrochloric acid and filtered for the removal of potassium chloride, was evaporated to a small volume. This solution gave no biuret reaction and on chilling in a freezing mixture deposited a few crystals of potassium acetate. Three repetitions of the experiment gave identical results. A similar experiment, in which 0.3 g. of actual biuret was added to the water in which the potassium cyanate was dissolved, gave a final residue which gave the biuret reaction with an intensity of color which corresponded to 0.24 g. of biuret or four-fifths of the amount which had been added.

Phenylbiuret from Potassium Cyanate.—A solution of 8.1 g. of potassium cyanate in 25 cc. of water was chilled and acidified with 6 cc. of glacial acetic acid. After five minutes, 9.3 g. of aniline was added. The mixture was stirred for five minutes, diluted with 100 cc. of hot water, filtered, freed from excess aniline and refluxed for two hours to convert the phenylurea into insoluble carbanilide. The filtrate on chilling yielded silky needles of phenylbiuret along with a small quantity of phenylurea. The product, recrystallized from water, amounted to 0.6 g., 3.3% of the theoretical, of ω-phenylbiuret, m. p. 165°.

Summary

Chemical evidence is presented which shows that cyanic acid in solution dimerizes in part to form dicyanic acid.

Allophanic esters and biuret are formed directly from the alcohols and from ammonia, respectively, not by the addition of cyanic acid to intermediate carbamic esters and urea.

Aqueous solutions of cyanic acid contain some substance, not biuret,

which gives a biuret test, which reacts with aniline to form phenylbiuret and with alcohols to form allophanic esters.

[COMMUNICATION NO. 377 FROM THE KODAK RESEARCH LABORATORIES]

EFFECT OF ANILINE ON CELLULOSE TRIACETATE

BY H. LEB. GRAY, T. F. MURRAY, JR., AND C. J. STAUD

RECEIVED JANUARY 8, 1929 PUBLISHED JUNE 5, 1929

Introduction

The action of aniline and similar compounds on cellulose triacetate has been studied but little by investigators in the field of cellulose chemistry. In a paper by E. Knoevenagel,[1] published in 1914, however, mention is made that triacetylcellulose may be heated with aniline without saponification of the ester. It is pointed out that marked differences in solubility result, which the author ascribes as possibly due to a stereoisomeric change of the cellulose acetate molecule, similar to that which produces mutarotation in the sugars. No polarimetric data are given.

That an ester like cellulose acetate could be kept in contact with a base like aniline at a high temperature for a protracted period of time without saponification seemed somewhat incongruous. Therefore, a study was made of the effect of aniline at various temperatures on cellulose triacetate.

Experimental

General Procedure.—The general procedure employed in these experiments was as follows. Fifteen grams of finely-divided cellulose acetate, containing 43.9% of acetyl (theoretical cellulose triacetate, 44.8% acetyl), and 300 cc. of aniline (b. p. 88–90' at 15 mm.) were placed in a 500-cc. ring-necked Pyrex flask equipped with an air condenser.

Three series of experiments were made. The first of these at the boiling point of the aniline–cellulose acetate solution (approx. 183°) was done in an oil-bath, the solution being refluxed continuously. The second at 148–151" was carried out by placing the flask in an air-bath, the temperature of which was maintained by the vapors of boiling cyclohexanol (b. p. 157–162°) and the third series was conducted at room temperature, 20–25°.

In the series in which elevated temperatures were employed, the solutions were cooled to approximately zero degrees and the mixtures were poured into 3 liters of ethyl alcohol. The products were washed with alcohol until free from aniline; this was followed by washing with ether. They were dried at 35°, after which the samples for analyses were dried at 105" for fifteen to twenty hours. Acetyl determinations were made according to the method of Eberstadt[2] as described by Knoevenagel,[3] with slight modifications. Optical rotations were determined using a Hilger polarimeter (accuracy 0.01") employing the 546.1 mμ line of the mercury spectrum as illuminant. Readings

were made at 25 ± 1°, in a 2-dm. tube. The concentration was 1% in chloroform–alcohol (85:15% by volume) and where possible in acetone.

Heating at 183°.—In Table I are given the results of the first series of experiments in which the aniline–cellulose acetate solutions were heated at the boiling point.

TABLE I

RESULTS AT 183°

Time, hours	Product recovered, g.	Equiv. wt of cellulose, g.	CH_3CO— in prod., %	$(\alpha)^{25°}_{546.1}$, $CHCl_3-EtOH$	$(\alpha)^{25°}_{546.1}$, acetone

50	8.7	7.9	8.7		
75	8.5	8.1	4.4		
100	8.5	8.4	1.5		
100	7.9	7.7	2.3		
		Av. 8.2			

From the above table it is seen that cellulose acetate is saponified by heating with aniline at the boiling point of the aniline–cellulose acetate solutions. This is shown graphically in Curve A of Fig. 1. The decrease in acetyl content is apparent after as short a time as two hours. After one hundred hours of heating, the acetyl content had decreased to 2.0%. The weight of the recovered material affords evidence that no appreciable hydrolysis to alcohol- or ether-soluble products, such as acetylated sugars, has taken place. The theoretical yield of cellulose obtainable from the saponification of 15 g. of cellulose acetate containing 43.9% acetyl is 8.4 g. If the weights of recovered cellulose acetate, after various times of heating, be calculated back to their cellulose contents, by multiplying the weight of recovered acetate by the percentage of cellulose which they contain (100 − % acetyl),[4] values between 7.4 and 9.1 grams are obtained.

---

[4] The value given does not rigorously represent the cellulose content since the CH_3CO removed would be replaced by an equivalent weight of hydrogen. Such calculation, however, is quite outside the accuracy of these experiments. It does not affect the results by more than 0.2 g. of cellulose.

The average recovered material, calculated to cellulose, is 8.2 g., which shows very acceptable agreement with this theoretical value, as does the material which has been almost completely saponified (2.0% acetyl) by heating with aniline for one hundred hours, the latter value being 8.2 g.

To test further the action of aniline on the product obtained after one hundred hours' heating, a 5-g. sample of this material was heated for an additional one hundred hours in 300 cc. of aniline at its boiling point. The material did not dissolve and at the end of the second one hundred hours of heating, 4.6 g. of material was recovered. On analysis this showed an acetyl content of 1.3%.

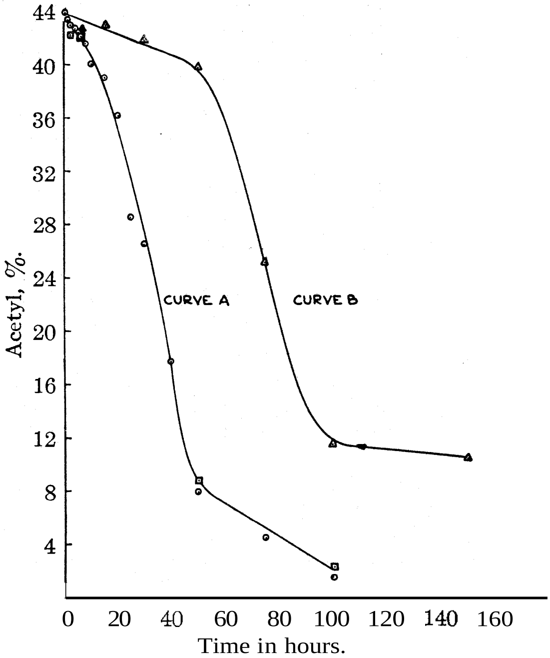

Fig. 1.—Acetyl content of cellulose acetate heated with aniline *vs.* time of heating.

According to Knoevenagel profound changes in the solubility of cellulose acetate are induced by the action of aniline, which he ascribes to stereoisomerism. It has been found that changes in solubility do take place, but they appear to follow the normal course observed in the saponification of cellulose acetate. In the experiments described it was observed that the cellulose acetate obtained, after heating with aniline for eight hours, was soluble in acetone and in a solution consisting of 85% chloroform and 15% ethyl alcohol by volume. After twenty-five hours' heating, the material obtained was practically insoluble in acetone and not entirely soluble in the chloroform-alcohol mixture mentioned above, but soluble in hot 75% ethyl alcohol. At the end of thirty hours' heating the product was soluble in aniline but not in the other solvents mentioned, and at the close of forty hours' heating it became insoluble, even in boiling aniline.

For the purpose of determining whether the final product of aniline saponification was cellulose or one or more of its decomposition products, **5** g. of the material obtained after one hundred hours' heating with aniline was reacetylated and **7.8** g. of a compound was obtained (theoretical for cellulose triacetate **8.9** g.) which contained 44.2% of CH_3CO (theoretical for cellulose triacetate, **44.8%)** and had a specific rotation of $-26.0°$, which is the same value as that of the starting material.

Heating at 148–151°.--To determine the difference in rate of saponification of cellulose acetate by aniline resulting from a change in temperature, a series of experiments was made at 148–151°, for a maximum time of 150 hours. At the close of this period the rate of hydrolysis had become very low. The data obtained are given in Table II.

TABLE II

RESULTS AT 148–151°

Time, hours	Product recovered, g.	Equiv. wt. of cellulose, g.	CH_3CO in prod., %	$(\alpha)^{25°}_{546.1}$, $CHCl_3-EtOH$	$(\alpha)^{25°}_{546.1}$, acetone

150	9.0	**8.1**	10.4		
		Av. **8.0**			

The decrease in acetyl content with time of heating is shown in Curve B of Fig. 1. It is seen to be of the same form as that obtained at the higher temperature. It appears of interest to note that both curves exhibit an S-form, in which the saponification is slow at the start, increasing during the intermediate stages with a marked decrease in the rate toward the close.

A calculation of the cellulose equivalent of the various cellulose acetates obtained in this series varied from 7.3 to 8.4 g., with an average of 8.0 g., which shows good agreement with the theoretical value of 8.4 g. previously mentioned, as well as with the yields obtained in the first series.

Effect of Standing at 20–30°.—Since in each experiment of the above two series the contents of the reaction flask were allowed to cool to room temperature and permitted to stand at that temperature for irregular periods of time before being poured into alcohol, a check on the action of aniline on cellulose acetate at room temperature seemed necessary to establish the validity of the results obtained at higher temperatures.

A 15-g. sample of the same cellulose acetate that was used in the previous experiments, therefore, was placed in **300** cc. of aniline and the containing flask was heated in a 148–151° bath for one hour. At the end of this time all of the cellulose acetate had dissolved. The solution was then allowed to stand at room temperature, and twenty-five hours after removal from the bath, a portion was precipitated in ethyl alcohol, washed with alcohol, dried and analyzed. The acetyl content was found to be 43.5%, and the specific rotation in chloroform–alcohol (85:**15)** was **−26.5". The** remainder of the solution was permitted to stand at room temperature for an additional 125 hours. It was then precipitated, washed and dried in a similar manner, and upon analysis gave the following values: acetyl content 43.2%; specific rotation, chloroform–alcohol (85:15) −25.5°. The difference between these values and those of the original cellulose acetate of 43.9% acetyl, and specific rotation of −26.0°, is so slight that it appears that no appreciable changes have taken place during the 150 hours' standing at room temperature. Since this time is far in excess of that during which any of the samples was permitted to stand before precipitation, it is concluded that the validity of this procedure is established and also that the deesterifying action of aniline on cellulose acetate at room temperature is exceedingly slow.

Discussion of the **Polarimetric** Data.—From the data given in the tabulations, it is obvious that there is a continuous decrease in specific rotation in chloroform–alcohol, within its solubility range, of the products obtained after various periods of heating in aniline, and conversely a progressive increase in specific rotation in acetone of the products which are soluble in this reagent.

If the phenomenon of change of solubility were one of stereoisomerism, comparable with the mutarotation of the sugars, from the definition of mutarotation,[5] a "steady state" should be found. The polarimetric data fail to indicate any such "steady state" and, in fact, since the acetyl values change continuously during the heating, a simultaneous change in optical rotation might be expected.

Summary

1. The effect of aniline on cellulose acetate has been investigated at room temperature and two higher temperatures.
2. The acetyl contents and specific rotations, where possible, have been determined on the products.
3. It has been found that the cellulose equivalent of all the products agrees approximately with the theoretical value.
4. Contrary to Knoevenagel, it has been observed that there is a continuous decrease in acetyl content with time of heating.
5. The specific rotations, so far as present interpretation permits, do not seem to indicate the possibility of a stereoisomeric change comparable with the mutarotation of the sugars, as suggested by Knoevenagel.
6. The product obtained by prolonged saponification with aniline at 183° is shown to contain approximately 2% of acetyl, and upon reacetylation to revert to a product having the analytical constants of cellulose triacetate.
7. It has been shown that in the saponification of cellulose acetate with aniline, at the boiling point of the aniline–cellulose acetate solution (*ca.* 183°) and at 148–151°, the acetyl–time curves present similar contours.

THE SYNTHESIS OF 4-(3,4-DIHYDROXYPHENYL)-THIAZOLES

BY TREAT B. JOHNSON AND ELIZABETH GATEWOOD[1]

RECEIVED JANUARY 14, 1929 PUBLISHED JUNE 5, 1929

So far as the writers are aware, organic combinations derived from the heterocyclic rings—oxazole, I, isoxazole, II, thiazole, III, and isothiazole, IV, have never been utilized in the practice of general therapeutics, nor

I

II

III

IV

has their pharmacology been systematically investigated. This paper is the first of a proposed series from this Laboratory dealing with such cycles, and in which we shall describe methods of synthesizing new amino derivatives of the sulfur cycle, thiazole, represented by Formula III. All of the amines thus far prepared are being examined to determine their pharmacological action. The study of derivatives of the other three cycles included in the above heterocyclic series will be taken up as our investigation progresses.[2]

The basic idea which guided us in the formulation of our program of research was one of determining what influence the incorporation of a thiazole ring, III, or bridging with this cycle, would have on the potency and toxicity of known physiologically active organic substances. To illustrate, by the term "bridging" we mean the introduction of the compound radical—thyazyl,[3] C_3HNS— into the molecule of an amino acid like di-iodotyrosine, for example, leading to the formation of the unknown α-amino acid—*thyazyldi-iodotyrosine*—represented structurally by Formula V. In other words, this would lead to an analog of thyroxine, VI, which may also be viewed as a bridged compound derived from di-iodotyrosine, in which the compound radical, $I_2C_6H_2O$, functions in place of thyazyl in V. If we limit ourselves to thiazole substitutions in positions 2 and 4 of this cycle, only one other isomeric thyazyldi-iodotyrosine is theoretically possible, namely, that represented by Formula VII. The study of practical methods leading to the synthesis of these two acids, V and VII, is now in progress in this Laboratory.

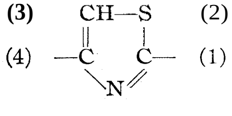
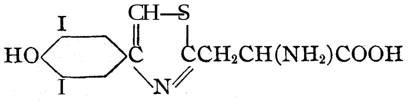
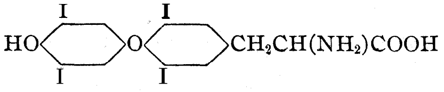
[2] Of the many possible constructions that may be derived from these four cycles, we are not interested, at present, in the different condensed ring systems of which henzovazoles and benzthiazoles, for example, are representative compounds.

[3] The thyazyl radical is represented structurally as



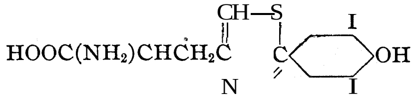


V

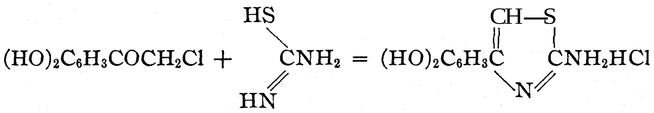


VI

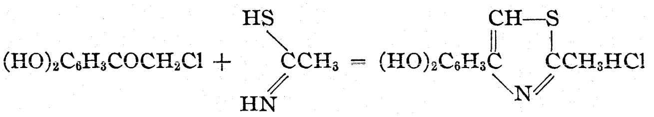
VII



In order to ascertain the influence of bridging with thyazyl, we first directed our attention to the study of methods of synthesizing thiazoles containing the catechol nucleus, $C_6H_3(OH)_2$. The catechol radical has been little used in drug synthesis except in the production synthetically of adrenaline and related compounds. The reaction which has led successfully to the synthesis of physiologically active thiazole derivatives is one based on the reactivity of an ω-chloroketone toward compounds containing thio-amide groupings. The mechanism of this reaction was first correctly interpreted by Hantzsch.[4] The only halogenated derivative of an aromatic ketone which has been extensively utilized in the development of thiazole chemistry is ω-chloro- or bromo-acetophenone, $C_6H_5COCH_2Br$. The halogenated ketone which served as the starting point of our research was chloro-acetocatechol, VIII, first described by Dzerzgowski,[5] and which served as the starting point for the first successful synthesis of adrenaline.[6] This chloro ketone interacts smoothly with every thio-amide construction that we have thus far examined, leading to the formation of thiazoles containing a catechol group in the 4-position of this cycle. The reactions with thiourea and acet-thioamnide, for example, are expressed below



VIII



In the Experimental Part of this paper is given a description of several new aminothiazoles containing the catechol group in the 4-position of the thiazole ring. An unexpected stability has been revealed in the case of the majority of the thiazole amines which we have thus far synthesized. Ordinarily, one expects to meet with organic constructions which easily undergo oxidation when experimenting with catechol derivatives. In our

new compounds the bridging with the thiazole cycle has a decidedly stabilizing effect and our new catechol combinations can be preserved without undergoing rapid oxidation changes. Methods for synthesizing thiazole amines containing the cathechol group in the 2-position of this cycle will be described in our next paper.

Experimental Part

Chloro-acetocatechol, $ClCH_2COC_6H_3(OH)_2(3,4)$.—The chloro-acetocatechol used in the various condensation reactions described in this paper was prepared from catechol, chloro-acetic acid and phosphorus oxychloride both by the method of Mannich and Hahn,[7] without the use of a solvent, and the more recent method of Ott[8] in which the reaction is carried out in benzene.

The yields by the first method were improved by warming the mixture very gradually on a water-bath for several hours instead of heating at 100° for one hour and by using more phosphorus halide (1 mole). A sticky mass forms if the solution becomes too hot and the reaction mixture foams vigorously. We also applied Ott's procedure of synthesis but with slight modification in technique.

The following procedure gave the best results and the chloro-acetocatechol may usually be obtained very pure and in a colorless form by only one recrystallization.

Twenty grams of catechol, 20 g. of chloro-acetic acid and 15 g. of phosphorus oxychloride were dissolved in 80 cc. of benzene and the solution was warmed on a water-bath at about 60° for twenty-four hours. At the end of this time the solution was still light colored and contained a heavy deposit of crystalline chloro-acetocatechol. The solution was cooled, the benzene decanted and water then added. The precipitated ketone weighed 15 g. The benzene liquor usually gave a gram or two more when it was evaporated and the residue obtained was triturated with water. After one recrystallization from hot water the ketone melted sharply at 173°.

Preparation of **Acetamino-acetonitrile,** $CH_3CONHCH_2CN$.—Ten grams of the hydrochloride of amino-acetonitrile[9] was carefully warmed with 50 cc. of freshly distilled acetic anhydride until the solution became clear and effervesced vigorously. After allowing to stand for a few minutes the solution was diluted with benzene and then allowed to evaporate on a hot-plate. The residue solidified and after washing with ether weighed 10 g. The compound is purified by dissolving in chloroform and then precipitating by diluting the solution with ether. It melts at 77°.

Acetamino-acetothioamide, $CH_3CONHCH_2CSNH_2$.—A solution of 20 g. of acetamino-acetonitrile in 75 cc. of absolute alcohol and 25 cc. of concentrated aqueous ammonia was cooled to 10° and saturated with hydrogen sulfide. On allowing the solution to evaporate spontaneously, the thio-amide separated in a crystalline form and was purified by recrystallization from absolute alcohol. The yield was 19 g. and it melted at 123–124°.

Anal. Calcd. for $C_4H_8ON_2S$: N, 21.20. Found: N, 21.20, 21.05.

2-Acetaminomethyl-4-(3,4-dihydroxyphenyl)-thiazole. Hydrochloride.—Prepared by interaction of the above thioamide and chloro-acetocatechol in alcohol solution. It is easily purified by crystallization from alcohol and melts at 188–190°.

Anal. Calcd. for $C_{12}H_{13}O_3N_2SCl \cdot C_2H_5OH$: N, 8.08; C_2H_5OH, 13.28. Found: N, 7.72, 7.81; C_2H_5OH, 13.19.

2-Aminomethyl-4-(3,4-dihydroxyphenyl)-thiazole, $(HO)_2C_6H_3\overline{C{=}CHSC(CH_2NH_2){=}N}$.—The hydrochloride of this thiazole base was obtained by digesting the above acetyl compound with concentrated hydrochloric acid. The salt was purified by dissolving in 85% alcohol and then precipitating by dilution with ether. It crystallized from hydrochloric acid in prisms melting at 225–230".

Anal. Calcd. for $C_{10}H_{10}O_2N_2S{\cdot}2HCI$: N, 9.49; Cl, 24.0. Found: N, 9.33; Cl, 24.3.

Acetylmethylamino-acetothio-amide, $CH_3CON(CH_3)CH_2CSNH_2$.—Twenty grams of methylamino-acetonitrile[10] was heated with 30 g. of acetic anhydride in benzene solution for thirty minutes. The solution was then evaporated to remove the solvent, the reaction product dissolved in cold saturated alcoholic ammonia, and the resulting solution saturated with hydrogen sulfide. We obtained 16 g. of thio-amide which crystallized from hot water in prismatic crystals melting at 156–157°. The compound is soluble in hot water or in alcohol and insoluble in ether.

Anal. Calcd. for $C_5H_{10}ON_2S$: N, 19.17. Found: N, 19.28, 19.21.

2-α-Acetamino-isopropyl-4-(3,4-dihydroxyphenyl)-thiazole, $(HO)_2C_6H_3\overline{C{=}CHSC(C(CH_3)_2NHCOCH_3){=}N}$.—a-Amino-isobutyronitrile was first prepared according to the method of Biltz and Slotta.[11] This was then acetylated[12] according to Hellsing's directions and from the acetyl compound was prepared the thio-amide by saturation in alcoholic ammonia solution with hydrogen sulfide. From 20 g. of the acetylated nitrile we obtained 14 g. of the thio-amide melting at 185–186°. Hellsing reports a melting point of 162°.

Five grams of this thio-amide and 5.6 g. of chloro-acetocatechol in 20 cc. of absolute alcohol were heated at the temperature of a boiling water-bath for thirty minutes. After cooling the hydrochloride of the thiazole was precipitated from this solution by dilution with ether. The yield was 8.0 g. It was purified by reprecipitation from alcohol and melted at 188–189°.

Anal. Calcd. for $C_{14}H_{16}O_3N_2S{\cdot}HCl$: C, 51.1; H, 5.2; N, 8.5. Found: C, 51.2, H, 5.3; N, 8.3.

This salt is readily hydrolyzed by the action of cold water giving the free acetylthiazole. The latter was purified by crystallization from dilute alcohol. It separated in the form of prismatic crystals and melted at 198–200°.

Anal. Calcd. for $C_{14}H_{16}O_3N_2S{\cdot}2H_2O$: N, 8.54; H_2O, 10.97. Found: N, 8.73, 8.51; H_2O, 10.78.

2-α-Amino-isopropyl-4-(3,4-dihydroxyphenyl)-thiazole, $(HO)_2C_6H_3\overline{C{=}CHSC(C(CH_3)_2NH_2){=}N}$.—Eight grams of the above hydrochloride of the acetylthiazole was digested with 50 cc. of strong hydrochloric acid for one hour. The hydrochloride of the aminothiazole began to separate from the solution almost immediately. We obtained 6 g. of the salt, which was purified by precipitating from alcohol solution with ether and recrystallization from hydrochloric acid. It melted with decomposition at 210–215°.

Anal, Calcd. for $C_{12}H_{14}O_2N_2S{\cdot}HCl{\cdot}H_2O$: N, 8.21; H_2O, 5.28. Found: N, 8.30, 8.50; H_2O, 5.17.

Summary

1. The halogenated ketone ω-chloro-acetocatechol, $ClCH_2COC_6H_3(OH)_2$, has been shown to interact smoothly with organic compounds containing thio-amide groupings.

2. These condensations lead to the formation of new thiazoles containing the catechol group in position 4 of the thiazole cycle.

3. In this paper we have given methods for preparing several new aminothiazoles. All of these compounds thus far examined have been found to be physiologically active.

4. They are characterized by their stability in the air, notwithstanding the presence of a catechol grouping in their respective molecules.

5. This research on thiazoles is being continued in this Laboratory. It will include a study of the pharmacology of our new synthetic compounds.

OPTICAL ROTATION AND ATOMIC DIMENSION. VIII. HALOGENO-HEPTA-ACETYL DERIVATIVES OF MELIBIOSE AND MALTOSE. THE STRUCTURES OF BIOSES AND CELLULOSE

BY D. H. BRAUNS

RECEIVED JANUARY 14, 1929 PUBLISHED JUNE 5, 1929

In preceding articles of this series it was reported that the relation between the specific rotational values and the atomic dimensions of the halogeno-hepta-acetyl derivatives of cellobiose, glucosido-mannose and gentiobiose deviate from the regular relationship for the monose sugars and that an agreement is obtained only by excluding the values for the fluoro derivatives. In this relationship these three bioses behave in the same manner, although their structure is not alike. In celloboise and glucosido-mannose the first carbon of the one monose is connected by an oxygen atom to the *fourth* carbon of the second, whereas in gentiobiose the first carbon of the one monose is connected by an oxygen atom to the *sixth* carbon of the other.

The preparation and rotational values of the pure crystalline fluoro-, chloro- and bromo-hepta-acetyl derivatives[1] of melibiose, which are described in the present article, have revealed the astonishing fact *that an exact agreement with the regular relationship for the monose sugars exists for these biose derivatives.* The recent establishment of the structure of melibiose[2] has shown that in this biose the first carbon of the one monose, galactose, is attached by an oxygen atom to the sixth carbon atom of the other, glucose, and, further, that melibiose is an *α-biose.*[3] Melibiose is therefore a-galactosido-6-glucose. *The bioses which have been investigated before,* cellobiose, glucosido-mannose and gentiobiose, are *β-bioses.*

Before making deductions from this striking difference in behavior of these a-and β-bioses, it seemed desirable to check this result. This pointed directly to the necessity of preparing the halogen derivatives of maltose, as it has been established that maltose[4] is a-glucosido-4-glucose and it was considered probable that an a-6-biose and an a-4-biose would behave in the same way. In addition to the melibiose derivatives this paper describes

---

[1] The crystalline iodo derivative was too unstable to allow a process of recrystallization. The rotational value of the yellowish crystals was found to be close to the value required by the atomic dimension relationship.

[2] Haworth, and co-workers, *J. Chem. Soc.,* 1527, 3146 (1927); Helferich and Bredereck, ***Ann.,*** 465,166 (1928).

[3] Bioses in which the reducing or first carbon atom of the one monose is connected by an α-glucosidic bond to one of the non-reducing carbons of the second monose are called a-bioses. The reducing (first) carbon of the second monose allows the substitution of its hydroxyl for halogen.

[4] Haworth, Loach and Long, *J.* Chem. *Soc.,* 3146 (1927).

the preparation of pure crystalline fluoro- and bromo-hepta-acetylmaltose[5] and gives their rotational values. The rotational value for the crystalline chloro derivative has been checked with that reported in the literature. The iodo derivative could not be obtained in crystalline condition. The data for the specific rotations of the melibiose and maltose derivatives together with those for the other bioses are given in Table I for comparison with the regular relationship of the monose sugars.

TABLE I

COMPARISON OF SPECIFIC ROTATIONS OF α- AND β-BIOSE DERIVATIVES[a] WITH REPRESENTATIVE MONOSE DERIVATIVES (INCLUDING FLUORO DERIVATIVES)

	a-Bioses Deriv. of		β-Bioses Deriv. of			Resp. sp. rot. diff.					Resp. sp. rot. diff. reduced					Sp. rot. diff., monoses

TABLE II

COMPARISON OF SPECIFIC ROTATIONS OF β-BIOSE DERIVATIVES WITH REPRESENTATIVE MONOSE DERIVATIVES (EXCLUDING FLUORO DERIVATIVES)

	β-Bioses Derivatives of Gentiobiose	Cellobiose	Glucomannose	Resp. sp. rot. diff.			Resp. sp. rot. diff. reduced			Sp. rot. diff., monoses
Cl	80.5	71.7	51.2							
				20.6	24.1	26.7	17	17	17	17
Br	101.1	95.8	77.9							
				25.0	29.9	33.6	21	21	21	21
I	126.1	125.7	111.5							

The foregoing data adequately support the conclusion that the a-biose derivatives follow the atomic dimension relationship, whereas the β-biose derivatives agree with this relationship only when the fluorine derivatives are excluded.

Directed by the atomic dimension relationship, I thus concluded that *a* fundamental difference between the finer structures of these a- and β-bioses must exist, as the numerical deviation of the atomic dimension relationship for each of the β-bioses must be an expression of this difference in structure.

---

[5] The preparation of pure crystalline bromo-hepta-acetylmaltose, which has been intermittently attempted by the author during many years, has revealed peculiarities which may be of interest from a chemical and crystallographical standpoint. The results are given under "Experimental Part."

Discussion of Results

Two postulates have been used for arriving at an insight into the finer structure of the bioses. The first postulate is the basis of stereo-chemistry of carbon compounds. The second postulate is based on the present view of the stereo-chemical behavior of oxygen.

Postulate I.—The directions of the four equal valences of the carbon atom are the same as the directions of the lines connecting the four corners of the regular tetrahedron with its center.

Postulate 11.—Two possibilities exist for the oxygen atom: *(a)* The directions of the four valences (two primary and two secondary) of oxygen are the same as those for the valences of the carbon atom. The oxygen atom displays valences of this kind in the ring system of the monoses. (b) The two primary valence directions of oxygen are nearly opposite each other. (In the present discussion it is assumed that valences of these types are displayed by the oxygen atom which connects the two monoses of *a*- and of β-bioses.)

For support of the second postulate I quote Huggins,[6] who states that "for one reason or another a valence may be forced away from its normal position. Thus in the quartz crystal the angle subtended at the atomic center by the two bond electron pairs around each oxygen atom is considerably greater than it would be if the pairs were in their normal positions at the corners of a regular tetrahedron (about 109°)."

Allowing these postulates, let us consider first one carbon atom to which four different single atoms are attached and call the first valence the α-valence and the second the p-valence. These ***a***- and β-valences are symmetrically arranged with respect to the plane going through the other two valences, in which plane the centers of the carbon atom and the third and the fourth atoms are also situated. The *a*- as well as the β-valence makes with this plane an angle of $109.5^\circ/2 = 54.75^\circ$, whereas the a-valence makes with the p-valence an angle of 109.5".

This regularity does not hold, however, for a ring system, as, for example, the amylene-oxide structure of the monose sugars. Using the facts laid down in the written formula of glucose, we will systematically build up in space the structure formula for this sugar and in this way bring out some peculiar differences in structure between the *a*- and β-forms of the monoses.[7]

Suppose we first make a row of the six carbons of glucose. The valence

---

[6] Huggins, Phys. ***Rev.***, **19,352** (1922).

[7] Dowel pins and wooden cubes with 26 holes (Bool Furniture Co , Ithaca, N. Y.) are recommended for making models. The rigid angles and the close connection of the blocks prevent the errors that are easily made when wire is used for the bonds. Tetrahedrons are easily constructed from the cubes. Oxygen is indicated by a black triangle on each face.

connecting the first with the second carbon is directed at a definite angle *upward* (with regard to a horizontal plane), whereas the valence connecting the second to the third carbon must necessarily be directed the *same angle downward,* and so on. The centers of these six carbons are thus situated in two horizontal lines, one above the other, the first, third and fifth in the lower and the second, fourth and sixth in the higher. We will call this the zig-zag chain of six carbons. The attaching of the hydroxyl groups to the carbons is not *directly* given by the conventional glucose formula of Fischer–Tollens–Haworth, because it must be realized which agreement had to be made in order that space relations could be expressed in a *plane* (of the paper). It follows from these agreements that if the model of the zig-zag chain of carbons is placed on a horizontal plane and viewed from above, *each* carbon must be viewed in succession and from such a side that the extension of the valences connecting this carbon to the former and to the next are *crossing this plane.* Therefore, if the second carbon in the zig-zag chain is situated in a horizontal plane *above* that of the first carbon, we can directly put the OH group at the right without being obliged to turn the model.[8] For the OH group of the third carbon, however, which should have a left position according to the written formula, we have to turn the zig-zag model around in order to view this carbon from the correct side (in which the extension of the valences connecting this carbon to the former and the next are crossing the horizontal plane on which the model is placed). Consequently the OH of the third carbon comes in the zig-zag chain model at the *same side* as the OH of the second carbon. The OH of the fourth carbon will come in the zig-zag model also under the OH of the preceding carbons, whereas the OH of the fifth carbon (represented by an oxygen block) will be situated at the *other* side of the zig-zag model, as will be easily seen by consulting the written formula for glucose.

In order to make the amylene-oxide ring we leave the connection between the first carbon and the second as it is, and turn the third carbon around the **2–3** axis until its OH group is opposite that of the second. Now we turn the fourth carbon around the **3-4** axis until its OH is opposite that of the third. At last the fifth carbon is turned around the 4–5 axis until its oxygen (represented by an oxygen block) closes the six-numbered ring by also turning the first carbon around the 1–2 axis.

The ring is formed without strain and the model has much regularity. If viewed from the side of the ring a perfect representation of Fischer's written glucose formula is given, the agreements being taken into account. The place of the sixth carbon, however, which is below the plane of the

---

[8] It is convenient to indicate the OH groups of the second, third and fourth carbons by dowel pins and omit the indication of the H atoms. However, the OH group of the fifth carbon is indicated by a block representing oxygen.

ring and which assumed this position by the turning of the 4–5 axis, could not be so easily found without the preceding logical deduction.[9]

I will give now a brief description of the finished model, bringing out peculiarities for the direction of the a- and β-valences. If the model is so placed that the ring is horizontal and the first carbon be situated farthest away from the observer with the second carbon at the left and the oxygen atom at the right, then the valence connecting the first carbon to the second is directed at a definite angle upward and that from the second to the third at the same angle downward, and so on. Consequently the centers of the first, third and fifth carbons will be in one horizontal plane, and those of the second and fourth carbons and the oxygen will be in a second horizontal plane slightly above the first. The unoccupied valences of the first carbon are always designated as a- and β-valence. It has been established that the a-valence for all-d-sugars must be at the top of this carbon in accord with the requirement[10] that for d-glucose it must be near the OH group of the second carbon which is at the top of the second carbon. Now we observe that *the a-valence is directed slightly upward to the front, making an angle with the horizontal ring system of about 19.5°, whereas the β-valence is directed about perpendicularly down, making therefore an angle of about 90° with that ring system.*[11] This result is entirely different from that obtained for a single carbon atom, to which four different atoms are attached and for which the α- and β-valences are *symmetrically* placed with regard to the plane in which the third and fourth atoms are situated. The explanation of this peculiarity for the monoses is that the directions of the a- and β-valences are not *primarily* dependent on the direction of the parallel planes of the ring systems, *but on the direction of the valence connecting the first carbon to the second* (or the first to the sixth).

Before we show how the experimental facts regarding the rotational relationship of the halogeno-acetyl derivatives of the bioses are well explained by structural peculiarities of the bioses, it seems well to point out plainly the two *assumptions* on which these *finer* stereo-chemical structures are based.

I. The particular ring structure of the monoses developed above is

---

[9] I am indebted to Prof. W. H. Dore of Berkeley (California) for valuable remarks establishing this place of the sixth carbon atom.

[10] Boeseken, Ber., 46,2612 (1913); Pictet, Helv. *Chim. Acta,* 3,649 (1920); Hudson, THIS JOURNAL, 31, 66 (1909). For the I-sugars the @-valence is that of the top as required by the nomenclature.

[11] The difference in direction of the α-valence and the @-valence with respect to the ring system has been logically derived from the tetrahedral orientation of the four valences of the carbon atom. The anisotropy of the carbon atom [see the interesting study on this subject by Mrs. K. Lonsdale-Yardley, *Phil.* Mag., 6, 433 (1928)] may also have a *minor* influence on this different behavior of the α- and @-valences.

only one of the several possible spacial arrangements of the atoms in the amylene oxide ring.[12]

II. It is assumed that the linking oxygen between the monose units has its valences opposite each other and that a free rotation of the monose units around this oxygen linkage can take place.

Important deductions can now be made regarding the structure of α- and β-bioses, which were studied in the forms of their halogen derivatives. We will apply a free rotation around the axis which connects the one monose by an a-(or β-) valence by means of an oxygen atom to the second monose for the *a*- and β-bioses, respectively. Taking into account the small angle (19°) which the a-valence makes with the ring system, it can be seen even without a model that for the a-bioses (melibiose and maltose) the halogen atom is too far away from the other monose to be influenced by secondary valences. We can turn the second monose entirely 360° around the connecting a-valence axis without an appreciable approach of the ring systems. With the investigated β-bioses, however, it is quite different. We will first connect the two ring systems through the β-valence and an oxygen atom to the fourth carbon (cellobiose and glucosido-mannose) in such a way that the second ring is situated in *front* of the other in a parallel horizontal plane below the first. When the second monose is turned from 90 to 180° around the β-biosidic axis, it is seen *that the halogen attached to the a-valence of the second monose faces the atoms attached to the ring system of the first monose. The same result* is obtained by connecting the two ring systems through the β-valence and an oxygen atom to the sixth carbon (gentiobiose). These model studies, directed by experimental results, clearly explain *that the halogens of the β-bioses are influenced by secondary valences, whereas the halogens of the α-bioses are not.* Further, these model studies indicate that some β-bioside derivatives, as β-glucosido-4-galactose, must follow entirely the atomic dimension relationship. Investigations will be taken up later for checking this result and also for determining more exactly which are the selectively influencing atoms of the second monose.

This insight into the finer structure of the bioses, resulting from the application of the atomic dimension relationship, gives also a suggestion regarding the structure of such important polysaccharides as *cellulose.* The old formula for cellobiose cannot be used for constructing the formula for cellulose, as the x-ray picture of cellulose fiber shows a diffraction pattern requiring C_{12} units, whereas the above old formula of cellobiose in chain formation would require a pattern of C_6 units.[13]

---

[12] See, e. *g.,* Lowry, *Chem. Industry,* 47, 1149 (1928).

[13] See Sponsler and Dore, "Colloid Symposium Monograph," Chemical Catalog Co., New York, p. 174, and THIS JOURNAL, 50, 1941 (1928); also, Hauser, *Ind. Eng. Chem., 21, 120* (1929). Nor does a ring formula of three units, for example, satisfy the requirements on account of the low molecular weight and weak secondary bonds of

However, the new structure formula for cellobiose in chain formation, in which one glucose of the cellobiose molecule is facing the other, *fulfils* the pattern *requiring* C_{12} *units,* although at this stage of the investigations it would also allow larger units such as C_{18}. An examination of a model of this chain of C_{12} units shows further that the oxygen atoms connecting the successive glucose units are alternately well protected and partly protected by surrounding groups[14] (especially by acetyl groups of the first and second carbon atoms), which fact explains why *cellobiose* is produced on acetolysis of *cellulose fiber,* as the one oxygen union will be hydrolyzed more quickly than the next.

These peculiarities, revealed by a study of the atomic dimension relationship, lead to a conclusion regarding the possibility of considering cellobiose as a building stone of cellulose opposite that heretofore adopted. We now see that the former conclusion was erroneous because a formula for cellobiose had been adopted for which sufficient detail in structure was lacking.

Experimental Part

General Remarks.—For all determinations of the specific rotation U. S. P. or purified chloroform[15] was used. The volume of the solution was made up in the same flask to 24.9767 cc. at 20°, which requires multiplication by the factor 4.0038 for obtaining 100 cc. The reading, which was made in the same 4-dm. tube at 20°, is given in circular degrees.

Melibiose.—A supply of β-melibiose dihydrate was prepared from raffinose according to the method of Hudson and Harding.[16] After one recrystallization the preparation gave a specific rotation in water of +128.9°, agreeing with the value obtained by Hudson and Yanovsky[17] of +129.5°.

β-Octa-acetylmelibiose was prepared by acetylating melibiose with acetic anhydride and anhydrous sodium acetate. It was recrystallized four times from 95% alcohol, yielding a product of constant specific rotation in chloroform of +102.6° and m. p. 177". Hudson and Johnson[18] report specific rotation in chloroform +102.5°; m. p. 177.5" (corr.).

Fluoro-hepta-acetylmelibiose was prepared from β-octa-acetylmelibiose in the manner previously described.[19] The distillation was finished in about twenty to twenty-five minutes and the reaction product was directly worked up. The sirup resulting from the extraction with chloroform did not crystallize readily. Crystallization was

---

the chain in contradiction to the tensile strength [Meyer and Mark, *Ber.*, 61,593 (1928); Hess and Trogus, *ibid.*, 61, 1982 (1928)].

[14] Acetyl or acyl groups are, of course, not extending from a carbon atom of the ring system in a straight line connecting the corner of the tetrahedron with its center, but are curved out from the ring system by the O—CO—C bond. As to the 50% yield of cellobiose octa-acetate from cellulose, see Friese and Hess, *Ann.*, **456,** 42 (1927).

[15] Brauns, THIS JOURNAL, 46, 1486 (1924).

[16] Hudson and Harding, *ibid.*, 37,2734 (1915).

[17] Hudson and Yanovsky, *ibid.*, 39, 1027 (1917)

[18] Hudson and Johnson, *ibid.*, 37,2752 (1915).

[19] Brauns, *ibid.*, 45,834 (1923).

started by adding some 70% methyl alcohol and scratching the walls of the dish. When crystallization started more 70% methyl alcohol was added gradually. The yield of impure crystals was 8 g. from 15 g. of β-octa-acetate. It was recrystallized several times by being dissolved in boiling 70% methyl alcohol with addition of decolorizing carbon and filtered through an ordinary folded filter. The filtrate was seeded and allowed to cool gradually. The first separations of the recrystallizations of the impure substance contain most of the impurities. The pure product crystallizes in small prismatic needles and is stable, colorless and tasteless. It is very soluble in most solvents except water and petroleum ether; m. p. 135°. The determination of the specific rotation in chloroform solution gave the following result.

Rotation.—Third recrystallization; first and second fractions, respectively. Subs., 0 5247, 0.6429: a = +12.445°, +15 374°; $[\alpha]^{20}_{D}$ = +148 12°, +149.31°. Fourth recrystallization: first and second fractions, respectively. Subs., 0.6225, 0.3722: α = +14.923°, +8.900°; $[\alpha]^{20}_{D}$ = +149.69°, +149.36". Fifth recrystallization: first and second fractions, respectively. Subs., 0 6412, 0 2132: a = +15.374°, +5.098°; $[\alpha]^{20}_{D}$ = +149.71°, +149.31°. Therefore \$149.70" is taken as the specific rotation of the pure substance.

Anal. Subs., 0.1679: CO_2, 0.2999; H_2O, 0.0847. Subs., 0.5000: CaF_2, 0.0269. Subs., 0.5000: 98.54 cc. of 0.25 *N* H_2SO_4, 246.35 cc. of 0.1 N NaOH. Calcd. for $C_{26}H_{35}O_{17}F$: C, 48.88; H, 5.53; F, 2.98; 62.67 cc. of 0.1 N NaOH for AcOH + F. Found: C, 48.71; H, 5.64; F, 2.62; 61.95 cc. of 0.1 *N* NaOH.

Chloro-hepta-acetylmelibiose was prepared by following the method described for chloro-hepta-acetylgentiobiose.[20] The sirup resulting from the concentration of the chloroform solution did not crystallize readily, a difficulty which was observed for all the halogen derivatives of melibiose. The following method was employed for obtaining the chloro derivatives in a crystalline condition. The sirup was kept first for a few hours in a vacuum desiccator. A small quantity of ether mixed with about one-fourth of its volume of petroleum ether was then added and the mixture was continually stirred while the sides of the crystallizing dish were scratched; the solid masses separating at the walls of the dish were broken down. Gradually a cloudiness appeared. A small quantity of ether was then added and the stirring was continued until small crystals separated. At this stage more ether was added, accelerating the crystallization. The crystals were separated on a suction filter. The yield of impure crystals was 6 g. from 20 g. of β-octa-acetate. A small quantity of crystals was always put aside for seeding the solution of the next recrystallization. Recrystallization was produced by dissolving in dry ether, filtering and slowly evaporating the solution under a bell jar with a current of dry air. The concentrated solution was seeded and the slow evaporation continued. The current of air was interrupted after fifteen minutes and the solution was allowed to stand undisturbed for ten to twenty minutes. In this way well developed crystals were obtained. The determination of the specific rotation in chloroform gave the following results.

Rotation.—Second recrystallization: first and second fractions, respectively. Subs., 0.6626, 0.6261: a = +20.416°, +19.238°; $[\alpha]^{20}_{D}$ = +192.39°, +191.86°. Third recrystallization: first and second fractions, respectively. Subs , 0.6327, 0.6299: a = +19.498°, +19.422°; $[\alpha]^{20}_{D}$ = +192.42°, +192.52°.

Therefore, 192.50" is taken as the specific rotation of the pure substance. The pure compound crystallizes in small prisms; m. p. 127". It is slightly bitter and stable when kept in a vacuum desiccator over sodium hydroxide in the ice box. It is readily soluble in ordinary solvents except petroleum ether and water, and slightly soluble in ether.

---

[20] Brauns, THIS JOURNAL, 49,3173 (1927).

Anal. Subs, 0 2019: CO_2, 0.3504; H_2O, 0.0990. Subs., 0.2315: AgCl, 0.0514. Subs., 0.5000: 98.54 cc. of 0.25 *N* H_2SO_4, 306.95 cc. of 0.1 NaOH. Calcd. for $C_{26}H_{35}O_{17}Cl$: C, 47.65; H, 5.39; Cl, 5.41; 61.10 cc. of 0.1 *N* NaOH. Found: C, 47.33; H, 5.48; Cl, 5.49; 60.60 cc. of 0.1 *N* NaOH.

Bromo-hepta-acetylmelibiose.—Twenty-five grams of octa-acetylmelibiose was dissolved in 85 cc. of acetic acid and 62 cc. of a saturated solution of hydrogen bromide in acetic acid was added. The mixture was kept in a stoppered Erlenmeyer flask at room temperature for one and one-half hours. It was then poured into a separatory funnel containing ice water, cracked ice and chloroform and shaken out five times with ice water. The chloroform extract was dried with calcium chloride, filtered and evaporated to a sirup at low temperature. The sirup was stirred with 15 cc. of petroleum ether and the petroleum ether solution was poured off. This process was repeated once. The petroleum ether solution crystallized overnight by evaporation in the air. The quantity of crystals was small but it was useful for seeding the ether solution of the sirup. The process for obtaining well-defined pure crystals was the same as that described for chloro-hepta-acetylmelibiose. The yield was small, being 4 g. from 25 g. of octa-acetate. The solutions for the rotations were prepared with purified chloroform.

Rotation.—First recrystallization. Subs., 0.6184: a = +20.642°; $[\alpha]^{20}_{D}$ = +208.-42". Second recrystallization. Subs., 0.6127: a = +20.538°; $[\alpha]^{20}_{D}$ = $209.30". Third recrystallization. Subs., 0.6336: α = +21.297°; $[\alpha]^{20}_{D}$ = +209.88°. Fourth recrystallization. Subs., 0.4256: a = +14.293°; $[\alpha]^{20}_{D}$ = +209.70°.

Therefore, +209.90° is taken as the specific rotation of the pure substance. The pure substance crystallizes in short prisms; m. p. 116". It is slightly bitter and can be kept in a vacuum desiccator over sodium hydroxide in the ice box. It is readily soluble in most solvents, less soluble in ether and slightly soluble in petroleum ether and water.

Anal. Subs., 0 2360: CO_2, 0.3842; H_2O, 0.1090. Subs., 0.1960: AgBr, 0.0529. Subs, 0.5000: 98.54 cc. of 0.25 N H_2SO_4, 303.46 cc. of 0.1 *N* NaOH. Calcd. for $C_{26}H_{35}O_{17}Br$: C, 44.62; H, 5.05; Br, 11.43; 57.20 cc. of 0.1 NNaOH. Found: C, 44.40; H, 5.17; Br, 11.48; 57.11 cc. of 0.1 NNaOH.

β-Octa-acetylmaltose was prepared by acetylating maltose with anhydrous sodium acetate and acetic anhydride. It was recrystallized twice from 95% alcohol, yielding in chloroform a product of constant specific rotation +62.87° and m. p. 159–160°. Hudson and Johnson[Z1] report $[\alpha]^{20}_{D}$ = +62.59° and m. p. 159–160°.

Fluoro-hepta-acetylmaltose.—Ten grams of β-octa-acetylmaltose was treated with anhydrous hydrofluoric acid in the manner previously described.[17] The distillation was finished in about twenty to twenty-five minutes and the reaction product was worked up directly. The sirup resulting from the extraction with chloroform was crystallized by stirring with petroleum ether, the yield of impure crystals being 7.5 g. from 10 g. of octa-acetate. It was recrystallized several times by dissolving in about 80 cc. hot 95% alcohol, filtering and cooling gradually, at last with ice. The pure product crystallizes in small prisms and is stable, colorless and tasteless. It is soluble in the ordinary solvents except petroleum ether and water; m. p. 174–175°. The determination of the specific rotation in chloroform gave the following results.

Rotation.—First recrystallization. Subs., 0.7097: α = +12.574°; $[\alpha]^{20}_{D}$ = +110.-62°. Second recrystallization. Subs., 0.7208: a = +12.806°; $[\alpha]^{20}_{D}$ = +110.93°. Third recrystallization. Subs., 0.7143: α = +12 709°; $[\alpha]^{20}_{D}$ = +111.10°. Fourth recrystallization. Subs., 0.6975: α = +12.411°; $[\alpha]^{20}_{D}$ = +111.10". Therefore, +111.1° is taken as the specific rotation of the pure substance.

Anal. Subs, 0.2066: CO_2, 0.3717; H_2O, 0.1062. Subs., 0.5067; CaF_2, 0 0251.

[21] Hudson and Johnson, THIS JOURNAL, 37,1276 (1915).

Subs., 0.5000: 106.18 cc. of 0.25 *N* H_2SO_4, 328.35 cc. of 0.1 N NaOH. Calcd. for $C_{26}H_{35}O_{17}F$: C, 48.88; H, 5.53; F, 2.97; 62.67 cc. of *N* NaOH. Found: C, 49.06; H, 5.75; F, 2.41; 62.90 cc. of 0.1 *N* NaOH.

Chloro-hepta-acetylmaltose has been obtained in crystalline condition by Foerg[22] by saturating an acetic anhydride suspension of maltose with hydrochloric acid at low temperature. The container was sealed and kept for two weeks at room temperature. Foerg separated from the reaction product crystalline chloro-hepta-acetylmaltose, but made an error in recording the sign of the specific rotation, which was corrected by Schliephacke,[23] who found for the specific rotation in chloroform solution +158.68°. By applying the chlorination method of von Arlt, modified by Skraup and Kremann,[24] described for the preparation of chloro-tetra-acetylmannose,[25] I prepared pure chloro-hepta-acetylmaltose in a few days.

The reaction product, a colorless sirup, crystallized when stirred with petroleum ether. The yield of impure crystals was 9 g. from 15 g. of β-octa-acetate. Recrystallization was produced by dissolving in warm ether, filtering and adding so much petroleum ether that seeding or scratching started the crystallization. Recrystallization was repeated until a constant-rotating substance was obtained. The pure product crystallizes in small prisms and is stable when kept in a desiccator over sodium hydroxide in the ice box. It is soluble in the ordinary solvents except petroleum ether and water; m. p. 125". Foerg and Schliephacke report m. p. 118–120°. The determination of the specific rotation in chloroform gave the following results.

Rotation.—First recrystallization. Subs., 0.6044: $a = +15.370°$; $[\alpha]_D^{20} = +158.79°$. Second recrystallization. Subs., 0.6471: $a = +16.504°$; $[\alpha]_D^{20} = +159.25°$. Third recrystallization. Subs., 0.6484: $\alpha = +16.549°$; $[\alpha]_D^{20} = +159.36°$. Fourth recrystallization. Subs., 0.6145: $a = +15.693°$; $[\alpha]_D^{20} = +159.46°$. Therefore +159.50° is taken as the specific rotation of the pure substance.

Anal. Subs., 0.1878: CO_2, 0.3263; H_2O, 0.0899. Subs., 0.2733: AgCl, 0.0605. Calcd. for $C_{26}H_{35}O_{17}Cl$: C, 47.65; H, 5.39; Cl, 5.41. Found: C, 47.39; H, 5.36; Cl, 5.47.

Bromo-hepta-acetylmaltose.—Crystalline bromo-hepta-acetylmaltose has been described by Fischer and Armstrong[26] in a short communication. They obtained it by the action of liquid hydrobromic acid on octa-acetylmaltose under high pressure at room temperature, evaporating the hydrobromic acid and crystallizing the reaction product from hot ligroin. Prismatic needles were obtained melting at 84°. A bromine determination gave correct figures for a monobromo derivative, but no other properties were recorded. In a later paper Fischer[27] stated that by repeating this method of preparation an amorphous product resulted, which was largely the monobromo derivative, as a high percentage of crystalline hepta-acetyl-

[27] Fischer, ibid., 44, 1898 (1911); also E. Fischer and H. Fischer, ibid., 43, 2522 (1910).

maltose could be obtained from it. Later investigators have always used this amorphous product, for example, Karrer.[28] In the course of the present investigation the following facts were brought out which are important for preparing the crystalline bromo derivative.

1. The use of liquid hydrobromic acid, which requires the cooling with liquid air, yields a crude product which does not differ from the crude products of more simple methods of preparation.

2. It is advantageous to prevent so far as possible the formation of the dibromo derivative (which is not easily separated from the monobromo derivative) by shortening the time of reaction.

3. The crude amorphous product crystallizes from hot ligroin only if the cooling or concentrating is extremely slow. This slow cooling was produced by the use of unsilvered Dewar flasks and slow evaporation by a very weak current of dry air.

Preparation.—Five grams of octa-acetylmaltose was dissolved in 17 cc. of acetic acid which had been cooled to about 15°. Then 11 cc. of a saturated solution of hydrogen bromide in acetic acid was added and the whole was cooled to about 0°. The mixture was kept in a stoppered Erlenmeyer flask in ice water for half an hour and was then poured into a separatory funnel containing ice water and cracked ice and shaken out five times with ice water, yielding a neutral chloroform solution. This was dried with calcium chloride, filtered and evaporated to a sirup at low temperature by a current of dry air. The sirup was allowed to stand in a vacuum desiccator for two hours, after which it was converted to a sticky white powder by stirring with ligroin (b. p. 70–90°). This powder was boiled on the steam-bath in an Erlenmeyer flask with about 100 cc. of ligroin for some five minutes, forming a sticky substance which was stirred with a glass rod. The hot solution was then poured without filtering into an unsilvered Dewar flask, the sticky sediment remaining in the Erlenmeyer flask. This process was repeated. The wall of the Dewar flask was then scratched with a glass rod, which was first rubbed in some crystalline bromo derivative (obtained by repeatedly pouring off a ligroin solution from amorphous separations). After standing overnight crystalline material separated at the walls and amorphous substance at the bottom of the Dewar flask. The mother liquor was poured into beakers and very slowly evaporated under a bell jar by a weak current of air. By seeding and scratching the walls of the beakers brilliant short prisms of about one mm. in thickness and length were obtained. The amorphous product, which separates at the bottom of the Dewar flasks, can be converted to crystals by repeating the foregoing process. The analysis of the amorphous substance yields figures which are near those required for the monobromo derivative and its specific rotation is only a few degrees lower than that for the pure crystalline compound. Its melting point, however, is different as it melts at 80–83°. Heated quickly to near its melting point it was found that crystalline bromo-hepta-acetylmaltose melts at 112–113°, whereas Fischer reported a melting point of 84°. As crystallization seems to be connected with an orientation of the molecules before they separate out of solution, it is likely that for a quick separation the many secondary valences present in the α-biose derivatives prevent an *orientated or crystalline separation,* whereas for the β-bioses this difficulty does not exist in this measure, as their secondary valences have been largely saturated. Crystalline bromo-hepta-acetylmaltose was obtained in pure condition by regulating the time of reaction as described above, thus preventing the

---

[28] Karrer, *Helv. Chim. Acta,* *4,* 169, 263, 678 (1921).

formation of the dibromo derivative, which could not be removed. from the monobromo derivative by recrystallization. Analysis proved that the pure compound had been separated. The crystalline compound is easily soluble in ordinary solvents except petroleum ether and water. It is slightly bitter and was kept for many months without decomposition in a desiccator over sodium hydroxide in the ice box.

Rotation.—Subs., 0.6101: a = +17.640°; $[\alpha]_D^{20}$ = +180.54°. Recrystallization. Subs., 0.3872: a = +11.177°; $[\alpha]_D^{20}$ = +180.24°.

Other preparations gave values near +180.10°, which is taken as the specific rotation of the pure substance.

Anal. Subs., 0.1718: CO_2, 0.2827; H_2O, 0.0808. Subs., 0.2177: AgBr, 0.0581. Calcd. for $C_{26}H_{35}O_{17}Br$: C, 44.62 H, 5.05; Br, 11.43. Found: C, 44.88; H, 5.26; Br, 11.36.

Summary

The pure crystalline fluoro, chloro and bromo derivatives of acetylated melibiose and maltose have been prepared and described. The specific rotational values of these a-biose derivatives show an agreement with the atomic dimension relationship of the monose sugars, whereas the values for the halogen derivatives of the β-bioses, investigated before, agree with this relationship only by excluding the values for the fluoro derivatives. An explanation of this behavior is obtained by model studies, which show that the ***direction*** of the 6-valence allows the constituting monoses to face each other, with a resulting selective influence, whereas the direction of the a-valence does not allow this position. The new (more detailed) structure formula for cellobiose suggests a structure formula for cellulose. As compared with formulas heretofore suggested this new formula gives a better interpretation of the chemical and physical properties of cellulose.

THE MERCURATION OF NAPHTHALIC ACIDS

BY G. J. LEUCK AND R. P. PERKINS WITH FRANK C. WHITMORE

RECEIVED JANUARY 17, 1929 PUBLISHED JUNE 5, 1929

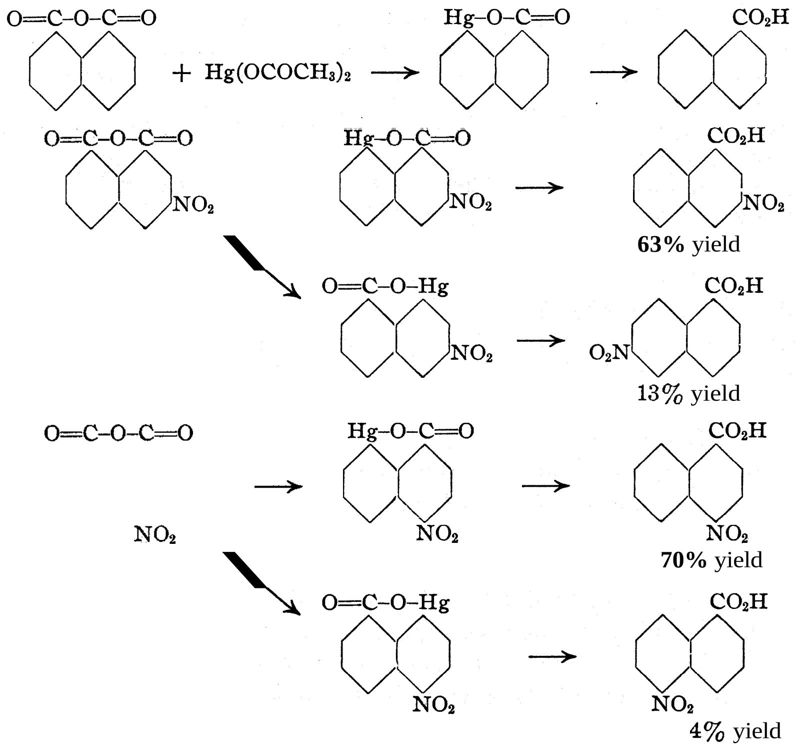
While the replacement by mercury of one of the carboxyl groups in phthalic acid has long been known,[1] the effect of changes in structure on this reaction has not been studied extensively.

In the present study naphthalic acid, 3-nitronaphthalic acid and 4-nitronaphthalic acid have been submitted to the reaction of Pesci. In each case one of the carboxyl groups was replaced by mercury. Naphthalic acid gave anhydro-8-hydroxymercuri-1-naphthoic acid. With 3-nitronaphthalic acid the carboxyl in the 8-position was replaced more than that in the 1-position. With 4-nitronaphthalic acid the replacement was almost entirely in the &position, only a small amount of replacement taking

---

[1] Pesci, *Atti. accad. Lincei,* [5] 10, 1, **362** (1901).

place in the I-position. In each case the products were identified by replacement of the mercury by hydrogen by means of hydrochloric acid.



In addition to the theoretical interest in these reactions they offer the best methods of preparing 3-nitro-1-naphthoic acid and 4-nitro-1-naphthoic acid in a high state of purity and in good yields.

Experimental Part

The **Mercuration** of Naphthalic Acid.—Acenaphthene was oxidized by sodium dichromate in glacial acetic acid.[2] From 100 g. of 75% acenaphthene was obtained 90 g. of purified naphthalic acid (1,8-naphthalenedicarboxylic acid), m. p. 270–271° (85% yield).

A filtered solution of 50.5 g. of naphthalic acid in 1.2 liters of water and 31 g. of sodium hydroxide was mixed with a solution of 55 g. of mercuric oxide in 150 cc. of water and 40 cc. of glacial acetic acid. A slight excess of acetic acid was added and the mixture was refluxed for ninety-eight hours. No more carbon dioxide was evolved and a test sample of the mixture dissolved in sodium hydroxide. The solution gave no metallic mercury when tested with a clean copper wire. The precipitate which had formed was collected on a filter and washed. It was dried at 105°. The yield of anhydro-8-hydroxymercuri-1-naphthoic acid was 84.6 g. (97.6% of the theoretical).

Anal. Calcd. for $C_{11}H_6O_2Hg$: Hg, 54.1. Found: Hg, 52.2, 53.7, 53.4.

---

[2] Graebe and Gfeller, *Ber.*, 25, 652 (1892).

Attempts to purify the anhydro compound were unsuccessful. It is insoluble in organic solvents. Acidification of its alkaline solution gives a gelatinous precipitate which is very difficult to wash and dry.

Sodium 8-hydroxymercuri-1-naphthoate was obtained by evaporating a strongly alkaline solution of the anhydro compound until large white crystals separated on slowly cooling. The crystals were washed with alcohol and dried at 50°.

Anal. Calcd. for $C_{11}H_7O_3HgNa$: Hg, 48.8. Pound: Hg, 48.1, 48.2.

The salt is readily soluble in water containing a little sodium hydroxide. It is readily hydrolyzed by pure water.

A hot solution of 46.5 g. of the sodium salt in 500 cc. of water was treated with 200 cc. of concd. hydrochloric acid and boiled for three hours. The **1-naphthoic** acid obtained was crystallized from hot alcohol; m. p. 162°; wt. 17 g. (87% yield). 1-Naphthoic acid was also prepared from the anhydro compound and hydrochloric acid; yield, 90%.

The Mercuration of **3-Nitronaphthalic** Acid—The anhydride was prepared from naphthalic acid in concd. sulfuric acid solution and solid potassium nitrate at 10–15°.[3] The product after removing impurities with hot toluene (4 cc. per g.) melted at 247–250"; yield, 300 g. from 298 g. of naphthalic anhydride (81% of the theoretical). The pure anhydride was obtained by crystallization from nitrobenzene (225 cc. per 100 g.) or glacial acetic acid (3 liters per 100 g.); m. p. 252–253°.

The anhydride was mercurated in the usual way. From 304 g. of 3-nitronaphthalic anhydride was obtained 505 g. of a mixture of anhydro-3-nitro-8-hydroxymercuri-1-naphthoic acid and the corresponding 6-nitro compound (97% of the theoretical). It is a creamy white powder.

Anal. Calcd. for $C_{11}H_5O_4NHg$: Hg, 48.2. Found: Hg, 48.3.

No way was found for purifying the product.

Sodium 3-nitro-8-hydroxymercuri-1-naphthoate was prepared by dissolving the crude mercurated product in a slight excess of sodium hydroxide and evaporating until crystals separated on cooling. The salt is much less soluble than the corresponding naphthoic compound. It forms large yellow crystals.

Anal. Calcd. for $C_{11}H_6O_5NHgNa$: Hg, 44.0. Found: Hg, 43.3, 43.8.

Sodium **8-Mercuribis-3-nitro-1-naphthoate** ("No. 93").—Starting with 480 g. of naphthalic acid, 70 g. of the desired sodium salt was obtained. The conversion of the hydroxymercuri compound to the mercuri*bis* compound was effected by refluxing with an excess of alcoholic sodium iodide. The product was free of iodides.

Anal. Calcd. for $C_{22}H_{10}O_8N_2HgNa_2$: Hg, 29.6. Found: Hg, 28.9.

Structure of the Mercuration Products.—The mixture of mercury compounds obtained from 3-nitronaphthalic acid was treated with hydrochloric acid for two hours. From 200 g. was obtained 103 g. of a light cream-colored powder (98% of the theoretical). This was dissolved in 1.5 liters of hot glacial acetic acid, filtered from a slight residue and cooled. Fine needle crystals separated, m. p. 265.5°; yield, 65.8 g. (63% of amount theoretically obtainable from the mercurated material). This was nearly pure 3-nitro-1-naphthoic acid. In another run the yield was 60.5 g., m. p. 269–270°. The highest melting point obtained for this acid by repeated crystallization from alcohol was 270.5–271.5°. With smaller runs slightly higher yields were obtained. All the mother liquors were saved for the recovery of 6-nitro-1-naphthoic acid.

Anal. Calcd. for $C_{11}H_7O_4N$: C, 60.8; H, 3.23; N, 6.45. Found: C, 60.5, 60.7; H, 3.09, 3.32; N, 6.39.

---

[3] Graebe and Briones, *Ann.*, 327, 84 (1903).

Ethyl 3-nitro-1-naphthoate was prepared from the acid by thionyl chloride and absolute ethyl alcohol. It formed yellow needles from alcohol and rhombic plates from ethyl acetate, m. p. 87.5–88.5°. The ester did not react with ammonia in water, in alcohol or when fused.

3-Nitro-1-naphthamide was prepared from the acid with thionyl chloride and ammonia, m. p. 264–269°. The amide is difficultly soluble in ethyl alcohol, insoluble in water, difficultly soluble in xylene, slightly soluble in carbon tetrachloride, acetone and benzene, and very soluble in glacial acetic acid. Several crystallizations from ethyl alcohol raised the melting point to 280–280.8°.

Anal. Calcd. for $C_{11}H_8O_3N_2$: N, 12.96. Found: Hg, 12.9.

When 3-nitro-1-naphthamide was treated with sodium hypochlorite or sodium hypobromite, the expected 3-nitro-1-aminonaphthalene was ***not*** obtained.* The products were apparently halogen derivatives of this substance. This behavior was in marked contrast to that of the 6-nitro-1-naphthamide, which gave 6-nitro-1-aminonaphthalene without any complications.

The hydrochloride of 3-amino-1-naphthoic acid was obtained in 90% yield by reducing the nitro compound with sodium hydrosulfite. The preparation of the free amine proved to be very difficult. It was obtained from the hydrochloride in small yields as straw-colored aggregates of needle crystals, m. p. 181–182°.

Anal. (of impure material, m. p. 170–172°). Calcd. for $C_{11}H_9O_2N$: N, 7.49. Pound: N, 7.83.

3-Acetamino-1-naphthoic acid was prepared from the amine and acetic anhydride as cream-colored needles, m. p. 254–255°. The hydrochloride was converted into the known[6] 3-hydroxy-1-naphthoic acid by diazotizing at 0° and pouring into boiling 30% copper sulfate solution. The product extracted with ether melted at about 210°. Two crystallizations from water gave yellow needles, m. p. 228–231°. Purification by sublimation raised the melting point to 239–241° (Royle and Schedler give 242–243°). Solutions in ether, in aqueous alcohol and in benzene have a blue-purple fluorescence. It gives a deep red-brown color with ferric chloride.

The acetyl derivative of 3-hydroxy-1-naphthoic acid was prepared in the usual way, m. p. 172° (Royle and Schedler give 169–170°).

The mother liquors from the crystallization of the mixed acids from 200 g. of the mercury product from 3-nitronaphthalic acid were evaporated to dryness on the steam-bath under reduced pressure; wt., 35 g. This material was treated with 250 cc. of absolute alcohol, saturated with dry hydrogen chloride, refluxed for a short time, allowed to stand for several days, cooled and filtered. The product consisted of lumps of white crystals, m. p. 105–107°; wt., 13.7 g. This was fairly pure ethyl 6-nitro-1-naphthoate. Further crystallization from ethyl alcohol raised the melting point to 111.5–112°. Evaporation of the alcoholic mother liquors gave a mixture of esters of the 3- and 6-nitro compounds which was not further separated.

The ester of 6-nitro-1-naphthoic acid was hydrolyzed to give an acid melting at 207–220°. Several crystallizations from glacial acetic acid raised the melting point to 224–225.5°. Another crystallization from toluene gave the melting point 225–226°. Sublimation gave the highest melting point obtained, 227–227.5°. This was 6-nitro-1-naphthoic acid.

Anal. Calcd. for $C_{13}H_{11}O_4N$: C, 60.8; H, 3.23; N, 6.45. Found: C, 60.7; H, 3.31; N, 6.66.

[5] Royle and Schedler, *J. Chem. Soc.*, **123**, 1642 (1923).

6-Nitro-1-naphthamide was prepared in the usual way. Two crystallizations from alcohol gave fine cream-colored needles, m. p. 216.5".

Anal. Calcd. for $C_{10}H_8O_2N$: N, 12.96. Found: N, 13.0.

Treatment with sodium hypochlorite gave **6-nitro-1-aminonaphthalene,** m. p. 172–173° (Veselý and Dvořák, ref. 4, give 167°).

6-Nitro-1-acetaminonaphthalene was prepared, m. p. 237–238° (Veselý and Dvořák give 232–233').

Reduction of the nitro acid by sodium hydrosulfite in 6 N sodium hydroxide gave the known[6] **6-amino-1-naphthoic** acid, m. p. 205.5–206.5° (Harrison and Royle give 203°). An alcoholic solution gives a green fluorescence.

6-Acetamino-1-naphthoic acid was prepared in the usual way. It forms light yellow needles from dilute acetic acid, m. p. 253° (Harrison and Royle give 170–172°).

Mercuration **of 4-Nitro-1-Naphthalic** Acid.—Acenaphthene was nitrated and the nitro compound was oxidized to give 4-nitro-1-naphthoic anhydride.' From 91 g. of 75% acenaphthene was obtained 63 g. of 4-nitro-1-naphthalic anhydride, m. p. 220–224°. Purification through the calcium salt and crystallization from glacial acetic acid raised the melting point to 230'. The anhydride was mercurated in the usual way. The time of refluxing was fifty hours. From 50 g. of the anhydride were obtained 79.7 g. of mercurated product, mainly **anhydro-4-nitro-8-hydroxymercuri-1-naphthoic** acid and a little of the 5-nitro compound.

Anal. Calcd. for $C_{11}H_5O_4NHg$: Hg, 48.2. Found: Hg, 48.4, 48.7.

Treatment of this mixture with hydrochloric acid gave a 95% yield of mixed acids, m. p. 210–218°. Ten g. of the mixed acids on several crystallizations from glacial acetic acid gave 7.1 g. of 4-nitro-1-naphthoic acid, m. p. 225–226'. Repeated attempts to obtain any other acid from the mother liquors failed. The mixed acids were esterified by treatment with thionyl chloride and ethyl alcohol. It was not possible to separate any ester other than the 4-nitro compound.

Ethyl 4-nitro-1-naphthoate and the corresponding methyl ester were prepared from the pure acid; m. p. of ethyl ester, 57–58'; methyl ester, 107.5–108.5°.

The mother liquors from a batch of 4-nitro-1-naphthoic acid were evaporated to dryness; wt., 4 g.; m. p. 216–222°. This was converted to the mixed amides by thionyl chloride and ammonia. After repeated fractionation from dilute ethyl alcohol the insoluble end gave 0.6 g. of **5-nitro-1-naphthamide,** m. p. 230–232°.[8] This corresponded to about 4% of the original mixed acids. A known sample of the 5-nitro-1-naphthamide was prepared from 5-nitro-1-naphthoic acid.[9] A sample of this amide melting at 233–235° was mixed with the amide from the mixed acids. The mixture melted at 230–233°. Recrystallized from benzene the amide melts at 235–236°.

Summary

1. Naphthalic, 3-nitronaphthalic and 4-nitronaphthalic acids were treated with mercuric acetate. In each case one carboxyl was replaced by mercury. With the nitro acids the replacement was mainly in the ring not containing the nitro group.

2. The following mercury compounds were prepared: anhydro-8-

---

CALYCANTHINE. I. THE ISOLATION OF CALYCANTHINE FROM MERATIA PRAECOX

BY RICHARD H. F. MANSKE[1]

RECEIVED JANUARY 17, 1929 PUBLISHED JUNE 5, 1929

The first chemical investigation of the alkaloid, calycanthine, was made by Gordin.[2] He obtained it from Calycanthus glaucus, Willd., and described a convenient procedure for its isolation. In later papers by the same author[3] we are informed that a second lot of seeds, presumably identical with the first, yielded only an isomeric base, namely, isocalycanthine.

Recently a contribution by Spath and Stroh[4] elucidated some obscure points in Gordin's work and established the empirical formula $C_{22}H_{28}N_4$, although the present author is of the belief that $C_{22}H_{26}N_4$ is not entirely excluded.

It was decided to subject the alkaloid to a more rigorous examination and, if possible, to elucidate the relation between calycanthine and isocalycanthine, if indeed the latter has an existence. It may be mentioned that botanists do not appear to be in complete accord in regard to the nomenclature of the various species of Calycanthus, but it may be taken for granted that Calycanthus floridus L., and Calycanthus *fertilis*, Walt. (C. glaucus, Willd.) are two distinct species. From the former the author has isolated about 1.2% of an alkaloid which appears to be identical in all respects with Gordin's calycanthine and also with the base examined by Spath and Stroh.[4] No evidence of the presence of isocalycanthine has been forthcoming although other bases appear to be present in small amounts. The possibility is not excluded that Gordin's second lot of seeds in reality consisted of C. *fertilis*, whereas the first was C. floridus. When the former seeds become available an attempt will be made to determine this point.

The author was impressed by the fact that so far calycanthine had been found only in plants native to America. Such would be a unique fact, since all other alkaloids found in American plants have been found elsewhere.

The natural order *Calycanthaceae* embraces only two well-defined American and a few Asiatic species, and it was thought that an examination of Asiatic species might reveal the presence of calycanthine or a closely related alkaloid. Actually, it was found that Meratia praecox, Rehd. and *Wils.*, contained mare than 2.5% of calycanthine, identical in all respects with the alkaloid from C. *floridus*. In addition, two other bases were found in minute amount.

The following description was kindly furnished by Mr. John Murray of the Marsh Botanical Garden, Yale University.

Meratia praecox, *Rehd.* and *Wils.* (order Calycanthaceae). Meratia species are often united with *Calycanthus*, but differ in their scaly winter-buds, the yellow flowers appearing long before the leaves on short scaly stalks from axillary buds on branches of the previous year, and in the 5 or 6 stamens. M. praecox is a deciduous shrub growing to a height of 3 meters. The leaves are elliptic-ovate to ovate-lanceolate, 7–15 cm. long, acuminate, bright green and lustrous above, and glabrous beneath. The flowers are about 2.5 cm. broad, very fragrant, the outer sepals yellow, the inner striped purplish-brown; fruit ellipsoid, about 4 cm. long, inclosing several dark brown seeds with a very tough and hard epicarp. Cultivated in China and Japan as an ornamental shrub, and introduced to America in 1766.

Experimental

In a preliminary extraction 50 g. of seeds was ground to a coarse powder and extracted in a Soxhlet extractor with the solvents in the order named.

Solvent	Petroleum ether	Chloroform	Methanol (abs.)	
% of extract	22.7	0.9	18.8	Total, 52.4
Alkaloid isolated	2.6			

The methanol extract was acidified with dilute hydrochloric acid, largely diluted with water, the solution basified and the precipitated alkaloid thoroughly washed with water. The portion soluble in acetone weighed 1.3 g. The petroleum ether and the chloroform extracts contained a further small amount of base.

For the purpose of obtaining the alkaloid in quantity, four kilos of seeds, ground as finely as practicable, was extracted completely with a mixture of 2 volumes of chloroform and 8 volumes of petroleum ether (40–60°). This removed all of the fat, sterols, waxes and a trace of alkaloid.[5] The residue was freed of solvent and extracted in a

---

[5] The examination of the fat has yielded thus far a large amount of unsaponifiable matter, together with an unsaturated acid, presumably oleic, which on hydrogenation yielded stearic acid. It is hoped that the result of a further investigation of this extract, together with that from C. *floridus*, will form the subject of an early communication.

continuous apparatus with absolute methanol. The extract consisted of a dark colored sirupy mass, which was almost completely soluble, but for a small amount of amorphous and gelatinous material, in water made just acid with hydrochloric acid. Filtration offered some difficulty, but treatment of the warm solution with norite tended to coagulate some of the colloidal material and filtration through a layer of norite in a large funnel became possible. The dark brown though clear solution was cautiously basified, and by seeding and scraping the walls of the vessel the crude base was obtained crystalline at once. After a short time it was filtered off, washed with much water and dried. Two recrystallizations from acetone, by the cautious addition of water, yielded **70** g. of pure alkaloid, melting alone or admixed with a specimen from *C. floridus,* at 219–220°.[6] **A** specimen dehydrated by means of potassium carbonate in chloroform melted sharply at 245°. Admixture with a specimen similarly prepared from *C. floridus* did not depress the melting point. Comparison of crystals of the alkaloid from the two sources under the petrographic microscope failed to show any differences.

Examination of the Aqueous Filtrate from the Base.—A small portion of the aqueous alkaline filtrate was acidified with acetic acid, extracted several times with ether, to remove coloring matter, the ether removed by warming, the solution treated with phenylhydrazine and heated on a steam-bath for a short time. The voluminous crystalline precipitate of an osazone was filtered off and washed first with water and then with acetone. It was recrystallized from 95% alcohol and then consisted of the characteristic crystals of glucosazone, which alone or admixed with a genuine specimen melted at **207–208°.**

Isolation of Two Other Bases.—Repeated attempts to isolate other bases by extracting the aqueous solution with immiscible solvents resulted in such a concentration of impurities that only tarry products could be obtained. The following abortive attempt to obtain crystalline water-soluble products resulted in isolating minute amounts of two other alkaloids.

The remaining basic filtrate was treated with a stream of carbon dioxide until neutral and allowed to stand for four weeks. The clear, supernatant liquid was decanted from some residue which had separated and evaporated to a thick sirup under reduced pressure. The latter was extracted once with a liter of 95% alcohol and the solution evaporated. The residue was dissolved in water and sugars were removed by fermentation with yeast. The filtered solution was clarified with basic lead acetate, excess lead was removed by a stream of hydrogen sulfide and the filtrate evaporated to a thick sirup *in vacuo.* The residue was taken up in 95% alcohol, the solution evaporated to dryness and extracted with absolute methanol. This extract was evaporated to a sirup and poured into a large volume of acetone. The acetone solution was evaporated to a thick sirup and extracted repeatedly with boiling ether. The combined ether extracts on being evaporated yielded about **0.5** g. of colorless prismatic crystals, which after one recrystallization from acetone melted at **197–198**" with a slight darkening.

This base, which will be designated a-alkaloid, is sparingly soluble in ether, acetone or water, but readily soluble in dilute acids. The absence of phenolic hydroxyl groups is proved by the insolubility in alkali. A test for nitrogen was strongly positive. With Ehrlich's reagent it gives a beautiful red color, and on heating in a glass tube to a high temperature the odor of indoles becomes apparent.

The mother liquor from the a-alkaloid, from which no more of this base could be obtained, was converted to the hydrochloride and evaporated to a thick sirup. This was extracted several times with boiling chloroform and the extract evaporated. The residue was triturated with a little acetone and then readily crystallized to a magma of microscopic needles. This was filtered off, washed with acetone and recrystallized by

---

[6] Melting points are corrected.

adding acetone to a concentrated alcoholic solution. As thus obtained the hydrochloride melts at 219–220°. Calycanthine hydrochloride melts at 217°, but a mixture of the two began to sinter at 205° and melted completely at 208°. The free base, which will be designated β-alkaloid, was only obtained as a colorless oil, readily soluble in ether. Seeding with a-alkaloid did not induce crystallization. This base also gives a red color with Ehrlich's reagent.

Isolation of Xylose from the Epicarp of the Seeds.—The residue after thorough extraction consisted of the inner fleshy portion of the seed together with the still tough and dark brown epicarp in large flat pieces. By virtue of a difference in density, the two parts could be easily separated by a process of flotation with water, the epicarp sinking. When most of the fleshy portions had been removed by this means, the residue of hulls was hydrolyzed with 2% boiling sulfuric acid for three hours, neutralized with calcium carbonate, filtered, the solution evaporated to a thick sirup *in vacuo* and the latter extracted once with a large volume of absolute methanol. The extract, on evaporation, yielded about 6% of almost colorless crystals which, after two recrystallizations, melted at 150° alone or admixed with a genuine specimen of *l*-xylose. It may here be mentioned that the epicarp from *C. floridus* under similar treatment yielded the same sugar in approximately the same amount.

Summary

1. The alkaloid, calycanthine, has been isolated from *Meratia praecox*, Rehd. and *Wils.*, a shrub native to Asia. Its identity with the alkaloid from *Calycanthus floridus*, L., has been established.

2. Two other alkaloids were isolated in small amounts, but the investigation of these is delayed until more material is available.

3. The existence of glucose, or a sugar which gives glycosazone, in the seeds has been shown.

4. Xylose was isolated from the epicarp of the seeds by hydrolysis with dilute sulfuric acid.

CHARACTERISTICS OF THE NON-EXPLOSIVE OXIDATION OF PROPANE AND THE BUTANES[1]

By Robert N. Pease[2]

Received January 21, 1929 Published June 5, 1929

The reactions between hydrocarbon vapors and oxygen are of interest for a number of different reasons. Information as to their nature is of

---

[1] This paper contains results obtained in an investigation on "Catalytic Methods Applied to Petroleum Hydrocarbons" listed as Project No. 7 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the cohperation of the Central Petroleum Committee of the National Research Council. Professor Hugh S. Taylor of Princeton University is Director of Project No. 7.

[2] American Petroleum Institute Research Associate, Princeton University.

importance in connection with the utilization of hydrocarbons, especially in connection with their combustion; and from the purely chemical standpoint the mechanism of these reactions demands investigation. Other investigators have studied the oxidation of methane, ethane, ethylene, acetylene and some of the higher paraffins. We have chosen to investigate the oxidation of the intermediate paraffins, propane and the butanes. The investigation has been comprehensive rather than exhaustive. In particular, the nature of the liquid products has been disregarded and conclusions are based entirely on the analyses of gaseous reactants and products.

Apparatus and Procedure

The flow method has been used. Known volumes of reactants at known rates were passed into a reaction tube and the corresponding off-gas collected and analyzed. The gases passed from cylinders through calibrated flow meters (equipped with overflows to maintain constant head) and calcium chloride drying tubes, into $^1/_4$-inch pyrex tubes which extended into the electric furnace used for heating. These tubes were joined within the furnace to a short length of 2-mm. capillary which served as a mixing chamber, and this in turn was joined to the reaction tube. The gases then issued through a length of 2-mm. capillary to which was sealed a three-way stopcock, by means of which communication could be made either with the air or with the collecting system. The latter consisted of a trap of 5-cc. capacity and a 500-cc. mercury aspirator bottle. This was a pyrex flask to which had been sealed a three-way stopcock. The whole of the off-gas was collected in this bottle during a measured time interval, the rate of inflow of reactant gases being controlled by careful regulation of the rate of outflow of mercury from the bottle. During collection of the off-gas, the trap was cooled in carbon dioxide-ether mixture to remove liquid products. Condensable gases were, of course, trapped simultaneously. These were subsequently evaporated by allowing the trap to warm up to room temperature. The gases were then mixed by expansion and compression and submitted to analysis. After analysis the total volume of off-gas was measured and the volumes of the individuals were calculated. All gas volumes were reduced to 25° and 760 mm.

Analysis was carried out with a Williams apparatus to which had been added a copper oxide combustion tube. The confining fluid was water. Carbon dioxide was determined by absorption in potassium hydroxide solution, unsaturated hydrocarbons in dilute bromine water (less than 0.2% of bromine) and oxygen in alkaline pyrogallol. Carbon monoxide and hydrogen were obtained by oxidation with copper oxide at about 300° followed by absorption of carbon dioxide. The saturated hydrocarbons were burned over copper oxide at about 550°, with subsequent absorption of carbon dioxide.

A chromel-wire-wound furnace jacketed with magnesia pipe covering was used. Its interior dimensions were 30 inches length and 4 inches diameter. The wire was wound on a piece of stovepipe covered with asbestos paper. The ends of the furnace were packed with loose magnesia, the central third constituting the actual heating space. Temperatures were measured with a single-junction chromel–alumel thermocouple, the hot junction being at the center of the furnace.

The gases were obtained from cylinders. Their compositions were as follows

Oxygen—O_2, 98.5%; "CH_4," 1.0%; N_2, 0.5%
Nitrogen—N_2, 99.0%; "CH_4," 0.5%; O_2, 0.5%
Carbon dioxide—CO_2, 100.0%
Hydrogen—H_2, 98.5%; "CH_4," 1.0%; O_2, 0.5%

Methane—CH_4, 95.5%; N_2, 4.5%
Propane—C_3H_8, 98.5%; "CH_4," 1.0%; N_2, 0.5%
n-Butane—C_4H_{10}, 99.0%; ["CH_4," (-1.0%)]; N_2, 2.0%
*Iso*butane—C_4H_{10}, 95.5%; "CH_4," 2.0%; O_2, 1.0%; N_2, 1.0%

The boiling points of the normal and isobutane were nearly constant and close to −1 and −10°, respectively, thus further ensuring their purity. These and the other hydrocarbons were originally obtained from natural gas.

The experimental procedure was as follows The furnace was brought to temperature and the gases were allowed to flow through the system for one to two hours to ensure steady-state conditions. The off-gas was then sent through the trap and connecting tubes for one minute. The carbon dioxide–ether mixture was applied to the trap (which was shut off at both ends), and one minute later connection was made through the trap with the gas collector. The whole of the off-gas was then collected for a measured time interval. At the end of this time the trap was warmed to room temperature and the condensed gases were added to the main body, which was mixed and analyzed. The flow rates and sampling times were so adjusted that in all experiments **400** cc. of gas was introduced while the sample was being collected.

Nature of Experimental Data and Interpretation

Analytical Data.—The experimental results have been expressed as follows. The gas absorbed in caustic has been called carbon dioxide. It undoubtedly consists in part of formaldehyde and probably volatile alcohols and acids. Gas absorbed by bromine water has been called simply unsaturated compounds. These are doubtless chiefly olefins. The oxygen, carbon monoxide and hydrogen determinations are unequivocal. The data on saturated hydrocarbons have been expressed in terms of the principal hydrocarbon and methane. This is, of course, arbitrary. Fortunately, however, analyses of the off-gas from the majority of the experiments indicated that the hydrocarbon introduced was the chief one present—no large quantity of new hydrocarbon had resulted from the oxidation. The same holds for the cylinder gases.

We have then to compare the volumes of carbon dioxide, unsaturates, oxygen, carbon monoxide, hydrogen, methane and original hydrocarbon in the off-gas with the volumes of oxygen and hydrocarbon introduced. We find that in general the principal gaseous products of reaction are carbon monoxide and unsaturates, sometimes one and sometimes the other predominating. Methane appears in increasing quantities as the furnace temperature is raised. Hydrogen and carbon dioxide, however, are only rarely important products.

The appearance of unsaturates, methane and hydrogen, all in amounts increasing with the furnace temperature, recalls the dissociation reactions of hydrocarbons, for example

$$C_3H_8 \longrightarrow C_2H_4 + CH_4$$
$$C_3H_8 \longrightarrow C_3H_6 + H_2$$

In most experiments, however, furnace temperatures were far below those required to produce appreciable dissociation by themselves; but off-setting this there is the exothermicity of the oxidation reactions. (The question of temperature is discussed below.) We choose therefore to regard the hydrogen and methane as products of dissociation of the hydrocarbon and to associate with them equivalent quantities of unsaturates. We therefore account for a part of the hydrocarbon reacting in terms of thermal dissociation, designating this as "Reaction I. Unsaturates by Dissociation." The amount of this type of reaction is given by the sum of the volumes of methane and hydrogen.

Thermal dissociation as thus evaluated only accounts for a portion of the unsaturates. The remainder must obviously be a product of oxidation. We cannot say what reactions are involved here, but we suggest that they be regarded as oxidations of those portions of the molecules which would be split off in dissociation leaving olefins. Thus, for example

$$\begin{aligned}
C_4H_{10} &\longrightarrow C_4H_8 + H_2 &&\longrightarrow C_4H_8 + H_2O\\
C_4H_{10} &\longrightarrow C_3H_6 + CH_4 &&\longrightarrow C_3H_6 + CH_3OH\\
& &&\longrightarrow C_3H_6 + HCHO, \text{ etc.}\\
C_4H_{10} &\longrightarrow C_2H_4 + C_2H_6 &&\longrightarrow C_2H_4 + C_2H_5OH\\
& &&\longrightarrow C_2H_4 + CH_3CHO, \text{ etc.}
\end{aligned}$$

These then are products of incipient dissociation completed by oxidation of the more saturated product of dissociation. We designate these reactions as of the type "Reaction II. Unsaturates by Oxidation." The amount of this type of reaction is given by the total of unsaturates less the sum of the volumes of methane and hydrogen.

Finally there remains that portion of the reacting hydrocarbon over and above the equivalent of unsaturates produced. In accounting for this we note that in those cases (low temperatures, empty reaction tube) in which little unsaturates, methane and hydrogen are formed, carbon monoxide is produced in amount roughly corresponding to the volume of hydrocarbon consumed, two volumes of oxygen disappearing simultaneously. This appears to be indicative of the type of reaction which Edgar and Pope[3] have found in the case of the higher hydrocarbons and of which an example would be

$$\begin{aligned}
C_3H_8 + O_2 &\longrightarrow C_2H_5CHO + H_2O\\
C_2H_5CHO + O_2 &\longrightarrow CO + H_2O + CH_3CHO, \text{ etc.}
\end{aligned}$$

In any event we take care of the hydrocarbon unaccounted for in Reactions I and II by a third type, an oxidation which is designated "Reaction III. Aldehyde Reaction," The amount of this is obtained by subtracting the volume of unsaturates produced from the volume of hydrocarbon consumed.

We analyze our results then in terms of three reaction types of which the following would be examples: Type I, Unsaturates by Dissociation, *e.* g., $C_3H_8 \longrightarrow C_3H_6 + H_2$; Type II, Unsaturates by Oxidation, *e.* g.,

---

[3] Edgar and Pope, Swampscott Meeting, 1928.

$C_3H_8 + \frac{1}{2}O_2 \longrightarrow C_3H_6 + H_2O$; Type III, Aldehyde Reaction, e. g., $C_3H_8 + 2O_2 \longrightarrow CO(+ CH_3CHO + 2H_2O)$. This establishes a basis for the comparisons of the effects of altering the variables. We do not insist that the possibilities are exhausted by the above types or that the method of calculating the relative amounts is infallible. Methane and hydrogen may well be formed in part by dissociation of intermediate products; the unsaturates may not represent olefins exclusively. Especially, the arbitrary method of representing the hydrocarbons as consisting only of the original and methane doubtless introduces errors. We have, however, a definite basis for the presentation and discussion of the data and we are inclined to think that the scheme and its application are not wide of the mark.

Temperature.—With respect to the reported temperatures, the following is to be kept in mind. These reactions are as a whole exothermic and take place rapidly. Exposure times are of the order of a few seconds. The gases are, therefore, unquestionably at a higher temperature than the surroundings. However, the whole question of temperature under such conditions is decidedly vague. Newly-formed molecules are necessarily highly energized. No matter what the total reaction rate may be, the unchanged molecules with which these product molecules first come in contact are subjected to far more extreme conditions than would correspond to many hundreds of degrees general rise in temperature. Only under such conditions that every newly-formed molecule made many wall collisions before meeting an unchanged molecule would anything corresponding to an isothermal state be set up. In our preliminary work much time was spent in attempting to adjust temperatures down the reaction tube by using a number of independent heating elements. Arrangements were made for determining temperatures at various positions. It was always found, however, that if reaction took place at all, the thermocouple at the entrance to the reaction tube registered from 25 to 50° above that somewhat farther down. We came, therefore, to the conclusion that a better arrangement was simply to place the reaction tube in a constant-temperature bath—the furnace—over its entire length, and to measure and record its temperature. This is at least definite and should be reproducible. The reaction then takes place in a manner that is partly adiabatic and partly isothermal. Since the gases were heated prior to mixing, the recorded temperatures are also the initial temperatures of the reaction mixture.

Heating Time.—Some uncertainty exists as to the exact times of heating in these experiments. When there is no change in the number of molecules on reaction, the temperature is known and constant and the flow is uniform across the reaction tube, the heating time is obtained by dividing the volume of the tube by the flow rate corrected to the temperature and pressure at which reaction is occurring. However, in these reactions, the number of molecules changes on reaction in so far as dissociation is a factor and the actual temperature of the reacting mixture is uncertain. Instead of trying to estimate these effects in separate experiments, and adjusting the flow rate to give a uniform contact time, we have been content to maintain a constant flow rate (measured at room temperature and pressure) throughout any one series of experiments. The average heating time in any series has then been taken as the ideal heating time at a temperature of 472° (745° A., which is $2\frac{1}{2}$ times the average room temperature, 298°). As experiments were conducted over the range 300–625°, this temperature is an average for all experiments. Room temperature might as well have been the basis of calculation, but the above gives more nearly the actual heating times.

The larger empty reaction tube had a volume of 21.6 cc. and the total flow rate at 25° and 760 mm. was 40.0 cc./min. The average heating time was therefore

$$\frac{21.6}{40.0 \times \frac{745}{298}} \times 60 = 13.0 \text{ seconds}$$

The *packed* tube had a volume of 15.8 cc., and the total flow rate was 30.0 cc./min. The average heating time was 12.6 seconds. The results of experiments in the two large tubes are therefore directly comparable as to heating time.

The smaller, empty tube had a volume of 2.6 cc. and the flow rate was 40.0 cc./min. The average heating time was 1.6 seconds. Heating times in this tube are therefore approximately one-eighth as long as in the larger tubes.

The large, empty tube was 1.65 cm. in internal diameter, 11 cm. long with 2-mm. walls. The small empty tube was 0.5 cm. in internal diameter, 10 cm. long with 1-mm. walls. The large, packed tube was 2 cm. in internal diameter, 11 cm. long with 2-mm. walls. It contained 46 g. of broken glass of 6–20 mesh. The glass surface in this tube was 10 to 15 times that in the empty tube.

Results and Discussion

Wall Action.—The first point to be settled was, of course, the influence of the walls of the reaction tube on the reaction. The result was unexpected. In order to determine whether or not the wall material (pyrex glass) catalyzed the reaction, a comparison was made between reactions taking place in an empty tube and in one packed with broken pyrex glass. (The tubes were cleaned with hot concentrated nitric acid and rinsed with water before use.) The result of the comparison was that whereas in the empty tube reaction between oxygen and propane was complete at 375°, in the packed tube there was no reaction below 500°. The glass packing therefore *strongly suppresses* reaction rather than accelerates it, and we must conclude that the walls have a predominantly negative rather than positive catalytic effect. This is in harmony with the observations of Hinshelwood and Thompson on the hydrogen–oxygen combination.[4] Related observations are those of Gautier and Hélier[5] on the explosibility of hydrogen-oxygen mixtures in a tube packed with porous porcelain.

This inhibitory influence of wall surface undoubtedly has to do with the more efficient transfer of energy from the reaction mixture to the surroundings. On the older view the initial temperature is more nearly maintained in presence of the glass packing; on the newer view excited molecules of product are de-activated by the walls instead of transferring excitation to fresh molecules of reactant. We will return to this point later.

There was still the possibility that in addition to this inhibitory influence of wall, which was regarded as physical in nature, the wall material was capable of exerting a positive catalytic effect on the oxidation. If this

were the case it should be possible to poison the active surface and obtain a further reduction in the amount of reaction. Poisoning the surface amounts to covering it with some material which is itself inactive. Alkali halides suggested themselves as substances which might fulfil this object. Accordingly the tubes were rinsed out with **20%** potassium chloride solution, drained and again put to use. It was found that there was no alteration in the amount of reaction of oxygen and propane in the empty tube. In the packed, "coated" tube, however, the temperature at which reaction began was raised from around **500** to 575°, and reaction was still incomplete at 625°, whereas prior to coating it had been nearly complete at 550°. We have then to deal not only with an inhibitory action of the walls but also with a positive catalytic effect which, however, can be markedly decreased (and possibly eliminated) by poisoning. In the large, empty tube, on the other hand, we are safe in assuming that the observed reaction is almost exclusively homogeneous.

We will designate the reaction taking place in the large, empty, coated tube as the "free reaction," and that in the large, packed, coated tube as the "inhibited reaction." It is of interest to consider these two in some detail. Because it is in some respects the simpler and more normal of the two, the inhibited reaction will be first discussed.

The Inhibited Reaction

Propane.—Data on the reaction between propane and oxygen in the packed, coated tube are given in Table I. (In all these experiments close to **400** cc. of gas was introduced while the sample of off-gas was being collected, the actual amount being, of course, used in the calculations. For the sake of clearness, the amounts in round numbers are entered in

the tables under "Gas in." In addition, the temperature, volumes in cc. of hydrocarbon and oxygen reacting and of gaseous products formed and the percentages of total hydrocarbon introduced which have reacted according to the reaction types in which the results have been expressed are given.)

The first point to be noted is that approximately the same fraction of propane reacts whether the initial propane–oxygen ratio is 3 to 1 or 1 to 3. The conversion of propane is therefore approximately first order with respect to its own concentration. Since a large proportion of what reacts appears as dissociation products, one might suspect that the chief reaction was a purely thermal dissociation. When, however, nitrogen is substituted for oxygen as diluent, it is found that only one-third to one-half as much propane reacts. Hence it is clear that the dissociation has been for the most part excited by the simultaneous oxidation reactions. It is nevertheless significant that one has to approach conditions conducive to thermal dissociation before any reaction occurs. The oxidation reaction is evidently contingent on the possibility of dissociation, and at the same time promotes dissociation. It is as though the underlying reaction were still the unimolecular dissociation of the hydrocarbon but that the degree of activation requisite for reaction were lowered.

It is to be noted that little if any carbon monoxide, carbon dioxide or hydrogen is formed. Since less hydrogen is obtained from the oxidation than from the dissociation, it is evident that some has been burnt—under circumstances, it may be added, such that little hydrogen alone would have reacted. There is fairly clear indication here of removal of hydrogen directly from the hydrocarbon molecule by oxidation. This was given as an example of one of the type reactions, and for this reason. The absence of carbon monoxide and carbon dioxide shows that such carbon-oxygen linkages as have been formed have issued in liquid products. The marked difference in this respect between experiments before and after coating with potassium chloride will be noted.

It is a peculiarity, attributable to the unimolecular character of the reaction, that more oxygen is consumed from the mixture which is deficient in oxygen. It should be noted also that the mixtures richer in oxygen, although the more explosible because of their greater potential energy content, are under these conditions the less reactive.

The Free Reaction

Propane.—We turn now to a consideration of the very different type of reaction between propane and oxygen which takes place first at 300–400° (as compared to 575–600°) in our larger, empty tube. Carbon monoxide is now the principal gaseous product. The reaction is of a highly spontaneous character and gives every evidence of being of the chain type. Results are presented in Table II.

[a] In these and many other experiments with excess of oxygen, the saturated hydrocarbon in the off-gas averaged slightly higher in carbon than the original hydrocarbon. There would thus be no indication of the presence of methane. Small quantities of saturated hydrocarbons of higher molecular weight than the original appear to be formed under these conditions. The discrepancy never exceeded a few cc. and no attempt has been made to allow for it.

The reaction does not follow any conventional scheme. It starts abruptly within a 25° temperature interval, and, in the case of the $3C_3H_8{:}1O_2$ and $2C_3H_8{:}2O_2$ mixtures, runs immediately to complete consumption of the oxygen. Somewhere between $C_3H_8{:}O_2$ ratios of 2:2 and 1:3 there is another abrupt change such that at the lower propane concentrations only one-half to one-fourth of the oxygen reacts, although the start of reaction as the temperature is raised is still abrupt. Moreover, the reaction has under such conditions a quite definitely negative temperature coefficient, although it eventually becomes mildly explosive.

At first sight the diminished reactivity of mixtures low in propane appears to be in harmony with the results of the corresponding experiments in the packed tube at higher temperatures. There is, however, more than a suspicion that in the empty tube excess of oxygen rather than deficiency of propane is the important factor in limiting the reaction. Experiments were carried out in which one-third of the oxygen of the $1C_3H_8:3O_2$ mixtures was replaced by some other gas giving mixtures of the composition $1C_3H_8:2O_2:1$ diluent. The diluent gases were nitrogen, carbon dioxide, methane and hydrogen. Results are presented in Table III.

TABLE III

The substitution of diluent for part of the oxygen makes very little difference in the amount of reaction at 375°. There is a small decrease in the order O_2, CH_4, N_2, CO_2, H_2. At 425°, however, this effect becomes so pronounced that, in the presence of hydrogen, reaction is almost entirely suppressed. These diluent gases clearly have specific inhibitory effects on the oxidation, the effect being more pronounced at the higher temperature. The similarity of the results when oxygen is the diluent leaves little room for doubt that this substance itself is as well inhibitor as reactant, and especially that the negative temperature coefficient observed with excess of oxygen is intimately related to the inhibitory action of this substance. That propane does not have a similar effect may be seen by comparing the results of experiments with $2C_3H_8:2O_2$ mixtures (Table II) with the above.

So far as is known, no similar observations on homogeneous gas reactions have been noted except those involved in anti-knock action, which refer, of course, to precisely this type of reaction—the oxidation of hydrocarbons.

The characteristics of the free reaction convince us that we are dealing with a chain mechanism. The reactions in question are undoubtedly those suggested by Edgar and Pope[3] as the reactions of oxidation of the higher paraffins, and may be represented by the equations

$$C_3H_8 + O_2 \rightarrow C_2H_5CHO + H_2O$$
$$C_2H_5CHO + O_2 \rightarrow CH_3CHO + H_2O + CO, \text{ etc.}$$

In the case of propane the two reactions written above appear to be chiefly concerned, since in general we obtain 1 mole of carbon monoxide for 1 mole of propane and 2 moles of oxygen reacting. This is the sequence of reactions which is suppressed by diluents and KCl-coated, glass packing, and which has the chain mechanism. These reactions induce those yielding unsaturates and are the more effective in this respect as the temperature is raised.

Further information as to the nature of the free reaction is given by experiments in which 50% propane–oxygen mixtures were diluted with nitrogen. Results are presented in Table IV.

Results with mixtures containing 50% nitrogen are particularly striking. Considerable reaction took place at 350°, but not at 300, 400 or 450°. At 475° the mixture became very mildly explosive but a sample could still be taken. The reaction rate first increases with temperature (300–350°), then decreases to zero (350–450°) and finally again increases (450–475°). When the nitrogen content is increased to 75% the whole of the low temperature reaction is wiped out, and only the higher temperature region (500–600°), with its positive temperature coefficient but without the explosive character, remains. It is to be noted that when reaction does set in, the formation of unsaturates is considerable as compared to that of carbon monoxide. This is equally true for the 50% mixture at 475°.

We have seen that the reactions of propane and oxygen can be suppressed by dilution or by the use of a KCl-coated glass packing. It was desired to determine the effect of shortening the heating time. To accomplish this it was convenient to keep the flow rate the same and use a smaller reaction tube. Accordingly a tube of the same length as the larger, empty tube (about 11 cm.) but of about one-third the diameter (0.5 cm. as against 1.6 cm.) was made up. Results are given in Table V.

TABLE V

REACTION OF PROPANE AND OXYGEN IN THE SMALLER, EMPTY, COATED TUBE

Temp., °C.	Gas in, cc.		Reacted, cc.		Formed, cc.					% C_3H_8 introduced to reaction,			
	O_2	C_3H_8	O_2	C_3H_8	Unsats.	CH_4	H_2	CO	CO_2	I unsats. by dis.	II unsats. by ox.	III aldehyde react.	Total
600	300	100	12	10	11	0	7	4	1	7	4	0	11
625	Explosive												
500	100	300	Nil										
550			25	48	38	19	0	1	3	6	6	3	15
600			93	150	125	58	17	36	6	26	17	9	52

Reaction is again forced into the higher temperature region with the formation of unsaturates predominating.

The heating time in this smaller tube was one-eighth of that in the larger tube. This would be expected to decrease the amount of reaction correspondingly; but the observed decreases are so great as to warrant the conclusion that the decrease in tube diameter is effective of itself. Reaction only sets in at 500-600° instead of at 300–400°. In the smaller tube contact between gas molecules and the tube walls is facilitated. Apparently the difference in this respect between the smaller and larger tubes is sufficient to give the observed marked differences in reaction characteristics.

There is finally one more way in which the propane–oxygen reactions can be affected. This is by reducing the pressure. Experiments were carried out in which hydrocarbon–oxygen mixtures were caused to flow through a tube of large volume at 5 to 10 mm. pressure. The quantitative results were not very satisfactory owing to irregularity. Qualitatively, however, there was no question but that the suppression of reaction was very great. No reaction whatever took place below 600°. At higher temperatures there was certainly a parallelism between the amounts of hydrocarbon dissociating in nitrogen and the amount reacting in oxygen. It was not possible to conclude whether the same amount of hydrocarbon was involved in the two cases, or whether the two reactions were independent of each other. Once more, however, we find reaction finally setting in under conditions which are favorable to dissociation alone.

What has been said of the low pressure oxidation of propane applies as well to that of the butanes and aiso of ethane.

In the oxidation of propane we have then to deal with three types of reaction—that yielding unsaturates, and methane or hydrogen by dissociation, that yielding unsaturates and unidentified liquid products by oxidation and that yielding carbon monoxide and unidentified liquid products (again by oxidation). The first two types always appear together, sometimes one and sometimes the other predominating, and increase in amount as the temperature is raised. Unless the carbon monoxide reaction is taking place (as in the larger, empty tube) the reactions yielding unsaturates do not put in an appearance until the temperature reaches 550–600°. They give evidence of being more or less normal homogeneous gas reactions, first-order with respect to propane, which are subject to excitation by the carbon monoxide reaction in amount which is small at the lower temperatures but increases as the temperature is raised.

In the carbon monoxide reaction we meet with a wholly different state of affairs. This reaction is promoted by excess of hydrocarbon but depressed by excess of oxygen. Dilution with other gases than oxygen likewise inhibits the reaction; the extent of inhibition is a specific property of the diluent, and suppression by any of the diluents (including oxygen) is greater at higher temperatures so that the reaction under these conditions has a negative temperature coefficient. This reaction is likewise suppressed by a glass packing, particularly when this is coated with potassium chloride; it is suppressed in reaction tubes of small diameter; and it is suppressed when the pressure is lowered to a few millimeters. These are characteristics to be expected of a chain reaction, and we do not hesitate to state that a chain mechanism is here involved.[6] We have, however, no evidence bearing on the nature of the chain, though the formation of aldehydes and the possibilities of peroxide formation are to be borne in mind.[7]

That the reactions are as a whole exothermic is shown by the fact that a jacketed thermocouple will register a temperature 25–50" higher in a small region close to the inlet end than in the rest of the tube. A spontaneous development is not surprising. Rather, what requires explanation under these circumstances is the fact that other possible reactions

---

[6] We have recently found that this reaction is also faintly luminous.

[7] See Mardles, J. Chem. *Soc.,* 133,872 (1928)

are not more influenced, in particular, the fact that the excess of hydrocarbon which is always present is not more radically and more completely decomposed. The evidence is all in favor of the conclusion that the reaction energy is not as a whole available for heating the gases but is largely retained in some special form by product molecules to be given up to the walls or to be devoted by a specific mechanism to the continuance of the particular reaction to which it is due.

Reactions of the Butanes with Oxygen.—It remains now to present data on the reactions of the butanes with oxygen under conditions corresponding to those of the propane–oxygen reactions which have aready been presented and discussed in detail. The relations are essentially the same as with propane. Reaction is in general more ready and suppression is more difficult. Of the two, n-butane is the more reactive.

The Inhibited Reaction.—Results with the packed coated tube are presented in Table VI.

[a] The interpretation of the analyses for saturated hydrocarbons in the off-gas are the more uncertain in these cases because of the probability that ethane is also present.

A comparison of these with the corresponding results for propane shows that whereas the latter only reacted at 600° with very little carbon monoxide formation, the butanes are reacting at 500° and considerable carbon monoxide is produced. The packing, therefore, does not repress the "aldehyde reaction" so readily in these cases. A finer packing might perhaps be more effective. As between the two, reaction development is the more ready in n-butane but the differences are not great, particularly when oxygen is in excess.

The Free Reaction.—Reaction between the butanes and oxygen in the larger, empty, coated tube takes place in a manner not very different from that with propane. A greater proportion of oxygen is consumed and reaction passes more readily into explosion. Indeed, *n*-butane–oxygen mixtures of composition 2:2 or 1:3 showed no region of quiet reaction. Results are presented in Table VII.

With 3:1 hydrocarbon–oxygen mixtures (when all of the oxygen is consumed) the proportions of reactants and products are much the same as with propane. The 1:3 *iso*butane–oxygen mixture reacts only incompletely when it does not explode (e. g., at 350°) as in the case of the cor-

responding propane mixture, though a greater proportion of the oxygen is consumed. There is less indication of suppression by diluents, however. Data referring to the smaller, empty, coated tube are given in Table VIII.

It is seen that in the smaller, empty, coated tube the butanes again react more readily than propane, and that *n*-butane is the more reactive of the two. In this case the system of interpretation appears to be strained somewhat by the appearance of excessive quantities of unsaturates. It is possible that the formation of ethane is responsible, or that in some cases two molecules of ethylene are formed from one of butane.

A comparison between the amounts of reaction of 3:1 butane–oxygen mixtures at 450° in the larger and smaller empty tubes is available and is of some interest. It will be recalled that the two tubes give heating times in the ratio of 1 to 8 (1.6 and 13 sec., respectively) their diameters being in the approximate ratio of 1 to 3. Results are given in Table IX.

TABLE IX

COMPARISON OF 3:1 BUTANE–OXYGEN MIXTURES AT 450° IN SMALLER AND LARGER, EMPTY, COATED TUBES

Tube	Reacted, cc.		Formed, cc.					C_3H_8 introduced to reaction, %			
	O_2	H. C.	Unsats.	CH_4	H_2	CO	CO_2	I unsats. by dis.	II unsats. by ox.	III aldehyde react.	Total
					Isobutane						
Small	22	13	18	0	0	0	5	0	7	0	7
Large	100	100	68	33	9	41	7	15	9	11	35
					n-Butane						
Small	70	49	42	4	2	17	13	2	12	4	16
Large	96	91	77	42	7	39	12	17	10	5	32

The differences are ascribed to an increase principally in the amounts of dissociation, along with a considerable increase in the amount of carbon monoxide, which, however, does not appear in the analysis of results as due to our aldehyde reaction, though doubtless this would be the correct interpretation.

We conclude that there is no essential physico-chemical difference between the reactions of the butanes with oxygen and those of propane and that the same considerations are applicable. This being the case, we are inclined to believe that the same will be true of the higher hydrocarbons. Differences will necessarily appear in the study of the lower hydrocarbons, methane and ethane, because of the impossibility of certain types of reaction, and these will require special study. The appearance of carbon monoxide and water as the principal products of methane oxidation is suggestive of a similarity in some sense. In the case of ethane the slowness of the reactions when oxygen is in excess, as shown by Bone and Stockings,[8] is exactly in accord with results found for propane and the

---

[8] Bone and Stockings, J. Chem. *Soc.*, 85,693 (1904).

butanes. It may be added that Bone and Wheeler[9] and Bone and Andrew[10] find the same effect in the slow oxidation of ethylene and of acetylene, pointing to chain mechanisms in these cases also.

These results are admittedly incomplete. What was aimed at was a survey of the field. The points that will interest us especially in further investigations are the nature of the chain reaction and especially of the diluent effect, and the behavior of the lower hydrocarbons.

It may be pointed out that the indications are that liquid products containing the same number of carbon atoms as the original hydrocarbon are not formed in quantity. The aldehyde with one less carbon atom should be obtainable in a fairly pure state by oxidation at the lowest possible furnace temperature with excess of hydrocarbon. High temperatures and the maximum suppression give good yields of what are undoubtedly olefins, under conditions which are more convenient than those required for ordinary dissociation. In fact, this is unquestionably a suitable method to prepare olefins from saturated hydrocarbons. We have no very clear ideas as to the nature of the reactions producing unsaturates by oxidation except that the burning off of hydrogen to give the olefin of the same chain length is one reaction, and that reactions such as

$$C_3H_8 + {}^1/_2O_2 \rightarrow C_2H_4 + CH_3OH$$

$$C_3H_8 + O_2 \rightarrow C_2H_4 + HCHO + H_2O$$

are possible. We are inclined to believe that the formation of alcohols, which probably occurs, is referable to the first of these reactions and may be regarded as due to the tendency of the hydrocarbon to undergo demethanation. The formation of acids is perhaps due to secondary oxidation of aldehydes but we have no evidence on this point for or against.

There is no question but that the proportions of these various reactions can be altered profoundly by relatively minor changes in the methods of carrying out the oxidation. This is to be borne in mind by those interested in arriving at a more precise idea of the nature of the liquid products, or in forcing the reactions in some one particular direction. One point in particular is worth bearing in mind. Probably any catalyst will act to suppress what we have called the aldehyde reaction just as a glass packing does. On top of this effect will be superimposed the specific action of the particular catalyst employed. The role of the catalyst will thus be always a dual one.

Summary

1. A study has been made by the flow method of the reactions of mixtures of oxygen with propane and the butanes. No attempt has been made to analyze the liquid products and all conclusions are based on the results of gas analyses.

---

[9] Bone and Wheeler, on ethylene, *J. Chem. Soc.*, **85**, **1637** (1904)

[10] Bone and Andrew, on acetylene, *ibid.*, **87**, **1232** (1905).

2. The reactions are classified into three types, which (with examples) are as follows: (I) Unsaturates by Dissociation, Example—$C_3H_8 \longrightarrow C_3H_6 + H_2$; (II) Unsaturates by Oxidation, Example—$C_3H_8 + {}^1/_2O_2 \longrightarrow C_3H_6 + H_2O$; (III) Aldehyde Reaction, Example—$C_3H_8 + 2O_2 \longrightarrow CO + 2H_2O + CH_3CHO$.

3. Types I and II give evidence of being more or less normal homogeneous gas reactions which appear at 500–600°, but are subject to induction by Type III at lower temperatures in amount increasing with the temperature.

4. Type III may begin at temperatures of 300–350° and gives every indication of being a chain reaction. Its development is highly spontaneous, and at the same time it is sensitive to relatively minor variations in the conditions of reaction. In particular, it is subject to suppression by a broken-glass packing (especially when this is coated with potassium chloride), and by use of a reaction tube of small diameter. Lowering the pressure to a few millimeters has a like effect. Dilution with oxygen, methane, nitrogen, carbon dioxide or hydrogen depresses the reaction in amount increasing in the order named; this effect is the greater at higher temperatures. Under these conditions the reaction thus has a negative temperature coefficient, though eventually becoming explosive. Excess of hydrocarbon promotes the reaction.

5. Under suppression, there may be no reaction up to 500–600°. Types I and II then appear, accompanied by Type III in varying amount.

6. Considerations bearing on the isolation of particular reactions are set forth.

THE STRUCTURE OF METAL KETYLS. I. THE SCHMIDLIN FORMULA

BY CHARLES BUSHNELL WOOSTER[1]

RECEIVED JANUARY 23, 1929 PUBLISHED JUNE 5, 1929

The highly colored products formed by the addition of one atom of an alkali metal to one molecule of certain aromatic ketones were named "metal ketyls" by Schlenk and his co-workers,[2] who concluded that these substances comprised a new class of compounds containing trivalent carbon. This view was criticized by Schmidlin,[3] who contended that they should be regarded as molecular compounds analogous to those formed between

[3] Schmidlin, "Das Triphenylmethyl," Stuttgart, 1914, pp. 186–188.

the ketones and metal chlorides[4] and could best be represented by the formula RR′C═O···Me.

Such a formula has little or no definite significance until the meaning of the symbols employed (particularly the dotted line) has been defined in terms of the properties to be expected of the substance represented. In his consideration of the reactions of these compounds Schmidlin gave a very clear definition of the meaning of his formula. In every case he assumed that a dissociation into the ketone and free metal occurred, and was immediately followed by interaction of the latter with the reagent employed. When the product of this interaction was capable of reacting further with the ketone, derivatives were obtained which were identical with those resulting from a mixture of the ketone, the reagent and the alkali metal. Otherwise, the entire amount of ketone was recovered at the end of the reaction.

The mechanism proposed by Schmidlin for the reaction between metal ketyls and alkyl halides may be subjected to a very exacting test by carrying out this reaction in the presence of some additional reagent capable of reacting with any intermediate organo-alkali products which might be formed. A suitable material is liquid ammonia and its influence upon this reaction has been studied under conditions permitting the collection of all gases formed in the process. Two trials gave identical results; only a negligible quantity of gas insoluble in water was collected. If sodium ethyl[5] had been formed as an intermediate step, reaction with the ammonia would be expected, resulting in the formation of ethane

$$C_2H_5Na + NH_3 \longrightarrow NaNH_2 + C_2H_6 \qquad (1)$$

Furthermore, if dissociation of the ketyl into ketone and free metal had occurred, as Schmidlin supposes, the formation of ethane might be expected in any event, for this gas has been shown to be a product of the action of ethyl iodide on sodium in liquid ammonia.[6]

The only assumption that can harmonize these results with the Schmidlin formula is that a competition occurs between the ketone and the solvent ammonia in their reactions with the product formed from sodium and ethyl bromide and that the reaction with the ketone preponderates because of its greater rapidity. The validity of this assumption was then tested by adding metallic sodium to a solution of benzophenone and excess ethyl bromide in liquid ammonia. Ethane, in an amount equivalent to the sodium used, was evolved in both of the experiments carried out.

The Schmidlin formula, as defined and interpreted by its author, requires that the action of ethyl bromide on the ketone–metal compound

---

[4] (a) Pfeiffer, *Ann.*, **383**, 97 (1911); (b) K. H. Meyer, *Ber.*, 42, 1149 (1909); 43, 157 (1910).

[5] Schmidlin actually suggested a complex of the type C_2H_5NaBr.

[6] Lebeau, *Compt.* rend., 140, 1043 (1905).

and that of the metal itself on the ethyl bromide–ketone mixture be identical. The fact that these two reactions lead to quite different results in the presence of liquid ammonia demonstrates conclusively that *the Schmidlin formula is incorrect.*

However, the interpretation of the reactions of these compounds proposed by Schlenk and his co-workers is not the only alternative to be considered. For instance, it has been observed that monosodium benzophenone results from the action of benzophenone upon its disodium derivative in liquid ammonia

$$(C_6H_5)_2C(Na)ONa + (C_6H_5)_2C{=}O \longrightarrow 2\ (C_6H_5)_2CONa \qquad (2)$$

If it is assumed that this reaction is to some extent reversible and that under the influence of any reagent which attacked the very reactive sodium atom in the disodium compound, the transformation could be caused to proceed to completion in the sense of Equation 2 as read from *right* to *left;* it would be expected that the products would consist of the ketone and of the equivalent of an equimolecular quantity of the di-metallic derivative in the form of the materials ordinarily resulting from the action of the reagent upon it. It is a noteworthy fact that the substances actually isolated and identified after decomposition of the ketyls with numerous reagents have been identical with those which are thus predicted, with the single exception that in certain instances the products of hydrolysis of the solid also contained a quantity of the pinacol; this may be ascribed to partial polymerization of the ketyl to the pinacolate. These considerations are of particular significance since they suggest that none of the reagents hitherto employed attack the ketyls *directly* and consequently such reactions scarcely reveal the structure of the ketyls themselves.

Experimental Part

Apparatus.—A diagram of the apparatus used in these experiments appears in Fig. 1. A pyrex reaction tube A fitted with two ground-in introduction tubes B was attached to the system with de Khotinsky cement. It could be evacuated by means of a mercury vapor pump and ammonia introduced from a cylinder attached at C. This cylinder, which is not shown, was filled with liquid ammonia from a commercial fifty-pound tank, a few pieces of sodium metal having been previously introduced. Ammonia thus dried was always used as the solvent for the reacting materials and was transferred from the cylinder by distillation. A manometer D permitted the pressure within the tube to be regulated so that pure ammonia could be condensed therein when it was surrounded by a cylindrical Dewar flask containing a bath of commercial liquid ammonia. The ammonia which was allowed to evaporate at the end of a reaction was permitted either to escape through outlet E into a carboy of water, or could be passed into the gas-collection tube F. This tube contained water for the absorption of ammonia and the volume of any insoluble gas which collected in the tube could be measured. Fresh water could be introduced through a tube which led to the upper part of the collection tube. Since the density of aqua ammonia is less than that of water, it was very convenient to be able to lead the fresh water to the upper surface of the absorbing column The collected gas could also be transferred into the drying system G and the density of a sample determined by removing and weighing the bulb H. Liquid or solid products were examined after the reaction tube had been removed from the system. The addition of a liquid reagent was accomplished by replacing one of the introduction tubes B with the small buret I. A two-way stopcock J permitted a gaseous reagent to be bubbled through the solutions and, when necessary, the entire system could be filled with a gas other than air or ammonia by means of the inlet K.

The Action of Ethyl Bromide on Monosodium Bemophenone.––The ketone was put in the reaction tube, which was then connected to the apparatus and evacuated. The reaction tube was then filled with ammonia gas, the ground-in fitting B removed and the sodium in the form of spherical pellets dropped into it. It was replaced at once and the apparatus again evacuated, after which the condensation of ammonia in the reaction tube was carried out. The sodium pellets were obtained by cutting the metal into small pieces, melting it under paraffin, washing with petroleum ether and weighing under "Nujol," which was removed by a second washing in petroleum ether. After a suitable quantity of ammonia had been condensed, the sodium was added by turning the fitting in its socket and tapping it gently until the pellets dropped in. They could thus be added one at a time or all at once, as desired. When the formation of the ketyl was completed and the entire line connecting the reaction tube with the collection tube thoroughly swept out with ammonia gas, the ethyl bromide was added through the buret I and the evolved gases were collected. In two experiments employing 1.82 and 1.92 g. of ketone, 0.26 and 0.25 g. of sodium and about 6 cc. of ethyl bromide only about 4 cc. of gas was collected. This might well have been hydrogen, since the ammonia had been dried with sodium, which slowly reacts with the solvent forming sodamide and hydrogen. The possibility that air dissolved in the water might be displaced from solution as the ammonia dissolved and the absorbing liquid became warm was

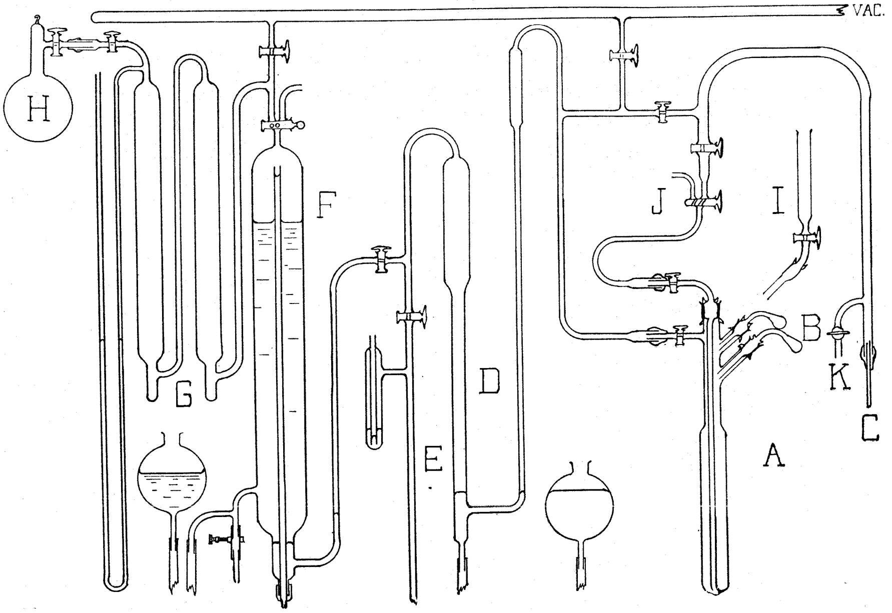

Fig. 1.—Apparatus for studying reactions in liquid ammonia.

largely eliminated by using at all times water which had been previously boiled and cooled in a closed vessel.

The non-volatile products of this reaction were examined in a previous investigation[7] and sodium bromide, benzophenone and diphenylethyl carbinol were identified, but since a quantitative separation of the organic materials was not accomplished the additional formation of gaseous products was not excluded.

The Action of Sodium on Ethyl Bromide and Benzophenone.—These experiments were carried out in a manner similar to that just described except that the ethyl bromide was added before the sodium. It dissolved the ketone and held it in solution in the presence of the liquid ammonia used. The sodium reacted vigorously with this mixture and considerable quantities of gas were evolved. In the two experiments 0.348 and 0.381 g. of sodium added to solutions containing 1.90 and 1.92 g. of ketone and about 6 cc. of ethyl bromide yielded 171 and 189 cc. of gas (under standard conditions); calcd., 170 and 186 cc. of ethane from the equation

$$C_2H_5Br + 2\,Na + NH_3 \longrightarrow NaBr + NaNH_2 + C_2H_6 \qquad (3)$$

The density of the gas was determined by collecting and weighing a dried sample in the density bulb: 339.3 cc. of gas at 24.6° and 223 mm. weighed 0.1317 g., at 25° and 239 mm., 0.1413 g.; mol. wt., 32.3, 32.4; calcd. for ethane, 30.06.

The excess ethyl bromide and ethylamine (formed from ethyl bromide and sodamide) distilled out when the ammonia was allowed to evaporate. The residue was extracted with water to remove sodium bromide and was then soluble in ether. Evaporation of the ether left a residue which was completely converted into benzophenone oxime (m. p. 140°) by treatment with hydroxylamine hydrochloride and sodium hydroxide in dilute alcohol solution. Thus it is evident that the benzophenone remained unchanged in this reaction.

The Action of Benzophenone on Disodium Benzophenone.—The disodium compound was prepared by treating the ketone with two equivalents of sodium in liquid ammonia and an equal amount of ketone was then added. The presence of a definite monosodium compound and the absence of an appreciable amount of ketone in the reaction product were demonstrated by the procedure previously employed[7] for a similar purpose.

Summary

1. It has been shown that the reaction of ethyl bromide with monosodium benzophenone in liquid ammonia is not identical with that between sodium and a solution of ethyl bromide and benzophenone in the same solvent. This fact furnishes conclusive evidence that the Schmidlin formula for the metal ketyls is incorrect.

2. It has been pointed out that the interpretation of the reactions of these compounds proposed by Schlenk and his co-workers is not necessarily the only alternative to be considered.

PREPARATION OF NORMAL-BUTYLMAGNESIUM BROMIDE

BY P. BORGSTROM, F. C. WAGNER AND H. C. GRIFFIN

RECEIVED JANUARY 28, 1929 PUBLISHED JUNE 5, 1929

Introduction

In the course of preparing certain compounds in fairly large amounts by means of the Grignard synthesis, it seemed of interest to make a study of the conditions giving the best yields of the Grignard reagent formed from *n*-butyl bromide, especially with a view to determining the extent to which the results of Gilman and Meyers[1] obtained with 0.05 molar quantities would hold for runs made on a large scale.

When n-butyl bromide and magnesium are brought together in ether solution, it is well known that at least three reactions may occur[2]

$$C_4H_9Br + Mg \longrightarrow C_4H_9MgBr \qquad (a)$$
$$C_4H_9MgBr + C_4H_9Br \longrightarrow MgBr_2 + \text{hydrocarbons} \qquad (b)$$
$$C_4H_9Br + Mg + BrC_4H_9 \longrightarrow MgBr_2 + \text{hydrocarbons} \qquad (c)$$

It is the conditions favoring the first of these reactions and minimizing the other two which are of interest in securing as high yields as possible of the Grignard reagent.

Materials, Apparatus and Procedures

The n-butyl bromide used was prepared from n-butyl alcohol (b. p. 117.2–117.5°) by the hydrobromic–sulfuric acid method,[3] and had a boiling point of 101.2–101.5°. An average of 300 cc. of absolute ether per mole of n-butyl bromide was used in each run. The magnesium was in the form of moderately fine turnings.

All of the runs, except No. 5 for which a 12-liter flask was used, were made in 5-liter, three-necked flasks fitted with stirrer, reflux condenser and dropping funnel. The top of the flask was packed in ice during all of the runs. By this means cooling the contents of the flask by an ice-water bath to prevent too rapid refluxing was avoided, except for brief periods in one or two of the fastest runs. Usually no refluxing occurred.

Samples for analysis were taken at the end of each run (except 14–17) by means of sampling tubes having a capacity of about 5 cc. A weighed sample was taken at the completion of Runs 14–17 by means of a thin-walled sampling bulb, and the weight of the whole contents of the flask was determined; the weight of the bromide added being known, the percentage recovery of bromide could be calculated. The analysis of the sample taken with the sampling tubes determined only the amount of bromide which had reacted, called in the tables "Recovered Br." Samples were taken after the addition of each mole of butyl bromide in Runs 6 and 17 in order to follow the course of the reaction.

Analysis for the amount of Grignard reagent present was by the acid titration method,' using $N/5$ nitric acid and $N/10$ sodium hydroxide. Some of the analyses for

The percentages of Grignard reagent formed on the basis of bromide used were determined for Runs 14–17 as follows: Run 14, 87.6; Run 15, 93.9; Run 16, 91.7; Run 17, 91.9. The percentages of bromide recovered in these runs were: Run 14, 100.1; Run 15, 98.9; Run 16, 98.2; Run 17, 97.0.

Discussion of Results

Rate of Addition of Butyl Bromide.—Runs 1–4, in which the rate of addition of the bromide did not vary markedly, agree closely in their yields of Grignard reagent. Run 4 developed marked turbulence after the addition of the fourth mole, though the rate of addition was slightly slower than in any previous run. No explanation of this which seemed adequate could be formulated. It was, however, a somewhat larger run than those preceding, so the amounts used in Run 5 were larger still, the object being to determine whether a large amount of magnesium present in the early stages of the reaction had a definite accelerating effect and whether runs on a ten-mole scale could be made satisfactorily. The run proved to be a quiet one with a markedly increased yield. The quantities of materials used were not employed again as the large amounts were unsatisfactory in further manipulations. The increased yield led to the procedure adopted for Run 6, in which a sample was taken after the addition of each mole of butyl bromide in order to find out the quantities of Grignard reagent present in successive stages of the reaction. The results, shown in Table II, were disappointing in that, through accident, the rates of addition of the third and fifth moles were so much greater than the thirty-minute rate desired. The marked drop in the OH:Br ratio after the addition of the third mole in place of the rise shown in Run 17 shows very plainly the bad results obtained by adding the alkyl halide too rapidly.

Runs 8–17 show, with the exception of Number 14, a reasonable uniformity of yield; it will be noted that the molar rate of addition was in every case forty minutes or more and that no marked gain in yield is secured by any increase over this time—a complete verification of the conclusions of Gilman and Meyers. Further evidence might be found in the results of Run 17, in which a progressively decreasing time of addition of each successive mole of butyl bromide was used, finally getting, for the sixth mole, below the forty-minute limit, with resultant decrease in the OH:Br ratio. Run 14 was intentionally made at a rapid rate as a final confirmation of the lowered yield to be expected from increased rate of addition.

Reverse Process of Addition.—Run 7 was carried out with the suspicion—amply justified by the results—of poor yields to be obtained by adding magnesium to the alkyl halide, since by this procedure the latter is present in excess throughout the reaction. The completeness with which the results of this run justified the suspicions entertained may be seen from the figure for percentage yield given in Table I.

Excess of Butyl Bromide.—A consideration of the reactions given in an introductory paragraph will afford an explanation of why an unduly high concentration of butyl bromide results, as has been found always to be the case, in reduced yields of Grignard reagent. Any reaction, such as b and c, which uses up butyl bromide while producing no butylmagnesium bromide, obviously reduces the amount of the latter which can be secured from a given amount of the former by Reaction a. To the fact that a slow addition rate of butyl bromide to magnesium keeps the concentration of butyl bromide at a minimum may be ascribed the high yields obtained by this method of operation. The drop in the OH:Br ratio after the addition of the third mole in Run 6 shows the bad effect of an excess of butyl bromide, brought about by its introduction at a rate greater than that at which it could react according to Equation a, and reacting instead according to one or both of Equations b and c. The further drop of 3% in the sample taken in this run after eighteen and one-half hours further indicates that this same factor is at work. Sample 6 had been taken in the evening after only fifteen minutes' stirring subsequent to the addition of the sixth mole. When the stirrer was started the next morning enough heat was spontaneously developed to cause active refluxing, indicating the presence of unchanged butyl bromide which further stirring had caused to react, chiefly again according to one or both of Reactions b and c. It might be noted in passing that analyses made on this run on further standing show that the reaction was completed at this time and also point to the permanence of the Grignard reagent, already noted by others.[5] The very low yield obtained in Run 7 has already been given as essentially due to the constant presence of an excess of butyl bromide throughout the reaction. Just what amount constitutes an "excess" is not known; it has been repeatedly found, however, that when the ratio of the amount of free alkyl halide to the amount of active magnesium present in the reaction mixture exceeds a certain definite small value, low yields of Grignard reagent are obtained. In practice the value of this ratio is kept low by the slow addition of the alkyl halide. What has been said previously about the effects of the rate at which the butyl bromide is added and of the reverse process of addition are essentially corollaries of the effect of the presence of excess of butyl bromide.

Excess of Magnesium.—Comparison of results from Runs 8–17 shows no advantage in the half-mole excess of magnesium present in most of the runs, the highest yields (Runs 12 and 13) being obtained one with it and one without. It was used in most of the runs to make sure that the necessary slight excess would always be present. Equimolecular proportions of alkyl halide and magnesium will usually insure a sufficient excess, as pointed out by the investigators previously mentioned.

Yields.—An average of the percentage yields of Grignard reagent from the runs from which good yields could be expected (8–13, 15–17) gives 94.3% on the basis of the n-butyl bromide taking part in the reaction, or "recovered." An average of the yields based on the whole amount of n-butyl bromide used gives 92.5% for Runs 15–17 (the figure for Run 14 is omitted as being somewhat anomalous); while the average for the same runs on the basis of bromide recovered is 94.3%, which is 1.8% higher than the average based on bromide used. If this difference obtained in all the runs, the average percentage yield on the basis of bromide used would be 94.3 − 1.8 = 92.5%. This is somewhat (1.2%) higher than the figure given by Gilman and McCracken[6] as obtained with n-butyl bromide in their small quantitative runs but the agreement seems excellent

between experiments in which the quantities of reactants in one series were usually 120 times as great as in the other.

Summary

1. A study has been made of the following conditions affecting the yield of Grignard reagent formed from n-butyl bromide: rate of addition of butyl bromide, reverse process of addition, excess of butyl bromide and excess of magnesium.

2. The yields obtained on the large scale are in close agreement with those obtained by Gilman and co-workers in quantitative work on the small scale.

PHENOL-HALO-PHTHALEINS. PRELIMINARY PAPER[1]

BY F. F. BLICKE AND F. D. SMITH

RECEIVED JANUARY 31, 1929 PUBLISHED JUNE 5, 1929

Extensive practical use has been made of the fact that the halogens, chlorine, bromine and iodine, when introduced into certain synthetic organic compounds, greatly increase the hypnotic activity in some cases and in other instances augment the antiseptic power of the parent substance; chlorine and bromine are used especially for the former purpose, iodine for the latter.

It would be of considerable interest to know just what change could be effected by the introduction of fluorine instead of the other halogens. At present very little information is to be found in the literature regarding the physiological activity of any type of organic fluorine compounds;[2] to a large extent our lack of knowledge of these substances may be attributed to the fact that comparatively few organic fluorides have been prepared.

Phenolphthalein and various tetra-halogen substitution products have found extensive use in medicine, the former as a laxative, the latter as diagnostic agents. Fluoro derivatives of phenolphthalein have never been described. Since the effect of fluorine can be determined only by comparison of the fluoro compound with the corresponding chloro, bromo and iodo derivatives, we decided to attempt the preparation of the complete series of substances—phenol-fluoro-, -chloro-, -bromo- and -iodophthalein.

We prepared, first, five mono-halogenated phthalic acids, the 4-fluoro-,

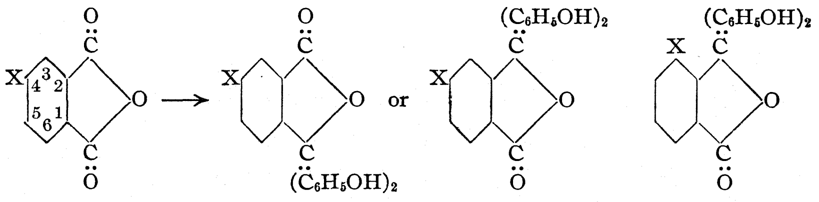
4-chloro-, 4-bromo-, 4-iodo- and the 3-iodophthalic acid. After a considerable number of attempts had been made to obtain these acids from the corresponding aminophthalic acids and from the aminophthalimides by the aid of the Sandmeyer reaction, it was found, finally, that the halogenated phthalic acids could be prepared most satisfactorily from the aminodiethylphthalates. Each acid was then converted into its anhydride and the latter condensed with phenol to form the phenol-halo-phthalein.

Obviously the condensation of a 4-halophthalic anhydride with phenol may yield two isomeric phenol-halo-phthaleins, I or II, or a mixture of these compounds.



I II III

In the case of the 3-halo derivatives, likewise, two types of isomeric phthaleins are possible. Hitherto, as far as we have been able to discover, no mono-substitution products of phthalic anhydride have been condensed with phenol to form mono-substituted phthaleins. However, Stephens[3] has shown that 4-bromophthalic anhydride condenses with benzene to form a mixture of two isomeric bromobenzoylbenzoic acids; 3-bromophthalic anhydride and benzene yielded only one bromobenzoylbenzoic acid. From the condensation of benzene with 4-nitrophthalic anhydride and also with 3-nitrophthalic anhydride, Lawrance,[4] in each instance, isolated two isomeric nitrobenzoylbenzoic acids. According to Orndorff and Kline[6] benzoylbenzoic acids are intermediate products in the formation of phthaleins.

We found that all of the 4-halo-qhthalic anhydrides, when condensed with phenol, formed products which, based on halogen analysis, were pure phenol-halo-phthaleins. The products, however, showed great tendency to separate from solution in the form of oils which were very difficult to convert into a crystalline state. The crystalline material, when it was finally obtained, did not melt sharply but melted over a considerable range. 3-Iodophthalic anhydride, when condensed with phenol, was converted into a product which crystallized readily and melted sharply. These results indicate that 4-substituted phthalic anhydrides condense

[4] Lawrance, *ibid.*, 42, 1871 (1920).

[5] Orndorff and Kline, *ibid.*, 46,2276 (1924).

with phenol to form a mixture of isomeric phthaleins, but in the case of the 3-substituted phthalic anhydride only one phthalein is formed."

In order to secure proof that the phthaleins obtained from the 4-halo-phthalic anhydrides were mixtures, and to determine the structure of the phthalein obtained from 3-iodophthalic anhydride, the various phenol-halo-phthalein~were fused with alkali. Baeyer[7] showed that phenolphthalein, when fused with alkali, yields *p,p'*-dihydroxybenzophenone and benzoic acid, A compound of Structure I should yield, accordingly, a m-halo-benzoic acid, or a *m*-hydroxybenzoic acid if the halogen were removed during the fusion, and *p,p'*-dihydroxybenzophenone, while from Compound II there should be formed, in addition to the ketone, a *p*-halo- or *p*-hydroxybenzoic acid. We found that the phthaleins obtained from the condensation of a 4-halo-phthalic acid and phenol yielded upon fusion with alkali small amounts of *p,p'*-dihydroxybenzophenone and a mixture of *m*- and p-hydroxybenzoic acids; the acids were separated in the form of their p-nitrobenzyl ester-ethers.[8] Prom the alkali fusion of the phthalein prepared from 3-iodophthalic anhydride and phenol there was obtained only *m*-hydroxybenzoic acid. It appears, therefore, that condensations of 4-halo-phthalic anhydrides with phenol yield mixtures of phthaleins of the type I and II, while a 3-halo-phthalic anhydride condenses with phenol to form only one phthalein, a substance of Type III.

Several questions arose in connection with the alkali fusions. Is the decomposition into dihydroxybenzophenone and substituted benzoic acid quantitative and are these fusion products stable under the conditions to which they are subjected during the fusion? The first question should be answered, we believe, in the affirmative. From the fusion of phenolphthalein with potassium hydroxide results were obtained which indicate that the initial fusion is probably quantitative. *p,p'*-Dihydroxybenzophenone, however, as Baeyer has shown,[9] is converted into phenol and carbon dioxide by vigorous fusion with alkali. Since a more prolonged alkali treatment was required to decompose the phenol-halo-phthaleins than was necessary for phenolphthalein, it is not surprising that phenol and only small yields of dihydroxybenzophenone were obtained from the fusion of phenol-halo-phthaleins. It was shown by experiment that under the conditions used in our fusions dihydroxybenzophenone was decomposed to a considerable extent but no p-hydroxybenzoic acid resulted

---

[6] We had hoped to obtain further evidence to support this view by a study of the interaction of 3-fluoro-, 3-chloro- and 3-brornophthalic anhydride with phenol. However, due to certain circumstances, these condensations could not be studied at this time. It is our intention to investigate these reactions and to prepare, also, a series of halo-phenolphthaleins.

as a decomposition product; *p*-hydroxybenzoic acid, under the same conditions, remained unchanged. *p*-Bromobenzoic acid was converted practically quantitatively into p-hydroxybenzoic acid.

Experimental Part

4-Aminodiethylphthalate.—Phthalic anhydride was nitrated,[10] with the formation of 3- and 4-nitrophthalic acids. After nitration had been effected the reaction mixture was poured into 300 cc. of water. Twenty-four hours later the nitro acids, which had precipitated completely, were filtered through a Jena filter and washed with a small amount of concd. hydrochloric acid in order to remove nitric and sulfuric acids. It was found that the nitrophthalic acids which are very soluble in water are only moderately soluble in concd. hydrochloric acid. The nitro acids were dried thoroughly and then suspended in an amount of absolute alcohol equal to one and one-half times the weight of the nitro acids. After the mixture had been partially saturated with hydrogen chloride, it was refluxed for twenty-four hours. The greater part of the alcohol was removed under diminished pressure and the residue was poured into three times its volume of water. The oily ester layer, which consisted of a mixture of the diethyl ester of 4-nitrophthalic acid and the mono-ethyl ester of 3-nitrophthalic acid, was washed thoroughly with small amounts of water and then treated with 10% sodium carbonate solution. The former compound remained undissolved while the latter passed into solution in the form of the sodium salt.[11] After separation of the insoluble diethyl ester of 4-nitrophthalic acid, it was dried over fused sodium sulfate and fractionated under diminished pressure. The portion which boiled at 210–213° under 21-mm. pressure, a light yellow, viscous oil, was dissolved in an equal volume of absolute alcohol and cooled with ice. After some time the ester separated in crystalline form. The material was filtered quickly through a Büchner funnel which had been cooled previously to 0°. Unless the mixture of ester and alcohol is kept cold, the ester redissolves in the solvent. The crystalline ester was suspended in a small amount of absolute alcohol, cooled to 0° for a short time and filtered again. The compound was then obtained in the form of colorless crystals; m. p. 33–34°.[12]

In order to prepare 4-aminodiethylphthalate, 26 7 g. of the 4-nitrophthalic ester was dissolved in 100 cc. of absolute alcohol and reduced with hydrogen in the presence of 0.1 g. of platinum oxide catalyst,[13] under an initial pressure of 4 atmospheres. The reduction was complete in twenty minutes; some heat was evolved during the reaction. The catalyst was used for several reductions without reactivation with air and showed only a slight decrease in activity. The colorless or slightly yellow alcoholic solution was filtered and the filtrate concentrated on a steam-bath. After the oily residue had been cooled the amino ester was obtained in the form of colorless crystals which melted at 97–98' after recrystallization from alcohol. The melting point of this substance recorded in the literature[14] is 95°. The yield was 21.5 g. or 92% of the calculated amount.

4-Fluorodiethylphthalate.—Eleven and eight-tenths g. of 4-aminodiethylphthalate was dissolved in a mixture of 20 cc. of concd. hydrochloric acid and 10 cc. of water, the solution was cooled to 0° and then diazotized with 3 5 g. of sodium nitrite dissolved in 15 cc. of water. To the cold, diazotized solution there was added a solution of hydro-

[14] Miller, *Ann.*, 208,237 (1881).

borofluoric acid. The latter had been prepared previously by the addition of 9.2 g. of pure boric acid to 21.8 cc. of pure 48% hydrofluoric acid in a bakelite beaker. The mixture was stirred rapidly, whereupon the diazonium borofluoride of diethylphthalate precipitated in crystalline form.[15] The latter was filtered and washed with absolute alcohol and then absolute ether. The diazonium compound was dried in a vacuum desiccator over sulfuric acid for twenty-four hours. The yield was 16.5 g. or 98% of the calculated amount. The compound decomposes at 125° with the evolution of nitrogen and boron fluoride.

Ten g. of the dry diazonium compound was placed in a 500-cc. round-bottomed flask connected to a wash bottle which contained a 10% solution of sodium hydroxide. The flask was heated slowly to 125° in an oil-bath and when the evolution of gases had abated the temperature of the bath was raised to 140° and maintained there for one hour. The oily residue was dissolved in carbon tetrachloride, the solution washed with 10% aqueous sodium hydroxide, separated and dried over fused sodium sulfate. The solvent was removed and the residue distilled. There were obtained 3.5 g of a product which boiled at 165–170° under 25 mm. pressure and 2.5 g. of material which boiled at 200–250°. The lower-boiling portion was 4-fluorodiethylphthalate; the yield corresponded to 50% of the calculated amount.

4-Fluorophthalic Acid.—Twenty-one g. of the fluoro ester was added to 20 g. of sodium hydroxide dissolved in 50 cc. of 50% alcohol. The mixture was then refluxed for three hours, the alcohol removed and the solution acidified with sulfuric acid; the fluorophthalic acid was extracted with ether, the solvent removed and the oily residue allowed to crystallize. After recrystallization from acetic acid the acid melts at 147–148° in a sealed tube. It is very soluble in water, acetic acid and ether.

4-Chlorodiethylphthalate.—Eleven and eight-tenths g. of 4-aminodiethylphthalate was dissolved in a mixture of 20 cc. of concd. hydrochloric acid and 10 cc. of water and diazotized with 3.5 g. of sodium nitrite dissolved in 15 cc. of water. Cuprous chloride had been prepared previously from 21 g. of copper sulfate, 5.4 g. of sodium chloride, 4.4 g. of sodium bisulfite and 3 g. of sodium hydroxide.[16] The cuprous chloride was suspended in a mixture of 100 cc. of water and 25 cc. of concd. hydrochloric acid. The diazotized solution was introduced slowly and with rapid stirring below the surface of the suspension of cuprous chloride. The mixture was then heated on a steam-bath for some time. The oily layer was extracted with carbon tetrachloride, the solution washed with dilute hydrochloric acid and then dried over fused sodium sulfate. The solvent was removed and the residue distilled. The greater portion of the material boiled at 185–190° under 25 mm. pressure.[17] The yield was 9 g. or 70% of the calculated amount.

4-Chlorophthalic Acid.—Thirty-five g. of 4-chlorodiethylphthalate was hydrolyzed with 30 g of sodium hydroxide which had been dissolved in 60 cc. of 50% alcohol. The chloro acid, after recrystallization from acetic acid, melted at 150° in a sealed tube[18] The acid is soluble in water, ether and acetic acid.

4-Bromodiethylphthalate.[19]—Eleven and eight-tenths g. of the 4-amino ester was

---

[15] The preparation of nuclear fluorine compounds by means of diazonium borofluorides has been patented by Bart (German Patent 281,055) and has been used by Wilke-Dorfurt and Balz, Ber., 60, 115 (1927); Balz and Schiemann, *ibid.*, 60, 1186 (1927), and by Schiemann and Bolstad, *ibid.*, 61, 1403 (1928).

[16] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1923, Vol. III, p. 33.

[17] Rée, *Ann.*, 233, 238 (1886), states that the substance, prepared by esterification of 4-chlorophthalic acid with ethyl alcohol, boils at 300–305° under ordinary pressure.

[18] Egerer and Meyer, *Monatsh*, 34, 81 (1913), record the melting point as 150°.

[19] 4-Bromodiethylphthalate has been prepared by Faust, Ann., 160, 64 (1871), by esterification of the acid.

dissolved in a mixture of 20 cc. of 48% hydrobromic acid and 10 cc. of water and was then diazotized with 3.5 g of sodium nitrite dissolved in 15 cc. of water. Cuprous bromide was suspended in 100 cc. of water and 15 cc. of 48% hydrobromic acid and the diazotized solution introduced slowly below the surface of the suspension with rapid stirring. The cuprous bromide had been prepared from 10.5 g of copper sulfate, 5 5 g. of sodium bromide, 2.2 g. of sodium bisulfite and 1.5 g. of sodium hydroxide [20] The mixture was heated on a steam-bath and the oily layer was extracted with carbon tetrachloride. The carbon tetrachloride solution was washed with dilute hydrochloric acid, dried over fused sodium sulfate and the solvent removed From the residue there was obtained 11 g. of material which boiled at 225° under 60-mm. pressure. The yield is 70% of the calculated amount.

4-Bromophthalic Acid.—Forty-two g. of the above ester was hydrolyzed with 30 g. of sodium hydroxide and 100 cc. of 50% alcohol. The bromo acid was recrystallized from acetic acid; m. p. 170° in a sealed tube. Stephens[21] found 170.5" as the melting point.[22]

4-Iododiethylphthalate.—Eleven and eight-tenths g. of 4-aminodiethylphthalate was dissolved in a mixture of 20 cc. of concd. hydrochloric acid and 10 cc. of water and diazotized with 3.5 g. of sodium nitrite dissolved in 15 cc. of water. The diazotized solution was treated with 12 g. of potassium iodide in 100 cc of water. The iodo ester was obtained in the form of a red oil [23]

4-Iodophthalic Acid.—Thirty-two g. of iodo ester was hydrolyzed with 25 g. of sodium hydroxide in 75 cc. of 50% alcohol. The crude acid was dissolved in water and boiled with charcoal. After filtration the filtrate was concentrated to a small volume. The iodo acid was recrystallized from acetic acid; m. p. 185–186° in a sealed tube. Edinger[23] found 182°. The yield based on the iododiethylphthalate was 59% of the calculated amount. The acid is soluble in water, ether and acetic acid.

3-Aminodiethylphthalate.—The solution of the sodium salt of the motlo-ethyl ester of 3-nitrophthalic acid was acidified with hydrochloric acid. Most of the acid ester was precipitated in the form of an oil, which was separated from the aqueous layer and then washed several times with small amounts of water. The acid ester was converted into the ammonium salt and precipitated as the silver salt with silver nitrate.[24] The silver salt was thoroughly dried, suspended in benzene and then refluxed with an excess of ethyl bromide for eight hours.[25] The silver bromide was filtered and the benzene removed on a steam-bath. The oily residue was dissolved in absolute alcohol and the ester reduced with hydrogen and platinum oxide catalyst. The amount of ester obtained from 0.1 mole of silver salt was reduced with hydrogen under an initial pressure of 4 atmospheres in the presence of 0.1 *g.* of catalyst. After ten minutes no more

---

[20] This preparation of cuprous bromide is entirely analogous to the preparation of cuprous chloride given in "Organic Syntheses," except that sodium bromide was used instead of sodium chloride.

[21] Stephens, THIS JOURNAL, 43, 1952 (1921).

[22] At the time this investigation was finished, Baker published a note, J. Cham. *Soc.*, 2829 (1928), stating that he had prepared *p*-bromophthalic acid from 4-nitrodiethylphthalate. The latter substance was reduced by means of zinc and hydrochloric acid, the amino compound was converted into the bromo derivative by the aid of the Sandmeyer reaction and the bromo ester finally hydrolyzed by barium hydroxide. The melting point of 4-bromophthalic acid was recorded as 173–175°.

[23] Edinger, J. *prakt. Chem.*, [2] 53,386 (1896).

[24] Miller, *Ann.*, 208, 244 (1881).

[25] The diethyl ester of 3-nitrophthalic acid has been prepared by Miller[24] from the di-silver salt of 3-nitrophthalic acid and ethyl iodide.

hydrogen seemed to be absorbed. The alcohol was then removed and the 3-aminodiethylphthalate obtained in the form of an oil.[26] The amount of hydrogen absorbed indicated the presence of 0.07 mole of 3-aminodiethylphthalate.

3-Iododiethylphthalate.—The oily residue obtained from the previous experiment was treated with 20 cc of concd. hydrochloric acid and 10 cc. of water and then diazotized. The diazotized solution was introduced slowly, with rapid stirring, below the surface of a solution prepared from 12 g. of potassium iodide and 100 cc. of water. The oily layer which formed was decolorized by the addition of sodium bisulfite and then cooled. The crystalline material which formed melted at 70°.[23] The yield, based on the silver salt of the mono-ethyl ester of 3-nitrophthalic acid, was 40% of rhe caicuiated amount.

3-Iodophthalic Acid.—3-Iododiethylphthalate was hydrolyzed with alcoholic sodium hydroxide.[23] The alkaline solution was acidified with sulfuric acid, the organic acid extracted with ether, the ether layer separated and the solvent removed. The residue was dissolved in water and the solution boiled with charcoal. After filtration and concentration of the filtrate, the 3-iodophthalic acid separated in crystalline form; m. p. 206°. The compound is soluble in water, ether and acetic acid.

The acid was prepared by a second method. 3-Nitrophthalic acid was reduced with stannous chloride and hydrochloric acid.[27] The hydrochloride of the amino acid which formed was filtered, suspended in dilute hydrochloric acid, diazotized and then treated with potassium iodide.

[c] Egerer and Meyer, *Monatsh.*, 34, 81 (1913), state that the anhydride boils at 297° and melts at 98°.

[d] Stephens, ref. 3, states that the compound melts at 104106".

[e] Prepared by heating the acid for ten minutes with an equal weight of acetic anhydride. The iodo-anhydride separated when the solution was cooled. The material was recrystallized from acetic anhydride and washed with absolute ether.

Phenol-halo-phthaleins

Preparation.—Five-hundredths mole of the halo-phthalic anhydride, 0.10 mole of freshly distilled phenol and 0.10 mole of fused zinc chloride were heated by means of an oil-bath at 115–130° for twenty-four hours. An additional quantity of phenol, 0.10 mole, was added and the mixture heated for twenty-four hours longer.

The reaction mixture was treated with 20 cc. of concentrated hydrochloric acid and 10 cc. of water and steam distilled for one hour. The hot supernatant liquid was de-

---

[26] Miller, *Ann.*, 208,246 (1881).

[27] Bogert and Jouard, THIS JOURNAL, 31,484 (1909).

canted from the oily residue and the latter again steam distilled for one hour. The combined supernatant liquors were cooled and extracted with ether. The ether layer was washed with dilute hydrochloric acid, the solvent removed and the residue dissolved in water, filtered and the filtrate evaporated to dryness. The residue was unchanged halo-phthalic acid. The oily water-insoluble residue from the steam distillation solidified to a resinous mass when cooled. The latter was pulverized, extracted with 10% sodium hydroxide, filtered and the filtrate acidified with dilute hydrochloric acid, whereupon the phenol-halo-phthalein was precipitated. There was obtained a small amount of alkali-insoluble material, which was probably a halo-fluoran.

The crude phthalein was filtered, washed with water and dissolved in **100** cc. of methyl alcohol; then **40** cc. of water and 2 g. of charcoal were added and the mixture refluxed for three hours. The hot solution was filtered and the solvent allowed to evaporate slowly. **A** gum was obtained, which was dissolved in 10% sodium hydroxide, filtered, the filtrate diluted to **500** cc. and the phthalein precipitated with dilute hydrochloric acid. The precipitate was filtered, washed well and air dried. The substance obtained was electrostatic and was very soluble in practically all organic solvents; it had no definite melting point. The resinous material was dissolved in acetic acid. After several days the crystalline material which had deposited was recrystallized from acetic acid. The amount of alkali-insoluble material from the several halo-phthalic anhydrides varied from 0.05–1.3 g The amorphous phthaleins were very soluble in all organic solvents but after conversion into the crystalline state they were found to be very insoluble except in hot acetic acid. In the case of 3-iodophthalic anhydride the reaction product became granular during the steam distillation. The granular material was recrystallized from dilute methyl alcohol and then from acetic acid.

TABLE II

3- AND 4-HALO-PHTHALIC ANHYDRIDES AND PHENOL

Anhydride	Yield of alkali-soluble material[a] (halo-phenol phthalein), %	M. p. of crystalline material, °C.	Analyses (Volhard), % Calcd. for $C_{20}H_{13}O_4X$		Found	
4-Fluoro	54	230–240	F[b]	5.65	5.34	5.42
4-Chloro	76	214–233	Cl	10.05	9.86	9.93
4-Bromo	73	226–236	Br	20.15	20.20	20.00
4-Iodo	63	240–255	I	28.58	28.68	28.30
3-Iodo	45	252–254	I	28.58	28.70	28.80

Alkali Fusions

Two g. of phenolphthalein was fused with 10 g. of potassium hydroxide[28] and 1-2 cc. of water in a nickel crucible until the color of the reaction mixture had changed to a light yellow. It was not necessary to fuse the material longer than three to four minutes to effect this change. The fusion mixture was dissolved in **75** cc. of water and acidified with dilute sulfuric acid, whereupon *p,p'*-dihydroxybenzophenone and benzoic acid precipitated. After the mixture had cooled the crystalline material was filtered and the latter treated with dilute ammonium hydroxide until the solution was alkaline to phenolphthalein. The ammoniacal solution was extracted twice with 25-cc. portions of ether. Upon evaporation of the solvent there was obtained almost pure *p,p'*-dihydroxybenzophenone; after recrystallization from water the material melted at 212–213°.[29]

---

[28] Baeyer, **Ann., 202,** 127 **(1880).**

[29] Montagne, *Rec. trav. chim.*, **39,348** (1920).

The yield was 1.15 g. which is 80% of the calculated amount. The aqueous alkaline layer from the ether extraction was acidified and the precipitated benzoic acid filtered. The latter weighed 0.59 g or 73% of the calculated amount; m. p. 121°. More benzoic acid remained dissolved in the filtrate but through an oversight this was not isolated.

One g. of *p,p'*-dihydroxybenzophenone was fused with 10 g. of potassium hydroxide for ten minutes at 200–250°. Sixty per cent. of the material was recovered unchanged, the remainder having been converted into phenol and carbon dioxide." No *p*-hydroxybenzoic acid was obtained.

One g. of *p*-bromobenzoic acid was fused with 10 g of potassium hydroxide for ten minutes at 200–250°. The fusion mixture was dissolved in water, acidified and extracted with ether. From the ether layer there was obtained p-hydroxybenzoic acid; m. p. 208–210°.[31]

One g. of p-hydroxybenzoic acid was fused with 10 g. of potassium hydroxide for ten minutes at 200–250°. Ninety-five per cent. of the acid was recovered; m. p. 210–211°.

Phthalein from 4-Fluorophthalic Anhydride.—Two g. of the phthalein was fused with 8 g. of potassium hydroxide and 1–2 cc. of water at 200–250°. The fusion mixture was dissolved in 50 cc. of water, acidified with dilute sulfuric acid, cooled and the *p,p'*-dihydroxybenzophenone which had precipitated was filtered off. It weighed 0.5 g. or 39% of the calculated amount; m. p. 208–210°. The aqueous, acidic filtrate was extracted with ether. After removal of the solvent the residue was dissolved in water, boiled with charcoal, filtered and the filtrate evaporated to dryness. There was obtained 0.8 g. of a mixture of m- and p-hydroxybenzoic acids; the yield corresponds to 97% of the calculated amount.

The general procedure used to separate the mixture of hydroxybenzoic acids obtained from the alkali fusions was as follows. The mixture of acids and one molecular equivalent of potassium carbonate were dissolved in 5 cc. of water. This solution was added to 2.1 molecular equivalents of p-nitrobenzyl bromide dissolved in 15 cc. of pure acetone. The mixture was refluxed for two hours, cooled and the crystalline material filtered. The latter was treated with cold, dilute sodium hydroxide and the undissolved portion recrystallized from acetone. The dinitrobenzyl derivative of the para acid8 is practically insoluble in hot acetone while the meta derivative is much more soluble in this solvent; a practically complete separation of the two derivatives can be effected by two recrystallizations from acetone. The yield of the di-nitrobenzyl derivative of the *p*-hydroxy acid was about twice that of the meta compound. The melting point of the former substance was 196–198°, mixed melting point, unchanged. The melting point of the meta derivative was 140–143°, mixed melting point, 138–141°.

Phthalein from 4-Chlorophthalic Anhydride.—From the fusion of 2.0 g. of the phthalein there were obtained 0.7 g. of a mixture of m- and p-hydroxybenzoic acids and 0.6 g. of *p,p'*-dihydroxybenzophenone; the mixture of acids melted from 160–190". The yield of the ketone was 50% and that of the acids 91% of the calculated amount. The mixture of acids was treated as outlined previously and the same relative amounts of each derivative were obtained as in the case of the phthalein from 4-fluorophthalic anhydride. The melting point of the di-nitrobenzyl derivative of the para acid was 195–197°; that of the meta isomer, 138–141°.

Phthalein from 4-Bromophthalic Anhydride.—From the alkali fusion there were obtained a 63% yield of *p,p'*-dihydroxybenzophenone and a 92% yield of a mixture of m- and p-hydroxybenzoic acids; the mixture of acids melted from 165–195". The acids were separated and identified after they had been converted into their *p*-nitrobenzyl derivatives.

---

[30] Baeyer, *Ann.*, 202,127 (1880).

[31] Fischer, *ibid.*, 127, 145 (1863).

Phthalein from **4-Iodophthalic** Anhydride.—In this instance there were obtained from the alkali fusion only a small amount of *p,p'*-dihydroxybenzophenone and an 86% yield of a mixture of m- and *p*-hydroxybenzoic acids; the mixture melted from 165–190°.

Phthalein from 3-Iodophthalic Anhydride.—From the alkali fusion there was isolated a small amount of *p,p'*-dihydroxybenzophenone; however, m-hydroxybenzoic acid, which melted from 190–195° was obtained in a 89% yield. The hydroxy acid was further identified by conversion into the *p*-nitrobenzyl ester ether; the latter melted from 135–140° and a mixed melting point with the pure ether ester was unchanged.

The following crystallographic data have been determined by Dr. C. B. Slawson. These measurements were made upon crystals formed by the slow evaporation at room temperature of acetic anhydride solutions.

4-Fluorophthalic Anhydride.—Crystals of this compound consist almost invariably of pseudo-hexagonal twins. The twins consist of interpenetrating triclinic needles, at an angle of 8°, resembling at the terminations twinned augite crystals, though the front pinacoid is not present. The prism angle is 51°55'. The reentrant terminal angle is about 60° and the terminal faces are very poorly developed. The reentrant angle in the prism zone is about 8"; $\alpha = 1.400$; $\beta\gamma = 1.74$; 2V = 3–5"; optically negative with very pronounced $r > v$ dispersion. Extinction (following the augite analogy) is nearly parallel on 100 and —38" on 010. Bxa is very commonly observed on crushed fragments.

4-Chlorophthalic Anhydride.—This compound forms elongated triclinic needles with three pairs of faces parallel to the elongation. The measured values between these faces are 23°4', 47°46' and 109°8'. The terminations of the needles are poorly developed. $\alpha = 1.500$; $\beta = 1.700$; $\gamma = 1.775$; 2V = 55–60°; optically negative; crystals lying so that the extinction is nearly parallel to the elongation give a value close to a-perpendicular to the elongation. The extinction angles on the three faces are 3, 9 and 14°.

4-Bromophthalic Anhydride.—These crystals resemble very closely in appearance the 4-iodo crystals described below except that the prisms are 210, the clino domes are 041 and the negative orthodome is absent. The axial ratio is 1.095:1:1.091; $\beta = 59°35'$. The measured interfacial values are $210–2\bar{1}0 = 50°32'$, $\bar{1}00–\bar{1}01 = 60°9'$ and $014–0\bar{1}4 = 26°32'$. It was impossible to measure γ but a = 1.545 and $\beta = 1.700$; 2V = 90°±; optical character indeterminate; X A c + 15–16", and Z = b.

4-Iodophthalic Anhydride.—The crystals of this substance are monoclinic with an axial ratio of 1.123:1:1.139, $\beta = 73°29'$. They are elongated parallel to the *c* axis with a pronounced development of the clino-pinacoid. Other faces present are 110, 101, $\bar{1}01$ and 012. The measured interfacial angles are $110–1\bar{1}0 = 94°12'$, $101–\bar{1}01 = 89°37'$, $012–0\bar{1}2 = 57°20'$. Because of its high index of refraction it was impossible to determine γ, but $\alpha = 1.555$ and $\beta = 1.77$, 2V = 60–70°; optically negative; X very nearly *c;* and $Z = b$.

The iodo and bromo compounds are probably isomorphous. The chloro and fluoro compounds, being triclinic, may be considered either dimorphous with forms which fall in the iodo–bromo series or distinctly different. In the case of the chloro compound we have many similarities to the bromo especially in the optical properties, so the first supposition is probably correct. With the fluoro compound there is no evidence which shows such a similarity; in fact, what evidence there is seems to support the second supposition, although that cannot be definitely established from the crystallographic data.

Summary

4-Fluoro-, 4-chloro-, 4-bromo-, 4-iodo- and 3-iodophthalic anhydrides have been condensed with phenol to form phenol-halo-phthaleins. From the 4-halophthalic anhydrides, mixtures of isomeric phthaleins were obtained but in the case of 3-iodophthalic anhydride only one phthalein was found.

Data obtained by Dr. Slawson have shown that 4-fluorophthalic anhydride does not fit into the same crystallographic scheme with the three other 4-halophthalic anhydrides.

THE MECHANISM OF THE VAPOR PHASE OXIDATION OF ISOMERIC OCTANES. I. NORMAL OCTANE[1]

BY J. C. POPE, F. J. DYKSTRA AND GRAHAM EDGAR

RECEIVED FEBRUARY 1, 1929 PUBLISHED JUNE 5, 1929

I. Introduction

The oxidation of hydrocarbons represents a subject which has attracted the attention of many investigators, yet it cannot be said that the fundamental mechanism of such reactions has been made perfectly clear. Perhaps this has been partially due, on the one hand, to a natural tendency to generalize from results obtained on the simpler hydrocarbons and, on the other, to failure to differentiate between liquid phase reactions and vapor phase reactions.

The results of the present investigation on octanes may perhaps contribute to the interpretation of the behavior on oxidation of hydrocarbons intermediate in complexity.

No attempt will be made to give an elaborate survey of the literature on the general subject of oxidation, but a few references to vapor phase oxidation of normal paraffins may be cited. Bone[2] and his associates demon-

---

[1] Presented in part at the Fall Meeting of the American Chemical Society at Swampscott, Massachusetts, September, 1928.

[2] Bone and co-workers, *J. Chem. Soc.*, 81, 535 (1902); 83, 1074 (1903); 85, 693 (1904); 89, 660, 1614 (1906).

strated that the simpler normal hydrocarbons oxidize with the intermediate formation of aldehydes. These authors interpreted their results as indicating that an alcohol is first formed which is then rapidly oxidized to an aldehyde, a theory since well known as the hydroxylation theory. Wheeler and Blair[3] investigated the oxidation of hexane and noted the copious formation of aldehydes. A process of oxidation was formulated based on the hydroxylation theory and involving the possibility of several simultaneous points of attack on the hexane molecule.

Recently Callendar[4] has reported "acetaldehyde, formaldehyde, valeraldehyde, etc.," among the products of the vapor phase oxidation of normal hexane.

It is not possible from these data to determine by what process oxygen attacks a long carbon chain in the vapor phase and by what steps the reaction progresses.

In the present study octanes were selected for investigation because their molecular weight is about the average of commercial gasolines, the mechanism of whose oxidation is a problem of great interest. Part I presents data on the oxidation of n-octane and the oxidation of n-heptaldehyde and *n*-butyraldehyde, which were studied in order to clarify certain observations on the oxidation of n-octane; Part II will discuss the oxidation characteristics of five isomeric octanes. The reactions were studied entirely in the vapor phase, by the dynamic method.

II. Apparatus and Experimental Methods

(a) General.—Mixtures of octane vapor and air were passed through a heated glass tube and samples of the gas were taken for analysis In certain experiments the liquid products of oxidation were collected and examined. Certain details of technique seem worthy of full description. The entire apparatus is illustrated in Fig. 1.

(b) Furnace and Thermocouples.—The furnace was a tube of pyrex glass 1″ in internal diameter and about **36**" long with a reaction space of 367 cc. It was wound with resistance wire and heavily lagged with asbestos. The lagging was thicker at the ends so that in the absence of reaction the temperature was approximately constant over the entire furnace length. Temperature was controlled by external resistance. When runs were made with rising temperature, the heating current was altered by hand to keep the temperature rising smoothly. **A** run over the range of 200–650° usually occupied about two hours.

Two thermocouples were provided, one of which was inserted through either end. They could be moved to investigate the temperature gradient of the furnace but were usually placed in definite positions, one at the entrance end, *2* inches from the reaction mixture inlet (see below), the other at about 10 inches from the exit end.

(c) Method of Obtaining Combustible Mixture.—Where it is necessary to preheat the fuel for vaporization, as is the case with a high-boiling material like n-octane, it becomes essential to avoid exposure to oxygen until the proper experimental temperature

---

[3] Wheeler and Blair, J. *Soc. Chem. Ind.,* 42, 491T (1923).

[4] Callendar, Aeronautical Research Committee, London, Reports and Memoranda, No. 1062, "Dopes and Detonation," second report.

is reached. Hence the principle followed was to preheat and vaporize the fuel in nitrogen only, and to mix it as suddenly as possible with the requisite amount of oxygen when the furnace temperature had been reached.

The vaporization and mixing devices are shown in Fig. 1. The fuel was led from a 50-cc. buret reservoir to a 5-cc. buret graduated in 0.02 cc., from which it was allowed to flow at intervals into the slightly inclined arm of the feed device. The liquid head in the latter was thus maintained at any selected point by intermittent additions of small volumes. The difference in head on the shallow incline, produced by each addition, was so slight and the resistance of the capillary tube so great, that very constant rates of feed were obtained. Further, the volume fed from the small buret was read every few minutes, thus giving a continuous oversight of the fuel mixture. From the inclined arm the fuel passed through a long capillary ending in a flat ground surface within the preheater tube. Here nitrogen purified by passage through alkaline pyrogallol and dried over the calcium chloride was passed over the emerging liquid and the resulting mixture was then led to the large annular tube by which it entered the furnace. Oxygen dried over calcium chloride was led into the furnace by the inner annular tube. (The two annular tubes extended about 6 inches within the furnace heating coil.) Mixing took place in a device consisting of a glass spiral placed concentrically with the annular tubes carrying the two gases. On meeting the gases were diverted from their straight course and forced together round the spiral, in which process they became intimately mixed. The efficiency of mixing was proved by tests with oxygen and nitrogen alone, in which the gases were analyzed shortly after leaving the mixing tube.

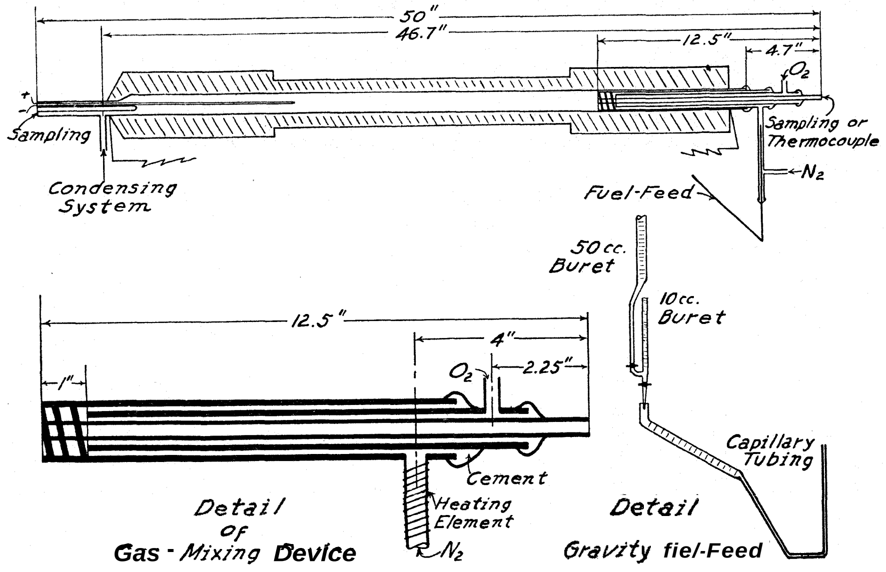

Fig. 1.

(d) Control of Mixture.—The oxygen and nitrogen were passed into the furnace at a rate identical for all experiments and were measured and controlled by flow meters. The final mixture of these gases contained about 20.5% of oxygen. The oxygen–fuel ratio was governed entirely by the amount of fuel used, and in the experiments described herein with n-octane was between 11 and **13** to 1, the theoretical ratio for octane being 12.5 to 1. These figures refer to the input of materials.

(e) Period of Contact.—The minimum time necessary for the gases to pass through the furnace was about 25 seconds at 650" and the maximum about 50 seconds at 200°. Since the reaction occurs almost entirely in a narrow zone, the actual time of reaction is less than these figures indicate.

(f) Sampling System.—Gas samples were taken over mercury. They were collected through a T-piece placed in the line beyond the condensing system, except when investigating the course of the reaction at different positions in the furnace. The samples correspond to a narrow range of temperature, when taken on a rising temperature, since the sampling occupied about ninety seconds, corresponding to a rise of furnace temperature of not over 6°. The mean sampling temperature was used as the reaction temperature of such samples.

For collecting the liquid condensate when required, four units were used, one ice-cooled glass coil, one filter cartridge to stop mist and two glass coils, cooled with carbon dioxide snow.

(g) Analytical Methods.—Gas samples were analyzed in an apparatus of the Burrell type. Analysis was made for carbon dioxide, gases absorbed by sulfuric acid, oxygen and carbon monoxide. Occasional analyses were carried through for hydrogen and methane. A blank analysis was made in each experiment of the oxygen–nitrogen mixture without fuel.

Determinations of the following constituents, acid, aldehyde, peroxide and water, were made on certain condensates from the oxidation of normal octane. The condensate was weighed, then washed from the various condensing units with water and a little alcohol, and the total volume of the solution determined. After thorough mixing, samples of known volume were taken for the determinations. Acid was determined by titration with $N/100$ sodium hydroxide, with phenolphthalein as indicator. Following the neutralization, aldehyde was determined on the same sample by the method of Ripper.[5] For the determination of peroxide, an acidified solution of potassium iodide was added to a condensate sample and the flask flushed with nitrogen, blanks (lacking only condensate sample) being treated similarly. The flasks were kept in a dark place. The titrations with $N/10$ thiosulfate were carried out in a stream of nitrogen, the addition of thiosulfate being continued until no further liberation of iodine was observed.

NOT%—It may be stated that if this determination is carried on in the presence of air, as has usually been done by previous investigators, much higher results for peroxide are obtained, caused probably by interaction of aldehydes and oxygen during the shaking A sample of pure heptaldehyde in the presence of air will give a test for peroxide, and since aldehyde and air are both present among the reaction products in the present investigation, the actual source of the peroxides found is uncertain.

For the determination of water, a separate collection of condensate was made and the liquid allowed to remain in the condensing train after weighing. The whole train was then connected to a series of gas-drying tubes containing anhydrous copper sulfate and air at room temperature was aspirated through towers of anhydrous copper sulfate and allowed to evaporate the condensate and carry it through the weighed tubes. Passage of air was continued until the weight of copper sulfate remained approximately constant.

(h) Materials Used.—The n-octane used was synthetic material with a boiling range 124.9–125 3° (763 mm., uncorr.).

The aldehydes were Eastman products, further fractionated. The boiling ranges were n-heptaldehyde, 152.1–152.6"; n-butyraldehyde 74.0–74.6° (763 mm., uncorr.).

III. Description of Results

n-Octane

(a) General.—In studying exothermic reactions of this character, where the actual temperatures of the reacting mixture may be considerably higher than the furnace temperature, and always vary at different positions in the furnace, it is somewhat of a problem to decide what temperatures are to be considered as the temperatures of reaction. Since the greater part of the reaction occurs in a short zone of the reaction tube, it was considered in this investigation that the actual temperature registered by the thermocouple in this zone was the most satisfactory basis for comparison, and these "maximum furnace temperatures" have been employed throughout in considering the effect of temperature.

Experiments were carried out in two ways: (a) at constant furnace temperature, for the purpose of examining the temperature distribution at different parts of the furnace, of collecting liquid oxidation products and of observing the extent of reaction at different positions in the furnace (for this purpose the heating current and fuel feed were held constant for a long period of time to secure equilibrium conditions before samples were taken); (b) with slowly rising temperature (about 4° per minute), gas samples being taken for analysis from time to time until any given temperature range had been covered. The mean temperature while the sample was being taken was recorded as the temperature of reaction.

As far as gaseous products were concerned the two methods gave results differing slightly quantitatively, as would be expected because of the somewhat different relationship between the temperature of the wall and that of the charge. These differences were not sufficient, however, to indicate any appreciable change in the nature of the reaction.

As will be indicated below there are certain temperature ranges in which rather abrupt changes occur in the reaction characteristics, and in these ranges it was impracticable to maintain constant temperature conditions. The phenomena observed in these temperature ranges contributed greatly to the interpretation of the reaction and the runs with rising temperature have, therefore, been selected for the detailed discussion.

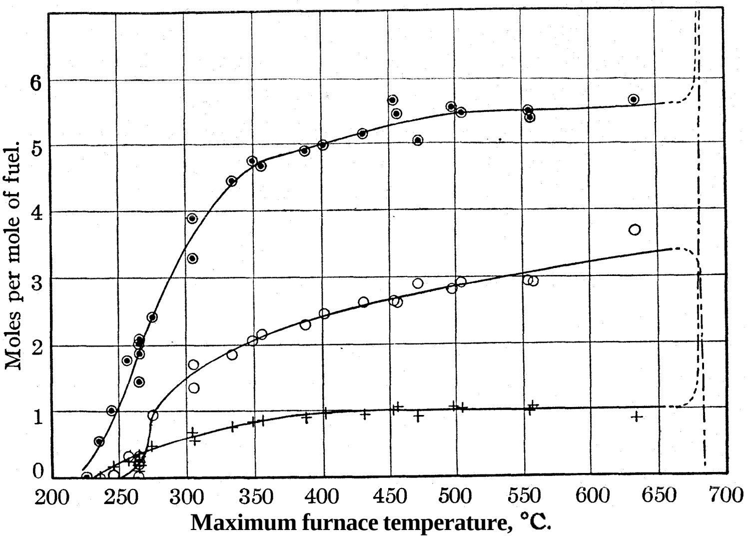
(b) Runs at Constant Temperature.—The analyses of the gaseous products of oxidation at constant temperature do not add materially to the knowledge gained from the runs at slowly rising temperature, which will be discussed fully below. They will, therefore, not be considered further, except to point out that it was clear from the results that the reaction when considerable in extent was largely localized in the first 20% of the tube length. This was shown by temperature measurements at different positions in the tube, which showed a sharp rise in temperature immediately after mixing when the reaction was proceeding to a considerable extent, and by analysis of the gaseous products, which showed little change in oxygen consumption between 20% of the tube length and the extreme end. While no corresponding measurements were made in runs with the furnace temperature rising, it seems most probable that the results would be essentially the same. A few runs at constant temperature were carried out for a sufficient length of time to collect a small portion of liquid, condensed as indicated above, from the gaseous products. These liquid oxidation products invariably contained considerable aldehyde and water. At low temperatures some unoxidized octane was recovered. Aldehyde and water were the first oxidation products detectable. Traces of peroxide (probably) were found, and at low temperatures small amounts of acid were present, diminishing as the temperature was raised and disappearing entirely at about 400°. The general nature of the oxidation products at low temperatures is shown by the following analyses at 260° (figures per mole of octane input): unoxidized octane, 0.55; aldehyde, 0.33; acid, 0.25; peroxide (?), 0.07; water, 0.36. On account of the difficulty in analyzing these small amounts of liquid and because of the possible presence of small amounts of other substances which might escape the analytical methods employed, these figures must be considered as very approximate. For these reasons the quantitative aspects of the liquid products will not be considered in the detailed discussion of the mechanism of the reaction.

(c) Runs **with** Slowly Rising Temperature.—The reactions may be divided fairly definitely into three temperature zones: 200–270°, 270–650°, above 650°, the significance of which will be discussed below. For convenience the phenomena covering the whole temperature range are described under the heads (1) oxygen consumption, (2) gaseous oxidation products and (3) luminescence. The analytical results on oxygen consumption and gaseous products are expressed graphically in Fig. 2. All data are expressed on a basis of moles per mole of octane input, and the temperatures are those recorded by the thermocouple in the center of the reaction zone. Data from five separate runs are included.

(1) Oxygen Consumption.—Below 200" no oxygen consumption is indicated by analysis. Between 200 and 270° the oxygen content of the gas decreases regularly until the consumption calculated per mole of octane amounts to about two moles. At a temperature of about 270° some alteration in the nature of the reaction is indicated by pulsations of the flow meters. The pulsations at first occur at ten to fifteen seconds apart, but gradually become more frequent and weaker until at 300–320° they are no longer noticeable. During this time there is a slightly increased rate of rise of temperature of the first thermocouple, followed by localization of the heat evolution near the thermocouple, which may then record a temperature more than 100° higher than that given by the other. Throughout this period the oxygen consumption rises steadily, but the curve gradually

becomes less steep (Fig. 2) and above 350° rises very gradually, the oxygen consumption increasing by one 1 mole from 350 to 650°, where it is nearly 6 moles. Above 650° the nature of the reaction changes again, strong pulsations are noted in the flow meters and the oxygen consumption rises to approximately the theoretical for complete combustion to carbon dioxide and water.

(2) Gaseous Oxidation Products.—The gaseous oxidation products of n-octane are carbon monoxide, carbon dioxide and a small amount of some gas absorbed by fuming sulfuric acid, the nature of which was not determined. Its amount was normally less than half that of the carbon dioxide, and may represent only uncondensed organic residues, such as aldehyde vapors. Hydrogen and methane could not be detected in any case examined for these gases.



◉, O_2 reacted; ○, *CO* produced; +, CO_2 produced.

Fig. 2.—Normal octane (theoretical air/fuel ratio).

Although there is an appreciable consumption of oxygen between 200 and 270°, the gaseous oxidation products are very small in amount. Carbon monoxide is practically absent until temperatures just below 270° are reached. Carbon dioxide rises regularly from zero at 200° to about 0.4 mole at 270°.

The change in reaction character noted above, occurring at about 270°, is marked by the sudden appearance of carbon monoxide in relatively large amount in the gases. This gas is found consistently after the first pressure surge and within a range of a few degrees progressive samples may be obtained containing no measurable carbon monoxide and quantities greater than one-half mole. By the time the surges cease the gas contains about one mole of carbon monoxide per mole of octane. Thereafter the carbon monoxide increases almost mole for mole with the oxygen consumption and at 650° it is present to the extent of 3.5 moles.

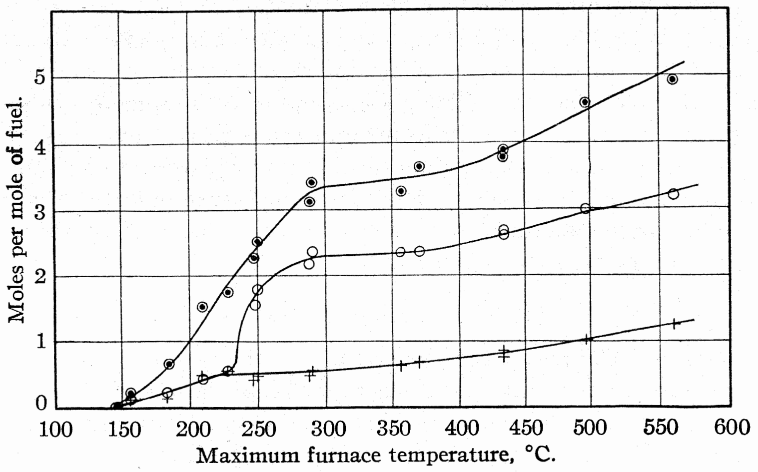
Entrance into the second stage of reaction (at 270°) makes no change in the rate of carbon dioxide production. The amount of this gas rises regularly until it reaches one mole at 400°, after which it remains practically constant. This appears to be the case under all conditions of heating. With the incidence of the third stage (above 650°), the carbon monoxide is reduced to a very low figure and is replaced by carbon dioxide.

(3) Luminescence.—The oxidation of octane is luminescent in certain stages. The first temperature zone, 200–270°, does not show luminescence. The entrance into the second zone may be noticed in the dark by the sudden filling of the tube with a feeble white glow which appears to move counter current to the gas. It forms repeatedly, coincident with the pressure surges, dying away completely in the intervals between them. As the temperature rises, the intervals between flashes grow successively shorter, the initial point of the flash apparently moving toward the inlet point. Ultimately the glow becomes stationary on the gas inlet, where it remains up to 650°. The high temperature pulsations, above 650°, are characterized by a much brighter blue flash which seems to move in the same direction as the gas stream. After the passage of the blue flame, the original pale glow of the second stage is still visible at the inlet. When the temperature becomes sufficiently high, the blue flame likewise settles at that point. The phenomena may be observed in reverse order on cutting off the heating current.

Heptaldehyde and Butyraldehyde

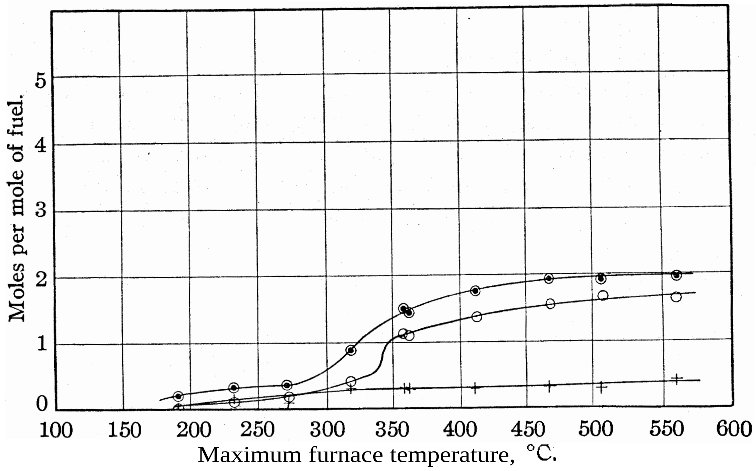
(a) General.—The oxidation of the two aldehydes was studied in a manner similar to that used with n-octane. The same oxygen–nitrogen mixture was used and the fuel rate adjusted to give sufficient oxygen for complete combustion. Thus the oxygen–fuel ratio was about 10–1 for heptaldehyde and about 6–1 for butyraldehyde. The time of passage through the furnace was essentially the same as in the case of n-octane. The curves showing the oxygen consumption and carbon oxides formation for heptaldehyde and butyraldehyde are presented in Figs. 3 and 4, respectively, referring to rising temperature runs.

(b) Heptaldehyde.—Heptaldehyde commences to absorb oxygen at about 150°, the oxygen consumption curve rising steeply, but slightly less so than in the case of octane. At about 300° the curve becomes almost flat; it then rises more gently. In contrast to the behavior of n-octane, both carbon monoxide and dioxide are produced together from the beginning, until at about 235° they are each present to the extent of about 0.5 mole. At this point pulsations in the flow meters occur as with octane, accompanied by luminescence, and carbon monoxide is at once produced in larger quantities, rising to over 2.0 moles at 275°. (That the carbon monoxide formed is produced by oxidation of n-heptaldehyde and not by thermal decomposition was proved by experiments with both heptaldehyde and butyraldehyde made in the absence of oxygen, in which carbon monoxide was not observed at the temperatures in question.) As in the case of octane, also, the carbon dioxide is unaffected by this critical point and it proceeds to rise at the same rate at least up to 570°.



◉, O_2 reacted; ○, CO produced; +, CO_2 produced.

Fig. 3.—Normal heptaldehyde (theoretical air/fuel ratio).



◉, O_2 reacted; ○, CO produced; +, CO_2 produced.

Fig. 4.—Normal butyraldehyde (theoretical air/fuel ratio).

The high temperature pulsations, observed with heptaldehyde under somewhat different conditions, were not encountered in these experiments.

(c) **Butyraldehyde.**—The oxidation of butyraldehyde presents the same general features as that of heptaldehyde. It exhibits, however, a long period (200–335°) over which there is a very slight oxygen absorption, with small amounts of carbon monoxide and dioxide. A sharp rise in carbon monoxide occurs at 335°, corresponding to flow meter pulsations. These pulses, however, are very feeble and the temperature range of their duration is very short. The carbon dioxide remains almost constant after this stage, at about 0.3 mole. The high temperature pulsations were not observed in these experiments, in which the maximum temperature was 560°. No luminescence observations were made.

IV. Discussion of Results

(a) General Course of the Reaction.—So many possibilities exist as to the reactions which may take place in the oxidation of as complex a molecule as that of n-octane, and so involved do the phenomena described above appear that it seemed at first most unlikely that the data could be interpreted by any simple set of reactions. Careful consideration of the data, however, led to the conclusion that the reaction proceeds below 650° practically entirely according to a very simple mechanism, and all phenomena observed may be accounted for on this basis. The nature of the reaction above 650° will be discussed below.

The early appearance of aldehyde and water among the reaction products, the invariable presence of considerable aldehyde under all conditions and the general similarity of the oxidation curves of n-octane and the aldehydes suggest strongly that the primary oxidation product of octane is an aldehyde, and that this aldehyde is further oxidized with the formation of other aldehydes of lower molecular weight. The simple hypothesis was therefore made that the oxidation of n-octane proceeds according to the following steps:

$$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3 + O_2 = CH_3CH_2CH_2CH_2CH_2CH_2CH_2CHO + H_2O \quad (1)$$

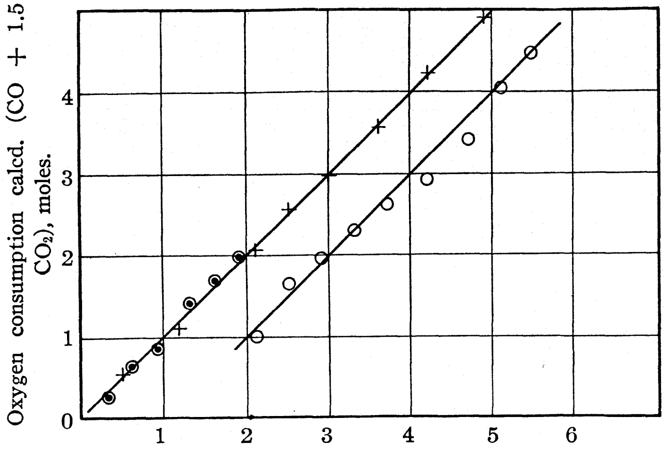
Main reaction, $CH_3CH_2CH_2CH_2CH_2CH_2CH_2CHO + O_2 =$
$CH_3CH_2CH_2CH_2CH_2CH_2CHO + H_2O + CO$ (2a)

Side reaction, $CH_3CH_2CH_2CH_2CH_2CH_2CH_2CHO + 1.5\,O_2 =$
$CH_3CH_2CH_2CH_2CH_2CH_2CHO + CO_2 + H_2O$ (2b)

Reaction (2) was assumed to continue in the same way, yielding each time an aldehyde of the next lower number of carbon atoms to that oxidized.

This hypothesis was tested as follows. (I) According to the assumptions above, the oxidation of n-octane differs from that of an aldehyde only by the amount of oxygen necessary to convert octane to octaldehyde. Therefore, under conditions in which no unoxidized octane remains, the number of moles of oxygen consumed by n-octane should be greater by one mole than that consumed by heptaldehyde or butyraldehyde for corresponding quantities of carbon monoxide and carbon dioxide formed. The results of calculations based on the curves of Figs. 2, **3** and 4 are given in Fig. 5, in which the sum of the moles of carbon monoxide and 1.5 times the moles of carbon dioxide is plotted against the experimental oxygen consumption. It is clear that the curve for heptaldehyde and butyraldehyde differs from that of n-octane by a figure very close to unity.

(2) The total oxygen consumed by *n*-octane at any temperature should, therefore, be the sum of unity (Reaction 1) plus the moles of carbon monoxide produced (Reaction 2a) plus 1.5 times the moles of carbon dioxide produced (Reaction 2b); while for heptaldehyde and butyraldehyde the total oxygen consumed should be the sum of the moles of carbon dioxide produced plus 1.5 times the moles of carbon dioxide produced. Calculations were made accordingly and the data are compared in Fig. 6 with the experimental data for oxygen consumed. The agreement is surprisingly good, considering the complexity of the octane and aldehyde molecules and the number of reaction products which are possible.

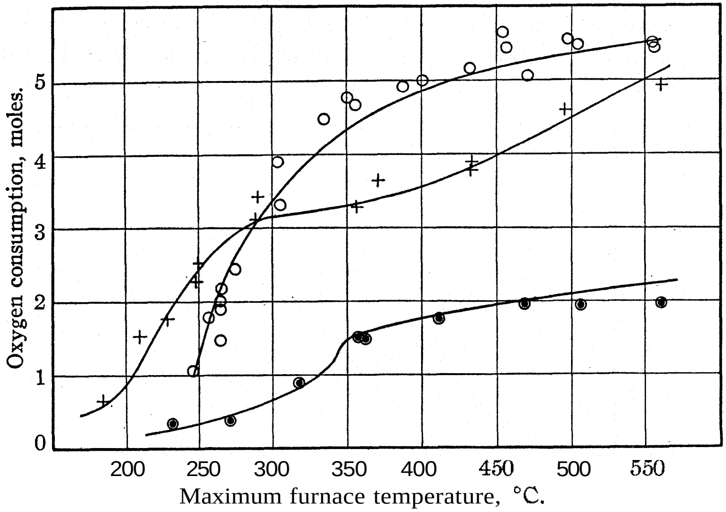


Oxygen consumption, observed, moles.

◉, n-Butyraldehyde; +, *n*-heptaldehyde; ○, *n*-octane.

Fig. 5.

It was found possible to fit the experimental data for *n*-octane reasonably well by making other hypotheses concerning the initial point of attack, but no other hypothesis than the one cited above gave a simple interpretation of the oxidation of the aldehydes as well. Any attack of the aldehyde chain other than at the end would involve more oxygen consumption for a given amount of carbon oxides formation than is found experimentally. Such consumption of oxygen, if appreciable, whether by the formation of water and an unsaturated compound, or the formation of a glycol, or ketone (which would lead to the rupture of the carbon chain at some other position than the end) would make the calculated figures for oxygen consumption diverge from the experimental more widely than is found to be the case. Since practically all of the oxygen consumed is accounted for by the reactions in question, it seems reasonable to suggest that the oxidation of *n*-octane in the vapor phase proceeds substantially according to the simple hypothesis postulated above.



Lines—calculations. Points—experimental. +, *n*-Heptaldehyde; ○, n-octane; ◉, n-butyraldehyde.

Fig. 6.

(b) Mode of Initial Attack.—(1) It has been suggested that the initial attack of oxygen upon a hydrocarbon molecule involves the formation of peroxides. The data cited above offer little evidence for or against such an hypothesis, since such compounds would be expected to be unstable and to exist at any one time in very small amount. Traces of substances reacting with aqueous potassium iodide were found in the liquid oxidation products examined, their actual concentration varying very little. It has been pointed out above that their significance is doubtful. It would appear from this that if those substances represent the peroxides supposedly involved in the initial attack of the hydrocarbon, they are involved in the further oxidation of the aldehydes also, since they appear at temperatures where several moles of oxygen are consumed as well as at low temperatures where the primary oxidation is chiefly concerned. Certainly there is no evidence here of their accumulation at any stage of the reaction.

(2) As in the case of other investigations of vapor-phase oxidations no experimental evidence was obtained of the formation of alcohols. This has been explained, by proponents of the hydroxylation theory, by the supposed ready oxidation of such alcohols to aldehydes. The recent work of Layng and Youker[6] on the oxidation of heptyl alcohol (which confirms the authors' experience with ethyl alcohol) has indicated that alcohols are oxidized in the vapor phase with extreme difficulty in the absence of catalysts. It appears, therefore, much more probable that aldehydes and not alcohols are the primary oxidation products.

(c) Formation **of Carbon** Monoxide and **Carbon** Dioxide.—There appears to be a distinct difference in the nature of the reactions forming carbon monoxide and carbon dioxide. The latter reaction is unaffected by the rate of heating, and shows no abrupt change at any point. It does not become a large factor in the total reaction until temperatures above 650° are reached. Apparently it is a side reaction presenting no unusual characteristics and has been so considered by the authors.

The reaction involving the formation of carbon monoxide appears to be of an entirely different type. The suddenness with which it appears at about 270°, the sharp decrease in its temperature coefficient at slightly higher temperatures and its accompaniment by pressure surges and luminescent flashes, suggest that it belongs to the class of photochemical "chain" reactions, to which several simpler types of oxidation reactions have been shown to belong. This is supported by certain of the authors' experiments on the oxidation of *n*-octane in which the reaction tube was filled with glass tubing to increase surface exposure. The formation of carbon monoxide was substantially suppressed under these conditions, while the carbon dioxide formation was little affected. It seems probable that toward the end of Zone 1 activated molecules of some type are beginning to accumulate. That these molecules are those of aldehyde rather than of octane is indicated by (1) the fact that octane oxidizes at these temperatures very readily to aldehyde, and it is therefore present to a very small extent at the exit end of the reaction tube where the luminescent flashes originate; (2) the fact that entirely similar phenomena occur in the oxidation of heptaldehyde and butyraldehyde. The temperature at which they occur with a comparable aldehyde (heptaldehyde) is lower (235° against 270°), but it must be remembered that the concentrations and energy conditions of all reactants are somewhat different in the two cases.

The sudden reaction initiated by these accumulated activated molecules presumably corresponds to the surges and luminescence, the reaction becoming quiescent while fresh accumulation occurs. As the temperature is raised the intervals between the surges become shorter and the reaction is initiated nearer the inlet, finally occurring smoothly at this point.

With heptaldehyde alone the formation of carbon monoxide proceeds slowly at low temperatures without the appearance of surges or lumines-

---

[6] Layng and **Youker,** *Ind. Eng. Chem.*, **20,** 1048 (1928).

cence, probably because at these temperatures accumulation of active molecules is not occurring at a sufficient rate to initiate the sudden intermittent reactions which occur at somewhat higher temperatures.

(d) High Temperature Reaction.—At high temperatures (660–670° for *n*-octane, and higher than 570° for heptaldehyde and butyraldehyde) the oxidation proceeds practically explosively to carbon dioxide and water. When this reaction begins the temperature in the furnace rises rapidly to a point where it is necessary to discontinue the experiments in order to prevent softening of the glass. No detailed study of this phase of the reaction could therefore be made, and it is not possible to state definitely whether or not the fuels burn directly to carbon dioxide and water, or whether the primary oxidation products are further burned at this stage. The fact that the luminescence associated with the carbon monoxide reaction was still visible between the blue flashes of the second type of explosion would seem to argue for the latter explanation. Further discussion of this point will be given in Part II.

The abrupt changes in reaction character occurring at about 270 aqd 650" for n-octane have some similarity to certain phenomena involved in the spontaneous ignition of octane–oxygen mixtures, a matter which will be discussed in a later paper.

(e) Interpretation of the Oxygen Consumption Data.—In the light of the above interpretation of the experimental facts, it is interesting to examine the oxygen consumption curve (Fig. 2) of n-octane somewhat more closely. The first part of the curve (200–250°) must represent largely formation of water and aldehyde, the latter not oxidizing to any great extent until its concentration becomes appreciable. Its oxidation at these temperatures is largely to carbon dioxide (Reaction 2b) and perhaps partially to acid. As the temperature rises, the oxidation to carbon monoxide predominates, the reaction becoming luminescent and more intense (as evidenced by the sharp rise in temperature immediately after mixing). By the time the temperature has reached 400° the reaction has produced largely aldehydes of the order of butyraldehyde or lower, and these are so much more difficultly oxidized than those of higher molecular weight (compare heptaldehyde and butyraldehyde), particularly in the reduced oxygen concentration, that further reaction occurs very slowly as the temperature is raised until this becomes high enough (above 650°) to carry the oxidation completely to carbon dioxide and water. The oxidation of heptaldehyde slows down similarly when lower aldehydes, sufficiently difficult to oxidize, are formed. It is perhaps significant that the slowing down occurs with heptaldehyde when about three moles of oxygen have reacted, as compared with the similar slowing at five moles of oxygen reacted for n-octane. Presumably the nature of the oxidation products at these respective stages is very similar.

The oxygen consumption curves of heptaldehyde and butyraldehyde are somewhat similar to that of n-octane, but the difference in the nature of the early reaction is shown by the fact that in the case of the aldehydes the oxygen consumption corresponds to the carbon oxides formed, while in the case of octane the early stage involves very little of these oxidation products. Altogether it appears that the interpretation of the oxidation phenomena outlined above is in excellent agreement with the experimental facts and affords a simple explanation of most of the phenomena observed.

V. Summary

1. The vapor phase oxidation of n-octane, n-heptaldehyde and *n*-butyraldehyde has been studied in detail.
2. The results may be simply interpreted on the theory that the initial oxidation product of 7%-octane is octaldehyde, which in turn is further oxidized to aldehydes of successively smaller number of carbon atoms, carbon monoxide and some carbon dioxide being simultaneously formed.
3. The existence of luminescent "chain" reactions is indicated, apparently corresponding to the oxidation of the aldehydes to lower aldehydes, carbon monoxide and water.

TAUTOMERISM OF HYDROXYTRIARYLCARBINOLS. II

BY L. C. ANDERSON

RECEIVED FEBRUARY 5, 1929 PUBLISHED JUNE 5, 1929

By the combination of spectroscopic and chemical evidence presented in a previous paper[1] it has been shown that the quinonoid modification of 3-methyl-4-hydroxytriphenylcarbinol is not a mixture of the fuchsone and the benzenoid form of the carbinol. Further studies of the absorption spectra of the above-mentioned carbinols, of 3-methoxy-4-hydroxytriphenylcarbinol and of the 5-chloro- and 5-bromo-derivatives of 3-methyl-4-hydroxytriphenylcarbinol have given further evidence of the quinonoid forms of these hydroxytriarylcarbinols.

The quantitative absorption curves of ether solutions of the methanes, benzenoid modifications, quinonoid modifications and the fuchsones of the aforementioned carbinols have been determined and the points in the visible and ultraviolet portions of the spectrum (7600–2350 Å.) at which a maximum and a minimum of energy is absorbed by these solutions have been located. We have found in the curves for some of the quinonoid forms that the absorption band in the violet region and in the ultraviolet region adjacent to the visible is at a position different from that which it has in the corresponding fuchsone (Table I). This is a positive indication in

---

[1] Anderson and Gomberg, THIS JOURNAL, 50, 203 (1928).

itself that the color of our colored carbinol is not due to the presence of small quantities of the fuchsone and hence that this compound must itself be a quinonoid carbinol.

The quinonoid curve as compared to that of the fuchsone is displaced toward the shorter wave lengths in 5-chloro- and 5-bromo-*o*-cresyldiphenylcarbinols and toward the longer wave lengths in 4-hydroxy-triphenylcarbinol. In *o*-cresyldiphenylcarbinol and guaiacyldiphenylcarbinol the displacement is within our experimental error of determining the position of these peaks.

The similarity of the curves of the members within each class, the methanes, the benzenoid carbinols, the quinonoid carbinols and the fuchsones is very striking. As the molecular weight in each group of compounds is increased some of the peaks for the corresponding derivative in each class are shifted toward the longer wave lengths and some are shifted in the direction of shorter wave lengths. The positions of the bands between frequencies 2800 mm.$^{-1}$ and 2600 mm.$^{-1}$ in the curves for the fuchsones and for the quinonoid carbinols are displaced toward the longer wave length as the molecular weights of each type increase, but the displacement bears no simple relationship to the increase of molecular weight.

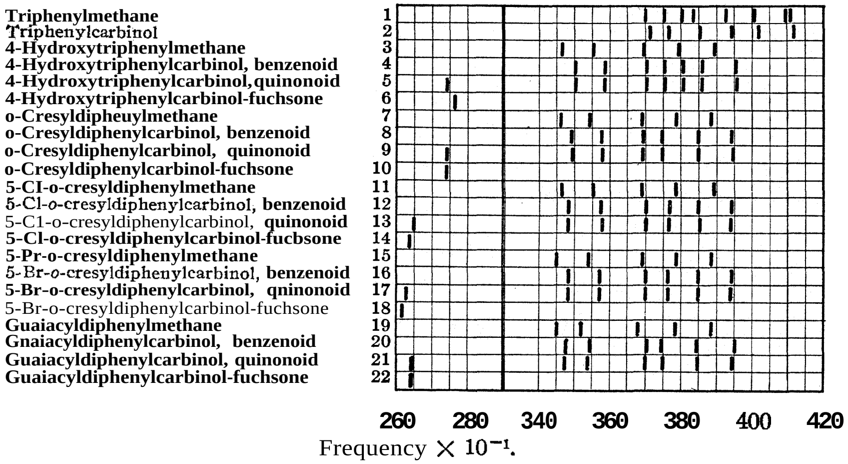

Fig. 1.

Procedure.—The method which we have used in obtaining data for plotting curves to show the quantitative absorption of light by solutions has already been described.[1] For determining the points of maximum and minimum absorption, the relative blackening of the photographed absorption spectra has been measured by means of a Moll recording microphotometer. The spectrograph plate is drawn past the slit of the thermopile at least twice, first, to obtain a curve (a) for the intensity of light in the beam which has passed through the solvent and, second, to obtain a curve (b) for the intensity of light in the beam which has passed through the solution. These curves appear superimposed upon the bromide paper used in the recording instrument. Wherever the two curves have the same slope at a given wave length, there is a point of maximum or minimum absorption. When the solvent curve (a) falls below the solution curve (b) the points of maximum absorption are those wave lengths at which the two curves are farthest apart. Black ink lines ruled upon the plate after exposure and development locate certain frequencies upon the photometer curve and allow any other frequency

to be found from calibration curves. The instrument was calibrated with the spectrograph and comparator by means of the copper spectrum.

The frequencies at which absorption bands have been located in ether solutions of the compounds under discussion are given in Table II and Fig. 1, which also include additional data upon curves already published. We have previously found by visual observation of the spectrograph plates only the four most prominent absorption bands in triphenylmethane and triphenylcarbinol.[2] By using the microphotometer, we have located other peaks in each of the curves and the positions of the bands as now found agree very well with data which have been published by Orndorff, Gibbs, McNulty and Shapiro upon the solutions of these compounds in alcohol.[3]

Purification of Materials

3-Methyl-4-hydroxy-5-chlorotriphenylmethane was obtained by reducing the corresponding fuchsone with zinc and acetic acid. The substance was recrystallized

---

[2] Anderson, This Journal, 50, 208 (1928).

from petroleum ether which had been purified until it showed no selective absorption of light between 2300 and 7500 Å.; m. p. 89–89.5°.

3-Methyl-4-hydroxy-5-chlorotriphenylcarbnol, benzenoid tautomer, was prepared by digesting the fuchsone, or the quinonoid form of the carbinol, with *N* potassium hydroxide solution. The solution was filtered and the colorless filtrate was saturated with carbon dioxide. The crystals were washed and dried; m. p. 145–146°.

3-Methyl-4-hydroxy-5-chlorotriphenylcarbinol, quinonoid tautomer, was prepared by dissolving the corresponding fuchsone in glacial acetic acid. Hot water was added to the solution until the acetic acid concentration had been reduced to 60%. The solution was filtered and the filtrate was allowed to cool very slowly. The crystals produced were filtered, washed with fresh solvent and then dried over a saturated solution of potassium hydroxide in an evacuated desiccator; m. p. 133–134°.

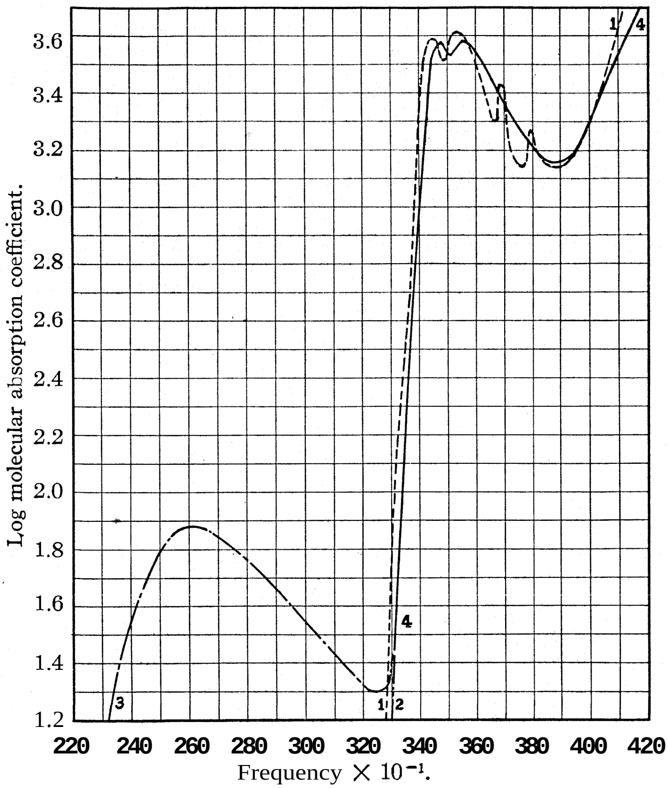

Fig. 4.—Guaiacyldiphenylcarbinol: 1 ---, methane; 2, —··—, benzenoid carbinol; 3, —·—, quinonoid carbinol; 4, —, both benzenoid and quinonoid carbinols.

3-Methyl-4-hydroxy-5-chloroquinodiphenylmethane, that is the fuchsone, was prepared by recrystallizing the corresponding quinonoid carbinol from glacial acetic acid; m. p. 195°.

3-Methyl-4-hydroxy-5-bromotriphenylmethane was prepared by reducing the carbinol with zinc dust and acetic acid. It was crystallized from ether and purified n-hexane; m. p. 119°.

3-Methyl-4-hydroxy-5-bromotriphenylcarbinol, benzenoid tautomer, was precipitated by passing carbon dioxide into a solution of the fuchsone in potassium hydroxide. It was crystallized from ether and optically clear petroleum ether; m. p. 144–145°.

3-Methyl-4-hydroxy-5-bromotriphenylcarbinol, quinonoid tautomer, was prepared by adding to a hot solution of the fuchsone in glacial acetic acid enough hot water to reduce the acetic acid concentration to 60%. The yellow crystals were filtered from the cold solution and were dried over "Ascarite" in a desiccator; m. p. 138–139°.

3-Methyl-4-hydroxy-5-bromoquinodiphenylmethane, the fuchsone of 5-bromo-*o*-cresyldiphenylcarbinol, was recrystallized from hot acetic acid. The crystals were washed with absolute ether until free from acid; m. p. 202–203°.

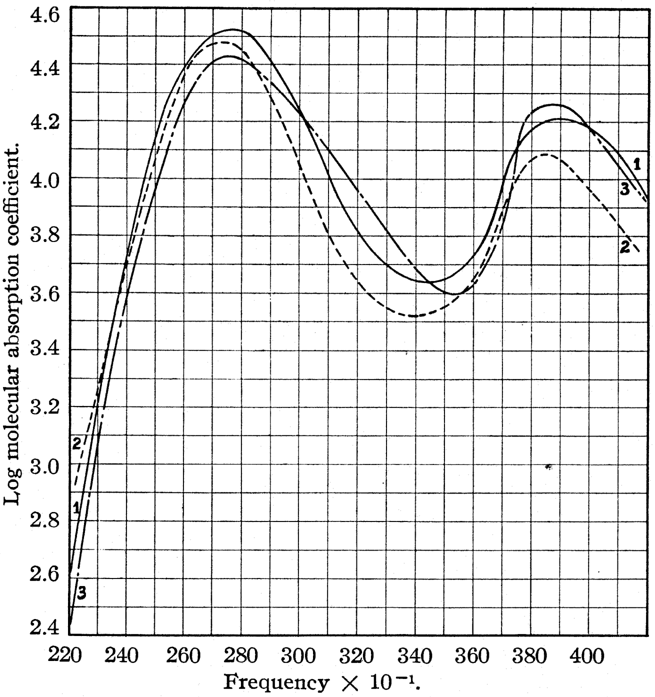

Fig. 5.—Fuchsones of: 1, ———, 5-chloro-*o*-cresyldiphenylcarbinol; 2, ----, 5-bromo-*o*-cresyldiphenylcarbinol; 3, —·—, guaiacyldiphenylcarbinol.

3-Methoxy-4-hydroxytriphenylmethane was prepared by the reduction of the carbinol with zinc and acetic acid. The colorless crystals were recrystallized from ether and n-hexane; m. p. 108°.

3-Methoxy-4-hydroxytriphenylcarbinol, benzenoid tautomer, was purified by several crystallizations from petroleum ether; m. p. 159°.

3-Methoxy-4-hydroxytriphenylcarbinol, quinonoid tautomer, was prepared by recrystallizing the benzenoid tautomer from 60% acetic acid. The bright yellow crystals were filtered off and dried either over saturated potassium hydroxide solution in an evacuated desiccator or over "Ascarite" at atmospheric pressure; m p. 154°. This compound has been previously described as brown crystals which melt at 147°.[4]

---

[4] Gomberg and Van Stone, THIS JOURNAL, 38,1592 (1916).

3-Methoxy-4-hydroxyquinodiphenylmethane, the fuchsone of guaiacyldiphenylcarbinol, was prepaied by crystallizing the quinonoid tautomer from glacial acetic acid. The yellow crystals were heated at 80° for several hours and were then recrystallized from ether; m. p. 182–183°.

Summary

1. Curves and tables have been prepared which show the quantitative absorption of ultraviolet light by ether solutions of the methane, the benzenoid carbinol, the quinonoid carbinol and the fuchsone of each of the following compounds: 5-chloro-o-cresyldiphenylcarbinol, 5-bromo-o-cresyldiphenylcarbinol and guaiacyldiphenylcarbinol.

2. Data have been tabulated which supplement those already published upon the quantitative absorption of light by ether solutions of triphenylmethane, triphenylcarbinol and the methane, benzenoid carbinol, quinonoid carbinol and the fuchsone of each, 4-hydroxytriphenylcarbinol and the o-cresyldiphenylcarbinol.

3. Further evidence based on spectroscopic data is presented to prove the existence of a quinonoid modification of hydroxytriarylcarbinols.

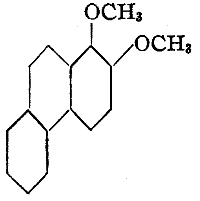
1,2-PHENANTHRENEQUINONE

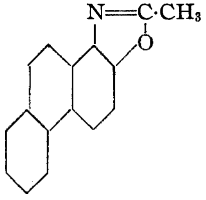
BY LOUIS FREDERICK FIESER

RECEIVED FEBRUARY 8, 1929 PUBLISHED JUNE 5, 1929

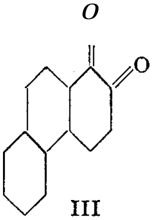
Having found a convenient method of preparing 3,4-phenanthrenequinone from 3-phenanthrol,[1] a similar series of reactions was applied to 2-phenanthrol in the hope of obtaining another isophenanthrenequinone. On reducing with sodium hyposulfite the dyestuff produced by coupling 2-phenanthrol with diazotized sulfanilic acid, an amino-2-phenanthrol was obtained in excellent yield, and the conversion of this substance into a quinone was nearly quantitative. Since both the diacetate and the triacetate of the new amino-2-phenanthrol are easily converted by thermal decomposition into an oxazole derivative, it may be concluded that the coupling has taken place in the ortho position, that is, in either the 1- or the 3-position. Thanks to the valuable synthetical work of Pschorr, a distinction between these two possibilities is not difficult. A dimethoxyphenanthrene was obtained by reducing the phenanthrenequinone and methylating the reduction product. This substance, which must have the structure of either 1,2-dimethoxyphenanthrene or 2,3-dimethoxyphenanthrene, proved to be different from the compound synthesized by Pschorr and Buckow[2] and known to have the structure of the 2,3-isomer. The new substance is thus 1,2-dimethoxyphenanthrene, I, and corresponding structures may be assigned to the oxazole derivative, II, and to the quinone, III.



I



II



III

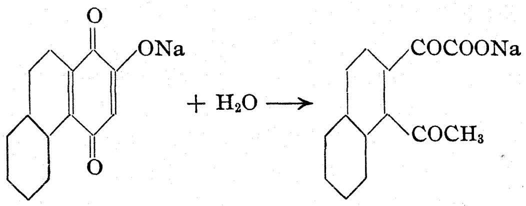
The marked chromophoric character of an isophenanthrenequinone nucleus in comparison with 9,10-phenanthrenequinone was noted in the case of the 3,4-isomer; this is also true of 1,2-phenanthrenequinone, for the substance forms large needles which are brilliant red in color. The similarity between the two isophenanthrenequinones is quite pronounced, and in all but one instance the reactions of 1,2-phenanthrenequinone and of its derivatives follow an entirely normal course. A description of these reactions may be found in the Experimental Part, and it will suffice at this time to call attention to the fact that the hydrolytic cleavage of an hydroxyquinone, noted for the first time in the case of 3-hydroxy-1,4-

---

[1] Fieser, THIS JOURNAL, 51, 940 (1929).

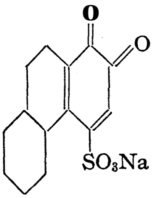
[2] Pschorr and Buckow, Ber., 33, 1831 (1900).

phenanthrenequinone,[1] takes place with great ease with the isomer, 2-hydroxy-1,4-phenanthrenequinone, IV; the reaction being represented as

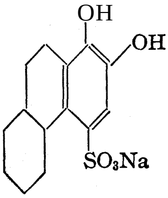


IV V

An interesting deviation from the behavior of other quinones was observed in studying the properties of sodium 1,2-phenanthrenequinone-4-sulfonate, VI. The substance was prepared from the hydroquinone, VII, which, in turn, resulted from the addition of sodium bisulfite to 1,2-phenanthrenequinone. Judging by the properties of other compounds of similar structure, one might expect that VI would react with aromatic



VI



VII

amines in such a way that the sulfonate group would be replaced by an arylamino group. Thus the following compounds all yield water-insoluble anilino- or *p*-toluidinoquinones on reaction with the corresponding amine: 1,2-naphthoquinone-4-sulfonate,[3] 1,2-anthraquinone-4-sulfonate,[4] 3,4-phenanthrenequinone-1-sulfonate,[1] 6,7-indazolequinone-4-sulfonate,[5] and 2-phenyl-benzotriazole-4,5-quinone-7-sulfonate[6] The normal reaction of such quinones with alkali involves, so far as is known,[5] the replacement of the sulfonate group by hydroxyl. 1,2-Phenanthrenequinone-4-sulfonate, on the other hand, undergoes a disproportionation when treated either with p-toluidine or with alkali. On adding alkali to a cold, aqueous solution of the quinone, the color changes at once from red to pale yellow and the solution is now found to contain the hydroquinone, VII. A quantitative study of the reaction, carried out in an indifferent atmosphere and under conditions permitting the detection of any hydrogen peroxide or oxygen which might be formed, showed that one molecule of the hydroquinone results from two molecules of the quinone and that no oxidation

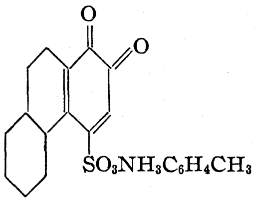
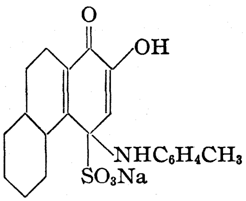
[6] Fieser and Ames, *ibid.*, 49,2614 (1927).

products of water are produced. Thus, while an organic oxidation product was not isolated, there can be little doubt that such a product is formed and that the reaction is of the Cannizzaro type. This reaction is not unusual for all quinones, but only for the particular type of sulfonated quinone under discussion. The unusual feature is that the normal replacement reaction does not occur.

The exceptional character of 1,2-phenanthrenequinone-4-sulfonic acid is even more evident in the reaction with p-toluidine. In neutral aqueous solution a disproportionation again takes place and the p-toluidine salt of the hydroquinone, VII, may be obtained by acidifying the solution. In the presence of mineral acids the disproportionation does not occur, but even under these conditions the replacement of the sulfonic acid group by the p-toluidino group does not take place, for the only reaction product is the *p*-toluidine salt of the quinone-sulfonic acid, VIII.



VIII



IX

The remarkable stability of the sulfonic acid group of this one quinone is probably due to the spatial arrangement of the molecule, for the presence of a benzene nucleus adjacent to the sulfonic acid group is the only structural feature which distinguishes the quinone from all of the similar compounds listed above. If it is supposed that the formation of a p-toluidinoquinone involves, as the first step, the 1,4-addition of the amine to a sulfonated quinone, the influence of the neighboring phenylene group in preventing the formation of an intermediate addition product, IX, is understandable, and this hypothesis appears to afford the most plausible explanation of the phenomenon.

Experimental Part[7]

1-Amino-2-phenanthrol.—The coupling of 2-phenanthrol with diazotized sulfanilic acid and the reduction of the dye by means of sodium hyposulfite proceeded in so nearly the same manner as in the case of 3-phenanthrol[1] that it is only necessary to state the modifications of the method already described, which are required in the present instance. The chief difference is that somewhat more water is required to dissolve sodium 2-phenanthrolate and l-amino-2-phenanthrol hydrochloride than the isomers. The azo compound was first prepared by Werner and Rekner.[8] Like these investigators, I was unable to obtain it in a crystalline condition; the coupling reaction gave a

---

[7] The Dennstedt contact star was employed in carrying out most of the analyses here reported, compare ref. 1, footnote 11.

[8] Werner and Rekner, *Ann.,* 321,307 (1902).

very viscous, colloidal solution of the dye. On reduction with hyposulfite, the aminophenanthrol separated in a very finely-divided condition but the solution filtered without difficulty. The product was often pink, rather than colorless, but this did not interfere with the preparation of the pure hydrochloride. In converting the amine into its salt, it was found expedient to use 6-7 liters of water and 130 cc. of concentrated hydrochloric acid to dissolve the material obtained from 97 g. of 2-phenanthrol. The yield was very close to the theoretical amount.

The free amine was obtained by drying the crude product on a porous plate and crystallizing it from alcohol containing a little sulfur dioxide. It formed glistening plates which were somewhat gray, but which have not undergone further change in nearly a year. The substance begins to darken at about 210°, and there is no definite point of decomposition It dissolves well in alcohol, but is only very sparingly soluble in benzene or ether. The xylene solution darkens on boiling.

Anal. Calcd. for $C_{14}H_{11}ON$: C, 80.35; H, 5.30. Found: C, 80.08; H, 5.51.

1-Amino-2-phenanthrol Hydrochloride.—The salt was purified for analysis by crystallization from an alcoholic solution to which considerable hydrochloric acid was added. A cotton-like mass of colorless micro-needles was thus obtained. The sample became slightly gray during drying; it decomposes in the vicinity of 250". The salt is only moderately soluble in water, but very readily soluble in alcohol. It gives a cherry-red solution on warming with concentrated sulfuric acid.

Anal. Calcd. for $C_{14}H_{12}ONCl$: C, 68.42; H, 4.93. Found: C, 68.59; H, 5.28.

The Acetylation of 1-Amino-2-phenanthrol

When the amine is heated with acetic anhydride for about three minutes, a thick paste consisting chiefly of crystals of the N-monoacetate results. If the heating is continued until the crystals just dissolve, the solution contains chiefly the diacetate, together with a little of the triacetate. Prolonged boiling, preferably with the use of sodium acetate as a catalyst, leads to the complete acetylation of the amine. Both the diacetate and the triacetate are converted quantitatively into the N-monoacetate on boiling the alcoholic solutions with hydrochloric acid. Thus this compound may be prepared from a mixture of the diacetate and the triacetate, while the triacetate is most conveniently prepared from the monoacetate.

1-Amino-2-phenanthrol Diacetate.—A mixture of 1 g. of the amine and 10 cc. of acetic anhydride was boiled until the crystals of the monoacetate just dissolved and the solution was cooled and poured into water. The product was crystallized from benzene until the melting point became constant at 222° (227°, corr.). The compound formed a cotton-like mass of fine, colorless needles; yield, 0.5 g. It is only sparingly soluble in benzene and insoluble in acids or alkalies.

Anal. Calcd. for $C_{18}H_{15}O_3N$: C, 73.69; H, 5.16. Found: C, 73.38; H, 5.18.

1-Acetylamino-2-phenanthrol.—The method of acetylation just described yields, as the crude product, a mixture of the di- and triacetates suitable for the preparation of the monoacetate, but it is convenient to add a little sodium acetate in order to hasten the reaction. The crude product, without being dried, was dissolved in alcohol, hydrochloric acid was added and the solution was boiled until there was no increase in the quantity of the glistening white plates of the monoacetate. The yield was practically quantitative. The substance may be dissolved in alkali and recovered without change. It is very sparingly soluble in alcohol, benzene or glacial acetic acid and it crystallizes from nitiobenzene, in which it dissolves readily, in the form of plates melting at 295°.

Anal. Calcd. for $C_{16}H_{13}O_2N$: C, 76.46; H, 5.22. Found: C, 76.56; H, 5.12.

I-Amino-2-phenanthrol **Triacetate.**—A mixture of equal parts of the monoacetate and fused sodium acetate with ten parts of acetic anhydride was boiled for one and one-half hours and the solution was then poured into water. The triacetate soon separated in the form of a clean solid melting at 122–123°, and the yield was close to that called for by theory. The substance, which dissolves very readily in alcohol or benzene, is best crystallized from ligroin, when it forms colorless scales melting at 125".

Anal. Calcd. for $C_{20}H_{17}O_4N$: C, 71.62; H, 5.11. Found: C, 71.63; H, 5.01.

Oxazole Derivative of 1-Amino-2-phenanthrol (II).—This compound was obtained from both the diacetate and the triacetate. The material was heated in a distilling flask with a sealed-on receiver until no more acetic acid or anhydride was given off and then distilled at a pressure of 3 mm. The oxazole is very readily soluble in alcohol, benzene or ligroin, but insoluble in acids or alkalies. It was crystallized from methyl alcohol, forming slender colorless needles on rapidly cooling the solution, and very large thick needles on slow cooling. The substance melted at 120°.

Anal. Calcd. for $C_{16}H_{11}ON$: C, 82.37; H, 4.76. Found: C, 82.03; H, 4.95.

Oxidation Experiments.—Attempts to convert the above oxazole derivative into a quinone were unsuccessful. It appeared that the substance is oxidized with difficulty and that, when the reaction does proceed, it quickly passes beyond the quinone stage. The triacetate of 1-amino-2-phenanthrol, treated with an equal weight of chromic acid in glacial acetic acid solution at 60°, gave a very small amount of a substance which appeared to be a quinone (orange color, green solution in alcoholic alkali), but the only product isolated in any quantity was aminophenanthrol diacetate. Thus the partial hydrolysis of the starting material is at least partly responsible for the failure to obtain a good yield of the quinone in this case.

1,2-Phenanthrenequinone

In preparing this quinone it is advisable to start with 2-phenanthrol and to carry out the various operations, including the oxidation of the aminophenanthrol, without isolating any of the intermediates. Quantities of the materials found convenient for the preparation are given below, while reference has already been made to the details of the coupling reaction and the reduction.

To a solution of 30 g. of 2-phenanthrol and 18.5 g. of sodium hydroxide in about 1 liter of water, ice was added until the mixture half filled a 4-liter beaker. After coupling with a suspension of an equivalent quantity of diazotized sulfanilic acid, in about 1 liter of water, reduction with a solution of sodium hyposulfite was carried out, the aminophenanthrol was collected and then washed back into the beaker. A little sodium bisulfite was added, the volume was made up to 2.5 liters with boiling water and 40 cc. of concentrated hydrochloric acid was added. The material rapidly passed into solution and left only a trace of residue on filtration. The solution was cooled rapidly, with stirring, in order that the amine hydrochloride which separated should come down in a finely-divided condition. After cooling to room temperature, an aqueous solution of 13.3 g. (1.3 Th.) of chromic acid and 11 cc. of concentrated sulfuric acid was added all at once. A dark precipitate was first produced, but this soon changed to a bright, finely-divided red product. In order to facilitate the collection and washing of this material, the mixture was heated to the boiling point, while stirring constantly, for this treatment serves to increase greatly the particle size without destruction of the quinone. Thoroughly. washed and dried, the 1,2-phenanthrenequinone formed a red powder weighing 29–31 g. (90–96%). This material is not quite pure, but it is satisfactory for many reactions.

The quinone was purified by crystallization from toluene, in which it dissolves fairly readily. A small amount of black material remained undissolved, and the solution was at first dull red; but by further crystallization from this solvent, with the use of animal charcoal, a brilliant red product was obtained which crystallizes in the form of needles. The substance is moderately soluble in alcohol or benzene and readily soluble in glacial acetic acid; it crystallizes well from the red solutions in all of these solvents. It softens at about 195° and melts with decomposition at 216° (222° corr.). The reaction with concentrated sulfuric acid is both characteristic and beautiful: the solution is at first brilliant blue in color but changes within a few seconds to an intense sap-green. In this respect the substance is similar to 3,4-phenanthrenequinone, though the two are easily distinguished by the test. The two quinones, in crystalline condition, are almost identical in appearance, but the 1,2-isomer is much the less soluble of the two.

Anal. Calcd. for $C_{14}H_8O_2$: C, 80.76; H, 3.88. Found: C, 80.62; H, 4.08.

1,2-Dihydroxyphenanthrene.—On warming an aqueous suspension of the quinone, best in the finely-divided condition in which it is first obtained, with a solution of sodium hyposulfite, the material soon became reduced and a somewhat dark precipitate of the hydroquinone was formed. Enough alcohol was added to bring the material into solution at the boiling point and the solution, after treatment with animal charcoal, was filtered and quickly cooled. The hydroquinone was thus obtained in the form of small, colorless needles which, however, darkened considerably on long storage. The compound melts at 178°. The alkaline solution is at first yellow, but the action of the air soon gives a precipitate of a green quinhydrone, or its salt. In a solution of alcoholic alkali the oxidation soon proceeds beyond this stage and the red sodium salt of 2-hydroxy-1,4-phenanthrenequinone soon separates.

Anal. Calcd. for $C_{14}H_{10}O_2$: C, 79.98; H, 4.80. Found: C, 79.63; H, 4.77.

1,2-Dimethoxyphenanthrene.—1,2-Dihydroxyphenanthrene was methylated in an atmosphere of nitrogen with dimethyl sulfate and alkali. The product was distilled at diminished pressure and crystallized from ligroin. It forms feathery clusters of short. colorless needles melting at 102°.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92. Found: C, 80.60; H, 5.88.

Attempts to convert the compound into a quinone were not successful,

2-Hydroxy-1,4-phenanthrenequinone

1,2,4-Triacetoxyphenanthrene.—This compound was easily obtained by applying the Thiele reaction to 1,2-phenanthrenequinone, but the yield was poor. Twenty-five grams of the finely powdered quinone was slowly stirred into a mixture of 160 cc. of acetic anhydride and 5 cc. of concentrated sulfuric acid, while cooling to room temperature. The quinone dissolved rapidly to give a dark brown solution, from which crystals of the triacetoxyphenanthrene began to separate within a few minutes. After standing for two hours, the mixture was cooled well, the walls of the vessel were scratched to relieve supersaturation and the product was then collected and washed with glacial acetic acid and with alcohol. The material (16 g.) melted at 180–182°, and gave 15.5 g. (36%) of pure 1,2,4-triacetoxyphenanthrene on crystallization. The acetic anhydride mother liquor, on decomposition with water, gave a very dark-colored, tarry product which is not profitably worked for the triacetate. It may be heated with alcohol and sodium hydroxide solution, when the sodium salt of 2-hydroxy-1,4-phenanthrenequinone separates, due to hydrolysis and oxidation. This salt, though mixed with much black material, is easily converted into the pure hydroxy compound, for the impurities are insoluble in water. In this way it is possible to obtain the equivalent of about 5 g. of the triacetate. 1,2,4-Triacetoxyphenanthrene crystallizes well from glacial acetic acid, benzene or benzene–ligroin and forms colorless needles melting at 186° (189°, corr.).

Anal. Calcd. for $C_{20}H_{16}O$: C, 68.16; H, 4.58. Found: C, 68.23; H, 4.65.

2-Hydroxy-1,4-phenanthrenequinone.—Since this quinone is destroyed very rapidly by boiling its alkaline solution, special precautions must be observed in preparing it by the hydrolysis and oxidation of the above triacetate. In the method which follows the process of hydrolysis, which requires either an elevated temperature or a prolonged period of reaction, was carried out separately, and then advantage was taken of the ease of oxidation of the cold hydroquinone solution and the slight solubility of the sodium salt of the oxidation product.

A suspension of 12 g. of 1,2,4-triacetoxyphenanthrene in 100 cc. of alcohol was swept free of oxygen with a stream of nitrogen and 50 cc. of oxygen-free 6 N sodium hydroxide was added. On warming to the boiling point, hydrolysis soon took place with the formation of an orange solution. The solution was then cooled, diluted with 100 cc. of water and treated with a stream of air until there was no further increase in the amount of the red precipitate of the sodium salt of 2-hydroxy-1,4-phenanthrenequinone. This material was then collected, washed with alcohol and dried; yield, 7.4 g. (88%). In order to obtain the free hydroxy compound, the sodium salt was added to *2* liters of boiling water, the solution was stirred vigorously in order to bring the salt into solution as quickly as possible and then filtered into dilute sulfuric acid. The quinone was thus obtained in a pure condition, in the form of an orange-yellow mass of micro-needles.

2-Hydroxy-1,4-phenanthrenequinone is only sparingly soluble in water, very readily soluble in alcohol and readily soluble in benzene or glacial acetic acid. The yellow solutions deposit cotton-like clusters of small, orange-yellow needles melting at 188° (190°, corr.) with decomposition. The solution in concentrated sulfuric acid is intensely green, the alkaline solution is red.

Anal. Calcd. for $C_{14}H_8O_3$: C, 74.99; H, 3.60. Found: C, 74.78; H, 3.62.

2-Methoxy-1,4-phenanthrenequinone.—The hydroxy compound is easily converted into the ether by boiling with methyl alcohol and hydrogen chloride. The ether separates from the hot solution in the form of long, yellow needles and the yield is quantitative. The ether is easily hydrolyzed by hot alkali; it is moderately soluble in alcohol and readily soluble in benzene; m. p., 172.5".

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.61; H, 4.23. Found: C, 75.37; H, 4.27.

The Allylation of 2-Hydroxy-1,4-phenanthrenequinone

This reaction proceeded less smoothly than is usually the case, and a considerable amount of tarry material was not identified. A suspension of 4.9 g. of the silver salt of the quinone in 70 cc. of benzene was boiled with 2 g. of allyl bromide for one hour and the benzene solution of the reaction products was concentrated in vacuum to a very small volume. From the very dark red solution there separated a solid product which was rather tarry but which was obtained in a fairly clean condition by washing with benzene. This was triturated with successive portions of dilute ammonia solution until no further material dissolved. The residue was found to contain chiefly 4-alloxy-1,2-phenanthrenequinone, of which 1 g. (26%) was obtained, while 1 g. of the product of C-alkylation was recovered from the ammonia solution.

4-Alloxy-1,2-phenanthrenequinone.—The crude material, which is readily soluble in alcohol or benzene, was crystallized repeatedly from ligroin. It formed dark red rather ill-formed needles melting at 128°. The quinone dissolves easily in sodium bisulfite solution with the formation of a rather sparingly soluble addition product.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77 25; H, 4.58. Found: C, 76.93; H, 4.64.

3-Allyl-2-hydroxy-1,4-phenanthrenequinone.—On crystallization from ligroin, in which it dissolves readily, the compound forms long, slender orange needles melting at 157°.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.25; H, 4.58. Found: C, 77.27; H, 4.85.

The alkaline solution of this quinone is grape-purple but the color disappears completely on boiling the solution for a short time and the acidification of the colorless solution causes the separation of an oil. The quinone thus appears to behave in a mannet similar to that described befow for 2-hydroxy-1,4-phenanthrenequinone. The allyl derivative dissolves in concentrated sulfuric acid with the formation of an intensely green solution; a dark purple-red substance precipitates on adding water.

The Cleavage of 2-Hydroxy-1,4-phenanthrenequinone by Alkali

In describing the preparation of this quinone, it was stated that the substance is extremely sensitive to the hydrolytic action of hot alkali. An aqueous solution of the pure sodium salt rapidly loses its color on boiling and becomes pale yellow, and the change is hastened by the presence of an excess of alkali. On acidifying the hot solution, after it has been somewhat concentrated, the cleavage product crystallizes in the form of large, well-formed, somewhat yellow plates. The substance has the composition of the starting material plus the elements of one molecule of water, and the properties of an α-keto acid. It is in every way similar to the isomeric substance obtained in the same way from 3-hydroxy-1,4-phenanthrenequinone,[1] and the structure follows from the same considerations as those detailed in the earlier paper. The cleavage occurs more rapidly in the present case than with the 3-hydroxyquinone.

I-Aceto-2-naphthyl-glyoxylic Acid (V).—The cleavage product is readily soluble in water and crystallizes best from an acidified aqueous solution. Several crystallizations are required to remove a trace of yellow coloring matter, though the melting point is little affected by the process. The compound melts at 181° with the evolution of carbon dioxide.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.41; H, 4.16. Found: C, 69.02, 69.48; H, 4.24, 4.28. *Neut. equiv.* Subs. 0.2038: 6.81 cc. of 0.1242 N $Ba(OH)_2$. Calcd. for $C_{14}H_{10}O_4$: mol. wt., 242.1. Found: 240.7.

The methyl ether was prepared by esterification with methyl alcohol and hydrogen chloride. It dissolves very readily in alcohol or benzene and fairly readily in ligroin. It is easily purified by the use of the latter solvent, but the crystals are not good; a paste of micro-crystals melting at 112° results.

Anal. Calcd. for $C_{15}H_{12}O_4$: C, 70.29; H, 4.72. Found: C, 70.19; H, 4.76.

Oxidation of 1-aceto-2-naphthyl-glyoxylic acid with hydrogen peroxide in alkaline solution gave naphthalene-1,2-dicarboxylic acid, while the same reagent, in glacial acetic acid solution, yielded 1,2-naphthindanedione. The oxidation products are thus the same as those obtained from the isomeric acid, 2-aceto-1-naphthyl-glyoxylic acid.' The present reactions were carried out in the same manner and the products were carefully compared and their identity established.

1,2-Phenanthrenequinone-4-sulfonic Acid

Salts of 1,2-Dihydroxyphenanthrene-4-sulfonic Acid.—The addition of sodium bisulfite to 1,2-phenanthrenequinone does not proceed as smoothly as is usually the case with *o*-quinones of this type because some of the material always undergoes reduction to the hydroquinone before the addition reaction has gone to completion. When the quinone was treated with concentrated bisulfite solution, very little reaction of any sort took place until a small volume of alcohol was added. Nearly all of the material then dissolved, but a considerable part of it was converted into 1,2-dihydroxyphenanthrene, which soon separated in an impure condition. The formation of this substance was to some extent hindered by using a mixture of sodium bisulfite and sodium sulfite.

Twenty grams of 1,2-phenanthrenequinone was ground to a fine paste with 60 cc. of water and a solution of 40 g. of sodium bisulfite and 4 g. of sodium hydroxide in 90 cc. of water was added. The quinone rapidly disappeared, giving a dark brown solution containing some suspended matter. After a few hours it was diluted to a volume of 400 cc., warmed to about 80° in order to coagulate the particles of 1,2-dihydroxyphenanthrene and filtered. A solution of 27 cc. of concentrated sulfuric acid in water was then added, together with a few drops of caprylic acid to prevent foaming, and the sulfur dioxide was boiled off. The solution, on cooling, now deposited crystals of sodium 1,2-dihydroxyphenanthrene-4-sulfonate. This material was dissolved in water containing some sodium hyposulfite, and salted out with a solution of sodium chloride. An almost colorless product resulted; yield, 19.7 g. (65%). A further crystallization gave a sample containing the calculated percentage of sodium, though the compound does not crystallize well but forms a faintly gray crystalline powder. It is very readily soluble in water.

Anal. Calcd. for $C_{14}H_9O_5SNa$: Na, 7.36. Found: 7.19.

The potassium salt is somewhat less soluble but it also forms poor crystals. The sample was dried at 80°.

Anal. Calcd. for $C_{14}H_9O_5SK \cdot 2H_2O$: K, 10.73. Found: 10.83.

The p-toluidine salt was precipitated by adding p-toluidine and an excess of hydrochloric acid to a solution of the sodium or the potassium salt. It crystallizes well from water acidified with hydrochloric acid, forming faintly yellow, lustrous plates melting at 240° (248°, corr.), with decomposition. It darkens somewhat on exposure to the sunlight.

Anal. Calcd. for $C_{21}H_{19}O_5NS$: C, 63.45; H, 4.82; S, 8.07. Found: C, 63.25; H, 5.01; S, 8.04.

Sodium **1,2-Phenanthrenequinone-4-sulfonate.**—The oxidation of sodium 1,2-dihydroxyphenanthrene-4-sulfonate in aqueous solution with a slight excess of chromic acid–sulfuric acid solution takes place readily at room temperature, but some caution is necessary in purifying the product for it decomposes rather easily when in an impure condition. The deep red solution which resulted from the oxidation was treated with an equal volume of saturated sodium chloride solution, causing the separation of the red sodium salt of the quinone. This material, which was rather finely divided, was collected and dissolved, while still moist, in boiling water. The solution was filtered without delay, treated with about one-third of its volume of alcohol and at once cooled. This time the quinone separated in the form of fine crystals, so that the material could be thoroughly washed. It was then dissolved in a minimum quantity of water, a small amount of alcohol was added to the filtered solution and crystallization was allowed to proceed slowly. The quinone then separated in the form of large, bright red plates. The pure material shows little tendency to undergo decomposition in solution, but solutions of less pure samples rapidly lose their bright red color on standing, even at room temperature, and deposit a very dark, or even black, product. The quinone dissolves readily in hot water, but it is much less soluble than sodium 3,4-phenanthrenequinone-1-sulfonate. The sample for analysis was dried at 100° in a vacuum.

Anal. Calcd. for $C_{14}H_7O_5SNa \cdot H_2O$: Na, 7.01. Found: 6.76.

The behavior of this quinone toward alkalies and amines is unique. When dilute sodium hydroxide solution is added to a suspension of the quinone in water, the red crystals lose their color at once and become green. On warming the material all dissolves to give a yellow solution. If a saturated solution of the quinone in water is treated with an equal volume of 6 *N* sodium hydroxide, the color changes at once from red to yellow. If such a solution is acidified at once, the red color reappears, but if the alkaline solution is allowed to stand for about one hour, acidification causes only a change to a paler yellow. If this solution is sufficiently concentrated, the sodium salt of 1,2-dihydroxyphenanthrene-4-sulfonate will separate. The identity of the substance was established by adding p-toluidine hydrochloride to the pale yellow solution, when the p-toluidine salt of 1,2-dihydroxyphenanthrene-4-sulfonate crystallized in the form of plates of characteristic appearance; it was identified by mixed melting point determinations.

The reaction of the quinone with p-toluidine follows a similar course. When a solution of the quinone in hot water was treated with an equivalent quantity of the amine, a very small amount of dark red tar was formed, but in about five minutes the solution lost its red color and became pale yellow. On concentrating the solution and adding hydrochloric acid, the p-toluidine salt of 1,2-dihydroxyphenanthrene-4-sulfonic acid, which was again identified by melting-point determinations, separated

In order to determine what substance becomes oxidized in the course of the reduction of the quinone in these two cases, the following experiment was carried out. A weighed sample of the quinone was dissolved in water in an oxidation–reduction vessel in which the potential of the solution could be measured. Pure nitrogen was passed through a definite volume of alkali, then into the quinone solution and then into a second oxidation–reduction vessel containing an alkaline solution of sodium anthraquinone-β-sulfonate and its reduction product. Since this solution is very sensitive to oxygen, the presence of even a trace of this gas could be detected by a change in the potential of the solution. After all of the oxygen had been removed from the system, the alkali was transferred under a pressure of nitrogen into the vessel containing the quinone solution. It had seemed possible that either oxygen or hydrogen peroxide might be produced in the reduction of the quinone, but no oxygen was detected even when the mixture of the quinone and alkali was boiled. After the solution had stood for ten to fifteen hours, always protected by an atmosphere of nitrogen, a volume of sulfuric acid calculated to give a $N/10$ acid solution was added and the amount of the hydroquinone present was determined by electrometric titration with a dichromate solution. From 0.2009 g. of the quinone there was found present an amount of hydroquinone equivalent to 0.0980 g. of quinone, which indicates that 48.7% of the quinone had been converted into the hydroquinone. This indicates that one molecule of the hydroquinone is produced from two molecules of the quinone. The conclusion was supported by the results of a somewhat cruder experiment in which the amount of the hydroquinone formed was determined by precipitating it in the form of its p-toluidine salt. From 0.511 g. of the sodium salt of the quinone, there was obtained 0.317 g. of the nearly pure p-toluidine salt (m. p. 234°); on the basis of the above hypothesis, 0.309 g. should result.

The **p-Toluidine** Salt of **1,2-Phenanthrenequinone-4-sulfonic** Acid **(VIII).—The** disproportionation of the sulfonated quinone in a solution containing a basic substance such as sodium hydroxide or p-toluidine does not occur in a neutral or acidic solution. One thus might expect that the quinone would react with p-toluidine in an acidic solution in a manner similar to other sulfonated quinones of the same type, that is, with the formation of a water-insoluble p-toluidine-quinone. It was found, however, that no such substance is produced, but that a simple amine salt of the quinone sulfonic acid is the sole reaction product. The salt was prepared by adding a solution of p-toluidine in an excess of dilute hydrochloric acid to an aqueous solution of sodium 1,2-phenanthrenequinone at the boiling point. On cooling, the salt separated in the form of slender, flat, bright red needles which, washed with a little cold water, were analytically pure. The substance decomposes very easily and it darkened considerably when crystallized even from an acidic solution containing p-toluidine hydrochloride to decrease the solubility. The salt is very readily soluble in water and it decomposes on heating at an indefinite temperature.

Summary

1,2-Phenanthrenequinone has been prepared for the first time and it has been used in securing various other phenanthrene derivatives, notably 2-hydroxy-1,4-phenanthrenequinone and sodium 1,2-phenanthrenequinone-4-sulfonate. The former compound exhibits an interesting type of hydrolytic cleavage by alkalies, observed heretofore in only one other case, while the sulfonated quinone is characterized by a remarkable stability of the sulfonic acid group, a property which appears to be connected with the spatial arrangement of the molecule.

SYNTHESIS OF EPHEDRINE AND STRUCTURALLY SIMILAR COMPOUNDS. II. THE SYNTHESIS OF SOME EPHEDRINE HOMOLOGS AND THE RESOLUTION OF EPHEDRINE

BY RICHARD H. F. MANSKE[1] AND TREAT B. JOHNSON

RECEIVED FEBRUARY 11, 1929 PUBLISHED JUNE 5, 1929

In Paper I of this series the authors described some new reactions which led to the synthesis of ephedrine. For the benefit of anyone desirous of repeating the synthesis emphasis is to be laid on the importance of using highly purified methylamine. Owing to the presence of undetermined impurities in the different preparations supplied for our research the most satisfactory results have been obtained only from Kahlbaurn's hydrochloride of this base.

It was desirable to determine the generality of the reaction and to ascertain its limitations. Thus far the chief drawback has been the difficulty of preparing certain desired 1,2-diketones, although 1-phenylpropane-1,2-dione itself may be easily prepared. The troublesome cases are those in which methoxyl or hydroxyl groups are attached to the benzene nucleus. It has been found that ketonic aldehydes as well as the diketones may be used, and all primary aliphatic amines so far tried have given the expected product. In the case of aniline the product had somewhat indefinite properties, and no ephedrine-like substance was obtained from p-amidophenol.

Details of the synthetic products are given in the annexed table.

It is of some interest to mention that only in one or two cases was there any evidence of the presence of a second isomer, presumably related to ψ-ephedrine. An extensive search was made in the case of the N-ethyl analog of ephedrine but no isomer could be isolated.

The preparation of the p-ethyl derivative (see table) yielded a small

quantity of an isomeric base, but since the original starting material for the synthesis, *p*-ethylpropiophenone, was prepared by the Friedel–Crafts reaction, there is the possibility of some o-isomer being present.

Inactive ephedrine forms readily crystalline salts with many optically active acids, among which may be mentioned tartaric, d-camphorsulfonic and mandelic acids. No resolution could be effected with the first two and an attempt to use d-camphoric acid yielded a small amount of crystals which, however, contained only dl-ephedrine. The mandelic acids are very well suited to the purpose, the d-acid-d-base and, conversely, the 1-acid-1-base, compounds being far less soluble in 95% alcohol than the other possible combinations. Three recrystallizations suffice to obtain optically pure products and the yields are good. Incidentally, the resolution of mandelic acid is very readily accomplished by means of natural 1-ephedrine. Furthermore, the authors suggest the use of natural \$-ephedrine to prepare I-tartaric acid from the racemic acid, since Spath and Gohring[4] have shown that dl-\$-ephedrine can be resolved readily by means of the active tartaric acids.

Experimental Part

The compounds described in the table were prepared and isolated as in the case of ephedrine. For the purpose of purification the hydrochlorides were dissolved in a small volume of alcohol; the solution was filtered, evaporated somewhat and treated with a small volume of acetone. Where necessary this procedure was repeated. To obtain the N-β-phenylethyl analog free of β-phenylethylamine, the crude mixture was conveniently recrystallized from a small volume of water, in which the ephedrine salt is sparingly soluble.

The primary amines required in the syntheses were, for the greater part,

---

[2] Melting points are corrected.

[3] Hyde, Browning and Adams, This Journal, 50, 2292 (1928), give the melting point of their product as 190–192°.

[4] Spath and Gohring, *Monatsh.*, 41,319 (1920).

commercial preparations. Benzylamine and β-phenylethylamine were prepared by hydrolyzing the corresponding phthalimides with hydrazine hydrate.[5]

Resolution of dl-Ephedrine.—A mixture of 13.8 g. of dl-ephedrine and 7.7 g. of *d*-mandelic acid was dissolved in 30 cc. of hot 95% alcohol. On cooling the d-ephedrine-d-mandelate crystallized out. After two recrystallizations from a small volume of alcohol the product consisted of colorless, rhombic plates, melting at 170^{e} with previous sintering at 167°. The combined mother liquor yielded a further small amount of this product. The salt as thus obtained was basified with potassium hydroxide and the base was extracted with ether. The ethereal solution was evaporated to a small volume and treated with alcoholic hydrogen chloride. The d-ephedrine hydrochloride as thus obtained melted at 218 to 218.5"and had $[\alpha]_D^{24}$ + 35.6" in 2% aqueous solution; yield, 5.3 g.

The mother liquor from the mandelate of the d-base was basified and the extracted base treated with 7.7 g. of *l*-mandelic acid. The crystalline mandelate was twice recrystallized from a small volume of alcohol; m. p. 170° with previous sintering at 167". The 1-ephedrine hydrochloride obtained from the mandelate melted at 218 to 218.5°, alone or admixed with a purified specimen from Ma Huang, and had $[\alpha]_D^{24}$ —35.5° in 2% aqueous solution; yield, 6.7 g.

It was now possible to obtain a further amount of d- and then I-base from the mother liquor from the mandelate crystallizations by alternate treatment with d- and I-mandelic acid, respectively.

Resolution of Mandelic Acid.—Considerable quantities of mandelic acid were required in the resolution of ephedrine and as far as the authors are aware the most convenient source of d-mandelic acid is from the sparingly soluble cinchonine salt. This process was described almost simultaneously by McKenzie[6] and by Rimbach.[7] McKenzie prepared a number of salts of d- and 1-mandelic acid with various alkaloids and recorded their melting points among other physical properties. Rimbach did not record melting points. Recently Ward, Chrisman and Nicholas: while in agreement with McKenzie in so far as the resolution is concerned, pointed out a discrepancy in the melting points as recorded by the latter for the quinine salts of the d- and 1-acids. The present authors found for the melting point of cinchonine-d-mandelate 176–177". McKenzie gives 79–80 °. Probably this author interchanged a number of his figures.

Undoubtedly the simplest method of preparing I-mandelic acid is by resolution with I-ephedrine when this base is available. For this purpose 12 g. of 1-ephedrine and 12 g. of dl-mandelic acid are heated together in 40 cc. of 95% alcohol. The crystals obtained on cooling are twice recrystallized from a small volume of alcohol. The optically pure mandelic acid obtained by acidification, extraction with ether and recrystallization by spontaneous evaporation of an acetone solution melted at 133.5° and had $[\alpha]_D^{20°}$ – 156.9° in 2% aqueous solution. The yield was 5.9 g.

Some d-mandelic acid was obtained from the combined mother liquor from which no more crystalline salt was obtainable. The acid after several recrystallizations from water melted at 132°.

Summary

1. A series of bases, structurally similar to ephedrine, has been prepared in order to demonstrate the generality of the reaction described in Paper I.

---

[6] McKenzie, J. Chem. Soc , **75,** 966 (1809).

[7] Rimbach, *Ber.,* 32,2385 (1899).

[8] Ward, Chrisman and Nicholas, J. *Chetn. Soc.,* 2186 (1928)

2. Synthetic ephedrine has been resolved into its dextro- and levo-rotatory antipodes, one of which is identical with the base obtained from the Chinese drug, Ma Huang.

3. The resolution was effected by means of d- and *l*-mandelic acid and, conversely, natural I-ephedrine lends itself admirably to the preparation of pure *l*-mandelic acid.

PHENYLISOTHIOCYANATE AND ORTHO-TOLYLISOTHIOCYANATE AS REAGENTS FOR PRIMARY AROMATIC AMINES

BY THEO. OTTERBACHER AND FRANK C. WHITMORE

RECEIVED FEBRUARY 19, 1929 PUBLISHED JUNE 5, 1929

Isothiocyanates (mustard oils) react with primary amines to form substituted thioureas suitable for purposes of identification. They are easily crystallized and have convenient melting points. The two isothiocyanates studied in the present work are readily available. They do not react readily with water or alcohol.

The reactions were carried out in alcohol solution. In some cases they took place spontaneously with the evolution of heat, while in others the mixture had to be heated to induce reaction. Since there were no by-products and since the products ciystallized well, they were easily purified to constant melting points by crystallization from alcohol. The yields were almost quantitative.

Phenylhydrazine was also treated with phenylisothiocyanate. It reacted violently with two molecules of the mustard oil.

Hydrazobenzene also reacted with two molecules of mustard oil.

Experimental Part

The substituted thiocarbanilides were prepared by dissolving the calculated amounts of the amine and mustard oil in a convenient quantity of alcohol. From 10 to 50 g. of the amines were used as the thiocarbanilides were desired for another purpose. If no reaction took place in the cold, the contents of the flask were heated to boiling. After gentle boiling for a minute or two, the reaction mixture was allowed to cool. If the product did not separate, even when the wall of the tube was rubbed with a glass rod, the process was repeated until the desired effect was produced. (All of the amines will react in the cold if allowed to stand long enough.) The substituted thiocarbanilide was then filtered off and dissolved in boiling alcohol, filtered while hot and the material separating from the filtrate on cooling was recrystallized again from boiling alcohol. This was usually sufficient to give a sharp melting product. The yields of recrystallized products were 65–80%. The nitrogen content was determined by the Kjeldahl method.

Summary

1. Phenyl mustard oil and o-tolyl mustard oil are satisfactory reagents for many primary aromatic amines, forming well-crystallizing and sharply melting thiocarbanilides in good yields.
2. The reagents do not react with water or alcohol, and a determination may be made in their presence.
3. There are no by-products of the reaction.

SOME UREAS AND THIOUREAS DERIVED FROM VANILLYLAMINE. RELATIONS BETWEEN CONSTITUTION AND TASTE OF PUNGENT PRINCIPLES

BY N. A. LANGE, H. L. EBERT AND L. K. YOUSE

RECEIVED FEBRUARY 20, 1929 PUBLISHED JUNE 5, 1929

Capsaicin, the pungent principle of cayenne pepper, and piperin or chavicin, the pungent principle of black pepper, are both acid amides; capsaicin (I) is the vanillyl amide of A^{6}-8-methylnonenic acid; piperin, δ-piperonylvinylacrylopiperidide, is the piperidine amide of piperic acid; spilanthol, the reduction product of the pungent principle of para-cress is n-decoisobutyl amide.[1]

Since these natural pungent principles are acid amides, it is naturally conceivable that a relation might exist between pungency and the amide structure. The synthesis of a number of more or less closely related amides has indeed shown this relation to exist and has also led to conclusions as to the effect on pungency which accompanies changes in the molecular structure. Thus in compounds similar to capsaicin it has been found that a free phenolic group (preferably in the para position to the side chain) in the amine portion is necessary to produce pungency, that the methoxy group in the meta position exerts a favorable influence toward pungency (aromatic bases resembling aniline when replacing the hydroxy benzylamine bases diminish pungency), that the pungency is a maximum when the acid portion consists of nine to ten carbon atoms and that the pungency is not influenced by the position of the double bond in the acid portion. As to the effect of the presence or absence of un-

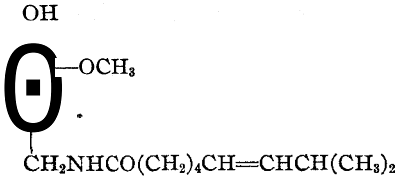
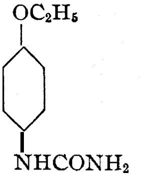
saturation in the acid portion there is still a difference of opinion, some investigators believing that pungency is diminished by the absence of a double bond while others find the saturated derivatives to be equal in pungency to the unsaturated acid derivatives. Capsaicin and closely related substances, aside from the pungent taste, are practically devoid of odor and flavor; dulcin (II) which is the carbamic amide of phenetidine is many times as sweet as cane sugar; studies which have been made on compounds closely related to dulcin have shown that nearly every change in structure causes a lowering or complete loss of sweetness[2] Recently attention has been called to the same effect when one or more of the hydrogen atoms of the nitrogens of the urea are replaced by groups.[3]

Since both capsaicin and dulcin are acid amides derived from an amine having a p-hydroxybenzene structure, it seemed of interest to prepare a series of compounds which would have a rather close similarity to both. As typical of such a condition series of carbamicamides of vanillylamine (III) were prepared and tested particularly for their taste.



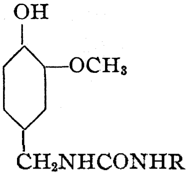
I

Capsaicin, pungent



II

Dulcin, sweet



III

Vanillylamine prepared by the reduction of vanillyl oxime[1] formed the starting product for these syntheses, being converted into the thiourea or urea by treatment with a thiocyanate or cyanate. In this way the following compounds were prepared: vanillylurea, vanillylthiourea, phenylvanillylurea, phenylvanillylthiourea, p-tolylvanillylthiourea and *o*-tolylvanillylthiourea. None of these compounds are sweet but the last three possess pungent properties.

Experimental Part

Preparation of **Vanillylurea (p-Hydroxy-m-methoxybenzylurea),** $(HO)(OCH_3)$-$C_6H_3CH_2NHCONH_2$.—This compound was obtained by mixing **1** mol of vanillylamine hydrochloride with **1.2** mol of potassium cyanate in water solution. Upon standing overnight, light brown crystals of the urea separated and were purified by recrystallizing first from hot water and then from hot alcohol; yield, **90%.** It is fairly soluble in ethyl alcohol, methyl alcohol or water; very slightly soluble in ether, acetone, carbon tetrachloride or chloroform and insoluble in benzene or petroleum ether; m. p. **178.5"** (corr.); it is tasteless in the dry state and in aqueous or alcoholic solutions. The values obtained

on analysis do not agree as closely as they should with the calculated composition; however, repeated attempts at further purification changed neither the analytical values nor the melting point; from the method of preparation we assume that the product was vanillylurea.

Anal. Calcd. for $C_9H_{12}O_3N_2$: C, 55.07; H, 6.17; N, 14.3. Found: C. 55.96, 55.74, 55.96; H, 6.79, 6.74, 6.77; N, 14.0.

Preparation of Vanillylthiourea (p–Hydroxy–m–methoxybenzylthiourea), $(HO)(OCH_3)C_6H_3CH_2NHCSNH_2$.—To 9.5 g. of vanillylamine hydrochloride dissolved in a small volume of water, 5.9 g. of potassium thiocyanate was added. After a few minutes a light brown product began to separate. This solution with its precipitate was evaporated to dryness on a steam-bath and the residue was extracted with boiling water. The vanillylthiourea crystallized from the hot extract. On recrystallizing from water, the solution supercools and no crystals separate until after several hours; a 60% yield was obtained; m. p. 167.5" (corr.). The dry compound as well as the aqueous and alcoholic solutions were tasteless. It is soluble in ethyl alcohol, or methyl alcohol, fairly soluble in water, very slightly soluble in acetone or chloroform and insoluble in ether, carbon tetrachloride, benzene or petroleum ether.

Anal. Calcd. for $C_9H_{12}O_2N_2S$: C, 50.90; H, 5.70. Found: C, 50.28; H, 5.63.

Preparation of Phenylvanillylurea (a–Phenyl–p–p–hydroxy–m–methoxybenzylurea), $C_6H_5NHCONHCH_2C_6H_3(OCH_3)(OH)$.—Vanillylamine base was prepared from the aqueous hydrochloride solution by adding the calculated amount of sodium hydroxide to neutralize the combined hydrochloric acid, shaking and allowing the mixture to stand for several hours, then filtering, washing with cold water and drying in a desiccator; it is easily decomposed by alkalies, boiling water or continued exposure to light. Equimolecular amounts of the base and phenylisocyanate were mixed in a beaker. Heat was evolved and the mixture soon solidified, giving a 63% yield of the urea. Colorless crystals of phenylvanillylurea are obtained by recrystallizing from ethyl alcohol. The compound is fairly soluble in ethyl alcohol, methyl alcohol or acetone, very slightly soluble in ether, chloroform, carbon tetrachloride or benzene and insoluble in water or petroleum ether; m. p. 190.5° (corr.) Solutions of this compound in alcohol are tasteless.

Anal. Calcd. for $C_{15}H_{16}O_3N_2$: C, 66.14; H, 5.93. Found: C, 66.26; H, 5.92.

Preparation of **Phenylvanillylthiourea** (α-Phenyl-β-*p*-hydroxy-*m*-methoxybenzylthiourea), $C_6H_5NHCSNHCH_2C_6H_3(OCH_3)(OH)$.—Five g. of vanillylamine and 4.4 g. of phenylisothiocyanate are mixed; after an initial warming to start the reaction, it proceeds rapidly with an evolution of heat and the formation of a solid mass. The compound was obtained in 92% yield; on treatment with charcoal and recrystallization from alcohol it gave colorless crystals, m. p. 138–138.5° (corr.); it is soluble in acetone, fairly soluble in ethyl alcohol, methyl alcohol or benzene, slightly soluble in chloroform or carbon tetrachloride, very slightly soluble in ether and insoluble in water or petroleum ether. Solutions of the compound in alcohol have a decidedly pungent taste accompanied by a slightly bitter taste

Anal. Calcd for $C_{15}H_{16}O_2N_2S$: C, 62.45; H, 5.60; S, 11.1. Found: C, 62 67; H, 5.57; S, 10.8.

Preparation of ***p*-Tolylvanillylthiourea** (α-*p*-Tolyl-β-*p*-hydroxy-*m*-methoxybenzylthiourea), $CH_3C_6H_4NHCSNHCH_2C_6H_3(OCH_3)(OH)$.—A mixture of 4.6 g. of *p*-tolylisothiocyanate and 4.8 g. of vanillylamine was warmed on a steam-bath for three hours and then recrystallized from alcohol; a 75% yield of *p*-**tolylvanillylthiourea** was obtained; the compound is fairly soluble in ethyl alcohol, methyl alcohol, chloroform, acetone or benzene, very slightly soluble in carbon tetrachloride or ether and insoluble in water or petroleum ether; m. p. 138.5–139° (corr.). Solutions of the compound in alcohol have a decidedly pungent taste accompanied by a slightly bitter taste.

Anal. Calcd. for $C_{16}H_{18}O_2N_2S$: C, 63.53; H, 6.00; S, 10.6 Found: C, 64.04; H, 6.06; S, 10.4.

Preparation of **o-Tolylvanillylthiourea** (α-*o*-Tolyl-β-*p*-hydroxy-*m*-methoxybenzylthiourea), $CH_3C_6H_4NHCSNHCH_2C_6H_3(OCH_3)(OH)$.—Equimolecular quantities of *o*-tolylisothiocyanate and vanillylamine are mixed and then warmed. The compound, obtained in 80% yield, on treatment with charcoal and recrystallization from alcohol gave colorless crystals; m. p. 138–138.5° (corr.); it is soluble in acetone, fairly soluble in ethyl alcohol, methyl alcohol, chloroform or benzene, very slightly soluble in ether or carbon tetrachloride and insoluble in water or petroleum ether. Solutions of the compound in alcohol have a decidedly pungent taste accompanied by a slightly bitter taste.

Anal. Calcd. for $C_{16}H_{18}O_2N_2S$: C, 63.53; H, 6.00; S, 10.6. Found: C, 63.51; H, 5.95; S, 10.7.

Summary

Six different substituted ureas and thioureas have been described; these ureas, being the carbamic or thiocarbamic amides of vanillylamine, are the analogs of the pungent principle of cayenne pepper—a carboxylic amide of the same amine. Three of the thiocarbamides were found to have the property of pungency but to a lesser degree than capsaicin. None of the compounds has a sweet taste, the effect of the phenyl and tolyl groups, which are known to repress the sweetness of compounds, predominating over the favorable effect of the methoxy group; the slightly bitter taste which is characteristic of many thioureas was also observed in several of these compounds.

THE ALGINIC ACID FROM MACROCYSTIS PYRIFERA[1,2]

BY WILLIAM L. NELSON AND LEONARD H. CRETCHER

RECEIVED FEBRUARY 23, 1929 PUBLISHED JUNE 5, 1929

The earlier researches on the chemistry of the carbohydrates in algae were mostly concerned with the isolation and identification of the sugars formed on the hydrolysis of the plant as a whole. The first attempt at separation of a particular carbohydrate component was made by Stanford[3] and was based on the fact that most marine algae contain a highly polymerized acid fraction which may be extracted by means of dilute alkali

[3] Stanford, *Chem. News*, 47, 254, 267 (1883).

and precipitated by the addition of mineral acid after the removal of the alkali-insoluble residue by filtration.

This substance has been called alginic acid or algin, and in the form of its salts it has a variety of important industrial uses.

Algin was thought by Stanford to contain nitrogen, but later investigations by Krefting,[4] Hoagland and Lieb,[5] as well as our own, have demonstrated that when pure it is nitrogen free. Stanford was apparently interested only in the commercial development of seaweed products, and it was not until 1913 that the algae were again investigated from the standpoint of the original carbohydrate complexes contained in them. Kylin[6] at this time isolated acidic materials from the plants which he later[7] submitted to acid hydrolysis. He reported that the hydrolysis of alginic acid produced apparently only pentoses.

At about the same time, Hoagland and Lieb[5] contributed the results of a careful investigation of the carbohydrates in algae. In the course of their work they prepared alginic acid from the *Macrocystis pyrifera.* After a thorough purification the material was obtained free of more than traces of ash and nitrogen. The neutralization equivalent was found to be 325. Analytical data indicated a compound of formula $C_{21}H_{27}O_{20}$ containing two replaceable hydrogen atoms. It was submitted to acid hydrolysis, the water-insoluble fraction removed by filtration and the filtrate treated with phenylhydrazine. An osazone was isolated having melting point, optical rotation and solubilities in close correspondence to those of the osazone of d-xylose.

Alginic acid, on the basis of these observations, might be considered a compound composed of an unknown acidic nucleus in combination with pentose sugars.

That the acidic nucleus in algin from *Laminaria* is glucuronic acid was recently suggested by Atsuki and Tomoda.[8] The idea that this algin does contain a uronic acid was rendered probable by the fact that their preparation lost 20% of its weight as carbon dioxide when boiled with hydrochloric acid (d. 1.06). No evidence, however, was presented by these authors in proof of the configuration of the acid.

Schmidt and Vocke[9] have hydrolyzed alginic acid from *Fucus serratus* and claim to have isolated, from the hydrolysate, d-glucuronic acid in the form of its cinchonine salt. Proof of the identity of this salt is limited to the determination of its melting point and is inconclusive.

The present authors are of the opinion that Schmidt and Vocke's method

[4] Krefting, English Patents, 11,583 (1896); 12,416 (1898).

[8] Atsuki and Tomoda, *J. Soc. Chem. Ind. (Japan)*, *29,* 509 (1926).

[9] Schmidt and Vocke, *Ber.*, 59, 1585 (1926).

of hydrolysis does not completely liberate the monomolecular uronic acids from their polymers and the cinchonine salt which they prepared and which melted at 204° was not of a simple C_6 aldehyde sugar acid. We have submitted the algin from Fucus serratus to more drastic hydrolysis and have obtained from the product a cinchonine salt melting at 152°. This is the melting point of the cinchonine salt of the C_6 aldehyde acid which we have isolated from Macrocystis *pyrifera*. The two acids are probably identical and are surely not glucuronic. It is to be admitted, however, that more than one uronic acid may be present in Fucus serratus.

We have isolated the alginic acid from Fucus serratus, *Laminaria* agardhii and Macrocystis *pyrifera*.[10]

In the case of the first mentioned algin, no analytical work has been done on the original material. The algins from the *Laminaria* agardhii and Macrocystis have, however, been studied analytically. These acids, free of more than traces of ash and nitrogen, were dried over phosphorus pentoxide to constant weight. They gave strong naphtho-resorcin tests and were therefore thought to contain uronic acids. Titration with standard alkali gave neutralization equivalents varying, with different samples, from **176** to **184.** Carbon and hydrogen determinations indicated the formula $(C_6H_8O_6)_n$, while boiling with hydrochloric acid caused the liberation of carbon dioxide to the extent of 24–25%. The pure acids do not reduce Fehling's solution. These facts indicate that algin is a polyuronic acid in which all carboxyl groups are free and all aldehyde groups conjugated.

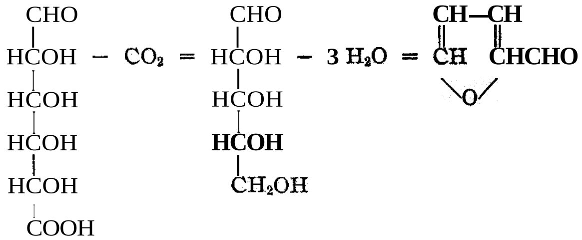
But little study beyond the determination of the analytical data has been made of the algin from Laminaria agardhii. That from Macrocystis *pyrifera* has been hydrolyzed to the free C_6 aldehyde acid, which was not obtained in crystalline condition. It did not have the properties of either d-galacturonic or d-glucuronic acid. These are the only aldehyde sugar acids which have been found in nature to date. That it was neither a mixture of these acids nor either of them in impure form was indicated by the fact that neither mucic nor saccharic acid could be isolated after oxidation with bromine or nitric acid and that the pure cinchonine salt of the aldehyde acid did not have properties in correspondence with those of the galacturonic or glucuronic salts of this alkaloid.

It was shown by Salkowski and Neuberg[11] that glucuronic acid may be converted, by bacteria, into d-xylose. It is also well known that uronic acids lose carbon dioxide on treatment with hot aqueous mineral acids and that furfural is a product. It may be assumed that a pentose sugar is intermediate in this process and that the reaction is as follows:

---

[10] Further investigation of *Fucus serratus* is now under way in this Laboratory and will be reported soon.

[11] Salkowski and Neuberg, Z. *physiol. Chem.,* 36, 261 (1902); 37, 464 (1903).



This would explain the formation of the pentoses which were reported by Kylin[7] and by Hoagland and Lieb.[5]

If the osazone isolated by the last mentioned investigators was actually that of d-xylose, it is identical with the osazone of the epimer of d-xylose, namely, d-lyxose. The identification of the uronic acid was thus simplified somewhat, inasmuch as it must be of such configuration as to form either d-xylose or d-lyxose on loss of carbon dioxide. A consideration of the conventional stereochemical formulas of the hexoses will reveal that of the sixteen possible hexuronic acids, only four can meet this condition. d-Glucuronic and *l*-iduronic would form d-xylose; d-mannuronic and l-guluronic would form d-lyxose. Glucuronic was excluded by experiment. Iduronic and guluronic being derivatives of sugars not as yet found in nature were thought improbable. Inasmuch as *d*-mannose is widely distributed in nature, and as we found mannitol in the Macrocystis to the extent of 4–5%, we assumed, as a working hypothesis, that the algin contained d-mannuronic acid. Evidence in support of this hypothesis is given in the Experimental Part.

Experimental Part

Isolation of **Mannitol** from Macrocystis **Pyrifera.**—One hundred and fifty grams of air-dried fronds were extracted by boiling in 1000 cc. of alcohol. After filtering, the fronds were extracted again with 500 cc. of alcohol. After filtering and washing with alcohol, the filtrate was evaporated to a small volume. During the evaporation, colorless needles separated from solution. The solution was filtered and the solid washed with alcohol. After once recrystallizing, the compound melted at 166°. The melting point of mannitol as determined by Landolt[12] is 166°. It was converted into a tribenzal compound according to the method of Fischer. The compound melted at 218–222° (corr.), the temperature of melting of tribenzalmannitol as determined by Fischer and Fay.[13]

Preparation of **Alginic** Acid from Macrocystis.—The air-dried fronds containing 18% moisture and 25.5% ash were washed several times with water and allowed to stand completely immersed in 0.5% hydrochloric acid for twenty-four hours. The acid was decanted and the process twice repeated. After again washing thoroughly with water, the leaves were covered with 2% sodium carbonate solution. and allowed to stand overnight. Almost immediately on addition of the alkali the fronds swell, lose their shape and the solution becomes very viscous. Frequent stirring facilitates the

[13] Fischer and Fay, *Ber.*, 28, 1975 (1895).

extraction of the alginic acid. The solution was diluted to the point where it could be filtered through a medium finely woven scrim without suction. The residue was extracted again with 2% sodium carbonate and filtered.

The combined filtrate was warmed to 60° and filtered, under suction, through a thin layer of decolorizing carbon on a coarse filter paper. After the solution had cooled to room temperature, the alginic acid was precipitated by the addition of hydrochloric acid under vigorous stirring. The precipitated acid was filtered on scrim and allowed to drain as dry as possible. It was then washed with water, transferred to a large crock, allowed to stand overnight under a large volume of 0.5% hydrochloric acid and filtered. This process of extraction with dilute acid is for the purpose of removing both ash and acid soluble nitrogen compounds. It was repeated thrice. The hydrochloric acid was then removed by several similar treatments with distilled water.

The alginic acid so prepared is a very highly hydrated gel from which water cannot be removed by centrifugation or filtration.

In order to effect dehydration, the gel was treated with 95% alcohol and allowed to stand overnight. This treatment also extracts a considerable amount of alcohol-soluble brown pigment. The alcohol and most of the water were then removed from the alginic acid by means of a hydraulic press and the alcohol extraction repeated. After pressing the second time, a hard cake was obtained. This was broken into small pieces and allowed to dry in the air and finally, in *vacuo,* over phosphorus pentoxide. The yield of purified algin obtained was about 15% of the weight of the fronds taken.

Properties of Alginic Acid.—The most striking physical property of alginic acid is its remarkable power of adsorption of water and salts. Hoagland and Lieb[5] state that "it is capable of adsorbing 200 to 300 times its weight of water" and "salts to the extent of 60%." While we have made no attempt to discover the upper limit of water absorption, we can state that when free of salts and mineral acid the water adsorbed may be considerably higher than 200%. Only by repeated dialysis with dilute acid can the ash be reduced to 0.1%, which gives the purest sample we have been able to prepare. The ash remaining after careful purification is composed largely of iron.

Alginic acid is very slightly soluble in water. It liberates carbon dioxide from carbonates and may be titrated with alkali to a definite end-point (phenolphthalein). It does not reduce Fehling's solution but rapidly forms reducing substances if dried at 100° or if boiled with water or dilute acid. Considerable amounts of carbon dioxide are liberated under the same conditions. Because of this sensitivity of alginic acid, its optical rotation and acid value vary with the time and temperature of drying. This important fact has apparently escaped the observation of previous investigators. The optical rotation of sodium alginate prepared from the alginic acid of the *Macrocystis pyrifera* is $[\alpha]_D^{20} = -133°$.

Analysis of Alginic Acid

Titration *with* **Alkali.**—0.3035 g. of sample required 16.93 cc. of 0.1 *N* NaOH, corresponding to a neutralization equivalent of 179.

Uronic Acid **Carbon** Dioxide.—On boiling a sample of alginic acid for five hours with 12% hydrochloric acid, it lost 21.5% of its weight as carbon dioxide. This corresponds to 86% of uronic anhydride. The neutralization equivalent, however, indicated almost 100%. A sample was therefore boiled with 18% hydrochloric acid. After five hours 0.5519 g. lost 0.1462 g. of carbon dioxide. Calcd. for $C_6H_8O_6$: CO_2, 25. Found: CO_2, 24.65.

Carbon and Hydrogen.—Calcd. for $C_6H_8O_6$: C, 40.91; H, 4.55. Found: C, 41.21; H, 4.75.

Hydrolysis of Alginic Acid.—Hydrolysis was first attempted by boiling with distilled water. After boiling for a short time, water-soluble reducing substances were formed. It was thought that the progress of the hydrolysis could be followed by determination of the ratio of aldehyde to carboxyl by titration. A polyuronic acid would theoretically be completely degraded to C_6 aldehyde acid when this ratio became 1:1. After ninety hours' heating, this ratio was obtained. The aldehyde was determined by the iodine titration method of Wiilstatter and Schudel[14] and the carboxyl by standard alkali. On attempting to isolate the free uronic acid, it was found that the product of the hydrolysis was a substance containing too little aldehyde for the uronic acid and that the apparent formation of a uronic acid was the result of a slow increase of aldehyde from hydrolysis and a gradual loss of carbon dioxide from the carboxyl groups.

During this process the hydrolysis and loss of carbon dioxide is quite rapid at first but becomes very slow after some hours. Even after prolonged hydrolysis, a water-insoluble residue of polyuronic acid remains. Apparently the loss of carbon dioxide is coincident with or follows the hydrolysis, as the water-insoluble residue was shown by analysis to be 100% polyuronic anhydride.

A sample of alginic acid was shown, by experiment, to lose 10% of the theoretical amount of carbon dioxide on boiling with distilled water for eighteen hours.

An air-dried sample of alginic acid containing 17% of moisture lost 0.82% *(dry* basis) of its carbon dioxide when dried at 100° for four and one-half hours.

Hydrolysis with Dilute Sulfuric Acid.—Hydrolysis with dilute sulfuric acid of various concentrations was attempted but soon abandoned because of the simultaneous loss of carbon dioxide.

It seems worthy of mentioo that we obtained, after hydrolysis with water for forty-two hours and then with 3% sulfuric acid for an additional five hours, a residue which was still a polyuronic acid. This residue was separated from the solution by centrifugation, was washed with water and alcohol, dried over phosphorus pentoxide and analyzed for aldehyde and uronic acid carbon dioxide. Its neutralization equivalent was 180. The carbon dioxide determination corresponded to 99.6% uronic anhydride, while the titration of aldehyde indicated a polyuronic acid, $C_{72}H_{98}O_{73}$, containing one free aldehyde and twelve carboxyl groups. The stability of this residue as to loss of carbon dioxide and its comparatively high resistance to hydrolysis indicate that the uronic acids in algin are not all similarly conjugated.

Hydrolysis with Nitric Acid.—It was thought that by treatment with nitric acid it might be possible, simultaneously, to hydrolyze and oxidize the aldehyde acid formed to a dibasic acid. At 55° with nitric acid of sp. gr. 1.2 the main product was oxalic acid. A water-insoluble residue was again obtained.

Hydrolysis with 80% Sulfuric Acid.—The hydrolysis of alginic acid was best accomplished in the following manner: 30 g. of the dry pulverized acid was thoroughly mixed with 90 g. of cold 80% sulfuric acid. The flask was stoppered and allowed to stand for five days at room temperature. The contents was then slowly poured into 900 cc. of water. The water-insoluble residue was removed by filtration and

---

[14] Willstätter and Schudel, *Ber.*, 51,780 (1918).

washed with water and alcohol. This residue was a polyuronic acid and weighed 6 g. This substance is now being studied but will not be discussed further in this communication.

The filtrate was heated to the boiling point and treated with the calculated amount of barium carbonate to remove the sulfuric acid. The barium sulfate was filtered off and washed with hot water. The combined filtrate and washings was treated with barium carbonate, with stirring, and heated over a water-bath for two hours after the solution had become neutral to Congo Red. Long heating is necessary*to convert the lactone of the aldehyde acid to the barium salt. The excess barium carbonate was removed by filtration and the filtrate evaporated under reduced pressure to 100 cc. The solution was allowed to stand in the ice box overnight. The small amount of dark brown precipitate formed was filtered off and discarded. The solution was treated with decolorizing carbon (Nuchar), filtered and evaporated, in *vacuo,* to 25 cc.; 100 cc. of 95% alcohol was added. The barium salt was precipitated as a heavy gum. After standing in the ice box for several hours, the supernatant liquor was removed by decantation. The gum was dried at 35–40" until it could be powdered. The yield of dry salt was 25 g. Analysis of this salt proved it to be mostly the barium salt of a C_6 aldehyde sugar acid, with small amounts of lactone and the barium salts of polyuronic acids which had escaped hydrolysis. No method was discovered for complete purification of this salt. On removal of the barium with sulfuric acid and evaporation of the solution, a sirup was obtained which we did not succeed in crystallizing.

Addition of excess barium hydroxide to a solution of the aldehyde acid causes the precipitation of a practically insoluble basic salt.

The Cinchonine Salt.—Inasmuch as the cinchonine salts of glucuronic and galacturonic acids have been described, a solution of the uronic acid was treated with cinchonine in the manner usual for the preparation of alkaloidal salts. The excess cinchonine was extracted with chloroform and the solution evaporated to a small volume. The cinchonine salt is quite soluble in water and separates, even from highly supersaturated solutions, very slowly. It was recrystallized from water to constant melting point and then once from alcohol. The alcohol crystallization did not alter the melting point, which was 152° corr. Melting is accompanied by effervescence.

Anal. Calcd. for $C_{25}H_{32}O_8N_2$: N, 5.72. Found: N, 5.95; 5.58. 0.2451 g. was dissolved in water and the cinchonine precipitated by addition of 5 cc. of $0.1N$ NaOH and filtered off. The filtrate was titrated for aldehyde. Calcd. for $C_{25}H_{32}O_8N_2$: 0.1 N iodine required, 10 cc. Found: 9.6 cc. Optical rotation. 0.3016 g. in 25 cc. of H_2O in a 2-decimeter tube gave an observed rotation of $+2.74°$; $[\alpha]^{25}_{D} = +113.6°$.

The physical constants of the cinchonine salts of *d*-glucuronic and d-galacturonic acids given in the literature are as follows: glucuronic, m. p. 204°,[15] 199–200°;[16] *[a]*= 138.6°,[15] 135°,[16] 139.9°;[17] galacturonic, m. p. 158°;[17] *la]* = 134°.[17]

Oxidation of the Aldehyde Acid.—Inasmuch as many of the dicarboxylic sugar acids are known and some of them are quite well characterized, it was thought that our unknown uronic acid could best be identified by oxidation to a dibasic acid. The method of oxidation was as follows:[18] 8 g. of the barium salt of the aldehyde acid was

---

[15] Neuberg, Ber., **33,** 3317 (1899).

[16] Ehrlich and Rehorst, ibid., 58, 1989 (3 925).

[17] Schwalbe, ibid., 58, 1536 (1925).

[18] This method of oxidizing an aldose by bromine water in the presence of a buffering salt such as barium benzoate was suggested to us by C. S. Hudson. An article fully describing the method and its application to various sugars will be published in the near future by C. S Hudson and H. S. Isbell.

dissolved in **250** cc. of water, **12** g. of barium benzoate and 5 cc. of bromine were added and the solution was allowed to stand at room temperature for three days. The excess bromine was removed by blowing a rapid stream of air through the solution and the precipitated benzoic acid removed by filtration. The solution was next extracted with chloroform to remove the dissolved benzoic acid.

Barium carbonate was added, with heating and vigorous stirring. It was heated for one and a half hours after the solution became neutral to Congo Red. It was then treated with decolorizing carbon and filtered. The filtrate was evaporated to **70** cc. under reduced pressure. On cooling, a small amount of brown material precipitated and was removed by filtration. The filtrate was poured into two volumes of alcohol. The solid barium salt was filtered off and ground under 50% alcohol. It was then filtered and washed with alcohol of the same strength. Barium was removed from the salt by sulfuric acid. After filtration the solution was evaporated to a sirup, which was treated with absolute alcohol. This precipitated traces of salts and a small amount of sticky carbohydrate material. The alcoholic solution was filtered and evaporated to a sirup which could not be induced to crystallize, even after samples of it were seeded with a crystal of d-mannosaccharic dilactone or mucic acid. A sample was neutralized with **50%** potassium hydroxide and then acidified with acetic acid but no potassium acid saccharate could be isolated from the reaction product.

The **Diamide.**—A sample of the sirup was treated with an excess of concentrated ammonia. On standing for some hours in the ice box a white crystalline compound was deposited. It was filtered off and washed with cold water, then with alcohol and finally with ether. It was recrystallized from hot water to constant melting point and rotation.

Anal. Calcd. for $C_6H_{12}O_6N_2$: N, **13.46.** Found: **N, 13.35.**

The compound melted at 189° with decomposition. A mixed melting point with d-mannosaccharic diamide was **189°.** The melting point of mannosaccharic diamide was found to be 189° by Fischer[19] and **188–189.5'** by Hudson.[20] **Our** sample of this diamide prepared from mannose melted at **189°**.

0.1552 g. of the diamide, prepared from algin according to methods already described, in **50** cc. of water, gave or $=$ **$-0.304'$** in a **4-dm.** tube, as an average of eight readings; $[\alpha]^{20}_{D} = -24.46°$. The rotation of *d*-mannosaccharic diamide, as determined by Hudson,[20] is $[\alpha]^{20}_{D} = -24.4°$.

The **Di-phenylhydrazide.**—A sample of the sirup was heated on a water-bath with an excess of phenylhydrazine acetate. The di-phenylhydrazide formed was very insoluble in hot water or alcohol. It was extracted once with boiling water and thrice with hot alcohol. It melted with decomposition at **212°**.

d-Mannosaccharic di-phenylhydrazide was prepared from pure crystalline *d*-mannosaccharic dilactone. It melted at 212°. This is also the melting point reported by Fischer.[19] A mixture of the two hydrazides melted at the same temperature.

Our thanks are due to Thornley and Company of San Diego, California, for their kindness in supplying us with the fronds of *Macrocystis pyrifera.*

Summary

1. Pure alginic acid has been prepared from the *Macrocystis pyrifera* and shown to be a polymer of the anhydride of an aldehyde sugar acid in which all aldehyde groups are conjugated and all carboxyl groups free.

---

[19] Fischer, *Ber.*, **24,539 (1891).**

[20] Hudson, THIS JOURNAL, **41, 1141 (1919).**

2. The uronic acid has not been obtained in crystalline condition. It may be oxidized to a dibasic C_6 sugar acid. The diamide and diphenylhydrazide of this acid correspond in properties to the analogous compounds prepared from pure d-mannosaccharic dilactone.

TIN TETRAPHENYL AS A PHENYLATING REAGENT

BY R. W. BOST AND P. BORGSTROM

RECEIVED FEBRUARY 25, 1929 PUBLISHED JUNE 5, 1929

Certain of the organo-metallic compounds have been used as phenylating reagents. Mercury[1] and magnesium diphenyl[2] have been used to introduce the phenyl groups into certain compounds. Aryl tin halides were first made by the reaction of mercury diphenyl and stannic chloride.[3] Later the reaction between tin tetraphenyl and halogens to form mono-, di and triaryl halides has been carefully studied.[4] More recently Goddard and his co-workers[5] have isolated products from tin tetraphenyl and thallic chloride, while no derivatives were obtainable with the chlorides of mercury and sulfur with tin tetraphenyl.

Since tin tetraphenyl is comparatively rich in phenyl groups, and since its toxicity is much lower than that of mercury diphenyl, it seemed desirable to study the possibilities of using it as a reagent for introducing the phenyl group into organic compounds. In this paper are presented the reactions of tin tetraphenyl with the following types of compounds: halogens, alkyl halides, acyl halides, sulfur, nitric acid and sulfuryl chloride.

Experimental Part

1. Action of Halogens.—Bromine and chlorine react violently with tin tetraphenyl. Even at 0° they react energetically to give excellent yields of the corresponding monohalides of benzene. The reaction using iodine is less active and low yields of phenyl iodide are obtained. Iodine monochloride reacts very readily and produces a good yield of phenyl iodide. No halogen disubstitution products of benzene were detected under the conditions of the experiment.

Bromobenzene.—Twelve and seven-tenths grams of bromine was slowly added with a dropping funnel to 8.5 g of tin tetraphenyl in a round-bottomed flask connected with a reflux condenser, the flask being cooled in an ice–salt mixture. The bromine was rapidly taken up, forming a colorless liquid, until most of the bromine had been

[5] Goddard and Goddard, J. *Chem. Soc.*, 121, 256 (1922); Goddard, Ashley and Evans, *ibid.*, 121,978 (1922).

added. Much heat was evolved in the reaction. After all of the bromine had been added, the reaction mixture was heated on a steam-bath for one hour. The phenyl bromide was removed by distillation, then washed, dried and redistilled. The fraction boiling from 154–156° was collected; yield, 94%.

Chlorobenzene.—To 8.5 g. of tin tetraphenyl in a cooled flask as above described was slowly added 5.7 g. of chlorine dissolved in carbon tetrachloride. A vigorous reaction took place, evolving much heat. After all of the chlorine had been added, the mixture was heated for thirty minutes on the steam-bath. The chlorobenzene was distilled off, washed, dried and the fraction boiling between 131–133" was reserved; yield, 91%.

Iodobenzene.—An apparatus similar to the one in the above experiments was used; 13 g. of iodine monochloride dissolved in 200 ml. of carbon tetrachloride was slowly added to 8.5 g. of tin tetraphenyl in a flask cooled with ice. The addition required about twenty minutes. The mixture was refluxed for four hours and set aside for twenty-four hours. The carbon tetrachloride was distilled from the steam-bath, and then the crude iodobenzene. The phenyl iodide was washed, dried and the fraction 187–188° reserved; yield, 74%.

2. Action of Alkyi Halides.—Certain alkyl halides were heated with tin tetraphenyl but poor results were obtained with this group of compounds. There seems to be a tendency for the alkyl halides to split off halogen acids, giving an unsaturated hydrocarbon, the triaryl tin halide and some unused tin tetraphenyl. This is true with *iso*-amyl bromide and to a certain extent with *tert.*-butyl bromide. Chloroform and bromoform gave no apparent reaction under ordinary conditions. The former in a sealed tube gave mostly triphenyl tin chloride.

***Tert.*-Butylbenzene.**—A mixture of 8.5 g. of tin tetraphenyl and 12 g. of *tert.*-butyl bromide was heated under reflux for eighteen hours. As the reaction proceeded the solution after first darkening became light in color The reaction product was filtered, excess of *tert.*-butyl bromide distilled off and the *tert.*-butylbenzene distilled under reduced pressure; yield, 8%. An unsaturated hydrocarbon, a halogen acid and the aryl tin halide were also formed.

Reaction with Iso-amyl Bromide.—Eight and five-tenths grams of tin tetraphenyl and 13 g. of iso-amyl bromide were refluxed for twenty hours. The reaction product gradually darkened. The presence of a halogen acid, an unsaturated hydrocarbon and the aryl tin halide were detected but the main product was unchanged tin tetraphenyl and iso-amyl bromide. No iso-amylbenzene was observed.

Reaction with Chloroform.—Twelve and seven-tenths grams of tin tetraphenyl and 4.7 g. of chloroform were heated in a sealed tube at 260° for twenty hours. The brownish-yellow residue was washed from the tube with ether and filtered. The insoluble portion consisted mainly of unused tin tetraphenyl The filtrate after being decolorized with charcoal yielded three grams of triphenyl tin chloride and traces of triphenylmethane.

3. Action of Acyl Halides.—The reaction between tin tetraphenyl and acetyl chloride, benzoyl chloride, and benzene sulfonyl chloride to form ketones was very slow under ordinary conditions. Only traces of phenyl ketones were obtained when boiled under reflux. High temperatures and pressures were necessary to produce an appreciable yield and even then the yield was poor in the case of acetyl chloride.

Acetophenone.—Eight and five-tenths g. of tin tetraphenyl and 10 g. of acetyl chloride were heated in a sealed tube at 100° for fifteen hours. A dark oil was obtained. This was filtered and the filtrate was washed, dried and distilled. After two fractionations a light yellow oil was obtained which boiled at 200–205°; yield of acetophenane, 1 g.

Benzophenone.—Eight and five-tenths g. of tin tetraphenyl and 12.5 g. of benzoyl chloride were heated in a sealed tube at 200° for ten hours. The reaction product was washed from the tube with ether and filtered. The ether was evaporated and the brownish oil repeatedly washed with hot water to destroy any unused benzoyl chloride. The brownish liquid partially solidified. It was transferred to a distilling flask and the portion coming over from 297 to 305° was reserved; crude yield, 7%; redistilled and recrystallized from alcohol, m. p. 48°.

Diphenylsulfone.—Eight and five-tenths g. of tin tetraphenyl and 14.1 g. of benzenesulfonyl chloride were heated in a sealed tube at 200° for eighteen hours. The dark viscous product in the tube was rinsed out with benzene and filtered. The filtrate yielded 34% of crude diphenylsulfone The crude produc was purified from hot water; m. p. 122–124°.

4. Action of Sulfur.—Reactions between tin tetraphenyl and sulfur were carried out under different conditions of time, temperature and concentrations of sulfur. As the temperature was increased the products changed from diphenyl sulfide to diphenyl disulfide and to thianthrene, using more sulfur for the second and third than for the first. It is necessary to carry out the reactions in a sealed tube to get the best results.

Diphenyl Sulfide.—Eight and five-tenths g. of tin tetraphenyl and 1.9 g. of flowers of sulfur (three atomic weights) were heated in a sealed tube at 170° for ten hours. The reaction product was a golden yellow liquid. The product was filtered and distilled. About two grams of benzene was obtained as a by-product. The diphenyl sulfide boiled at 295–297°; yield, 76%.

Diphenyl **Disulfide.**—Eight and five-tenths g. of tin tetraphenyl and **3.2** g. (five atomic weights) of sulfur were heated in a sealed tube at 190" for eight hours. The reaction product consisted of a brownish-yellow solid. This was extracted with hot ether, which upon evaporation and distillation yielded two grams of diphenyl sulfide and 4.8 g. of diphenyl disulfide (m. p. 60°).

Thianthrene.—Eight and five-tenths g. of tin tetraphenyl and 3.2 g. (five atomic weights) of sulfur were heated in a sealed tube at 250° for twenty hours. Hydrogen sulfide was given off when the tube was opened. The brownish-yellow product was extracted with ether and filtered. It was only slightly soluble in ether. It was then extracted with hot absolute alcohol and filtered From the filtrates were isolated 2 g. of phenyl sulfide, less than 1 g. of diphenyl disulfide and about 2 g. of thianthrene (m. p. 155–158°).[6]

5. Action with Nitric Acid.—To 8.5 g. of tin tetraphenyl in a flask cooled with an ice–salt mixture and fitted with a reflux condenser, was slowly added 5 ml. of concentrated nitric acid. At first only a gentle reaction occurred. Soon a violent reaction was set up. After the reaction had ceased the product was heated on a steam-bath for thirty minutes. The product was then washed, dried and distilled. The fraction boiling at 208–210° was reserved; yield, 2 g. Whether the nitrobenzene was formed when the tin tetraphenyl was decomposed or whether benzene was first formed and then nitrated is not known from these experiments.

6. Action of **Sulfuryl** Chloride.—From the product of refluxing 8.5 g. of tin tetraphenyl with 5.4 g. of sulfuryl chloride in benzene were isolated only unchanged tin tetraphenyl and a small amount of triphenyl tin chloride (m. p. 105–106°). When 8.5 g. of tin tetraphenyl and 20 ml. of sulfuryl chloride (without solvent) were refluxed, sulfur dioxide was evolved and only a small amount of diphenyl tin hydroxychloride (m. p. 184–185°) was identified. What the course of this reaction is and what other products are formed need further study.

---

[6] In all cases the compound isolated whose melting point or boiling point is given was checked by mixing with the same compound from another source and again determining the constant.

Summary

1. Tin tetraphenyl reacts with (*a*) halogens to form aryl mono halides, (b) acyl halides to form phenyl ketones, ***(c)*** sulfur to form diphenyl sulfide, diphenyl disulfide and thianthrene. The reactions with alkyl halides and sulfuryl chloride were not conclusive. With nitric acid nitrobenzene was isolated.

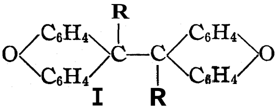
THE DISSOCIATION INTO FREE RADICALS OF SUBSTITUTED DIXANTHYLS. V. THE RATE OF DISSOCIATION[1]

BY JAMES B. CONANT AND MILDRED W. EVANS[1]

RECEIVED FEBRUARY 28, 1929 PUBLISHED JUNE 5, 1929

More than a dozen derivatives of dixanthyl of the type represented by Formula I have been prepared and studied in this Laboratory.[2]



I (R = an alkyl or aryl group)

All of them in solution absorb oxygen at room temperature and in many cases the reaction is so rapid that the speed of the process is limited only by the rate of solution of the gas. However, those compounds in which the substituting group may be represented as RCH_2CH_2— are much less rapid in their action and it is possible, therefore, to study their auto-oxidation at room temperature. A few approximate measurements of the rate of oxidation of these substances were made in connection with their preparation; these results have been reported in the previous papers of this series. In order to learn more about the nature of the reaction, we have now undertaken a more detailed study of the auto-oxidation of a typical representative of the class, di-n-butyldixanthyl. The results of this investigation, which we are about to describe, led to the unexpected conclusion that we were in reality measuring a rate of dissociation into free radicals. Since the relation between this rate and the tendency of the compound to dissociate on heating is a matter of great interest, we continued the work and included a study of a number of homologs of di-*n*-butyldixanthyl at different temperatures. A discussion of the results so obtained forms the concluding portion of this paper.

In the case of many compounds which are appreciably dissociated in

[2] Conant and co-workers, THIS JOURNAL, 47, **572,** 3068 **(1925); 48, 1743 (1926); 49,2080 (1927).**

solution below 100°, the reaction with oxygen at 25° (in solution) proceeds almost quantitatively according to the reaction

$$R_3C—CR_3 + O_2 \longrightarrow R_3C—O—O—CR_3$$

The maximum amount of oxygen absorbed is one mole per mole of substance and a crystalline peroxide may be isolated in amounts as large as 80% of the theoretical. Such is the case, for example, with dibenzyldixanthyl, which absorbs oxygen very rapidly in solution. There seems to be no reason to believe that there is any fundamental difference between such a reaction and the slower oxygen absorptions of such compounds as di-n-butyldixanthyl. Indeed, it is possible to isolate the peroxide in this case, also, although the yield is poor. There is, however, another side reaction involving further oxidation of the peroxide or some intermediate oxide, since the total amount of oxygen absorbed corresponds to more than one mole. In the case of some of the alkyl dixanthyls as much as 2.5 moles of oxygen can be absorbed by prolonged exposure of the solution to oxygen. The susceptibility of the first oxidation product to further oxidation obviously accounts both for the low yields of peroxide and the increased oxygen consumption. We may, therefore, regard the measured rate of oxygen absorption of di-*n*-butyldixanthyl as the sum of the relatively fast normal reaction and a slower secondary oxidation which becomes appreciable only after the reaction has proceeded for some time. This is illustrated in Fig. 1, in which the rate of oxygen absorption of di-n-butyldixanthyl over a long period of time was measured (Curve A). For the first half mole of oxygen absorbed this curve corresponds to that of a monomolecular reaction (Curve B). Assuming this to be the major reaction, the Curve C represents the slower side reaction which is responsible for the diminution in yield of peroxide.

We have centered our attention on a study of the rate of the oxygen absorption in that range (0 to 0.6 of a mole of oxygen) in which the side reaction mentioned above appears to be negligible. We have calculated the fraction of dixanthyl derivative which has reacted at any given time from the volume of oxygen absorbed at that time and the calculated volume corresponding to 100% peroxide formation. This procedure introduces no error in the range in which the side reaction is negligible.

In Table I are collected representative measurements from our preliminary study of the factors affecting the speed of the reaction. The differential pressure apparatus employed was that described in detail later in this paper. At the time these measurements were made the experimental error was of the order of 10%, although later experiments reduced this to about **3%.** The di-n-butyldixanthyl was dissolved in bromobenzene and the solution shaken with a large excess of air or oxygen. The volume of oxygen absorbed was calculated from the change in pressure. The concentration of dissolved oxygen throughout a given experiment was constant and therefore if the reaction were bimolecular, of the type $A + O_2 \longrightarrow AO_2$, the rate would nevertheless correspond to a first-order reaction. However, if the composition of the gaseous phase is changed, the concentration of dissolved oxygen must change. Thus, if the rate-controlling step involved the interaction of oxygen and the organic molecule, the rate should increase about five-fold on changing from air to oxygen. Actually there was no change (compare 1 and 2, 3 and 4, 5 and 6, in Table I). This fact shows that the combination with oxygen must be relatively fast and that

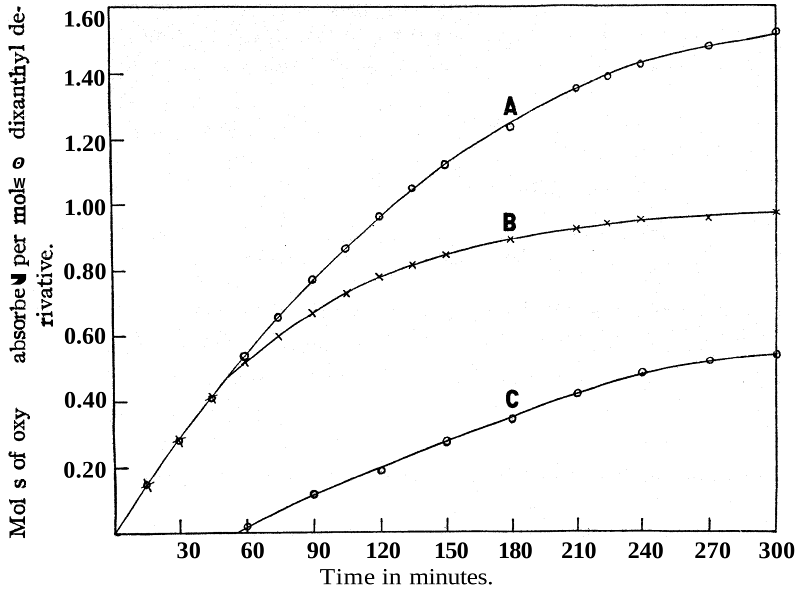

Fig. 1.—Rate of oxygen absorption of dibutyldixanthyl at 25° in bromobenzene solution. Curve A, observed rate; Curve B, calculated from first-order equation to correspond with A during first part of reaction; Curve C, difference between A and B.

TABLE I

THE RATE OF OXYGEN ABSORPTION OF DI-*n*-BUTYLDIXANTHYL

Expt.	Temp., °C.	Gas	Concn. of dixanthyl deriv., M	Fraction of dixanthvl derivative reacted in 10 min.	15 min.	20 min.	30 min.	45 min.	Remarks

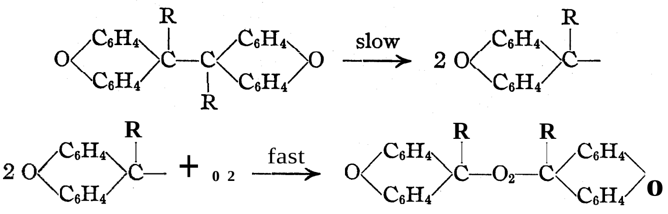
7	25	Oxygen	.005	.11	.15	.19	.30	.42	.53 at 60 min.
8	25	Oxygen	.003	.10	.15	.20	.30	.42	.55 at 60 min.
9	25	Oxygen	.002	.10	.14	.20	.29	.40	.54 at 60 min.

some slower reaction of the organic material alone controls the speed of the process. The reaction is of the first order with regard to the dixanthyl derivative (Expts. 6, 7, 8, 9, Table I).

Taking into account all that is known concerning the behavior of dixanthyl derivatives, it appears fairly certain that the rate-controlling step is the dissociation of the dixanthyl into free radicals. The mechanism of the oxygen absorption thus appears to be as follows



It is not surprising that the reaction is not subject to those marked catalytic effects which have been noted with so many auto-oxidation processes since it really is not an auto-oxidation which we are measuring. This lack of catalytic influence was clear both from the reproducibility of the results using different samples of dixanthyl compound and bromobenzene and also from the fact that no change was caused by the addition of 0.005% of hydroquinone, 3% of copper-bronze powder, powdered glass or a trace of sodium cyanide. It is further evident why the reaction has a rather unusually high temperature coefficient of the reaction velocity (an increase of 4–5-fold for 10° rise). The dissociation of a carbon–carbon linkage is the sort of process that might be expected to have a high temperature coefficient.

Having established to our own satisfaction the mechanism of the reaction, we then proceeded to a careful study of the rate of the dissociation of the simple alkyl derivatives of dixanthyl. The compounds studied were dimethyldixanthyl, diethyldixanthyl, dipropyldixanthyl, di-*n*-butyldixanthyl, di-n-amyldixanthyl and di-iso-amyldixanthyl. They were prepared and purified by the method described in earlier papers of this series. They were stored in an atmosphere of hydrogen in sealed ampules. Experiments with samples of the same compound prepared and purified at different times showed that the results were reproducible.

Apparatus and Procedure

The reaction vessel consists of a tincture bottle of 50-cc. capacity fitted with a ground-glass stopper carrying an entrance tube which was connected to one side of a manometer by means of about 10 cm. of heavy rubber tubing. Another bottle of the same shape and size was similarly connected with the other side of the manometer. Both bottles fitted into a holder which was immersed in a water thermostat and which was rocked back and forth by a suitable mechanism driven by a small motor. The manometer was of capillary glass tubing and contained bromobenzene colored with methylene blue. The difference in pressure was read on a millimeter scale placed directly beside the capillary tubing. The temperature of the thermostat was constant within ±0.1° and the bottles were completely immersed in the water.

In starting an experiment both bottles were charged with the same volume of bromobenzene (usually 4.0 cc.), oxygen bubbled through for five minutes from a tank, the stoppers quickly inserted and sealed with paraffin. The bottles were then placed in the holder and shaken until the manometer reading was constant; this required from ten minutes to half an hour. This equilibration of the solvent is essential if one wishes to obtain reproducible results with an accuracy of a few per cent. When equilibrium had been established, a sample (about 0.02 *g.)* of dixanthyl derivative was rapidly weighed to a tenth of a milligram in a small bulb with a long neck. This bulb was quickly introduced into the reaction bottle, which was removed from the thermostat and opened for a few seconds for this purpose. The stopper was sealed as before and the bottle placed in the thermostat for five minutes. During this time the sample did not come in contact with the solvent since the neck of the bulb-tube rested against the side of the vessel, keeping the tube upright. The levels of the manometer were now made equal by bringing both sides to atmospheric pressure by means of two three-way cocks. The cocks were then turned so that each side of the manometer was connected directly to one bottle. The bulb tube was now broken by one or two rapid shakes of the reaction bottle, which was immediately replaced in the holder and the shaking device started. The time was taken from this point and the manometer read. To assist in the rapid breaking of the bulb-tube a sharp pointed rod was usually inserted in the bulb-tube before it was placed in the reaction vessel. The solid dixanthyl derivative dissolves very rapidly; the error introduced by the time required for complete solution is probably slight and affects only the first few readings.

From the change in pressure as read on the manometer the volume of oxygen which has been absorbed may be calculated. In order to do this it is necessary to know the volume of gas displaced by the rise of the liquid in the manometer tube. This was found, by weighing a column of mercury, to be 0.006 cc. per centimeter. The total volume above the solution on each side of the system was 62 cc. The fraction of dixanthyl derivative which has reacted at any given time is equal to the volume of oxygen absorbed divided by the amount calculated on the assumptions in regard to the reaction discussed above (one mole of oxygen per mole of substance). The expression for this fraction, Z, in terms of the data just given and the difference in pressure expressed in millimeters of mercury, b, the barometric pressure P, the vapor pressure of C_6H_5Br, β, the weight of sample, w, and the molecular weight of the material (M.W.) is given in Equation 1, which is readily derived by an application of the gas laws.

$$Z = \frac{62b(0.0054P - 0.0054\,\beta + 62) - (0.0027)^2b^3}{(62 + 0.0027b)RT} \times \frac{\text{M. W.}}{w} \tag{1}$$

The term $(0.0027)^2b^3$ in the numerator and $0.0027b$ in the denominator may be neglected since b is never greater than 10. Variations in the barometric pressure between 750 and 770 mm. introduce errors less than the probable error of our measurements; the vapor pressure of bromobenzene may also be neglected. Taking an average value of P as 760, neglecting the terms just mentioned and substituting $m/9.05$ for b, where m is the pressure difference in millimeters of bromobenzene, we have Equation 2.

$$Z = 1.172 \times 10^{-4} m \frac{\text{M. W.}}{wT} \qquad (2)$$

Discussion of Results

A few typical experiments are reported in full in Table II. The same results are shown graphically in Fig. 2, in which $-\log (1-Z)$ (where Z = fraction reacted) has been plotted against the time in minutes. The straight line was drawn to pass through the greatest number of points. The slope of this line multiplied by *2.303* is the value of k, the usual velocity constant of a first-order reaction. Using this value of k, values of Z have been calculated corresponding to the experimental points. The agreement between the values thus calculated and those found is shown in the last columns of Table II. It is evident that the reaction rate corresponds within the experimental error to that of a monomolecular reaction over the range studied. It will be noted that in Fig. *2* the straight lines do not pass through the origin. This is probably because the initial time is uncertain, in part due to the time required for solution of the material. By using this graphical method of obtaining the best value of k, this error has been largely eliminated. The two curves A and B in Pig. *2* and the corresponding data in Table II were chosen as representative of the most satisfactory and the least satisfactory of our duplicate experiments.

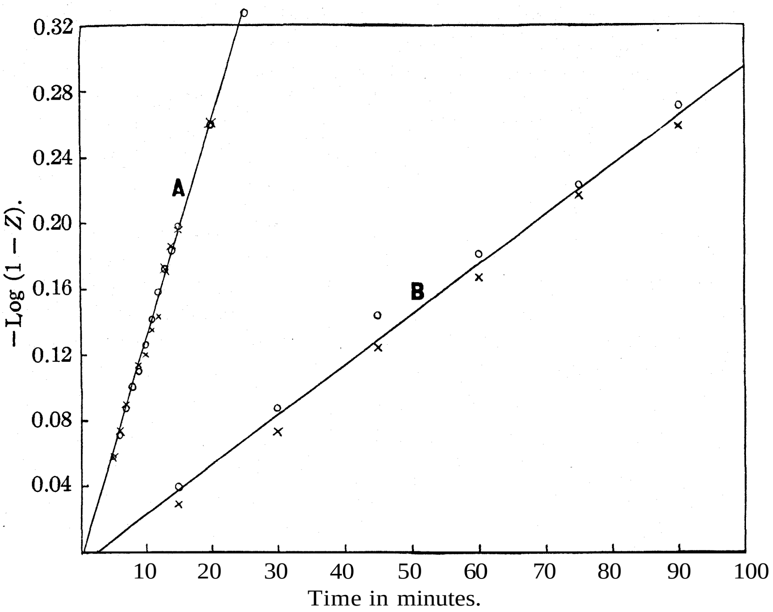


Fig. 2.—The rate of dissociation of dixanthyl derivatives as measured by rate of oxygen absorption: typical results. Curve **A** corresponds to Expt. 1, Table II; Curve B to Expt. 2; the crosses and circles indicate the points in the two duplicate runs.

In Table III are summarized all of our final measurements. The values of k were obtained by the graphical method illustrated by Fig. 2. We consider the value of k for each compound at each temperature to be subject to an error of not more than ±3%.

In Fig. **3** the values of log k are plotted against the reciprocal of the absolute temperature, the slope of each line multiplied by 2.303 being the value of E/R in the equation $d \ln k/dT = -E/RT^2$. The values of E calculated from the integrated form of this equation are given in Table III. The average values for the dimethyldixanthyl (34,000) and diethyldixanthyl (29,000) are higher than the average for all the other compounds (26,000–27,100). This difference appears to be outside the experimental error. It is perhaps significant that the larger value of E corresponds to

a lower value of k at a given temperature, though the ratio E/T_x (where T_x = the temperature at which $k \times 10^3 = 10$) varies from 110 for the methyl compound to 87.5 for the n-butyl compound. It seems unlikely that all this variation in E/T_x is due to experimental errors.

It is evident from Table III and Fig. 3 that the methyl and ethyl compounds cannot be distinguished the one from the other by our measurements. On passing from the ethyl to the n-propyl compounds there is an increase in k of six-fold, the normal propyl and butyl compounds are practically identical in their rates, but the n-amyl compound is somewhat slower. On the other hand, the iso-amyl compound is almost as rapidly dissociated as the n-propyl and n-butyl. The relationship between these higher homologs at 25° is n-C_5H_{11}:*iso*-C_5H_{11}:C_3H_7:C_4H_9 as 1:1.4:1.7:1.8. The practical identity in behavior of the methyl and ethyl compounds is somewhat surprising. In connection with the problem of the relationship between structure and speed of dissociation (the k of Table III), it must be remembered that di-isobutyldixanthyl (R = $(CH_3)_2CHCH_2$-) and dibenzyldixanthyl (R = $C_6H_5CH_2$-) absorb oxygen too rapidly for accurate measurements at room temperature (values of $k \times 10^3$ estimated as > 300) and the di-*iso*propyldixanthyl is appreciably dissociated in solution at room temperature and behaves like hexaphenylethane.

The parallelism between the rate of dissociation and the temperature required for appreciable dissociation (as judged by the color) in a 0.05 M solution is shown in Table IV. We have also included in this table some tests made by Dr. A. W. Sloan in this Laboratory on the rate of the reaction between a chloroform solution of the dixanthyl derivative and a dilute aqueous solution of ferric chloride and potassium ferricyanide. This reaction results in the more or less rapid formation of Prussian blue, presumably by virtue of the oxidation of the dixanthyl derivative to the corresponding carbinol and the reduction of the iron compound. If this reaction proceeds through the free radical (as it certainly does in certain cases),[3] the rate of the process might, like the rate of oxygen absorption, be controlled by the rate of dissociation. The results given in Table IV indicate that this is probably the case.

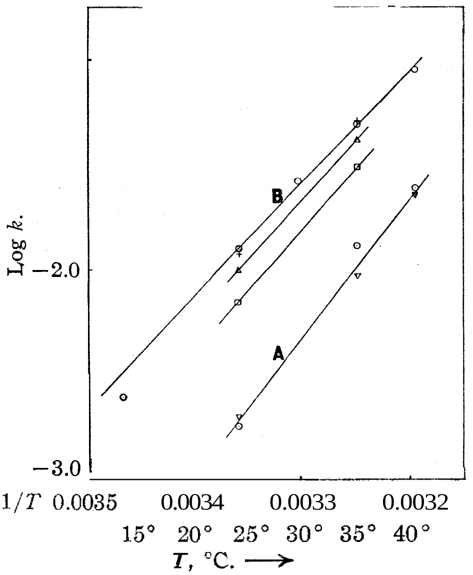

Fig. 3.—The rate of dissociation of dixanthyl derivatives at different temperatures. Line A, ○, dimethyldixanthyl; ▽, diethyldixanthyl. Line B and two shorter lines, ○, di-*n*-butyldixanthyl; +, di-*n*-propyldixanthyl; A, di-*iso*-amyldixanthyl-; □, di-*n*-amyldixanthyl.

It is clear from an inspection of Table IV that the measurements of the rate of oxygen absorption, the Prussian blue test and the appearance of color on heating, all place the compounds in the same groups and that the differences in each case are of the same order of magnitude. If ΔH for the dissociation is approximately the same for all dixanthyl derivatives, the figures in Col. 4 of Table IV may be taken as an indication of the order of the relative values of log K at 25° since $d \ln K/d(1/T) = \Delta H/R$. The higher temperature corresponds to the larger value of $-\log$ K. Since the dissociation constant $K = k_{\text{diss}}/k_{\text{ass.}}$, it is interesting that from Table IV there appears to be at least a rough parallelism between $k_{\text{diss.}}$ (the rate of dissociation) and the equilibrium constant, K. This suggests the possibility that the speed of association of the free radicals (in solution) is practically the same for all these related compounds. This might well be the case if the rate of association of these very reactive molecules were limited only by the number of collisions; this number would be essentially independent of the chemical nature of the free radicals themselves.

[3] Conant, THIS JOURNAL, 47, 1959 (1925).

Table IV

Comparison of the Rate of Dissociation of Dixanthyl Derivatives and the Temperature Required for Appreciable Dissociation

Subs. groups	Approx. rate of diss. in C_6H_5Br at 25°, $k \times 10^3$	Time req. for Prussian Blue Test (see below), min.[a]	Temp.[b] at which "appreciable color" dev. in a 0.05 M soln. in $C_6H_5COOC_2H_5$

C_2H_5		..	
n-C_4H_9	10	20	160°
n-C_3H_7		..	
iso-C_5H_{11}		15	
$C_6H_5CH_2$—	Estimated >300	0.2	100°
 $(CH_3)_2CH—CH_2—$		..	

[a] The Prussian blue test was carried out as follows: a few milligrams of the substance was dissolved in 3 cc. of chloroform and placed in a test-tube with 5 cc. of a very dilute aqueous solution of ferric chloride and potassium ferricyanide. The mixture was shaken vigorously for one minute and then allowed to stand. In the case of the most reactive dixanthyl derivatives there was an almost immediate formation of a blue precipitate; with the less reactive compounds the precipitate slowly formed at the interface between the solvents.

[b] The temperatures recorded in the fourth column were estimated by rapidly heating 0.05 M solutions (in $C_6H_5COOC_2H_5$) sealed in an inert atmosphere to 100, 160, 190, 210" and estimating the color by comparison with standards of dilute potassium dichromate solution. We estimate that the yellow color taken as "appreciable color" corresponds to about 1% dissociation but this value is, of course, very uncertain. Since all the experiments were performed exactly alike we feel that the relative temperatures required for the same degree of dissociation are significant and are probably correct within ±5°. The color due to dissociation was, of course, lost on cooling. Further information in regard to the reversible thermal coloring of the solutions has been given in the earlier papers of this series.

We hope to obtain further information along this line as a result of the studies which are now in progress in this Laboratory on the energetics and kinetics of free radical formation.

Summary

1. The rate of oxygen absorption of di-n-butyldixanthyl in bromobenzene solution at 25° has been measured by means of a differential pressure apparatus. The reaction is of the first order until about half a mole of oxygen per mole of dixanthyl derivative has been absorbed. The rate is independent of the concentration of the oxygen in the solution. It thus appears that the rate-controlling step is the dissociation of the dixanthyl derivative into a free radical.

2. The rates of dissociation of the following dixanthyl derivatives in bromobenzene have been measured at different temperatures by following the rate of oxygen absorption: dimethyl, diethyl, di-n-propyl, di-*n*-butyl,

di-n-amyl, di-iso-amyl. The energy of activation has been calculated from the temperature coefficient of the reaction velocity.

3. A parallelism has been found between the rates of dissociation and the temperature at which appreciable dissociation first occurs as evidenced by the appearance of color in a dilute solution.

PHENANTHRENEQUINONES RELATED TO ALIZARIN AND PURPURIN

BY LOUIS FREDERICK FIESER

RECEIVED MARCH 2, 1929 PUBLISHED JUNE 5, 1929

It is an interesting indication of the general difference in the chemistry of anthracene and of phenanthrene that alizarin was synthesized, produced commercially and the structure established all in the course of seven years, while over fifty years have elapsed since the first attempt was made[1] to obtain the corresponding phenanthrene derivative and the substance has not yet been described. Phenanthrenequinone is so sensitive to the action of alkalies, acids and oxidizing agents that it is doubtful if many of its derivatives will prove useful as dyestuffs; but the angular alignment possesses a greater chromophoric character than anthraquinone, and it is at least a matter of theoretical interest to know how the phenanthrenequinones having two or more hydroxyl groups in the ortho and para positions compare with the anthraquinone dyes.

Morpholquinone, the first substance of this type to be described, was obtained by Vongerichten[2] from a degradation product of morphine. Because it was a mordant dye similar to alizarin, Vongerichten at first regarded it as 1,2-dihydroxyphenanthrenequinone, but later[3] recognized it as the 3,4-isomer. The aim of several investigators to prepare this quinone from phenanthrene, or by applying the Pschorr synthesis, was finally achieved by Schmidt and Söll.[4] An unsuccessful attempt to synthesize 1,2-dimethoxyphenanthrene, from which 1,2-dihydroxyphenanthrenequinone might be obtainable, has been recorded,[5] and Mukherjee and Watson[6] found it impossible to hydroxylate 2-hydroxyphenanthrenequinone by the methods so useful for the preparation of alizarin and its congeners. Thus no dihydroxyphenanthrenequinones possessing dyeing properties, other than morpholquinone, were known until Brass under-

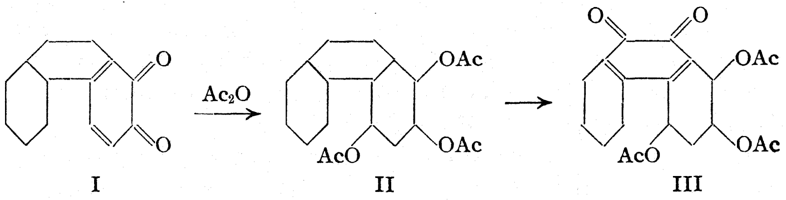
[6] Mukherjee and Watson, J. Chem. *Soc.*, 109, 617 (1916).

took a study of the rearrangement of the phenanthrenequinone azides. As a result of this work he was able to prepare 1,4-dihydroxyphenanthrenequinone[7] and the 2,3-isomer.[8] The only other polyhydroxyphenanthrenequinones known are 2,5-[9] and 2,7-dihydroxyphenanthrenequinone,[10] 2,3,4-trihydroxy-[11] and 2,7,?-trihydroxyphenanthrenequinone,[6] and 2,3,6,7-tetrahydroxyphenanthrenequinone.[12] None of these compounds presents any new points of interest.

In view of the scarcity of such compounds and the difficulty in finding methods suitable for their preparation, it seemed worth while to attempt to use the isophenanthrenequinones which recently have become available for the preparation of new 9,10-phenanthrenequinones. Thus an improved method of preparing morpholquinone has been found in the reductive acetylation of 3,4-phenanthrenequinone, followed by oxidation at the 9,10-positions and hydrolysis of the oxidation product.[13] In a similar manner 1,2-phenanthrenequinone[14] has now been converted into 1,2-dihydroxyphenanthrenequinone. The triacetate of 1,2,4-trihydroxyphenanthrenequinone, III, was obtained by hydroxylating 1,2-phenanthrenequinone, I, by the Thiele method and oxidizing the triacetoxy-phenanthrene, II, with chromic acid. 1,3,4-Trihydroxyphenanthrenequinone was prepared in the same way from 3,4-phenanthrenequinone.



The oxidation of an acetoxyl or alkoxyl derivative of phenanthrene seldom proceeds smoothly and in good yield, and the results are often negative. Thus Pschorr reports the failure to obtain a quinone from 1- or 4-methoxyphenanthrene, or from 1,5-dimethoxy-6-acetoxyphenanthrene,[15] and the author was unable to oxidize 3-methoxy-1,4-diacetoxyphenanthrene or 1-(*p*-toluidino)-3,4-diacetoxyphenanthrene.[13] The difficulty is partly due to the fact that the quinones are about as easily oxidized as the starting materials,[3] while a poor yield in some cases has been traced

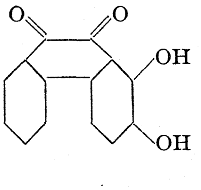
to the formation of a diphenanthryl derivative as a by-product.[16] In the present case the chief side reaction appeared to consist in the hydrolysis of the acetoxyquinones or of the starting materials, but, by carrying out the oxidation with an equal weight of chromic acid in glacial acetic acid solution at 40°, yields of from **30** to 60% were obtained.

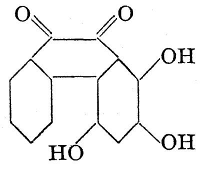
The new trihydroxyphenanthrenequinones are very easily oxidized by the air in alkaline solution. The intensely green solutions lose their color in a short time and it is thus necessary to hydrolyze the acetates in an indifferent atmosphere. 1,2-Dihydroxyphenanthrenequinone and morpholquinone are also oxidized under these conditions, though not as rapidly. Since this sensitivity to oxygen is characteristic only of the quinones having hydroxyl groups in the ortho or para positions, it is probable that the first step in the oxidation is the formation of a diquinone.

It may be noted that the new quinones exhibit no tendency to exist in any of the possible tautomeric forms, for they are all reconvertible into the original acetates, whose structures are fixed.

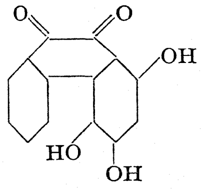
The new hydroxyphenanthrenequinones are in general inferior in dyeing properties to the isomers of the anthraquinone series. The trihydroxy-*o*-quinones, V and VI, are very poor dyes in comparison with purpurin. 1,2-Dihydroxyphenanthrenequinone, IV, which corresponds in structure to alizarin, dyes mordanted wool deep green, but it has little affinity for unmordanted cloth. The colors produced with IV are, to be sure, deeper than those from alizarin, just as 1,4-dihydroxyphenanthrenequinone surpasses quinizarin in tinctorial properties.[17] This is a further indication that phenanthrenequinone is a more powerful chromophore than anthraquinone.



IV



V



VI

On comparing the descriptions of the dyeing produced with the three o-dihydroxyphenanthrenequinones, it is found that there is a deepening in color on passing from the 2,3-isomer (brown-red),[8] to the 3,4-isomer (blue),[2] to the 1,2-isomer (green). It is rather surprising that the isomer having the true "alizarin structure" has less affinity for the fiber and gives less brilliant colors than morpholquinone. An hydroxyl group adjacent to the carbonyl group of phenanthrenequinone does not appear to favor

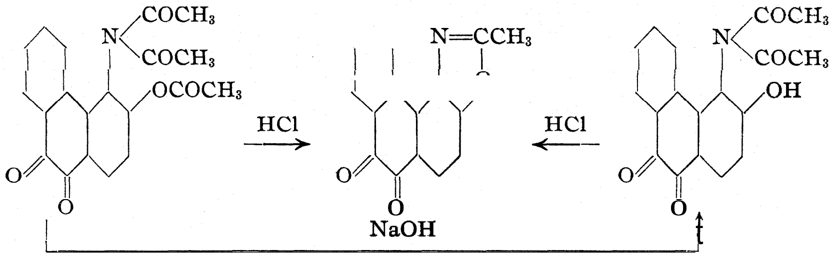
[17] Brass, *Z. angew. Chem.*, 37, 67 (1924).

particularly the formation of a color lake.[18] Dimroth and Roos recently have recorded a similar observation concerning the dihydroxynaphthoquinones.[19] It is also surprising that the trihydroxyphenanthrenequinones, V and VI, are much poorer dyes than the ortho or para dihydroxy compounds from which they may be considered to be derived.

Since Brass[7,8] has found that 2-amino-3-hydroxy- and 4-amino-1-hydroxyphenanthrenequinone possess some dyeing properties, an attempt was made to prepare the quinone corresponding to 4-amino-3-hydroxyphenanthrene.[13] The triacetate of this substance was converted without difficulty into the triacetate of 4-amino-3-hydroxyphenanthrenequinone, VII, but the complete hydrolysis of the latter compound was not accomplished. On acid hydrolysis, or by dissolution of the quinone in bisulfite solution, the substance was converted into the oxazole derivative, VIII, which is very resistant to the action of either acids or alkalies. The triacetate was easily hydrolyzed by alkalies, but the product obtained was the N,N-diacetate, IX. This compound was easily converted into the oxazole derivative, VIII, by the action of acids, but it was only very slowly attacked by alkalies and then only with the complete destruction of the molecule. Thus the desired aminohydroxyphenanthrenequinone was not obtained.



VII VIII IX

The stability of the diacetylamino group in the 4-position is somewhat surprising, but it is not unlike the unusual stability of the sulfonic acid group of 1,2-phenanthrenequinone-4-sulfonic acid.[14] In the latter case the phenomenon was attributed to the configuration of the molecule, and it is possible that the resistance of the above diacetate to alkaline hydrolysis is due to the blocking effect of the neighboring phenyl group.

Experimental Part

1,2-Diacetoxyphenanthrene.—A mixture of equal parts of 1,2-phenanthrenequinone,[14] zinc dust and sodium acetate, with 5 parts of acetic anhydride, was boiled until the solution became pale yellow, the mixture was diluted with glacial acetic acid,

---

[18] 1-Hydroxyphenanthrenequinone, which will be described in a forthcoming paper, imparts only a faintly pink color to mordanted wool.

[19] Dimroth and Roos, *Ann.*, 456,177 (1927).

filtered and carefully treated with water. The crude diacetate, m. p. 140°, was thus obtained in 89% yield. After repeated crystallization from dilute acetic acid and from ligroin-benzene, small, colorless needles melting at 146–147° were obtained. The compound is very readily soluble in benzene or glacial acetic acid and sparingly soluble in ligroin.

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.45; H, 4.79. Found: C, 73.24; H, 4.82.

1,2-Diacetoxyphenanthrenequinone.—Five grams of the diacetate was oxidized in glacial acetic acid solution at 40° with 5.2 g. of chromic acid. The mother liquor contained some unchanged diacetate, for a further quantity of the quinone was obtained by adding more chromic acid after collecting the first crop of crystals. The yield was 3.3 g. (60%). The quinone dissolves readily in glacial acetic acid and forms small orange needles which melt with decomposition at 251° (257°, corr.).

Anal. Calcd. for $C_{18}H_{12}O_6$: C, 66.65; H, 3.73. Found: C, 66.89; H, 3.85.

1,2-Dihydroxyphenanthrenequinone.—When the diacetate was covered with a mixture of sodium hydroxide and alcohol, hydrolysis took place at once. A dark green solution resulted and some of the sodium salt of the quinone separated. The mixture was diluted with water in order to bring the salt into solution, and acidified. The flocculent, dark red precipitate was digested for a short time at the boiling point and the more compact product was then easily collected and washed. The substance is only sparingly soluble in water, and very readily soluble in alcohol, acetone or glacial acetic acid. Clusters of small, very dark red crystals were obtained from acetone. The substance decomposes on heating. The alkaline solution is chrome green, and a green salt is easily precipitated by an excess of alkali. The solution in concentrated sulfuric acid is red; in pyridine it is crimson.

Anal. Calcd. for $C_{14}H_8O_4$: C, 69.99; H, 3.36. Found: C, 69.77; H, 3.48.

1,2-Dihydroxyphenanthrenequinone dyes unmordanted wool a pale bluish gray. Wool or silk mordanted with aluminum or chromium is dyed dark green. The tones are not as brilliant as those with morpholquinone.

1,2,4-Triacetoxyphenanthrenequinone.—In early experiments on the oxidation of 1,2,4-triacetoxyphenanthrene[14] it was found that the product was partially hydrolyzed when the reaction was carried out in glacial acetic acid solution at the boiling point, with the result that most of it was destroyed by further oxidation. The use of acetic anhydride, or of mixtures of this with acetic acid, was then tried but a somewhat elevated temperature was required and again hydrolysis products of the quinone, as well as of the starting material, were obtained. Thus 2-acetoxy-1,4-phenanthrenequinone (m. p. 146°) was identified in one experiment. More satisfactory results were obtained by dissolving 5 g. of the triacetate in 75 cc. of glacial acetic acid, cooling to 40° and adding a solution of 5 g. of chromic acid. The product, which separated after standing for some time, was washed with alcohol and crystallized from toluene, giving 1.7 g. (32%) of pure material. It forms orange plates melting with decomposition at 227–228°. The quinone is only moderately soluble in toluene and readily soluble in glacial acetic acid.

Anal. Calcd. for $C_{20}H_{14}O_8$: C, 62.82; H, 3.69. Found: C, 62.63; H, 3.72.

1,2,4-Trihydroxyphenanthrenequinone.—While the triacetate is very easily hydrolyzed, the extreme sensitivity of the hydroxyquinone to oxygen in the presence of alkali makes it imperative to exclude all air while carrying out the reaction. When the triacetate was covered with alcoholic sodium hydroxide solution in an atmosphere of nitrogen, hydrolysis proceeded without heating, giving a deep green solution. The green solution was diluted with water, filtered and acidified. The precipitate was at first somewhat gelatinous, but it coagulated on heating to give an easily filterable suspension. The dried material is black and decomposes on heating. No satisfactory method of crystallizing the compound was discovered. It is sparingly soluble in most solvents other than alcohol, in which it is extremely soluble. The red alcoholic solution deposited a red crystalline crust on slow evaporation, but this product, dried in vacuum at 100°, appeared to contain alcohol of crystallization.

Anal. Calcd. for $C_{14}H_8O_5 \cdot C_2H_5OH$: C, **66.24**; H, **4.32.** Found: C, **66.18**; H, **4.31.**

The precipitated material gave the following analytical results.

Anal. Calcd. for $C_{14}H_8O_5$: C, **65.62**; H, **3.15.** Found: C, **65.30**; H, **3.20.**

This quinone gives a green solution in alkali, but in the presence of air the color rapidly disappears and gives place to a pale red. The change may be noted in the film formed on shaking the green solution in a test-tube. A completely oxidized solution gives off carbon dioxide on acidification. The quinone dissolves in concentrated sulfuric acid with a green color. The solution in pyridine is cornflower-blue when fresh, but soon becomes brown on exposure to the air and deposits a black, sparingly soluble substance which has the properties of a quinone. The trihydroxyquinone is easily acetylated with acetic anhydride and sulfuric acid without heating, giving the original triacetate.

1,2,4-Trihydroxyphenanthrenequinone has scarcely any dyeing properties. A poor, dull brown is produced on aluminum-mordanted wool.

1,3,4-Triacetoxyphenanthrene.—This compound was obtained in good yield by the reductive acetylation of 3-hydroxy-1,4-phenanthrenequinone[13] with zinc dust, sodium acetate and acetic anhydride. It dissolves very readily in alcohol, readily in benzene and only sparingly in ligroin. Fluffy clusters of silken white needles melting at 138° were obtained on crystallization from benzene–ligroin.

Anal. Calcd. for $C_{20}H_{16}O_6$: C, **68.16**; H, **4.58.** Found C, **68.19**; H, **4.67.**

1,3,4-Triacetoxyphenanthrenequinone.—The above triacetate was oxidized in glacial acetic acid solution at 40° with an equal weight of chromic acid. After maintaining the specified temperature until yellow crystals of the quinone began to separate, the mixture was cooled and the nearly pure product was collected; yield, **47%.** The compound dissolves readily in glacial acetic acid and crystallizes from this solvent in the form of well-shaped yellow needles. The substance softens at about 220° and decomposes at about **240°**.

Anal. Calcd. for $C_{20}H_{14}O_8$: C, **62.82**; H, **3.69.** Found: C, **62.66**; H, **3.92.**

1,3,4-Trihydroxyphenanthrenequinone.—Working in an atmosphere of nitrogen, 1,3,4-triacetoxyphenanthrenequinone was covered with cold alcoholic sodium hydroxide solution. Hydrolysis took place readily and the solution became deep red and then green. A dark red, rather voluminous precipitate was thrown down on acidification. The product is only sparingly soluble in water but very readily soluble in alcohol, and it was obtained in the form of small, very dark red crystals on allowing the intensely red alcoholic solution to evaporate slowly.

Anal. Calcd. for $C_{14}H_8O_5$: C, **65.62**; H, **3.15.** Found: C, **65.47**; H, **3.25.**

The solution in alkali is intensely green when viewed in thin layers, but greenish-red when a considerable volume of the solution is viewed against a source of light. When exposed to the air, the color of the alkaline solution fades rather rapidly to a pale pink. The solution in concentrated sulfuric acid is deep red, while with pyridine a deep red solution is obtained which becomes green on dilution with water. The substance is easily acetylated by acetic anhydride, either in pyridine solution or with the aid of a few drops of concentrated sulfuric acid.

1,3,4-Trihydroxyphenanthrenequinone has poor dyeing properties. It dyes aluminum-mordanted wool or silk a dull green; with a chromium mordant a brown-gray is produced.

4-Amino-3-phenanthrol **Diacetate.**—This substance was prepared by adding acetic anhydride to a cold solution of 4-amino-3-phenanthrol hydrochloride[13] in pyridine. The product was precipitated by water and crystallized repeatedly from alcohol. It formed small, colorless plates melting at 208° (211°, corr.). It is sparingly soluble in benzene, moderately soluble in alcohol and insoluble in acids or alkalies.

Anal. Calcd. for $C_{18}H_{15}O_3N$: C, 73.69; H, 5 16. Found: C, 73.38; H, 5.11.

Oxazole Derivative of 4-Amino-3-phenanthrol.—Aminophenanthrol diacetate readily loses the elements of acetic acid on heating, with the closing of an oxazole ring. Since the same substance is formed by the loss of acetic anhydride from the triacetate,[20] a mixture of the di- and triacetates may be used for the preparation.

A mixture of 24.5 g. of 4-amino-3-phenanthrol hydrochloride, 9 g. of fused sodium acetate and 50 cc. of acetic anhydride was heated for one hour on the water-bath and the product was poured into water. The rather oily solid was heated in a distilling flask until all of the adhering water and all of the acetic acid formed in the reaction had been removed. The residue was then distilled at a pressure of 3 mm. The distillate solidified at once, giving 20 g. (86%) of a pale yellow product melting at 152°. Repeated crystallization from glacial acetic acid failed to remove the color, but yielded small, pale yellow plates melting at 155°.

Anal. Calcd. for $C_{16}H_{11}ON$: C, 82.37; H, 4.76. Found: C, 82.23; H, 5.02.

The substance dissolves readily in glacial acetic acid or benzene; it is moderately soluble in alcohol and insoluble in acids or alkalies.

Oxazole Derivative of 4-Amino-3-hydroxyphenanthrenequinone.—A solution of 4.7 g. of the above phenanthrene derivative in 150 cc. of glacial acetic acid was cooled to 70° and a solution of 8 g. of chromic acid (twice the theoretical quantity) in water, diluted with glacial acetic acid, was added in the course of ten minutes, while maintaining the initial temperature by cooling. In the early stages of the oxidation a brown precipitate was produced but this soon dissolved and orange crystals began to separate. After cooling the solution the product was collected and washed with alcohol. It was nearly pure; yield, 2.4 g (47%).

Crystallized from glacial acetic acid, in which it is only moderately soluble, this quinone formed small, orange needles melting at 275° (282°, corr.). It dissolves in concentrated sulfuric acid with a red-brown color and may be recovered unchanged from the solution. It dissolves to a slight extent in hot concentrated bisulfite solution and is recovered on the addition of acid or alkali to the solution. Attempts to hydrolyze this oxazole derivative with alcoholic sodium hydroxide solution were unsuccessful. The substance was attacked with such difficulty that the primary products were apparently destroyed during the process.

Anal. Calcd. for $C_{16}H_9O_3N$: C, 72.99; H, 3.45. Found: C, 72.78; H, 3.71.

4-Amino-3-hydroxyphenanthrenequinone Triacetate.—Werner[20] obtained triacetylaminophenanthrol by heating the aminophenanthrol with acetic anhydride in a sealed tube. It may be prepared more easily by boiling a mixture of 12 g. of 4-amino-3-phenanthrol hydrochloride, 4 g. of fused sodium acetate and 90 cc. of acetic anhydride for one hour. The mixture was poured into water and the product crystallized from alcohol; yield, 12.5 g. (76%); m. p., 170.5" (Werner, 169–170").

The conversion of the triacetate into a quinone was best accomplished by oxidizing a solution of 4 g. of material in 30 cc. of glacial acetic acid with a solution of 4 g. of chro-

---

[20] Werner, *Ann.*, 321, 298 (1902).

mic acid in 4 cc. of water and 8 cc. of glacial acetic acid at 55-60'. After ten minutes a little water was added gradually to the red solution; the quinone then separated in crystalline condition and was practically pure. The compound slowly dissolves on boiling with a rather large quantity of alcohol, but the resulting solution deposits crystals only after it has been concentrated to about one-tenth of the initial volume. Feather-shaped clusters of yellow needles melting at 204° (207°, corr.), with decomposition, are thus obtained.

Anal. Calcd. for $C_{20}H_{15}O_6N$: C, 65.74; H, 4.14. Found: C, 65.84; H, 4.45.

The only compounds isolated as the result of the hydrolysis of this substance were the oxazole derivative and a diacetate. The former is produced by boiling the alcoholic solution with hydrochloric acid, or by dissolving the quinone in bisulfite solution and adding hydrochloric acid.

4-Diacetylamino-3-hydroxyphenanthrmequinon—his was obtained by the alkaline hydrolysis of the triacetate. Working in an atmosphere of nitrogen, 2 g. of the triacetate was covered with 5 cc. of alcohol and 8 cc. of *3N* sodium hydroxide solution. The material rapidly dissolved to give a clear, deep red solution. When the solution was diluted with water and then acidified, a yellow solution resulted and in a short time yellow needles began to separate. The product (1.4 g.) did not dissolve easily in 95% alcohol, but the addition of a little water to a suspension which had been boiled for some time caused the material to go into solution rapidly. Crystallization now took place only after the solution had been well concentrated. Brown-yellow needles of what appeared to be the N,N-diacetate were thus obtained. The compound decomposes on heating at about 255–260°.

Anal. Calcd. for $C_{18}H_{13}O_5N$: C, 66.86; H, 4.05. Found: C, 66.81, 66.85; H, 4.64, 4.52.

The substance dissolves in alkali with a pure, intensely red color. The compound is slowly oxidized in alkaline solution by the air. It is not at all easily hydrolyzed. A strongly alkaline solution, heated on the water-bath in an atmosphere of nitrogen in order to prevent oxidation, still contained unchanged material after two hours. Hydrolysis products could not be isolated in pure condition. It is probable that further changes occur as rapidly as the hydrolysis. Acid hydrolysis of the diacetate yielded only the oxazole derivative. This reaction is easily brought about by boiling an alcoholic solution or suspension of the diacetate with hydrochloric acid. Orange needles of the oxazole soon separate.

Summary

A description is given of the preparation of 1,2-dihydroxyphenanthrenequinone and of 1,2,4- and 1,3,4-trihydroxyphenanthrenequinone from certain isophenanthrenequinones. An attempt to prepare 4-amino-3-hydroxyphenanthrenequinone met with failure owing to the resistance to hydrolysis of a diacetylamino group in the 4-position.

MECHANISM OF ORGANIC REACTIONS. II. THE "NON-EXISTENCE" OF A MIGRATORY METHYL GROUP IN THE CONVERSION OF GLYCEROL-DI-CHLOROHYDRIN INTO GLYCEROL MONOMETHYL ETHER

BY HAROLD HIBBERT AND MYRON S. WHELEN[1]

RECEIVED MARCH 25, 1929 PUBLISHED JUNE 5, 1929

The structure of carbohydrates and polysaccharides rests primarily on the data obtained by preliminary methylation of the material in question, followed by hydrolysis and identification of the resulting methylated product. The assumption has been made throughout that methylation processes are unaccompanied by (a) ring scission or ring shift, or (b) migration of one or more methyl groups during the methylation process.[2]

It has long been recognized that certain groups are particularly prone to migrate as, for example, in the case of acyl groups from oxygen to nitrogen[3] and more recently in connection with the wandering of this same type of group in the synthesis or analysis of glycerol esters.[4]

On the other hand, there are only one or two isolated cases known which appear to indicate the possibility of the migration of a methyl group, the most striking of which is that indicated in the conversion of glycerol-α,α'-di-chlorohydrin into the a-monomethyl ether of glycerol, as reported by Gilchrist and Purves.[5] These authors found that glycerol-α,α'-di-chlorohydrin (prepared by the action of hydrochloric acid on epichlorohydrin)[6] on methylation and subsequent hydrolysis yielded glycerol-α-monomethyl-ether and not the β-isomer as was to be expected. In other words, either a wandering of a methyl group had occurred, or the α,α'-di-chlorohydrin used was impure. No experimental details are given as to the actual method of isolating the glycerol-α,α'-di-chlorohydrin used by them.

They suggested the possibility of an impure starting material, although the homogeneous character and identity of the glycerol-α,α'-di-chloro-

hydrin thus prepared had been emphasized by Smith.[6] Furthermore, the experiments of Conant and Quayle,[7] who prepared the *p*-nitrobenzoate from Smith's product in excellent yield, appeared to disprove this idea, since this was found to have properties markedly different from those of the isomeric derivative prepared from glycerol-a,a^1-di-chlorohydrin. In view of this, the evidence offered by Gilchrist and Purves[5] appeared to be so unsatisfactory that considering the importance of the subject it seemed highly desirable to repeat their work taking the greatest possible precautions to utilize materials only after their identity had been definitely established.

It has been found that when pure glycerol-α,a$'$-di-chlorohydrin is methylated, then converted into the acetate, and the latter hydrolyzed, the expected glycerol-&methyl ether is obtained, there being no evidence whatever of any abnormality in the reaction implying a migration of the methyl group.

The glycerol-α,α'-di-chlorohydrin employed boiled constantly at 174 175° and on methylation with silver oxide and methyl iodide yielded a dichloroglycerolmethyl ether from which the unchanged glycerol-di-chlorohydrin was readily removed by washing with hot water. This α,α'-dichloroglycerol-&methyl ether boiled constantly at 156–159° and so far as could be judged from its physical properties represented a homogeneous chemical substance.

This material on heating with an aqueous alcoholic solution of potassium acetate under pressure was converted into the corresponding acetate. The latter on hydrolysis with a 3% aqueous alcoholic solution of hydrochloric acid[8] yielded a glycerol-monomethyl ether (b. p. 123–125° (13 mm.); $d_4^{17} = 1.1321$); yield, **33%.** The identity of this was established not only by its sharp boiling point and density on the one hand[g] but also by its conversion into *p*-nitrobenzylidene-glycerol-β-methyl ether and into the corresponding di-phenyl carbamate on the other.[9]

This synthesis has been repeated several times using glycerol-α,α'-di-chlorohydrin from various sources[10] and it was found that in all other cases the material used was an impure product consisting of a mixture of the isomeric glycerol-α,α'- and α,β-di-chlorohydrins.

It has been shown by Fairbourne and Foster[11] and more recently by Fairbourne and Cowdrey[12] that the structures assigned to many β-substituted monoglycerides are of doubtful value. The latter investigators have prepared a number of "α,β-" disubstituted glycerols from the corre-

sponding chlorohydrins and found them to be identical with their supposedly "α,α'-" isomerides. It is thus evident that conclusions drawn from results obtained by employing chlorohydrins for such syntheses must be regarded with grave suspicions in so far as they relate to questions of structure. Moreover, it is to be observed from the results of these investigators that migration often takes place when the hydroxyl group of the di-chlorohydrin is esterified by conversion into an acyl group followed by subsequent substitution of the halogen.

In the present investigation it is shown that a primary replacement of the hydrogen in the hydroxyl group of the glycerol di-chlorohydrin by an alkyl radical does not involve any migration during the subsequent hydrolysis and thus indicates that acyl groups are directly concerned, An earlier hypothesis put forward by Gabriel and Ohle[13] suggested that many of these conversions may be due to the formation of propylene oxide through loss of hydrogen chloride either during the reaction, or previously, with the production of an impure starting material, but as pointed out by Fairbourne and Cowdrey,[12] this in any event is evidently only applicable to specific cases.

In the writers' opinion the question of migration is intimately associated with the presence in the β-position of an acyl radical containing a reactive carbonyl group.

Under these conditions, as first pointed out by Fischer,[14] there exists the possibility of the ready formation of an unstable, intermediate, cyclic ester (Fischer's ortho-ester), which in undergoing spontaneous decomposition permits of a transfer of the acyl group in question.

The four cases reported in the literature involving a migration from the a- to the β-positions of either an alkyl or an acyl radical would seem to call for a reinvestigation in the light of the present results.

It is evident from the above, that conclusions with regard to structure based on the interconversion of glycerol halohydrins into monomethyl ethers may be accepted as involving no migration of the methyl group.

Experimental

Preparation of Glycerol-α,α'-di-chlorohydrin.—One hundred grams of epichlorohydrin (b. p. 117°) was treated with approximately 125 cc. of concentrated hydrochloric acid. The latter was added in small quantities, the mixture being shaken and cooled throughout the addition. After standing for several hours at room temperature, the reaction product separated into two layers. The mixture was neutralized by washing with sodium bicarbonate solution, at which stage the lower layer was separated, dried over anhydrous sodium sulfate, filtered and fractionated, yielding 110 g. of glycerol-α,α'-di-chlorohydrin boiling sharply at 174–175°.

Methylation of Glycerol-α,α'-di-chlorohydrin.—Fifty grams of glycerol-α,α'-di-chlorohydrin was methylated in the usual manner, using 100 g. of silver oxide and 125 g.

---

[13] Gabriel and Ohle, *Ber.*, **50,** 804 (1917).

[14] Fischer, *ibid.*, **53,** 1621 (1920).

of methyl iodide. The reaction mixture was extracted three times with ether, the ether removed and the remaining product freed from unchanged α,α′-glycerol-dichlorohydrin by shaking vigorously several times with hot water. After drying with anhydrous sodium sulfate, careful fractionation yielded **21.4** g. of **glycerol-α,α′-di-chlorohydrin-**8-methyl ether, b. p. **157–159"**; n_D^{17} = **1.4550.**

Anal. Subs., **4.988** mg.: CO_2, **6.072** mg.; H_2O, **2.548** mg. Calcd. for $C_4H_8OCl_2$: C, **33.56;** H, **5.56.** Found: C, **33.20;** H, **5.71.**

Hydrolysis of **Glycerol-α,α′-di-chlorohydrin-β-methyl** Ether.—The method used for replacement of the two chlorine atoms by hydroxyl groups was essentially that used by Gilchrist and **Purves**,[5] but was modified to the extent that the hydrolysis of the di-acetate was carried out in acid instead of alkaline solution, as it had been previously **shown**[16] that the presence of dilute mineral acids has no influence on the methyl group.

Twenty and four-tenths grams of glycerol-α,α′-di-chlorohydrin-β-methyl ether was heated in a sealed tube with **29** g. of crystalline potassium acetate, dissolved in **50** cc. of 75% aqueous ethyl alcohol, for sixteen hours at 115–130°. The potassium chloride formed was removed by filtration and the filtrate containing the di-acetate **refluxed** for one hour with **100** cc. of 75% ethyl alcohol containing 3% of hydrochloric acid. The reaction mixture was neutralized with lead carbonate, the solution filtered and concentrated to a small volume. At this point considerable solid material separated out on cooling; this was removed by Ntration. The filtrate was further concentrated and then fractionated under reduced pressure, yielding a clear colorless liquid, b. p. 110° **(4** mm.), which on redistillation yielded pure **glycerol-β-**methyl ether, b. p. 123–125° **(13 mm.)**;[15] d_4^{17} = **1.1321;** n_D^{17} = **1.4485;** yield, **5.2** g., equal to 33% calculated on the glycerol-α,α′-di-chlorohydrin-β-methyl ether employed. The product was further identified by conversion into the *p*-nitrobenzylidene-glycerol-**β-methyl ether**[9] (m. p. 106°) as well as into the di-phenyl carbamate, m. p. **101°.** Mixed melting point determinations of these compounds with known samples showed no lowering of the melting point. A mixed melting point of the di-phenyl carbamate, as obtained above, with a known sample of the di-phenyl carbamate of **glycerol-α-methyl** ether (m. p. 118°) melted indefinitely at 90°.

No trace whatever was found of the corresponding isomeric glycerol-or-methyl ether.

Preparation of **Glycerol-α,β-di-chlorohydrin-α-methyl** Ether.—Twenty-three grams of **allyl** methyl ether (b. p. 42–43°) in which had been dissolved a small crystal of iodine was treated with a slight excess of chlorine at 0°. The uncombined halogen was removed by bubbling dry air through the reaction mixture, the latter was thoroughly washed by shaking with water, the lower layer separated, dissolved in ether and dried over anhydrous sodium sulfate. Fractionation of this yielded **20.4** g. of glycerol-α,β-di-chlorohydrin-α′-methyl ether, b. p. 153–157°; n_D^{17} = **1.4489.** During the distillation hydrogen chloride was formed in slight amount due to a small amount of secondary decomposition.

Anal. Subs., **5.471** mg.: CO_2, **6.669** mg.: H_2O, **2.735** mg. Calcd. for $C_4H_8OCl_2$: **C, 33.56;** H, **5.56.** Found: C, **33.25;** H, 5.59.

Hydrolysis **of Glycerol-α,β-di-chlorohydrin-α-methyl** Ether.—The replacement of the chlorine atoms by acetyl groups was a much more difficult operation than in the case of the corresponding glycerol-α,α′-di-chlorohydrin-β-methyl ether. In marked contrast to the behavior of the latter with potassium acetate in aqueous alcoholic solution, it was found that glycerol-α,β-di-chlorohydrin-α′-methyl ether yielded a large amount of unsaturated derivatives, a reaction apparently common to organic products

---

[15] Hill, Whelen and Hibbert, THIS JOURNAL, 50, **2235 (1928).**

containing chlorine atoms attached to adjacent carbon atoms. Substitution of sodium formate for potassium acetate led to the same result. It was found, however, that the desired diacetate could be obtained (although in low yields) by heating **20.4** g. of glycerol-α,β-di-chlorohydrin-α′-methyl ether with **29** g. of fused potassium acetate and **30** cc. of glacial acetic acid under pressure at 165° for sixteen hours. The crude reaction product had a dark brown color. It was filtered from the solid material, the filtrate neutralized with solid potassium carbonate, again filtered and the filtrate concentrated under reduced pressure to a small volume. Further filtration and fractionation of the filtrate yielded **4.2** g. of a clear colorless liquid, b. p. 215–225°. Three grams of this material was hydrolyzed by refluxing for one hour with **25** cc. of 75% aqueous ethyl alcohol containing **3**% of hydrochloric acid. After neutralization with lead carbonate, filtration and concentration, the residual oil on distillation yielded **1.2** g. of glycerol-α-methyl ether; b. p. 111–112° **(13** mm.); d_4^{17} = **1.1189;** n_D^{17} = **1.4445.** Its identity as pure glycerol-a-methyl ether was further established by its conversion into the di-phenyl carbamate, m. p. **117"** C.[9] **A** mixed melting point of this material with a known sample showed no lowering, while a mixed melting point with the di-phenyl carbamate of glycerol-8-methyl ether melted indefinitely at **93°.**

Summary

1. Glycerol-α,α′-di-chlorohydrin on methylation and conversion of the α,α′-dichloro-β-methyl ether into the acetate, followed by saponification, yields only glycerol-β-methyl-ether.

2. Glycerol-α,β-di-chlorohydrin-α′-methyl ether on conversion into its acetate, followed by saponification, yields only glycerol-a-methyl ether.

3. Previous work in this field, pointing to the probability of the migration of a methyl radical in the conversion of glycerol-α,α′-di-chlorohydrin-β-methyl ether into the acetate and subsequent hydrolysis of the latter is based on the mistaken identity of the resulting product as glycerol-α-methyl ether.

4. The bearing of these results on the methylation of glycerol and carbohydrate derivatives is pointed out and the importance of the pure α- and @-glycerohnethyl ethers as "type substances" further confirmed.

MONTREAL, CANADA

NOTES

The Identification of **Ortho-, Meta-** and Para-Hydroxybenzoic Acids.—It was found necessary, recently, to isolate, purify and identify small amounts of *o*-, *m*- and *p*-hydroxybenzoic acids.

Lyman and Reid[1] have recommended the p-nitrobenzyl esters as suitable compounds by means of which these hydroxy acids can be identified. These investigators converted the acids into their sodium salts and heated these, dissolved in a mixture of water and alcohol, with p-nitrobenzyl bromide. We obtained unsatisfactory results by the use of this method since it was found that the esters, as soon as they are formed, react to some extent with p-nitrobenzyl bromide to form the p-nitrobenzyl

---

[1] Lyman and Reid, THIS **JOURNAL, 39,704 (1917).**

ethers, that is, the dinitrobenzyl derivatives of the hydroxy acids. In fact the substance described by Lyman and Reid as the *p*-nitrobenzyl ester of p-hydroxybenzoic acid was, in reality, the dinitrobenzyl compound.

The esters, or mononitrobenzyl compounds, are very soluble in organic solvents and hence are difficult to purify, but the dinitrobenzyl derivatives are much less soluble and can be recrystallized readily from acetone. The method was now modified in such a way that the formation of the dinitrobenzyl products was favored. As a result not only were compounds formed which could be recrystallized with less loss of material, but since the molecular weight of the dinitrobenzyl derivative is considerably higher than that of the mononitrobenzyl compound, a larger amount of material, in the case of the former substance, could be obtained from a given weight of the hydroxy acid. Furthermore, by the use of the dinitrobenzyl derivatives, it is possible to separate a mixture of two isomeric hydroxybenzoic acids; the derivative of the p-hydroxy acid is quite insoluble in acetone, that of the meta acid more soluble while the ortho isomer is fairly soluble.

The di-*p*-nitrobenzyl compounds were obtained in the following manner: 1.25 g. of p-nitrobenzyl bromide was dissolved in 10 cc. of pure acetone and a solution prepared from 0.35 g. of the hydroxy acid, **0.3** g. of sodium hydroxide crystals ($NaOH + H_2O$)[2] and 4 cc. of water was added. The mixture was refluxed for two hours. In the case of the p-hydroxy acid the dinitrobenzyl derivative separated in crystalline form from the hot reaction mixture; from the m- and o-hydroxy acids oils were obtained which solidified when cooled. The products were treated with 5 cc. of 10% sodium hydroxide and then filtered. The dinitrobenzyl compounds remained undissolved while the alkaline filtrate yielded, upon acidification, a small amount of the ether-acid. After three recrystallizations from acetone the derivatives were obtained in a nearly colorless state.

TABLE I

DI-*p*-NITROBENZYL DERIVATIVES OF HYDROXYBENZOIC ACIDS

	M. p., °C.	Analysis (Dumas), % Calcd. for $C_{21}H_{16}O_7N_2$	Found
o-Hydroxy[a]	137–139	N 6.86	6.50
m-Hydroxy[b]	142–144	N 6.86	6.86
p-Hydroxy[c]	196–197	N 6.86	6.83

[a] Readily soluble in hot acetone and somewhat soluble in the cold solvent, insoluble in ether and soluble in hot benzene.

[b] The solubilities are intermediate between those of the ortho and para isomers.

[c] Quite insoluble in hot acetone, ether and benzene.

The mononitrobenzyl derivatives, that is, the p-nitrobenzyl esters, were prepared as follows: 1.4 g. of the hydroxy acid and 0.55 g. of sodium hydroxide crystals were dissolved in 5 cc. of water. After the addition of 15 cc. of pure acetone, 2.15 g. of p-nitrobenzyl bromide was added in

---

[2] An equivalent amount of potassium carbonate may be used instead.

small portions during the course of one-half hour, the material having been refluxed during this period. The mixture was heated for an hour longer, then cooled, diluted with water, acidified with hydrochloric acid and the precipitated material filtered. The latter was treated with 5% sodium hydroxide and filtered to remove the dinitrobenzyl derivative and other alkali-insoluble compounds. The alkaline filtrate was acidified and the precipitate filtered. The product was dried and then dissolved in a very small amount of hot acetone. Water was added until the solution became turbid. When cooled the mononitrobenzyl derivative separated in crystalline form.

TABLE II

p-NITROBENZYL ESTERS OF HYDROXYBENZOIC ACIDS[a]

	M. p., °C.	Analysis (Dumas), % Calcd. for $C_{14}H_{11}O_5N$	Found
o-Hydroxy[b]	97– 98	N 5.12	5.15
m-Hydroxy[c]	106–108	N 5.12	5.23
p-Hydroxy[d]	180–182	N 5.12	5.22

[a] These compounds are all very soluble in cold acetone and alcohol.

[b] Lyman and Reid, THIS JOURNAL, 39, 710 (1917), obtained this substance but published no analytical results.

[c] Lyman and Reid, *ibid.*, 39, 710 (1917).

[d] Lyman and Reid, *ibid.*, 39, 711 (1917), obtained a compound which they supposed to be the p-nitrobenzyl ester of p-hydroxybenzoic acid; the substance melted at 198.5". This compound was undoubtedly the dinitrobenzyl derivative.

The p-nitrobenzyl ethers of the hydroxy acids were obtained as follows: 0.5 g. of the dinitrobenzyl derivative was hydrolyzed with **3** g. of potassium carbonate dissolved in 30 cc. of 50% alcohol. The alcohol was evaporated on a steam-bath and the aqueous mixture filtered from p-nitrobenzyl alcohol. The alkaline filtrate was acidified and the precipitated material recrystallized from a small amount of acetone.

TABLE III

p-NITROBENZYL ETHERS OF HYDROXYBENZOIC ACIDS

	M. p., °C.	Analysis (Dumas), % Calcd. for $C_{14}H_{11}O_5N$	Found
o-Hydroxy[a]	166–168	N 5.12	5.20
m-Hydroxy[b]	193–196	N 5.12	5.25
p-Hydroxy[c]	259–261	N 5.12	5.05

[a] This compound is soluble in hot acetone and alcohol.

[b] This substance is somewhat soluble in hot acetone and alcohol.

[c] Inasmuch as the dinitrobenzyl derivative of the *p*-hydroxy acid is insoluble in dilute alcohol, it is hydrolyzed into the ether much more slowly than the other isomeric dinitrobenzyl compounds. The ether is practically insoluble in hot acetone and hot alcohol.

Esters of Dimethylethylacetic Acid.—In the course of an investigation being carried on in this Laboratory we had occasion to synthesize several esters of dimethylethylacetic acid. This acid was prepared by treating *tert.*-amylmagnesium chloride with carbon dioxide; esterification was brought about by refluxing the acid and the required alcohol with sulfuric acid as catalyst.

Tert.-amyl chloride was prepared in the following manner. Four thousand cc. of concentrated hydrochloric acid was added, during fifteen to twenty minutes, with mechanical stirring, to 2500 g. of *tert.*-amyl alcohol[1] contained in a 12-liter earthenware crock. The mixture warmed up to 45°; stirring was continued for four hours. The upper layer, *tert.*-amyl chloride containing some unchanged alcohol, was transferred to a 12-liter flask and saturated with dry hydrogen chloride in the presence of anhydrous calcium chloride, the mixture being mechanically stirred throughout the process. Saturation required one and one-half hours; the mixture warmed up to 50°. The calcium chloride was then removed and the *tert.*-amyl chloride mixture was refluxed for an hour. After standing over anhydrous sodium carbonate for twenty-four hours the product was filtered. Twenty cc. of dimethylaniline was then added and the product distilled through a 50-cm. fractionating column. There is continuous evolution of hydrogen chloride during distillation if dimethylaniline is not added. The *tert.*-amyl chloride boiled at 84–86°; the yield was 1960 g., or 65% of the theoretical amount.

Dimethylethylacetic acid was prepared in 60% yield by treating *tert.*-amylmagnesium chloride with carbon dioxide. Our procedure was patterned after that of Puntambeker and Zoellner[2] for the preparation of trimethylacetic acid. The ether from which the dimethylethylacetic acid had been extracted by means of sodium hydroxide solution, by the above directions, contained two by-products—*tert.*-amyl alcohol (b. p. 99–103°, n_D^{23}, 1.4035) and a camphoraceous smelling liquid (b. p. 164–167.5"; n_D^{22}, 1.4335; molecular weight in acetone, 183) which we have not yet investigated.

The esters are colorless liquids. The methyl, ethyl and n-propyl esters have menthol–peppermint odors; the n-butyl, n- and iso-amyl esters have but little odor. The refractive indices were determined at 25.0 ± 0.1" by means of an Abbé refractometer; the densities were determined at 25.00 ± 0.02° by means of a pycnometer of about 8-cc. capacity. The weights used in the density calculations were corrected for buoyancy. The boiling points were determined by means of Anschütz thermometers (stem wholly immersed in vapor) which had been standardized by the U. S. Bureau

of Standards. The molecular weights were calculated using the Lorentz–Lorenz formula. Considerable difficulty was experienced in analyzing these esters, especially the lower ones, low results being obtained repeatedly. Correct results were finally obtained in all cases except that of the methyl ester by using a quartz combustion tube and high temperature.

Reaction of Alizarin and Mercuric Acetate.—The observation here reported was made some six years ago. Since the work is not to be continued, the facts obtained are presented as being of possible interest in anthraquinone chemistry.

Alizarin when heated with excess mercuric acetate gave large amounts of mercurous acetate, indicating an oxidation of the alizarin. The product contained organic mercury. Five runs with varying concentrations and times of heating varying from 30 to 100 hours gave almost identical results. The organic product appeared to be acetoxymercurydihydroxyalizarin. The following average analyses were obtained on the products from the five runs.

Anal. Calcd. for $C_{16}H_{10}O_8Hg$: Hg, 49.8. Pound: 49.5, 50.0, 49.8, 49.7, 49.7.

Treatment of the product with hydrochloric acid gave a yellow-red dye with properties similar to those of alizarin.

The mercury compound when treated with the amount of standard sodium hydroxide corresponding to the four hydroxyls gave a bluish-red solution. The solution at 20° then contained 0.2 g. per 100 cc. Warming the solution changed the color to red and precipitated some material which dissolved again on cooling. Both the cold and hot solutions were neutral to litmus.

The positions of the groups in the mercurated product were not determined. The results of other oxidation and substitution reactions on alizarin would make it appear probable that the product was 1,2,5,8-tetrahydroxy-4-acetoxymercuri-anthraquinone. Treatment of this product with halogens should give interesting halogenated tetrahydroxyanthraquinones.

The Reaction of Mercuric Acetate with *p*-Bromodiethylaniline.—The present observations are published because of their wide divergence from the results obtained with closely analogous substances. Dialkylanilines, including dimethyl, diethyl, di-n-propyl, di-n-butyl, methylethyl, and ethylbenzyl, react readily with mercuric acetate to give products containing acetoxymercuri groups in the para position.[1] If the para position is occupied, mercuration would be expected to take place in one of the free ortho positions. This proved to be the case with *p*-bromodimethylaniline, which gave an excellent yield of the ortho mercurated product.[2] At the time that work was done, attempts were made to extend it 'to the homologous dialkylanilines. Contrary to expectations, this proved to be impossible. The experiments have been repeated many times since under a great variety of conditions, but the results have been consistently negative. No organic mercury compound has been obtained.

The attempts at mercuration of p-bromodiethylaniline were carried out in 95% alcohol, 50% alcohol, glacial acetic acid, 50% acetic acid, ether, water and without a solvent. The temperature was varied from 0° to the boiling point of the solvent used and the times from a few hours to weeks. The concentrations of the reactants were varied over a wide range. In all experiments similar results were obtained; the products were unchanged material, mercurous acetate and unmanageable oxidation products.

NEW BOOKS

Matter, Electricity, Energy. The Principles of Modern **Atomistics and** Experimental Results of Atomic Investigation. By WALTER GERLACH, University of Tiibingen. Translated from the second German edition by Francis J. Fuchs, Ph.D., St. John's College. D. Van Nostrand Company, Inc., 8 Warren Street, New York, 1928. xii + 427 pp. 119 figs. 16 × 23.5 cm. Price, $6.00.

Since the first edition of this work was published in German, and reviewed in THIS JOURNAL, 46, 517 (1924), experimental advances in atomistics have all but kept pace with the unprecedented development of the theoretical side of the subject. Among newer subjects discussed here will be found Atomic Rays and the Compton Effect but, in general, no great effort appears to have been made to bring the book really up to date. It is gratifying that a book as good as this, yet which does not follow the lines either of an orthodox text or a reference work, can appear in translation. It should be useful to many students of modern physical developments.

NORRIS F. HALL

Collection of Czechoslovak Chemical Communications. Edited and published by E. VOTOČEK AND J. HEYROVSKÝ under the patronage of the Bohemian Royal Society of Sciences. 1929. Year 1, No. 1, January. Printed by "Politika," Prague. Agent U. S. A., Dr. N. V. Emelianoff, Havemeyer Hall, Columbia University, New York City. Subscription price, U. S. A., $5.00.

It appears that the limited knowledge of Czech outside of Bohemia has, on the one hand, forced the chemists of that country to publish their chief works in foreign journals and, on the other, has resulted in many important contributions remaining untranslated in the archives of the Czech learned societies and institutions. The Editors have founded this journal to remedy these difficulties by publishing in full the more important contributions of their countrymen in the field of "pure" chemistry, provided they have not been published previously in any widely known language. This journal will also include a bibliography of all publications of Czechoslovak chemists, as well as reviews of their books.

This first issue contains four articles, one on inorganic, one on physical-analytical and two on organic chemistry. One of these articles is in English; the other three are in French.

ARTHUR B. LAMB

Leçons sur la **Chimie Générale.** (Lessons in General Chemistry.) By RENÉ DUBRISAY, Professor at the National School of Bridges and Roads. Gauthier–Villars et Cie., 55 Quai des Grands-Augustins, Paris, France, 1929. vi + 246 pp. 16.5 X 25.5 cm. Price, $2.98.

This is a short course of lectures, intended as a second trip over the chemical field for students of engineering who have already studied descriptive chemistry. The author shows the application of physical chemistry to many industrial processes. The work is divided into an introduction and four parts which deal, respectively, with atomistics, thermodynamics, kinetics and equilibria, electrochemistry and surface chemistry. In part one, the treatment is rather too brief to be satisfactory but the material seems well selected. Figures one and two are misleading. In part two the discussion of oxidative catalysis and the drying of oils is interesting. In developing the fundamental equations for chemical equilibria and the phase rule, a rather detailed analytical discussion is used, in which the Gibbs Zeta-function is emphasized and this function is called the "thermodynamic potential" while the Psi-function is called the "free energy." A rather extensive use of phase diagrams is made in the section on metallography. In particular the T–X diagram for the system Cu–Sn is presented in considerable detail. In the section on ionization the hypothesis of Arrhenius is uncritically applied to strong electrolytes. The electrochemical section is very brief and modern solution theory finds no place in it. In the section on surface chemistry the Gibbs Zeta-function is used once more in developing the adsorption equation of Preundlich. Chapters on clays and cements conclude the book.

The style is clear and extremely concise and the methods of selection and presentation testify to the intelligence both of the lecturer and of French students of engineering.

NORRIS F. HALL

The Fundamentals of Chemical Thermodynamics. Part I. Elementary Theory and Applications. BY J. A. V. BUTLER, D.Sc., Lecturer in Chemistry in the University of Edinburgh. Macmillan and Co., Ltd., St. Martin's Street, London W.C. 2, England, 1928. xi + 207 pp. 51 figs. 12.5 × 19.5 cm.

In response to the need "of an elementary introduction to the subject which shall stress the underlying principles and at the same time give due attention to their applications" the author has "tried to present the subject in a logically precise, yet simple form, having in mind not only the student who intends to specialize in Physical Chemistry, but also that class of chemistry students which has only a very moderate knowledge of mathematics and little sympathy with mathematical methods." This volume is based mainly on cyclic processes, and ,comprises nine chapters, as follows: first law; second law; changes of state; solutions; homogeneous-gaseous reactions; the galvanic cell; electrode potentials; concentration cells and activities; electrolysis. To each chapter is appended a group of examples, taken from recent papers and not obsolete data copied from other textbooks. In his purpose the author has, I think, succeeded perhaps as well as is possible within the compass of 200 small pages; but one wonders whether it is not rather condensed nourishment, except for the few with thoroughly analytical minds, and whether for the others the thermodynamic pill must not be gilded with a more discursive treatment, with a large use of analogies, with philosophy and even with humor, if it is to produce any beneficial effect upon the patient. Indeed, I fear that it is nearly impossible to write a good brief exposition of thermodynamics—unless as a summary which would be amplified greatly by the teacher in class—which will appeal with any degree of success to the average student of chemistry; he should, however, find the texts written within the last fifteen years much less unattractive and less incomprehensible than the older books, many of them written by men who allowed but little real chemistry to slip in.

J. JOHNSTON

Introduction to Modem Physics. BY F. K. RICHTMYER, Professor of Physics at Cornell University. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1928. xv + 596 pp. 169 figs. 15 X 23.5 cm Price, $5.00.

This fairly large and leisurely book has already found a warm welcome among students and teachers of physics, and should equally please those chemists and other non-physicists who are forced by interest or necessity to follow as best they can the brilliant pageant of modern physical advance. Intending neither to produce a textbook of physics in general nor a work of reference, the author has been able to select his material with a relatively free hand.

His method is as follows. First, the whole history of physics is surveyed in a section of about seventy pages, which brings the account to the last decades of the nineteenth century. The electromagnetic theory of light is then expounded, followed by the story of the photoelectric effect from Hertz to Ives. Next is a long section devoted to thermal radiation, the origin of the quantum theory and its application to specific heats. Then comes a study of series relations in line spectra, the development of the nucleus-atom and its introduction into spectral theory. The arrangement of electrons in atoms is discussed in connection with both static and dynamic models and, finally, a complete survey of the history and present status of x-rays introduces a last chapter on the nucleus and radioactivity. Appendices contain valuable tables. This choice of subjects permits the author to dwell with each in turn, to regard it from different points of view, to raise interesting side issues and to show the essentially continuous and even recurrent character of the evolution of physics. Of course, not everything "modern" finds a place—there is no general and little special relativity, no matrix—or wave—mechanics, no ultrasonics, no electron tubes. There is even no treatment of sound, or of light as such, or of ordinary mechanics.

Therefore let the reader or purchaser of this book understand just what he is getting: a readable, solid and thorough *introduction* to those parts of physics which by common consent are regarded as most interesting. The diagrams have evidently been very carefully prepared..

A list of minor errors has been sent to the author.

NORRIS F. HALL

A Guide to the Literature of Chemistry. By E. J. CRANE, Editor of Chemical *Abstracts,* and AUSTIN M. PATTERSON, Professor of Chemistry, Antioch College, Formerly Editor of *Chemical Abstracts,* John Wiley and Sons, Inc., New York, 1927. ix + 438 pp. Illustrated. 15.5 X 23.5 cm. Price $5.00.

The literature of chemistry, including those closely related subjects which engage the chemist's attention, is more extensive than that of any other branch of science, and there is probably no other field of pure or applied science in which consultation of the existing literature is more highly essential. Even in routine work some contact with published information is desirable, while in investigation the use of existing records is imperative. Every research should begin with the literature of the subject; frequently it may end there.

The student of chemistry is given detailed instruction in the manipulation of the apparatus he is to use; but too frequently he is given only superficial instruction, or none at all, in the method of approaching the literature, though indexes and library catalogs are tools, also, and the technique of using them properly does not come intuitively. But while there are many books for the chemist in the laboratory, there have been very few for the chemist in the library. A pioneer work is the pamphlet by Miss Marion Sparks,[1] who up until her recent untimely death gave instruction in chemical literature to students at the University of Illinois. In his valuable guide to research in organic chemistry, Dr. E. E. Reid[2] of Johns Hopkins University wisely devoted approximately one-third of the space to libraries and literature. A recent work by Dr. M. G. Mellon,[3] based on instruction at Purdue University, gives considerable attention to actual library problems and assignments.

There are a few other brief guides, but the book by Crane and Patterson presents the maximum cross-section of the literature. Its content cannot be reviewed in detail here, but, in general, it surveys the important classes of literature (such as books, periodicals, patents, and trade literature), and indicates the approach thereto by means of the available tools (such as indexes, abstracts, reviews and bibliographies). Supplementing the

[3] Mellon, "Chemical Publications, Their Nature and Use," McGraw-Hill Book Co.. New York, 1928.

general instruction, there are useful features of rather special nature, for example, the principles of indexing, and the transliteration of Russian names.

The procedure for systematic searching of the literature is well outlined, and at least a part of the instruction given in the book should be incorporated in every formal course in chemistry, to the end that every chemist shall be able to find information in print, and to record it with such accuracy that his references will enable him, or anyone else, to find the material again. In addition to its value for actual study, the volume offers a large amount of reference material—mainly in the form of lists. These include a bibliography of chemical literature and lists of abbreviations, libraries, periodicals, societies, publishers and books—all considered from the viewpoint of the chemist. Some of these lists are of more ephemeral nature than the rest of the book and they will need occasional revision. At present, they are of enormous reference value and the book should be available for consultation in every laboratory which does anything beyond the most ordinary routine work.

Having been invited to review this "Guide" so long after its appearance, the present reviewer accepted because the book continues to justify its existence and (where used as it was intended to be) to evoke enthusiasm as evinced by the following comment in a letter from a personal friend who has had wide experience in the use of technical literature: "What a beautiful piece of work Crane and Patterson have done in their Literature of Chemistry. I admire it more and more every time I use it."

E. H. McClelland

Richter-Anschiitz Chemie der Kohlenstoffverbindungen oder **Organische** Chemie. (Organic Chemistry or the Chemistry of the Compounds of Carbon.) Edited by Dr. Richard Anschütz. Vol. I. Aliphatic Compounds. By Dr. Fritz Reindel, Lecturer in Organic Chemistry at the Technical High School of Munich, Twelfth edition. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 4, Leipzig C 1, Germany, 1928. xvi + 882 pp 18 figs. 16 × 24 cm. Price, unbound, M 57; bound, M 59.

After an interval of nineteen years, during which many of the friends of the "Richter–Anschiitz" began to fear that its faithful editors had succumbed to an ever-growing mass of facts, this first volume of the twelfth edition has appeared—thoroughly up to date, cleanly printed on good paper, therefore just as reliable and much more attractive than any of the preceding editions.

Since the plan of this text has remained the same throughout its long history, the differences between successive editions give a good indication of the subjects which from time to time have engrossed the interest of investigators in organic chemistry. In the present edition the sections dealing with alcoholic fermentation, polysaccharides, proteins, porphyrins, bile-acids, sterins and enzymes have been completely rewritten and considerably expanded. These sections contain the major changes from the eleventh edition but the entire text has been thoroughly revised and there is hardly a page in which no new material has been incorporated. Both the editors and the publishers are to be commended for the high quality of the present volume. It deserves to win a host of new friends for an old favorite.

E. P. KOHLER

Organic Syntheses. An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. IX. **Edited by JAMES B. CONANT, with ROGER ADAMS, H. T. CLARKE, HENRY GILMAN, C. S. MARVEL and FRANK C. WHITMORE. John Wiley and Sons, Inc., 440 Fourth Avenue, New York,** 1929. **v** + 108 **pp. 1 fig. 15.5 × 23.5 cm. Price, $1.75.**

The ninth annual volume of Organic Syntheses arrived on time, with a long list of contributors of whom many—perhaps most—appear for the first time in this edition. Evidently the little guide is enjoying increasing favor not only with those who look to it for assistance, but also with those who have had occasion to devise new methods or carefully study old ones for the preparation of organic compounds. The list of substances dealt with in the present volume is as follows: Acid ammonium o-sulfobenzoate, dkalanine, ammonium salt of aurintricarboxylic acid, anisole, benzoylpiperidine, p-bromophenacyl bromide, o-bromotoluene, n-butyl carbamate, n-butyl p-toluenesulfonate, n-butyryl chloride, o-chlorobenzoyl chloride, cyanoacetamide, ethyl cinnamate, hydrocinnamic acid, iodobenzene, levulinic acid, 1-menthone, mercury diphenyl, methylene bromide, monochloromethyl ether, 0-naphthol phenylaminomethane, o-nitroaniline, nitrostyrene, pentamethylene bromide, y-phenoxypropyl bromide, phloroglucinol, pyrrole, o-sulfobenzoic anhydride, *ac.*-tetrahydro-β-naphthylamine.
